Listeners were programmed with starting knowledge states initialized accordingly. Listeners with no exposure began the game with knowledge of 0 object-label pairs. Listeners with the same exposure of the speaker began with knowledge of five object-label pairs (3 high frequency, 1 mid frequency, 1 low frequency), based the average retention rates found previously. Lastly, the listener with twice as much exposure as the speaker began with knowledge of all nine object-label pairs. If the speaker produced a label, the listener was programmed to consult their own knowledge of the lexicon and check for similar labels (selecting a known label with a Levenshtein edit distance of two or fewer from the speaker's production), or select among unknown objects if no similar labels are found. Listeners could integrate new words into their knowledge of the lexicon if taught.

Crossing our 2 between-subjects manipulations yielded 6

conditions (2 utility manipulations: 'Low Relative Cost' and 'Higher Relative Cost'; and 3 levels of partner's exposure: None, Same, Double), with 80 participants in each condition. We expected to find results that mirrored our corpus findings such that rates of teaching would be higher when there was an asymmetry in knowledge where the speaker knew more (None manipulation) compared with when there was equal knowledge (Same manipulation) or when the listener was more familiar with the language (Double manipulation). We expected that participants would also be sensitive to our utility manipulation, such that rates of labeling and teaching would be higher in the 'Low Relative Cost' conditions than the other conditions.

Results

As an initial check of our exposure manipulation, a logistic regression showed that participants were significantly more likely to recall the label for objects with two exposures (B = 1.66, $p < 0.0001$) or with four exposures (B = 3.07, $p < 0.0001$), compared with objects they saw only once. On average, participants knew at least 6 of the 9 words in the lexicon (mean = 6.28, sd = 2.26).

Gesture-Speech Tradeoff. To determine how gesture and speech are trading off across conditions, we looked at a mixed effects logistic regression to predict whether speakers chose to produce a label during a given trial as a function of the exposure rate, object instance in the game (first, second, or third), utility manipulation, and partner manipulation. A random subjects effects term was included in the model. There was a significant effect of exposure rate such that there was more labeling for objects with two exposures (B = 0.91, $p < 0.0001$) or with four exposures (B = 1.83, $p < 0.0001$), compared with objects seen only once at training. Compared with the first instance of an object, speakers were significantly more likely to produce a label on the second appearance (B = 0.2, $p < 0.01$) or third instance of a given object (B = 0.46, $p < 0.0001$). Participants also modulated their communicative behavior on the basis of the utility manipulation and our partner exposure manipulation. Speakers in the Low Relative Cost condition produced significantly more labels than participants in the Higher Relative Cost condition (B = -0.84, $p < 0.001$). Speakers did more labeling with more knowledgeable partners; compared with the listener with no exposure, there were significantly higher rates of labeling in the same exposure (B = 1.74, $p < 0.0001$) and double exposure conditions (B = 3.14, $p < 0.001$).

Figure 3 illustrates the gesture-speech tradeoff pattern in the Double Exposure condition (as there was minimal teaching in that condition, so the speech-gesture trade-off is most interpretable). The effects on gesture mirror those found for labeling and are thus not included for brevity ($ps < 0.01$). Note that these effects cannot be explained by participant knowledge; all patterns above hold when looking *only* at words known by the speaker at pretest ($ps < 0.01$). Further, these patterns directly mirror previous corpus analyses demonstrating the gesture-speech tradeoff in naturalistic parental communicative behaviors, where lexical knowledge is likely for even the least frequent referent (see Yurovsky et al., 2018).

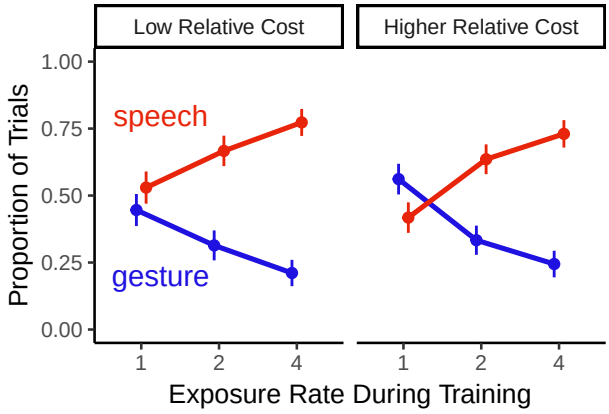

Figure 3: Speaker communicative method choice as a function of exposure and the utility manipulation. Data are taken from the Double Exposure manipulation. Rates of teaching were minimal and are not shown.

Emergence of Teaching. In line with our hypotheses, a mixed effects logistic regression predicting whether or not teaching occurred on a given trial revealed that teaching rates across conditions depend on all of the same factors that predict speech and gesture (see Figure 4). There was a significant positive effect of initial training on the rates of teaching, such that participants were more likely to teach words with two exposures (B = 0.26, $p < 0.05$) and four exposures (B = 0.25, $p < 0.05$), compared with words seen only once at training. There was also a significant effect of the utility manipulation such that being in the Low Relative Cost condition predicted higher rates of teaching than being in the Higher Relative Cost condition (B = -0.96, $p < 0.001$), a rational response considering teaching allows one to use a less costly strategy in the future and that strategy is especially superior in the Low Relative Cost condition.

We found an effect of partner exposure on rates of teaching as well: participants were significantly more likely to teach a partner with no prior exposure to the language than a partner with the same amount of exposure as the speaker (B = -1.63, $p < 0.0001$) or double their exposure (B = -3.51, $p < 0.0001$). The planned utility of teaching comes from using another, cheaper strategy (speech) on later trials, thus the expected utility of teaching should decrease when there are fewer subsequent trials for that object, predicting that teaching rates should drop dramatically across trials for a given object. Compared with the first trial for an object, speakers were significantly less likely to teach on the second trial (B = -0.84, $p < 0.0001$) or third trial (B = -1.67, $p < 0.0001$).

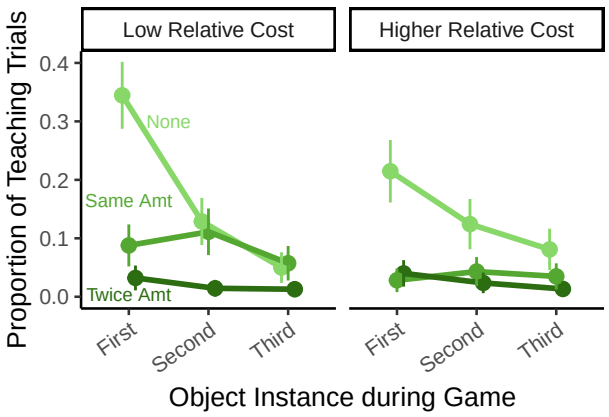

Figure 4: Rates of teaching across the 6 conditions, where the x-axis how many times an object had been the target object.

Discussion

As predicted, the data from our paradigm corroborate our findings from the corpus analysis, demonstrating that pedagogically supportive behavior emerges despite the initial cost when there is an asymmetry in knowledge and when speech is less costly than other modes of communication. While this paradigm has stripped away much of the interactive environment of the naturalistic corpus data, it provides important proof of concept that the structured and tuned language input we see in those data could arise from a pressure to communicate. The paradigm's clear, quantitative predictions also allow us to build a formal model to predict our empirical results.

Model: Communication as planning

The results from this experiment are qualitatively consistent with a model in which participants make their communicative choices to maximize their expected utility from the reference game. We next formalize this model to determine if these results are predicted quantitatively as well.

We take as inspiration the idea that communication is a kind of action–e.g. talking is a speech act (Austin, 1975). Consequently, we can understand the choice of *which communicative act* a speaker should take as a question of which act would maximize their utility: achieving successful communication while minimizing their cost (Frank & Goodman, 2012). In this game, speakers can take three actions: talking, pointing, or teaching. In this reference game, these Utilities (U) are given directly by the rules. Because communication is a repeated game, people should take actions that maximize their Expected Utility (EU) over the course of not just this act, but all future communicative acts with the same conversational partner. We can think of communication, then as a case of recursive planning. However, people do not have perfect knowledge of each-other's vocabularies (v). Instead, they only have uncertain beliefs (b) about these vocabularies that combine their expectations about what kinds of words people with as much linguistic experience as their partner are likely to know with their observations of their partner's behavior in past communicative interactions. This makes communication a kind of planning under uncertainty well modeled as a Partially Observable Markov Decision Process (POMDP, Kaelbling, Littman, & Cassandra, 1998).

Optimal planning in a POMDP involves a cycle of four phases: (1) Plan, (2) Act, (3) Observe, (4) Update beliefs. When people plan, they compute the Expected Utility of each possible action (a) by combining the Expected Utility of that action now with the Discounted Expected Utility they will get in all future actions. The amount of discounting (γ) reflects how people care about success now compared to success in the future. In our simulations, we set $\gamma = .5$ in line with prior work. Because Utilities depend on the communicative partner's vocabulary, people should integrate over all possible vocabularies in proportion to the probability that their belief assigns to that ($\mathbb{E}_{v\sim b}$).

$$EU\left[a|b\right] = \mathbb{E}_{v\sim b}\left(U(a|v) + \gamma \mathbb{E}_{v',o',a'}\left(EU\left[a'|b'\right]\right)\right)$$

Next, people take an action as a function of its Expected Utility. Following other models in the Rational Speech Act framework, we use the Luce Choice Axiom, in which each choice is taken in probability proportional to its exponentiated utility (Frank & Goodman, 2012; Luce, 1959). This choice rule has a single parameter α that controls the noise in this choice–as α approaches 0, choice is random and as α approaches infinity choice is optimal. For the results reported here, we set $\alpha = 2$ based on hand-tuning, but other values produce similar results.

$$P(a|b) \propto \alpha e^{EU[a|b]}$$

After taking an action, people observe (o) their partner's choice–sometimes they pick the intended object, and sometimes they don't. They then update their beliefs about the partner's vocabulary based on this observation. For simplicity, we assume that people think their partner should always select the correct target if they point to it, or if they teach, and similarly should always select the correct target if they produce its label and the label is in their partner's vocabulary. Otherwise, they assume that their partner will select the wrong object. People could of course have more complex inferential rules, e.g. assuming that if their partner does know a word they will choose among the set of objects whose labels they do not know (mutual exclusivity, Markman & Wachtel, 1988). Empirically, however, our simple model appears to accord well with people's behavior.

$$b'(v') \propto P\left(o|v',a\right) \sum_{v\in V} P\left(v'|v,a\right) b\left(v\right)$$

The critical feature of a repeated communication game is that people can change their partner's vocabulary. In teaching, people pay the cost of both talking and pointing together, but can leverage their partner's new knowledge on future trials. Note here that teaching has an upfront cost and the only benefit to be gained comes from using less costly communication modes later. There is no pedagogical goal– the model

treats speakers as selfish agents aiming to maximize their own utilities by communicating successfully. We assume for simplicity that learning is approximated by a simple Binomial learning model. If someone encounters a word w in an unambiguous context (e.g. teaching), they add it to their vocabulary with probability p. We also assume that over the course of this short game that people do not forget–words that enter the vocabulary never leave, and that no learning happens by inference from mutual exclusivity.

$$P\left(v'|v,a\right) = \begin{cases} 1 & \text{if } v_w \in v \& v' \\ p & \text{if } v_w \notin v \& a = \text{point+talk} \\ 0 & otherwise \end{cases}$$

The final detail is to specify how people estimate their partner's learning rate (p) and initial vocabulary (v). We propose that people begin by estimating their own learning rate by reasoning about the words they learned at the start of the task: Their p is the rate that maximizes the probability of them having learned their initial vocabularies from the trials they observed. People can then expect their partner to have a similar p (per the "like me" hypothesis, Meltzoff, 2005). Having an estimate of their partner's p, they can estimate their vocabulary by simulating their learning from the amount of training we told them their partner had before the start of the game.

Model Results

The fit between our model's predictions and our empirical data from our reference game study on Amazon Turk can be seen in Figure 5. The model outputs trial-level action predictions (e.g., "speak") for every speaker in our empirical data. These model outputs were aggregated across the same factors as the empirical data: modality, appearance, partner's exposure, and utility condition. We see a significant correlation of our model predictions and our empirical data (r = *0.94*, p<*0.0001*). Our model provides a strong fit for these data, supporting our conclusion that richly-structured language input could emerge from in-the-moment pressure to communicate, without a goal to teach.

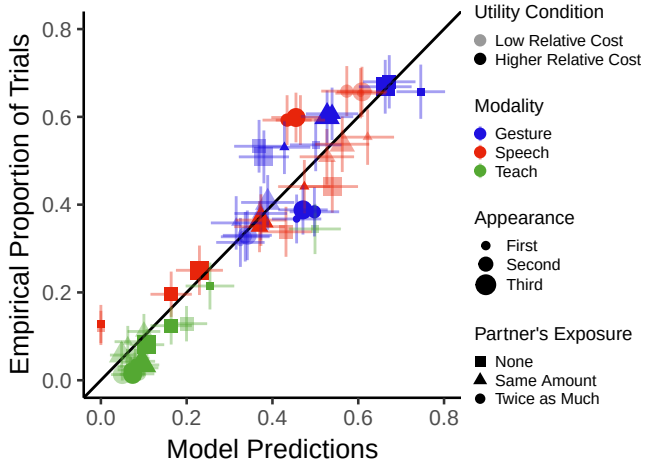

Figure 5: Fit between model predictions and empirical data.

General Discussion

We showed that people tune their communicative choices to varying cost and reward structures, and also critically to their partner's linguistic knowledge–providing richer cues when partners are unlikely to know language and many more rounds remain. These data are consistent with the patterns shown in our corpus analysis of parent referential communication and demonstrate that such pedagogically supportive input could arise from a motivation to maximize communicative success while minimizing communicative cost– no additional motivation to teach is necessary. Our account is not specific to any particular language phenomenon, though we have focused on multi-modal reference here. Given the right data or paradigm, our account should hold equally well when explaining how other information-rich language input could arise.

Of course, many aspects of language do not differ in speech to children (e.g., syntax, see Newport, Gleitman, & Gleitman, 1977). On our account, not all aspects of language should be calibrated to child's language development–only those that support communication. A full account that explains variability in modification across aspects of language will rely on a fully specified model of optimal communication. Such a model will allow us to determine both which structures are predictably unmodified, and which structures must be modified for other reasons. Nonetheless, this work is an important first step in validating the hypothesis that language input that is structured to support language learning could arise from a single unifying goal: The desire to communicate effectively.

Abstract

Both examples and verbal explanations play an important role in learning new concepts and categories. At the same time, learning from verbal explanations is not accounted for in most category learning models, and is not studied in the traditional category learning paradigm. We propose a *rational category communication* model that formally describes the process of communicating a category structure using both verbal explanations and visual examples in a pedagogical setting. We build our model based on the assumption that verbal instructions are best suited for communication of crude constraints on a category structure, while exemplars complement it by providing means for finer adjustments. Our empirical study demonstrates that verbal communication is indeed more robust to changes in stimuli dimensionality, but that its efficiency is adversely affected when distinguishing between categories requires perceptual precision. Communicating through examples has a reversed pattern. We hope that both the proposed experimental paradigm and the computational model would facilitate further research into the relative roles of verbal and exemplar communication in category learning.

Keywords: categorization; category learning; computational modelling; communication efficiency; communication channels

Introduction

Humans have a variety of information sources available to enrich or expand their knowledge. Imagine a person encountering an unfamiliar word or concept. She may infer its meaning from examples of how it is used, consult a dictionary, or use a combination of examples and definitions to understand a word or concept. In many cases, any of these sources alone is not sufficient (Fischer, 1994; Nagy, Herman, & Anderson, 1985).

Similarly, multiple sources of information are also often used to communicate a category or a concept. Imagine a family forest trip where a parent wants to teach their child about poisonous mushrooms. It is easy to envision a parent instructing their child through definitions, e.g., not to collect pale, thin-legged mushrooms with a flat cap since they are usually poisonous. Is also easy to imagine this parent giving examples, e.g. "look: this is one of the poisonous mushrooms I told you about". A key difference is that the former involves a verbal explanation of a rule, while the latter relies on non-verbal ways of concept communication (relevant examples only need to be pointed at). Contrary to the situation with word learning, however, in the context of perceptual categories, the relative contributions of verbal- and example-based communication are not well understood.

We know, however, that example- and verbal-based communication are not redundant: different aspects of category and concept knowledge may require different means of communication. Verbal instructions are well suited for communication of abstract rules, but give little information about specific stimuli characteristics (Longman, Milton, Wills, & Verbruggen, 2018). Examples, in turn, provide contextual information and help to understand how to apply knowledge to a particular problem (Reed & Bolstad, 1991; Fischer, 1994). Thus both example- and verbal-based communication play a significant role in shaping human learning. As such, they should be incorporated into contemporary theories and computational models of category acquisition.

In this work, we focus on the question of what are the fundamental differences between the verbal and exemplar channels of communication. We formalize the aforementioned intuitions about these differences and propose a computational model of the process. We also run an empirical study that investigates how people communicate perceptual categories using different combinations of communication channels. In particular, we investigate how different characteristics of a category structure affect the efficiency of verbal- and exemplar- based category communication.

Related work

The problem of communicating knowledge spans a broad range of disciplines, including educational and cognitive psychology, logic, linguistics, mathematics, and philosophy.

In the area of machine learning, there is a range of works on the problem of knowledge communication (e.g., (Winston, Binford, Katz, & Lowry, 1983)). In particular, there is a growing interest in the problems of few- and zero- shot learning techniques that focuses on learning through language without ever seeing an example (DeJong & Mooney, 1986). Notably, Mitchell (Mitchell, Keller, & Kedar-Cabelli, 1986) looked specifically into the ways of learning artificial cate-

gories from verbal explanations. In most cases, these attempts are, however, centered on applications in their respective domains and do not aim understand or model the fundamental roles that different communication systems play in human interaction and learning.

Surprisingly, verbal communication has not received much attention in empirical studies of category learning and has been largely ignored in corresponding computational models. Well-established paradigms for category learning focus on the communication and acquisition of categories through examples only and miss one of the critical sources of information used in real-world situations. Considering the overwhelmingly important role of verbal communication in education and the impact of internal verbalization on the learning outcomes (Vinner, 2002; Lombrozo, 2012; Williams & Lombrozo, 2010, 2013), this omission makes the well known ironic definition of category learning as the "class of behavioral data generated by experiments that ostensibly study categorization" (Kruschke, 2008) exceedingly appropriate.

We see two related reasons for this apparent oversight. First, the fact that people use definitions to acquire knowledge is so apparent, and, at the same time, so difficult to model rigorously, that it is very tempting to ignore either as "boring" or "impractical" to study. It is sometimes seen as an unstated assumption that verbal communication would allow to simply transfer the category knowledge.

Second, learning from definitions is inherently pedagogical, and, until recently, we lacked the tools to model such situations. Historically, category learning literature focused on extracting knowledge from a neutral environment (although there are notable exceptions: (Avrahami et al., 1997)), and the formal apparatus for modeling pedagogical reasoning in category learning was developed only recently (Shafto, Goodman, & Griffiths, 2014; Aboody, Velez-Ginorio, Laurie, Santos, & Jara-Ettinger, 2018; Frank & Goodman, 2012).

Even though recent years have witnessed a revived interest in empirical studies of these distinct ways of learning (Liefooghe, Braem, & Meiran, 2018; Longman et al., 2018), the modeling aspect is critically lacking.

Overall, we believe that now, when we have the tools to model pedagogical reasoning in category learning setting, it is a good time to make a step towards a formal model of both explanation- and example-based category learning.

Relation to categorization models

While the attempts to introduce learning based on verbal explanations into category learning models are scarce, many of the prominent categorization models could be naturally extended to partially account for verbal communication. For example, in the ALCOVE model (Kruschke, 1992), verbal communication could be introduced as transferring attention weights, thus speeding up subsequent example-based learning. On the other hand, there is no clear way to introduce purely verbal communication into this or most of the other exemplar models.

In the case of RulEx (rules with exceptions) model (Nosofsky, Palmeri, & McKinley, 1994), verbal communication could be introduced as a direct rule transfer, while examples may serve as illustrating exceptions, or as a way of adjusting rule boundaries.

Another prominent categorization model, COVIS (Ashby, Paul, & Maddox, 2011), includes the verbal (rule-based) and procedural (information-integration) components. These names partially acknowledge the potential importance of verbal reasoning, and difference in learning dynamics for "verbalizable" and "non-verbalazable" categories were extensively studied by G. Ashby (Ashby et al., 2011). At the same time, the verbal system is mostly seen as a component of internal learning dynamics, and its relation to knowledge communication is not usually studied.

Overall, there are many potential ways to introduce verbal communication into existing categorization models. At the same time, learning from verbal explanations is inherently pedagogical (somebody has to produce the explanations for a student). Therefore, we find it most promising to approach the problem from the rational analysis perspective which already offers an elegant account of pedagogical reasoning in category learning. In the next sections, we describe our approach.

Computational Model

We build upon the rational account of pedagogical reasoning, introduced in (Shafto et al., 2014). That work provided an answer to the question of how a rational teacher should select the most useful example to help a rational student learn a specific category.

In their approach, a rational teacher aims to choose an example that would maximize the student's learning outcome (probability of selecting a correct hypothesis). Thus, the teacher needs a model of the student. A rational student will also try to understand why their teacher selected a specific example which means that a student has to model the teacher. The authors formalize it as a pair of equations:

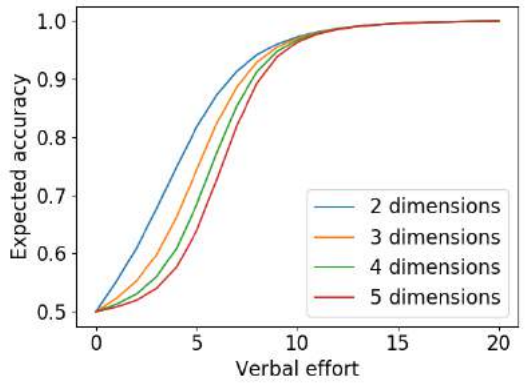
$$P_{teacher}(d|h) \propto (P_{learner}(h|d))^{\alpha} \tag{1}$$

and

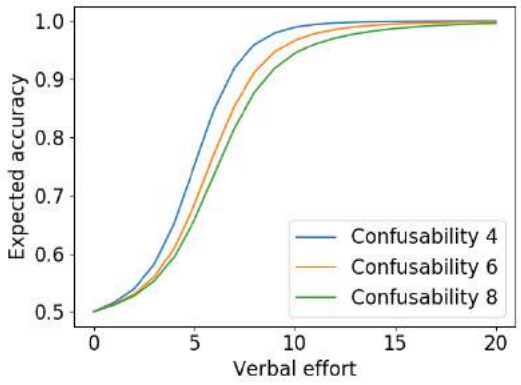
$$P_{learner}(h|d) = \frac{P_{teacher}(d|h)P(h)}{\sum_{h'} P_{teacher}(d|h')P(h')} \tag{2}$$

Where h stands for the hypothesis and d stands for the data.

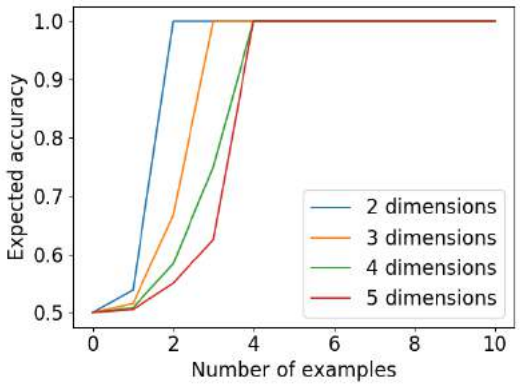
Equation 1 states that the teacher should select data points proportionally to the posterior probability of the correct hypothesis that a learner would infer after seeing these examples. Parameter α reflects how much is the teacher inclined to sample the most informative example. Thus $\alpha = 1$ corresponds to probability matching, while $\alpha = \infty$ corresponds to a deterministic selection of the best example. In the original model, an α of 1 was used in all experiments (Shafto et al., 2014).



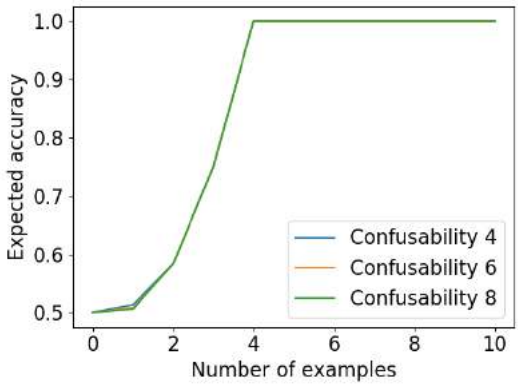
(a) The curves converge early.



(b) The curves only converge near their asymptote.



(c)



(d)

Figure 1: Simulation results of the effect of stimuli dimensionality and perceptual confusability on expected accuracy. In particular, the efficiency of exemplar channel of communication is not affected by perceptual confusability, while the number of dimensions has a noticeable impact on it. Additionally, verbal communication curves quickly converge for different stimuli dimensionality. Thus, the number of dimensions matters for low-quality verbal explanations, but their impact fades as the quality of explanations increases. On the other hand, perceptual confusability continues to matter even for high-quality explanations, highlighting the intuition that small perceptual differences may be very difficult to verbalize.

Equation 2 states that the learner should select hypotheses proportionally to how likely a rational teacher is to generate the available data under these hypotheses. A solution could be obtained by substituting one into another and iteratively updating some initial estimate until convergence.

In order to incorporate verbal communication into this model, as well as to make the model more broadly applicable, we need to make a number of changes. In the next sections we will first describe them conceptually, and then write down the resulting equations.

Sequential sampling

In (Shafto et al., 2014), authors exhaustively enumerated all possible datasets that could be communicated. Thus, if a teacher wants to show a student three examples, choosing among N possible examples every time, the space of possible datapoints is going to be N^3. This exponential data space is very limiting even for simple category learning tasks if a training session consists of more than just a few examples.

We assumed that the data is selected sequentially, in a greedy fashion. Thus, if a teacher had to select three examples, she would first select a single example that maximizes the probability of the correct category, then selects the second example conditional on the event that the student already saw the first one, and so on.

This does not guarantee an optimal sample in general, but it makes the model applicable in realistic conditions. For example, in traditional category learning experiments, which often include a large number of trials and high-dimensional stimuli as well as sequential, interactive teaching. In principle, it is also possible to combine sequential sampling with exhaustive enumeration, by adding a tractable number of examples on each step.

Formally, we rewrite Equations 1 and 2 introduce sequential dependencies (an addition to recursive teacher-student de-

pendencies already present).

$$P_{teacher}(d_i|d_{i-1},...,d_1,h) \propto (P_{learner}(h|d_i,d_{i-1},...,d_1,h))^{\alpha} \quad (3)$$

$$P_{learner}(h|d_i...d_1,h) = \\ = \frac{P_{teacher}(d_i|d_{i-1},...,d_1,h)P_{learner}(h|d_{i-1},...,d_1)}{\sum_{h'} P_{teacher}(d_i|d_{i-1},...,d_1,h')P_{learner}(h'|d_{i-1},...,d_1)} \quad (4)$$

Where d_i is a data point selected by a teacher on step i. This completes the formal description of the model for the case when all d_i are examples.

Verbal communication

The key problem we have to solve is incorporating verbal communication into the model, i.e., handling the case when d_i is a verbal explanation.

Explicitly mapping language to category structures that are communicated is an extremely difficult task. We sidestep the issue by modeling the process at a higher level: we simply assume that verbal communication channel allows us to transfer the information about which hypothesis is correct. If we view the problem this way, the problem of selecting which category structure to communicate is not relevant: we could assume that the teacher always intends to communicate the correct hypothesis.

This channel of communication has its limitations, which may depend on the category structure. For example, some hypotheses could be difficult or impossible to formulate verbally (Ashby et al., 2011), and some information could be lost due to miscommunication or misunderstanding.

To account for these phenomena, we assume that the channel is noisy. That is, even though the teacher always intends to communicate the correct hypothesis and "sends" it through the verbal channel, due to noise, instead of receiving an unambiguously decoded hypothesis, a student only receives a sample from a distribution over all possible hypotheses. The shape of this distribution depends on the hypothesis being sent and is determined by the noise model.

Noise model

It is reasonable to assume that the noise corruption is more likely to turn a hypothesis into a similar hypothesis, as opposed to turning it into something entirely unrelated. There are, however, different ways to define this similarity metric for the corruption model.

One approach is to restrict oneself to a certain class of rules and then define similarity in some intuitive way. One option would be to rely on syntactic similarity between formal expressions defining a concept (this would be similar in spirit to (Goodman, Tenenbaum, Feldman, & Griffiths, 2008)), or in some other way manually define the distance function between any two hypotheses.

We want our model to be applicable in a wide range of categorization experiments, and thus we chose not to rely on any specific choice of the hypothesis space. Instead, we model similarity between two categories simply as the similarity in the pattern of their predictions. Thus, two categories (hypotheses) are the maximally similar if they predict the same answer for all examples, and they are maximally dissimilar if they always predict different answers. We find this definition highly neutral as it builds upon the most basic definition of equality of categories: the categories are the same if the sets of things that belong to these categories are equal.

Apart from being flexible and unopinionated, our noise model captures some fundamental and intuitive properties of language: its ability to transfer the gist of the situation in broad-brush terms, and its difficulty in exactly communicating perceptual experiences. Instead of being hard-coded into the model, these properties naturally emerge from the concept similarity definition that we employed.

For example, when two rule-based categories differ only slightly in the thresholds that define them, or if two prototype-based categories differ slightly in prototype means, there would likely only be a few examples that would be misclassified if we confuse two such concepts. Thus, these categories would be similar according to our definition, and it would be difficult to discriminate between them using the verbal channel of communication.

At the same time, if two rules differ in the dimensions that are considered relevant for it, or if some dimension is "reversed" - the ramifications of confusion between such two rules would be dramatic. Such rules would be very dissimilar according to our definition, and it would be easy to distinguish between them using the verbal channel of communication.

Verbal effort

There are good explanations and there are bad ones. The same concept could be explained clearly, leaving little or no uncertainty on the student's side, or it could leave the student confused, knowing little more than before.

In order to capture this intuition, we introduce a concept of *verbal effort*. The more *verbal effort* a teacher puts into her explanation the less uncertainty there is about what was the communicated category.

Putting it together

In order to fully specify the model, we start with the Equations 3 and 4, and complement them with the case when d_i is a verbal message via the Equation 5.

$$P(h|d_i,...,d_1) \propto P(d_i|d_{i-1},...,d_1,h)P(h|d_{i-1},...,d_1) = \\ = \left[\sum_{d_i^{sent}} P(d_i|d_i^{sent})P(d_i^{sent}|h)\right] P(h|d_{i-1},...,d_1) = \\ = P(d_i|d_h^{sent})P(h|d_{i-1},...,d_1) \quad (5)$$

Where d_h^{sent} is the index of the correct hypothesis. The last equality holds since the teacher always (i.e. with probability

1) attempts to verbally communicate the true hypothesis.

Lastly, we define

$$P(d_i|d_i^{sent}) \propto \exp\{\sigma_{d_i,d_i^{sent}} \cdot \eta\} \quad (6)$$

Where $\sigma_{d_i,d_i^{sent}}$ is the correlation in predictions between the communicated hypothesis index d_i^{sent} and d_i, the (potentially noise corrupted) index of the received hypothesis. The softmax scale parameter $\eta \in [0,\infty)$ is the *verbal effort*. A verbal effort of zero corresponds to complete randomness: nothing useful was transmitted verbally. A verbal effort of infinity, in contrast, allows one to exactly identify the correct hypothesis. Currently, we fixed the steps on which the verbal communication occurs, but this restriction could be relaxed.

Overall, Equations 3, 4, 5, and 6 provide a formal definition of our model. See supplementary materials for the model implementation.

Evaluation

In the next sections we describe the experimental setting on which we collected both empirical and simulation data to test test the viability of our model.

Experiment

Method

Participants We recruited 357 participants (169 as *teachers* and 188 as *students*) through Amazon Mechanical Turk. They were native English speakers from the US. We excluded from the analysis teachers who did not reach predefined 85% accuracy threshold ($n = 40$) or failed to follow the instructions ($n = 28$), resulting in a final sample of 101 teachers.

Materials Schematic representations of fish (Rosedahl & Ashby, 2018) with possible variations in up to five visual features (fin, tail, belly color, etc.) were used as stimuli. We varied three independent variables between the participants: 1) *stimuli dimensionality* (two, three, or four dimensions) – the number of visual features varying in the presented stimuli, 2) *perceptual confusability* (low/high) – the visual similarity between stimuli of two categories, and 3) *rule type* (one- or two-dimensional). Exact visual features related to the rule dimensions were selected randomly.

Procedure Teachers learned the categorization rule by observing two sets of 15 stimuli labeled *Examples of type A* and *Examples of type B* (see Figure 2). Stimuli were presented simultaneously. Teachers had no time constraints and were able to explore each stimulus in more details by enlarging it. In the test phase, teachers had to categorize 30 stimuli presented sequentially (15 stimuli of each category including at least eight stimuli that were not presented before). Teachers who achieved the accuracy threshold of 85% in the test phase were asked to generate three training sets to teach other participants. There were three teaching formats (the order was counter-balanced across the teachers): *verbal*, *examples*, and *mixed*. In the *verbal* format teachers had to provide instructions that allow categorizing the stimuli. In the *examples* format they had to generate new stimuli of two different categories without any verbal explanations (category labels were provided). In the *mixed* format teachers were allowed to use both verbal instructions and visual examples (see Figure 2). Teachers could use as many words or visual examples as needed to explain the categorization rule, but they were instructed to be concise in their explanations and use only the minimum required amount of examples.

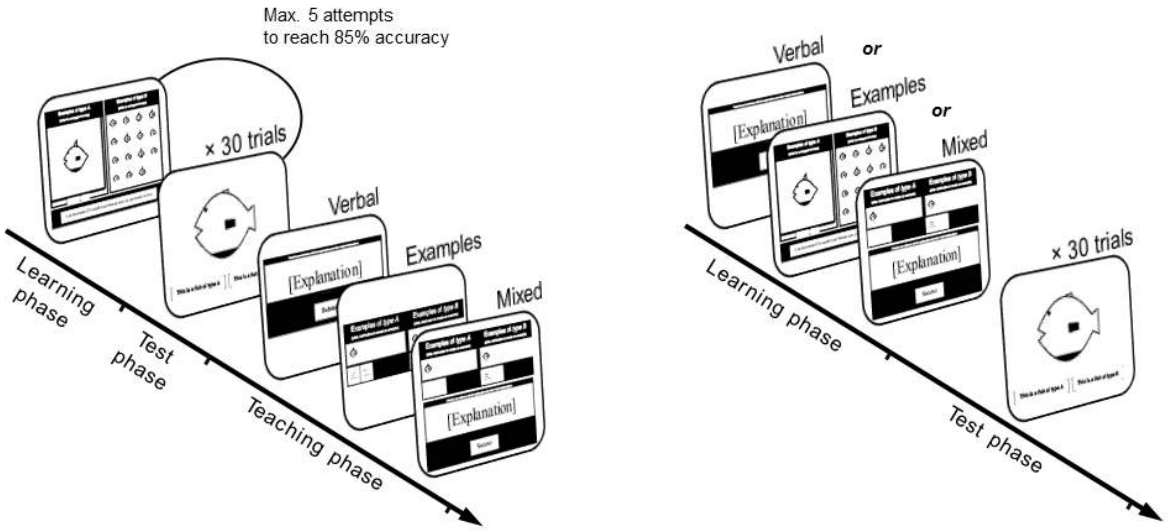
Students were randomly assigned to one of three learning conditions (verbal explanations, visual examples, or mixed), and received corresponding training materials prepared by one of the teachers. There were no time limits for the learning phase. The test phase was similar to the teachers' group.

Results

Students' performance More than 67 percent of students achieved 75% threshold criterion with median accuracy of 93 percent. Unfortunately, it results in overly low variability in the student accuracy variable. Some clear patterns were still present: one-dimensional rules result in higher performance $(.85)$ than two-dimensional $(.72)$, $p < .001$. As well as higher perceptual confusability decreased students' accuracy from .84 to .76 $(p < .001)$. However, it would be impossible to capture the more subtle interaction effects that are relevant to our study. Initially, we planned to investigate the effects of text length and explanation numbers on the students' accuracies, but students' surprisingly good performance rendered this approach impractical. Thankfully, we could switch to another interpretation to still gain insight into the problem. Since the teachers were able to create learning materials that in most cases allowed students to master the concept, we could focus on the study materials themselves: did the teachers adjust their teaching strategies to the situation? We used a Poisson regression and Generalized Estimating Equations approach to account for the teacher-to-teacher individual differences. We applied robust variance estimation techniques to compensate for potential model misspecifications.

Words per picture The average number of the visual examples provided by teachers was 4.28 in the mixed condition and 4.86 in the examples condition. The average length of the explanations increased from 28.37 in the mixed condition to 34.86 in the verbal condition because of the absence of visual examples. That is, to achieve comparable performance, the teachers needed to write approximately $34.86 \div 4.86 = 7.17$ words per example. These values could be used to map the verbal effort variable used in the computational model to the number of words in the explanation and thus put it on a more intuitive scale.

Predictors of text length and number of examples We found statistically significant effects of the rule type ($\beta = .58, p < .001$), the perceptual confusability ($\beta = .22, p = .044$), and the presence of visual examples ($\beta = -.19, p = .004$) on the length of verbal explanations (in symbols). The effects of stimuli dimensionality were not statistically signifi-



(a) Teachers

(b) Students

Figure 2: Experimental procedure illustration

cant ($\beta = -.03, p < .655$). However, the number of visual examples was predicted only by the stimuli dimensionality ($\beta = .18, p = .012$) and the rule type ($\beta = .46, p = .025$). There were also marginally significant effects of the presence of verbal explanations ($\beta = -.12, p = .052$) and the interaction of the perceptual confusability and the stimuli dimensionality ($\beta = .15, p = .089$). The effects of perceptual confusability were not statistically significant ($\beta = -.29, p = .149$).

Simulation results

We used identical experimental settings to test the performance of our computational model. We obtained initial estimates of $P(d_i|h)$ using a strong sampling assumption, and then iteratively updated them until convergence.

As shown in Figure 1, the simulation results closely correspond to the patterns we observed in the experiment. It is important to mention, however, that the behaviour depicted on Figure 1d depends on the choice of the parameter α. We used $\alpha = 1.1$ in our experiments.

Apart from capturing the key dynamics present in our data, the model also makes a range of important predictions and provides rich opportunities for further experimentation. For example, it is able to capture the mutually enriching nature of verbal and exemplar communication channels. Thus, it is possible to model situations in which using verbal explanations and exemplars together leads to dramatic leaps in performance, allowing to reach maximum accuracy, while individual channel performance is mediocre at best (0.76 for exemplars, 0.53 for verbal communication).

Discussion and conclusion

We see the main impact of our paper in identifying a fundamental limitation characteristic of most existing human category learning models (little to no account for the verbal communication) and proposing a principled and broadly applicable model to account for these phenomena.

Almost as important is the empirical demonstration of the qualitative and quantitative differences between the verbal and exemplar channels of communication. We observed that the exemplar channel is more robust to perceptual confusability of the category structures, i.e., it is more efficient in communicating categories that require higher precision in perceptual decisions. At the same time, the verbal channel is more robust to increases in the dimensionality of the stimuli.

Our simulations show that the proposed *rational category communication* model can capture the main qualitative properties of the empirical data. Additionally, the number of exemplars it chooses to ensure that a student learns a category is in close alignment with empirical data. Most importantly, it captures the difficulties of verbally explaining categories that require high perceptual precision and the robustness of exemplar communication channel to such changes.

Overall, the verbal and exemplar channels of communication have their unique strengths and weaknesses, and their relative efficiency largely depends on the structure of the hypothesis space.

While many of the reported results are preliminary, we hope that both the proposed experimental paradigm and the computational model would facilitate further research into the relative roles of verbal and exemplar information in communicating category structure. To further aid this goal, we make the model implementation openly available.

Lastly, we find that under our experimental settings, the answer to the question of "how many words is a picture worth?" is approximately 7.17.

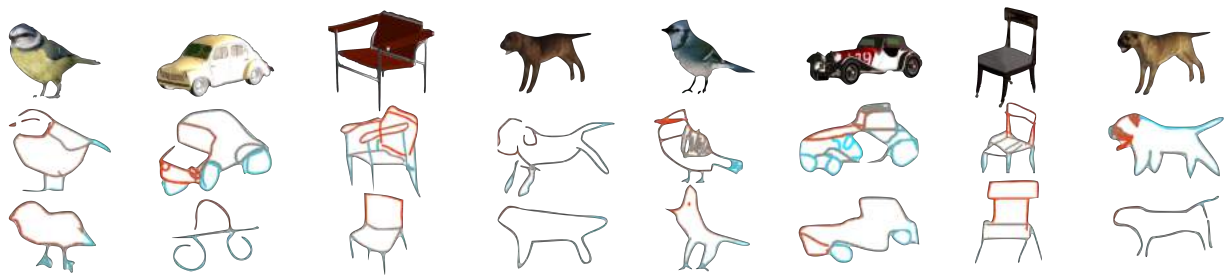

Figure 1: Objects used in communication game with example drawings below, where stroke color indicates different parts.

Abstract

We effortlessly grasp the correspondence between a drawing of an object and that physical object in the world, even when the drawing is far from realistic. How are visual object concepts organized such that we can both recognize these abstract correspondences and also flexibly exploit them when communicating them to others in a drawing? Here we consider the notion that the compositional nature of object concepts enables us to readily decompose both objects and drawings of objects into a common set of semantically meaningful parts. To investigate this, we collected data on the part information expressed in drawings by having participants densely annotate drawings of real-world objects. Our dataset contained both detailed and sparser drawings produced in different communicative contexts. We found that: (1) people are consistent in what they interpret individual strokes to represent; (2) single strokes tend to correspond to single parts, with strokes representing the same part often being clustered in time; and (3) both sparse and detailed drawings of the same object emphasize similar part information, although detailed drawings of different objects are more distinct from one another than sparse drawings. Taken together, our results support the notion that people flexibly deploy their abstract understanding of the compositional part structure of objects to communicate relevant information about them in context. More broadly, they highlight the importance of structured knowledge for understanding how pictorial representations convey meaning.

Keywords: compositionality; objects and categories; perceptual organization; sketch understanding; visual communication

Introduction

When we open our eyes, we do not experience a meaningless array of photons — instead, we parse the world into people, objects, and their relationships. The ability to represent semantically meaningful structure in our environment is a core aspect of human visual perception and cognition (Navon, 1977). As a testament to this ability, we effortlessly grasp the correspondence between a physical object in the world and a simple line drawing of it, even though such drawings lack much of the rich visual information present in real-world objects, including color and texture. How are visual object concepts organized such that they can robustly encode such abstract correspondences? Here we explore the notion that perceiving these correspondences is supported by our ability to decompose both objects and drawings into a common set of semantically meaningful parts (Biederman & Ju, 1988).

Recent advances in computational neuroscience have provided an unprecedentedly clear view into the algorithms used by the brain to extract semantic information from raw visual inputs, including drawings, exemplified by modern deep learning approaches (Fan, Yamins, & Turk-Browne, 2018; Yamins et al., 2014). Nevertheless, a major gap remains in adapting such deep learning models to emulate the structure and flexibility of human semantic knowledge (Lake, Ullman, Tenenbaum, & Gershman, 2017). A promising approach to closing this gap may be to exploit the parsimony and interpretability of structured representations that reflect how visual concepts are organized in the mind (Battaglia et al., 2018).

However, pursuit of this strategy relies upon a thorough empirical understanding of this conceptual organization and how people express this knowledge in natural behavior. We aim to contribute to this understanding by probing the expression of visual semantic knowledge in a naturalistic setting that exposes both its structure and flexibility: visual communication via drawing. This approach departs from the conventional strategy for inferring the organization of visual object concepts, which entails eliciting judgments with respect to a small number of experimenter-defined dimensions. Instead, drawing tasks permit participants to include any elements they consider relevant and combine these elements freely, yielding high-dimensional information about how people organize and deploy visual semantic knowledge under a naturalistic task objective.

Recent computational work using drawing tasks to probe visual concepts have focused on either recognition (Eitz, Hays, & Alexa, 2012; Yu et al., 2017) or generation (Ha & Eck, 2017; M. Li, Lin, Mech, Yumer, & Ramanan, 2019) of *entire* drawings. However, the question of how semantic information *within* drawings is organized has not been inves-

tigated as thoroughly (cf. L. Li, Fu, & Tai, 2018; Schneider & Tuytelaars, 2016). The goal of this paper is to present a systematic approach to analyzing the correspondence between semantic knowledge about the internal part structure of objects and the procedure by which people robustly convey this knowledge in their drawings. Specifically, this paper advances recent work investigating how drawings convey semantic information in three ways: *first*, we collect dense part annotations on freehand drawings of real-world objects, allowing an explicit focus on compositional part structure, *second*, we explore the link between this semantic structure and the dynamics of drawing production, and *third*, we examine differences in how visual semantic knowledge is expressed between contexts.

Methods

We developed a web-based crowdsourcing tool, built with `jsPsych.js` (de Leeuw, 2015), to collect dense semantic annotations of the stroke elements in drawings of real-world objects (Fig. 1).

Communicative drawing dataset

We first obtained 1195 drawings of 32 real-world objects from a previously collected experimental dataset in which pairs of participants played a drawing-based reference game (Fan, Hawkins, Wu, & Goodman, 2019).[1] Object stimuli were photorealistic 3D renderings belonging to one of four basic-level categories (i.e., bird, car, chair, dog), each of which contained eight exemplars. On each trial of the experiment, participants were presented with a shared context containing four of these objects. One participant (the sketcher) was privately cued to draw a target object so that the other participant (the viewer) could pick it out from the set of distractors. Across trials, the similarity of the distractors to the target was manipulated, yielding two types of communicative contexts: *close contexts*, in which all four objects belonged to the same basic-level category, and *far contexts*, in which objects belonged to different basic-level categories. This context manipulation led sketchers to produce relatively simpler drawings containing fewer strokes and less ink on far trials than on close trials, while still achieving high recognition accuracy in both contexts.

Prior works analyzing the semantic properties of drawing data have used a raster image representation (e.g., `*.png`), an expedient format for applying modern convolutional neural network architectures (Fan et al., 2018; Sangkloy et al., 2016; Yu et al., 2017). However, to investigate how semantic structure manifests during drawing production, it was critical to encode each drawing using a vector image format that preserves the inherently sequential and contour-based nature of drawing production (e.g., `*.svg`). Thus, each drawing in our dataset is represented as a sequence of individual strokes. A stroke is defined as the mark left by a virtual pen on a digital drawing canvas between being 'placed onto' the canvas and being 'lifted up'. We parameterized each stroke by a sequence of cubic Bézier curves, called *splines*. This format provides a compact representation of drawing data, which also preserves the sequence in which each element was produced.

[1] All materials and data are available at `https://github.com/cogtoolslab/semantic_parts`.

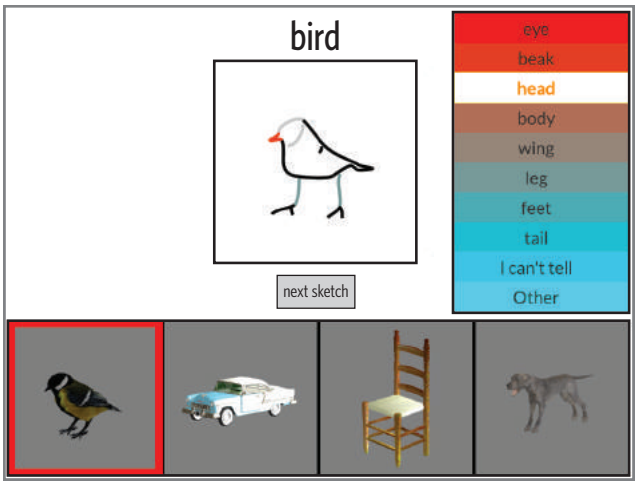

Figure 2: Annotation interface. Participants selected sub-stroke elements (splines) and tagged them with part labels.

Semantic part annotation

We crowdsourced dense semantic annotations for every spline in every stroke of the drawings from this dataset. We refer to our annotation data as *dense* because labels were provided for splines, which are at a finer level of granularity than strokes.

Participants 326 participants were recruited via Amazon Mechanical Turk (AMT) and provided informed consent in accordance with the Stanford IRB. Participants were given a base compensation of $0.35, plus $0.002 for every spline they annotated and $0.02 for every drawing they annotated completely.

Task procedure Each participant was presented with a sequence of 10 drawings that were randomly sampled from the communicative drawing dataset (Fig. 2). Their goal was to tag each spline with a label corresponding to the part it represented (e.g., seat, leg, back for a chair). To facilitate consistent tagging, participants were provided with a menu of common part labels that were associated with each basic-level category (Table 1). Participants could also generate their own part label if they believed none of the common labels applied. If any spline was too short for annotators to feasibly annotate it with their mouse cursor, it was concatenated with its neighboring splines until the resulting spline was long enough to easily select. To give participants full information about the original communicative context, we showed the drawing with the same array of four objects that the original sketcher had viewed, with the target object highlighted in red.

Data preprocessing We first standardized all 304 distinct labels provided by participants, mapping them to a common set of 24 part labels that applied to all objects in the dataset. This common set was defined as the superset of all labels that appeared in the part menu in the annotation task. Although most labels provided already exactly matched one in the common set (i.e., 90.1%), participants were permitted to assign their own custom label, resulting in additional lexical variation that we collapse over in the current analysis. For example, some custom labels were either synonymous with or more specific than one of the common labels (e.g., 'leg support', 'foot', or 'strut' for 'leg'). We manually constructed a part dictionary to map such custom labels to one of the common ones, ensuring a consistent level of granularity for all spline labels. We only examined drawings that were annotated by at least three distinct participants, providing a consistent way to evaluate annotation consistency across splines. To reduce bias due to missing data, we also restricted our analyses to annotation trials in which the drawing was completely annotated (i.e., all splines were tagged). After applying all preprocessing, our resulting dataset consisted of 864 drawings that had been completely annotated 3 times.

Results

How well do viewers agree on what strokes mean?

Before proceeding to use these annotations to examine how semantic information is conveyed during drawing production, we conducted a basic check of inter-annotator consistency. Specifically, we examined how often different annotators agreed on what each spline in a drawing represented. We found that 95.6% of all splines received the same label by at least two of the three annotators, and 67.8% of all splines received the same label by all three annotators. This shows that the way viewers interpret which part each stroke represents is systematic, validating our general approach. Further, it suggests that sketchers may exploit this systematicity to produce strokes that they expect viewers to interpret consistently. In subsequent analyses, we collapsed over inter-annotator variation: we assigned the modal label to splines to which at least two annotators had given the same label; for the remaining 4.4% of splines, we sampled one of the three labels provided.

How do strokes correspond to parts of objects?

When composing a recognizable drawing of a real-world object, how do people decide what information to convey with each stroke? A natural possibility is that their actions closely correspond to the part structure of that object. Concretely, we hypothesized that most strokes in our dataset would *not* cross part boundaries: that all splines within a given stroke would be assigned the same part label. Conversely, because depictions of parts can be arbitrarily detailed, and some parts re-occur throughout an object (e.g., multiple legs on a bird, chair, or dog), we hypothesized that there would often be more than one stroke per part (Fig. 3A).

category	part labels
bird	eye, beak, head, body, wing, leg, feet, tail
car	bumper, headlight, hood, windshield, window, body, door, trunk, wheel
chair	backrest, armrest, seat, leg
dog	eye, mouth, ear, head, neck, body, leg, paw, tail

Table 1: Part labels provided to annotators.

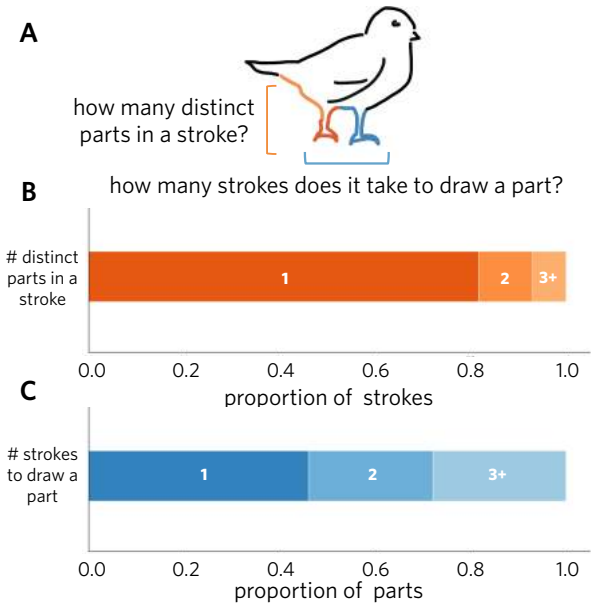

Figure 3: (A) Analyzing the correspondence between strokes and part labels: number of unique part labels assigned to different splines within the same stroke and number of different strokes used to draw each part. (B) Distribution over number of part labels within a stroke. (C) Distribution over number of strokes used to draw a part.

To evaluate the first hypothesis, we computed the number of unique part labels across all splines within each stroke. We found that for 81.6% of the strokes in our dataset there was only one part label; the remaining 18.4% of strokes were associated with two or more labels (Fig. 3B). In other words, most strokes represented exactly one part, but in a minority of cases they spanned multiple parts (e.g., a single stroke connecting the head and body of a bird, or an armrest and leg of a chair). We were concerned, however, that these proportions were inflated by strokes with very few splines.[2] To address this concern, we constructed a null model controlling for the number of splines. Part labels were randomly sampled from the full list of parts in the drawing such that each spline was equally likely to represent any part regardless of the stroke it belonged to. In simulations from this null model, only 55% of strokes corresponded to a unique part while 45% of strokes spanned multiple parts. Thus, individual strokes in our dataset were much more likely to correspond to a single part (i.e., not cross part boundaries)

[2]The modal number of splines per stroke (20% of cases) was 1, but there was a long tail; the mean number was 2.6.

than would be expected under random assignment of part labels to splines.

To evaluate the second hypothesis, we computed the number of strokes that were used to represent each part of an object (Fig. 3C). We found that 46.1% of parts were depicted using exactly one stroke, 26.0% using exactly two strokes, 11.3% using exactly three strokes, and 16.6% using four or more strokes. Thus, nearly half the time, a single action was sufficient to depict an entire object part. However, the remaining 53.9% of the time, more than one stroke was required to depict an entire part, which would be expected for those parts that consisted of multiple disconnected subparts within an object (e.g., wheels of a car, paws of a dog).

The findings so far show that the information people convey with each stroke systematically corresponds to the parts that objects contain. We next sought to understand how these properties may vary between drawings generated in different communicative contexts. Indeed, strokes spanning multiple parts were slightly more common in drawings produced in far contexts (19.4%, CI: [17.9%, 20.9%]) than close contexts (17.6%, CI: [16.1%, 18.8%][3], p= 0.07), suggesting that sketchers were somewhat more likely to use a single stroke to represent multiple contiguous parts in a context where a sparser drawing would be sufficient. And the proportion of parts requiring more than one stroke was slightly higher for close drawings (55.8%, CI: [53.7%, 58.6%]) than far drawings (52.0%, CI: [49.9%, 54.6%],$p = 0.02$), suggesting that sketchers may have included more detail per part in close drawings to distinguish the target object from similar distractors.

Do strokes representing the same part tend to be produced in succession?

In the previous section we discovered that slightly more than half of the parts in our dataset were depicted using multiple strokes. This result raised the question: to what extent are strokes depicting the same part drawn in succession, or interleaved among strokes depicting other parts?

To investigate this question, we estimated the mean length of 'streaks' containing strokes depicting the same part. First, we collapsed across the spline annotations examined in the previous section and represented each stroke by the modal part label assigned to its splines. We represented each drawing as the sequence of these part labels, and defined *part streak length* to be the number of consecutive strokes annotated with the same part label.[4] For example, in the drawing shown in Fig. 4A, two 'leg' strokes were placed before moving on to the 'foot', giving a streak of length 2. Finally, we averaged these streak length values over every drawing in the dataset to obtain our statistic.

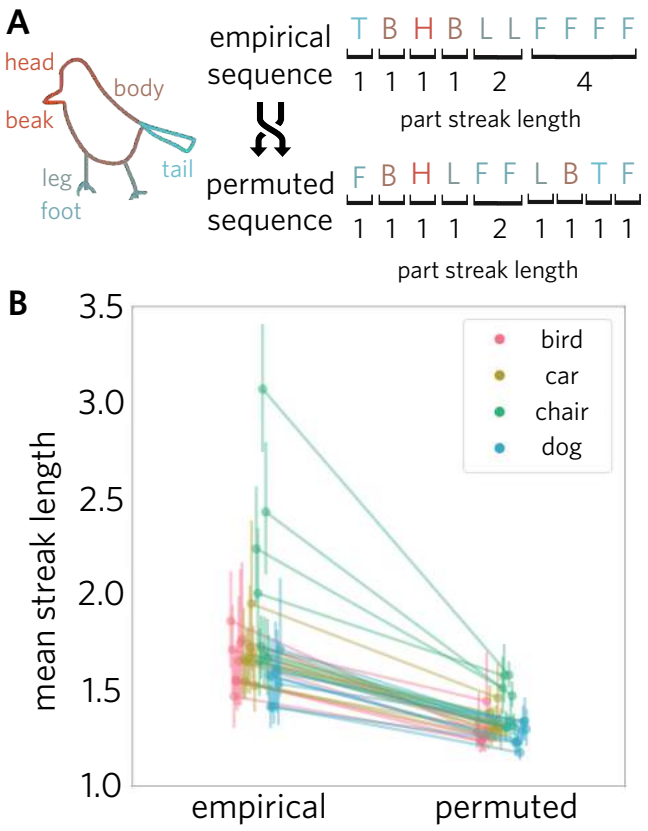

Figure 4: (A) Analysis of sequence in which strokes depicting each part were drawn. (B) Comparison of mean length of streaks consisting of strokes that depict the same part with null distribution of permuted stroke sequences.

To evaluate whether the empirical part sequences were more structured than expected if parts were drawn at random, we constructed a null model to serve as a baseline. For this null model, we permuted the part sequence such that the number of instances of each part was preserved, but the temporal structure was disrupted (Fig. 4A). We generated a null distribution of streak lengths for each drawing by repeating this permutation procedure 1000 times and measuring the mean streak length for each permutation. Finally, we obtained a z-score for each drawing by computing where the empirical streak length fell in the permuted streak length distribution. A drawing with a z-score near 0 had a streak length that was commonly obtained by placing strokes in a random order, while a drawing with a higher z-score is more structured than expected under the null.

We found that the empirical streak length was reliably higher for all objects than that of the permuted sequences (mean z-score across drawings: 2.07, CI: [1.90, 2.23]; Fig. 4B), and higher for the close drawings (mean z-score: 2.58; CI: [2.26, 2.90]) than far drawings (mean z-score: 1.56; CI: [1.38, 1.74]). The lower streak length for far drawings is consistent with their lower stroke count overall—when only

[3] 95% confidence intervals were estimated via stratified bootstrap resampling (N=1000 iterations) of drawings within each context condition.

[4] We excluded 78 out of the 864 drawings where this measure was not well-defined, i.e. sketches containing only one stroke or part label, or containing fewer than two strokes sharing the same part label.

one or two strokes are used per part, there is a ceiling on the mean streak length. However, when sketchers do use multiple strokes to convey a single part (i.e., because there are multiple subparts, or to add more detail), they tend to draw these in succession before moving on to a different part. These results suggest more broadly that the procedure by which people convey semantic information in drawings is organized by the part structure within objects.

How is part information emphasized in different communicative contexts?

Our findings so far bear on how the way people compose communicative drawings of objects reflects their semantic knowledge of the parts those objects are composed of. A key consequence of such semantically organized part knowledge is that it naturally supports flexible expression across different communicative contexts. For example, when communicating about a chair in a far context containing objects from other basic-level categories, sketchers may include only the essential information to indicate the presence of certain parts (e.g., armrests) that distinguish it at the category level. On the other hand, when communicating about that same chair in a close context containing other, perceptually similar, chairs sketchers may emphasize aspects of parts that distinguish it at the object level (e.g., the curvature of the armrests), by applying more strokes and/or more ink in each stroke.

We hypothesized that sketchers emphasize part information to preserve relevant distinctions in context. To explore this possibility, we asked the following questions: (1) How similarly is object-specific part information emphasized in both close and far contexts? (2) How do differences in how part information is emphasized *between* contexts affect how discriminable those drawings are?

To investigate these questions, we represented each drawing by a 48-dimensional *part-feature vector* that contained information about: (a) how many strokes and (b) how much total ink was allocated to each of the 24 unique part labels in our dataset. Specifically, the first 24 elements of each part-feature vector contained the number of strokes allocated to each part, and the remaining 24 contained the total arc length of all strokes allocated to each part. Because our primary goal was to understand *relative* differences in how much emphasis was placed on each part across drawings in our dataset, we first z-scored the raw stroke-count and arc-length measurements within each feature dimension, thereby mapping all features to the same unit-variance scale. We then collapsed across drawings within each object-context combination, yielding 64 average part-feature vectors (i.e., 32 objects x 2 context conditions).

Similar part information emphasized across different communicative contexts In order to investigate to what extent similar object-specific part information is emphasized in different communicative contexts, we computed the matrix of Pearson correlations between part-feature vectors. Formally, this entailed computing: $R_{ij} = {}^{cov(\vec{r}_i,\vec{r}_j)}/\sqrt{var(\vec{r}_i)\cdot var(\vec{r}_j)}$, where

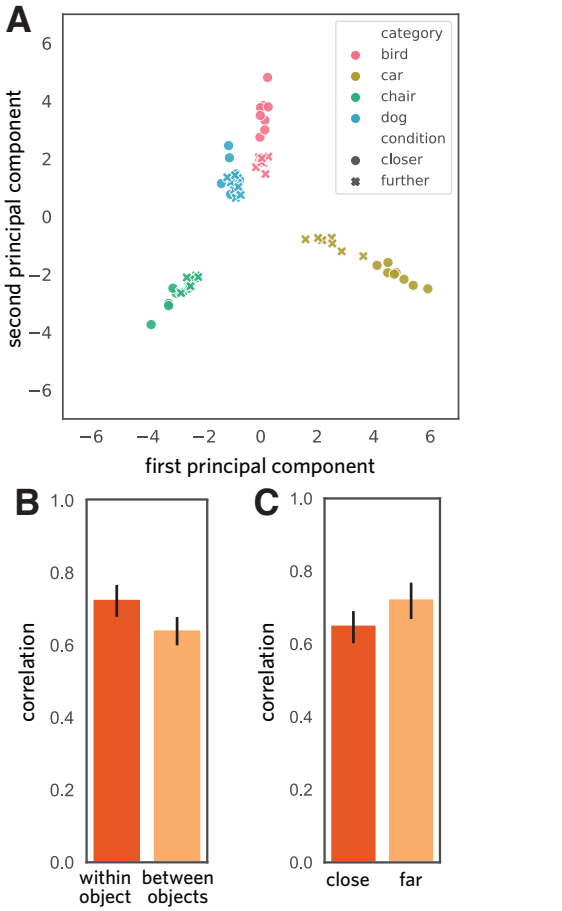

Figure 5: (A) Layout of mean part-feature vectors for each object-context combination, projected onto top two principal components. (B) Comparison of feature similarity between close and far drawings of the same object, relative to close and far drawings of different objects within a category. (C) Comparison of feature similarity between far drawings of objects within a category, relative to close drawings. Error bars reflect 95% CIs.

$\vec{r}_i$ and $\vec{r}_j$ are the mean part-feature vectors for the ith and jth object-context combinations, respectively.

While close and far drawings of an object differed in their overall amount of detail, we hypothesized that they would still emphasize part information in similar ways. Specifically, insofar as similar object-specific part information is emphasized in both close and far drawings of the same object, we predicted higher correlations between close and far part-feature vectors for the *same* object than for close and far part-feature vectors of *different* objects. Consistent with this, we found strong correlations between the feature vectors for close and far drawings of the same object ($r = 0.73$, CI: [0.68, 0.77][5]), which were significantly stronger than close and far drawings of *different* objects ($r = 0.64$, CI: [0.60, 0.68]; same objects vs. different objects: $p < 0.001$). These results show that close and far drawings of the same object exhibit similar

[5]95% confidence intervals were estimated via stratified bootstrap resampling (N=10000 iterations) of drawings within each object-context combination.

patterns of emphasis across different parts, and this similarity exceeded that expected due to merely being members of the same basic-level category (Fig. 5B).

Detailed drawings are more distinct from each other than sparser drawings While the above findings showed that close and far drawings of the same object exhibit similar patterns of emphasis on different parts, close drawings contain greater emphasis on these parts overall than far drawings (i.e., contained more and longer strokes). How were these additional strokes being spent?

We hypothesized that the additional part information provided in close drawings was being distributed across parts in different ways for different objects, thereby making them more distinguishable from one another in feature space. To evaluate this possibility, we computed the mean correlation between the part-feature vectors of close drawings of objects in a given category and compared this value with the mean correlation between far drawings of exactly the same objects. We found that close drawings were less similar to one another than far drawings were (close similarity: $r = 0.65$, CI: [0.60, 0.69]; far similarity: $r = 0.73$, CI: [0.67, 0.77]; close vs. far: $p = 0.007$), suggesting that sketchers discern which parts are most diagnostic of the target object among highly similar distractors and emphasize these parts accordingly (Fig. 5C). This was particularly apparent when we visualized the spatial layout of part-feature vectors: whereas far drawings were clustered closer together and near the origin, close drawings were spread further apart from other members of the same category and further from the origin (Fig. 5A). Observing these contextual differences is all the more remarkable given that this feature representation captures only the *amount* of emphasis allocated to each part during drawing production, setting aside their visual properties.

Discussion

In this paper, we explored how the way people compose communicative drawings of objects reflects their semantic knowledge about what objects are composed of. To accomplish this, we first collected dense semantic annotations of sub-stroke elements in communicative drawings of real-world objects that were produced in different contexts. This allowed us to interrogate the internal semantic structure within drawings, and relate this structure to the dynamics of drawing production in a naturalistic visual communication task. Overall, we found that: (1) people are highly consistent in how they interpret what individual strokes represent; (2) single strokes tend to correspond to single parts, with strokes representing the same part tending to be clustered in time; and (3) both detailed and sparse drawings of the same object emphasized similar part information, with detailed drawings of different objects tending to be more distinct from one another than simpler ones. Taken together, our results support the notion that people deploy their abstract understanding of the compositional part structure of objects in order to select actions to communicate relevant information about them in context.

These findings are resonant with classic and recent work that has argued for the importance of compositionality in human perception and cognition in general (Biederman, 1987; Battaglia et al., 2018; Lake et al., 2017), and for visual production in particular (Lake, Salakhutdinov, & Tenenbaum, 2015). However, unlike prior work which focused on the production of abstract symbols (Lake et al., 2015), we consider the challenge of how people transform perceptually grounded representations of real-world objects into procedures for producing figurative drawings that communicate not only what they see and know about them, but also what is relevant in context.

Our work is also related to recent progress in the development of computational models of drawing production (Ha & Eck, 2017; M. Li et al., 2019). While results from these efforts have been galvanizing, the development of principled metrics by which to rigorously evaluate how well they emulate human drawing behavior has not kept pace. By interrogating in detail how humans encode semantic information into their drawings, and flexibly adjust their production behavior in different contexts, this paper presents a first step towards such a set of behavioral metrics. Having such metrics is important because they would enhance our ability to distinguish between generative models, and thereby help advance further model development. It would thus be valuable to apply up our analytical approach to the large drawing datasets (Eitz et al., 2012; Sangkloy et al., 2016; Jongejan, Rowley, Kawashima, Kim, & Fox-Gieg, 2017) that have provided the basis for these modeling approaches.

In ongoing work, we are extending our analysis of how different part information is expressed in drawings beyond simple effort cost measures (i.e., number of strokes, amount of ink) to encompass content and style information (e.g., the shape of a bird's wing, caricaturization of a chair's armrest). We expect that augmenting current vision models with a combination of the requisite semantic part knowledge and the ability to discern perceptual properties of these parts, such as style, will enable us to build models that parse drawings in a more human-like way. More broadly, achieving this synthesis will lead to both more robust artificial intelligence and a deeper understanding of human cognition and behavior.

Abstract

Constraints on control-dependent processing have become a fundamental concept in general theories of cognition that explain human behavior in terms of rational adaptations to these constraints. However, theories miss a rationale for why such constraints would exist in the first place. Recent work suggests that constraints on the allocation of control facilitate flexible task switching at the expense of the stability needed to support goal-directed behavior in face of distraction. Here, we formulate this problem in a dynamical system, in which control signals are represented as attractors and in which constraints on control allocation limit the depth of these attractors. We derive formal expressions of the stability-flexibility tradeoff, showing that constraints on control allocation improve cognitive flexibility but impair cognitive stability. Finally, we provide evidence that human participants adapt higher constraints on the allocation of control as the demand for flexibility increases but that participants deviate from optimal constraints.

Keywords: cognitive control; task switching; stability-flexibility tradeoff; bounded rationality; capacity constraints

Introduction

Numerous theories of cognition are grounded in the assumption that there are fundamental constraints on the allocation of cognitive control (Anderson, 2013; Kurzban, Duckworth, Kable, & Myers, 2013; Shenhav, Botvinick, & Cohen, 2013). Theories that assume such limitations have been successful in explaining how humans rationally allocate control under such constraints (Lieder, Shenhav, Musslick, & Griffiths, 2018; Musslick, Shenhav, Botvinick, & Cohen, 2015; Shenhav et al., 2013). However, they do not provide a rationale for *why* such limitations would exist in the first place.

A recent line of work attempts to explain the limitations of control allocation in terms of fundamental computational dilemmas in neural processing systems. For instance, Musslick et al. (2017) suggest that neural architectures are subject to a tradeoff between learning efficiency that is promoted through the use of shared task representations (Bengio, Courville, & Vincent, 2013; Caruana, 1997), on the one hand, and multitasking capability that is achieved through the separation of task representations, on the other hand (Allport, 1980; Musslick et al., 2016; Meyer & Kieras, 1997; Navon & Gopher, 1979; Salvucci & Taatgen, 2008; Feng, Schwemmer, Gershman, & Cohen, 2014). From this perspective, limitations in multitasking may reflect a preference of the neural system to learn tasks more quickly (Musslick et al., 2017; Sagiv, Musslick, Niv, & Cohen, 2018).

One way to circumvent limitations in concurrent multitasking is to execute multiple tasks in series, through flexible switching between tasks (Salvucci, Taatgen, & Borst, 2009; Fischer & Plessow, 2015). The serial execution of tasks, however, gives rise to another tradeoff known as the stability-flexibility dilemma: allocating more control to a task results in greater activation of its neural representation but also in greater persistence of this activity upon switching to a new task, yielding switch costs (Ueltzhöffer, Armbruster-Genç, & Fiebach, 2015; Goschke, 2000). By considering the problem in terms of the parameterization of a nonlinear dynamical system, in which control signals are represented as attractors, Musslick, Jang Jun, Shvartsman, Shenhav, and Cohen (2018) showed that constraints on control allocation can promote cognitive flexibility at the expense of cognitive stability. Their simulations suggest that higher constraints on control allocation are optimal in environments with higher demand for task switches. While the simulations provide a computational rationale for constraints on control, a formal analysis of the problem is lacking. It also remains to be tested whether humans adapt their constraints on control in response to demands for flexibility.

In this work, we analyze the model by Musslick et al. (2018) from a dynamical system perspective and derive formal definitions for cognitive stability and cognitive flexibility. We then prove that higher gains of a network's activation function (equivalent to inverse temperature, and thought to reflect the effects of neuromodulatory neurotransmitters such as dopamine and norepinephrine; Servan-Schreiber, Printz, & Cohen, 1990; Liljenström, 2003; Cools, 2015) can balance this tradeoff towards cognitive stability at the cost of cognitive flexibility. To assess whether human participants adjust their constraints on control as a function of flexibility demands, we fit the model to participants who performed a task switching experiment with different rates of switching. We specifically test the hypothesis that the behavior of participants in highly flexible environments can be best described by a lower gain, reflecting higher constraints on control allocation. Finally, we use computational simulations to investigate whether participants adapt to the stability-flexibility dilemma in a rational manner, by comparing fitted constraints on control against optimal constraints on control.

Recurrent Neural Network Model

We analyze the stability-flexbility tradeoff in a recurrent neural network model described by Musslick et al. (2018). The model consists of a control module that simulates control configurations as activities of processing units. The pattern of activity associated with each control configuration evolves in an attractor landscape over the course of trials. Within each trial, the processing units bias an evidence accumulation process in the decision module that integrates information about the stimulus and generates a response.

Control Module

We simulate the amount of control allocated to a task as the activity of a corresponding processing unit in a recurrent neural network. Here, we consider environments with two tasks, and therefore two processing units, indexed by $i, j \in \{1,2\}$. The activity of each unit is determined by its net input

$$net_i(t) = w_{i,i} act_i(t) + w_{i,j} act_j(t) + I_i \tag{1}$$

which is a linear combination of the unit's own activity $act_i(t)$ multiplied by the self-recurrent weight $w_{i,i}$, the activity $act_j(t)$ of the other unit $j \in 1,2, j \neq i$, multiplied by an inhibitory weight $w_{i,j}$, and an external input I_i (i.e., an "instruction") provided to the unit (see Figure 1A). The activities for both processing units evolve across trials according to

$$\frac{dact_i(t)}{dt} = -act_i(t) + \frac{1}{1+e^{-g \cdot net_i(t)}} \tag{2}$$

where the g is the slope of a sigmoid activation function[1]. The sigmoid activation function constrains the activity of both units to lie between 0 and 1. The gain of the activation function g regulates the distance between the two control attractors, with lower gain leading to a lower activation of the currently relevant control unit and slightly higher activation of its competitor (see Figure 1B-C). From this perspective, lower gains impose higher constraints on the amount of control that can be allocated to a task but facilitate switches between tasks. Below, we provide a formal analysis of the stability-flexibility dilemma as a function of gain.

Decision Module

We simulate the decision process using the drift diffusion model (DDM, Ratcliff, 1978). On each trial, the decision module integrates information along two stimulus dimensions S_1 and S_2 of a single stimulus to determine a response. Each dimension (e.g., color or motion of a moving dot stimulus) can take one of two values (e.g., red or blue; up or down), each of which is associated with one of two responses (e.g. pressing left or right button). Each of the two tasks requires mapping the current value of one of the two stimulus dimensions to its corresponding response, while ignoring the other dimension. Since both tasks involve the same

[1]The non-linear dynamical system presented in this work is formally equivalent to the discrete time model by Musslick et al. (2018) for a rate constant of 1.

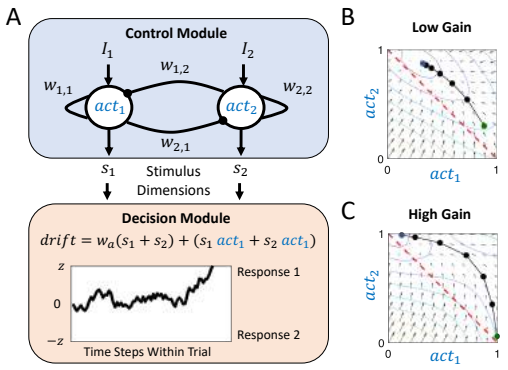

Figure 1: Model architecture. (A) The dynamics of the control module (blue) unfold over the course of trials and are determined by external input signals I_1, I_2, recurrent connectivity $w_{1,1}, w_{2,2}$ for each unit, as well as mutual inhibition $w_{1,2}, w_{2,1}$ between units. The activity of each control unit biases the processing of a corresponding stimulus dimension on a given trial. On each trial, the decision module accumulates evidence for both stimulus dimensions towards one of two responses until a threshold is reached. (B-C) Activation trajectories for models with a (B) low and (C) high gain are shown as a series of connected black dots, evolving from the control attractor for task 1 (green) to the control attractor for task 2 (blue). Contour lines and arrows indicate the energy and shape of the attractor landscape after a task switch from task 1 to task 2. Attractors for both tasks lie approximately on the antidiagonal of the state space (act_{dif}) shown in red.

pair of responses, stimuli can be congruent (stimulus values in both dimensions associated with the same response) or incongruent (associated with different responses). The drift of the DDM integration process is determined by the combined stimulus information from each dimension, weighted by input received from the control module (as described below), and evidence is accumulated over time until one of two response thresholds is reached. The drift rate is decomposed into an automatic and controlled component:

$$drift = \underbrace{w_a(S_1 + S_2)}_{\text{automatic}} + \underbrace{act_1 S_1 + act_2 S_2}_{\text{controlled}} \tag{3}$$

where the automatic component is weighted by w_a and reflects automatic processing of each stimulus dimension that is unaffected by control. The absolute magnitude of S_1, S_2 depends on the strength of the association of each stimulus with a given response and its sign depends on the response (e.g. $S_1 < 0$ if the associated response is to press the left button, $S_1 > 0$ if the associated response is to press the right button). Thus, for congruent trials S_1 and S_2 have the same sign, and the opposite sign for incongruent (conflict) trials. The controlled component of the drift rate is the sum of the two stimulus values, each weighted by the activation of the corresponding control unit. Thus, each unit in the control module biases processing towards one of the stimulus dimensions. As a result, progressively greater activation of a control

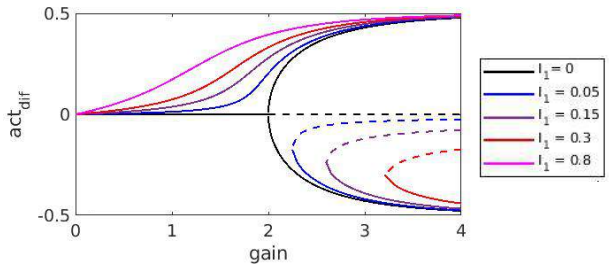

Figure 2: Difference in the activation of the two processing units (act_{dif}) for various magnitudes of I_1 in steady-state solutions to Equation (2), with $I_2 = 0$. Solid lines are stable attractors and dashed lines are unstable solutions. The black curve is the symmetric no-input system of Equation (6), for which with low values of gain the only attractor is the neutral state $act_{dif} = 0$. For values of gain greater than 2, two nonzero attractors emerge in a pitchfork bifurcation. Nonzero input to one of the processing units breaks the symmetry, splitting up the symmetric pitchfork into a continuous branch for the corresponding task and a cusp. The breakup is referred to as imperfect bifurcation (Golubitsky & Schaeffer, 1985).

unit improves performance – speeds responses and improves accuracy – for the corresponding task. Distributions of reaction times (RTs) and error rates for a given parameterization of drift rate at a given trial are derived from an analytical solution to the DDM (Navarro & Fuss, 2009).

Formal Analysis

Previous simulation work suggests that lower values of gain facilitate switches between tasks but limit how much control can be allocated to any given task (Musslick et al., 2018). Building on work by Franci, Srivastava, and Leonard (2015); Gray, Franci, Srivastava, and Leonard (2018), we derive a formal analysis of this tradeoff as a function of gain.

For unit weights $w_{1,2} = w_{2,1} = -1$ and $w_{1,1} = w_{2,2} = 1$, the attractors for both tasks are observed to lie near the antidiagonal in the activation space (see red dashed line in Figure 1B-C). We examine the dynamics of the system in a rotated frame of reference such that the attractors lie near the vertical axis. We introduce translated and rotated variables

$$\begin{pmatrix} act_{avg} \\ act_{dif} \end{pmatrix} = \frac{1}{2}\begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix}\begin{pmatrix} act_1 - 1/2 \\ act_2 - 1/2 \end{pmatrix} \tag{4}$$

where act_{avg} corresponds to the average of the two (shifted) activity states of the processing units, and act_{dif} is the average difference between the two activity states. Here, act_{dif} can be considered a proxy for cognitive stability, indexing how much control is allocated to one task versus the other. We can get an intuition for the dynamics of the system by first considering the symmetric case, in which the control module receives no input to either task processing unit $I_1 = I_2 = 0$.

The dynamical equations (2) with zero input decouple in

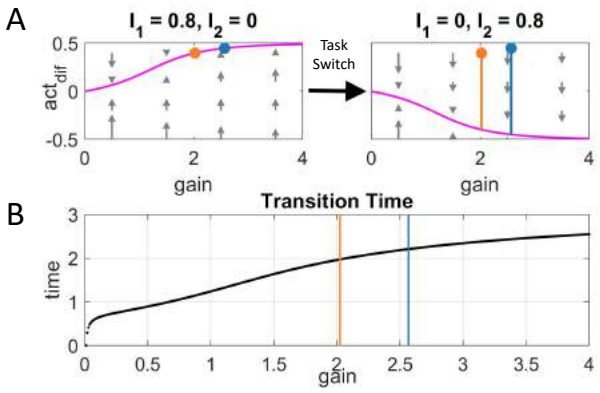

Figure 3: Relationship between act_{dif}, convergence time and gain. (A) Configuration of the system before and after a task switch. (B) Convergence time as a function of gain. Vertical lines mark examples for gain parameters that were fitted to participants' performance in environments with low (blue) and high (orange) rates of task switches.

the new variables:

$$\frac{d}{dt}act_{avg} = -act_{avg} \tag{5}$$

$$\frac{d}{dt}act_{dif} = -act_{dif} + \frac{1}{2}\tanh(g \cdot act_{dif}) \tag{6}$$

The attractors of the system are the stable steady-state solutions of (5), (6). Note that act_{avg} decays to zero and the no-input system always settles on the antidiagonal $act_1 + act_2 = 1$. According to the dynamics of act_{dif}, the available attractors vary with the value of the gain parameter (Figure 2).

With nonzero input, the dynamics on the diagonal and antidiagonal directions do not completely decouple. The contribution in the act_{avg} direction results in the system settling near the antidiagonal with a small offset rather than directly on the antidiagonal (Figure 1B-C). However, analogously to the symmetric no-input case, the dominant dynamical behavior is in the act_{dif} direction, shown in Figure 2. From this we can recover intuition for the tradeoff between cognitive stability and flexibility. The relationship between network gain g on the relevant domain ($0 < act_{dif} < 0.5$ when $I_1 \neq 0$ or $-0.5 < act_{dif} < 0$ when $I_2 \neq 0$) and act_{dif} is defined by

$$g = f(act_{dif}) = \frac{\tanh^{-1}(2act_{dif})}{act_{dif}} + E(|act_{dif}|, I) \tag{7}$$

where the first term is the explicit solution for steady state gain of the no-input system (6) and $E(act_{dif})$ is the deviation from the symmetric case, which is a monotonically decaying function of the magnitude of act_{dif}. We can approximate this deviation with a decaying exponential fit

$$E(|act_{dif}|, I) \approx 1.4e^{-5I^{-1.1}\cdot|act_{dif}|} + 0.6 \tag{8}$$

where I is the magnitude of input. Since (7) is locally invertible on the given domain, we can express cognitive stability as a function of the network gain, $act_{dif}(g) = f^{-1}(act_{dif})$.

Further, we can express cognitive flexibility in terms of the time it takes to switch from one task to another, that is, the time it takes for act_{dif} to pass through zero and switch sign. From simulation we observe that the transition time is a monotonically increasing function of the network gain (see Figure 3). For an input $I_j = 0.8$ we approximate the transition time with a linear fit $T(g) \approx 0.8g + 0.6$. Substituting (7) with $I = 0.8$ for g, we obtain an expression for the stability-flexibility tradeoff

$$T(act_{dif}) \approx 0.8 \frac{\tanh^{-1}(2act_{dif})}{act_{dif}} + 1.1e^{-6.4|act_{dif}|} + 1.1 \quad (9)$$

by relating convergence time and act_{dif}. This analysis supports intuitions from prior computational work, showing that a higher network gain promotes cognitive stability at the expense of cognitive flexibility (Musslick et al., 2018). Moreover, the formal results described in this section offer a quantitative interpretation of network gain in terms of both act_{dif}, as well as T, when fitting the model to human behavior.

Experiment

Our analysis results suggest that a system should adapt higher constraints on control (lower gains) if the demand for cognitive flexibility increases. To examine whether human participants rationally adapt constraints on control to the flexibility demands of their environment, we conducted a task switching experiment in which the rate of task switches was varied across participants. We then fit the network model to each participant and evaluated the fitted gain against the gain that optimizes the stability-flexibility tradeoff for each participant.

Method

Participants. We recruited 67 participants from Amazon Turk. All participants signed a consent form prior to participation and received $6 US for participation. The study was approved by the Institutional Review Board of Princeton University. We only included participants with an accuracy above 65% into our analysis, yielding a total of 31 participants in the low switch rate group and 27 participants in the high switch rate group.

Apparatus and Stimuli. Stimuli consisted of a web-based random-dot kinematogram (RDK) that we adapted from Rajananda, Lau, and Odegaard (2018). The RDK contained blue and red moving dots, some of which consistently moved in either an upward or a downward direction, and some of which moved in a random direction.

Task and Procedure. Participants switched between a color task, in which they had to indicate the color of the majority of the presented dots (red or blue), using the response buttons 'A' and 'L', respectively, and a motion task in which they had to indicate the direction of coherent motion (up or down), using the same response buttons 'A' and 'L', respectively. Participants performed each task over a mini-block of four to six trials. Each mini-block was preceded by a task cue (one of two cues for each task to control for cue repetition effects) that instructed participants which tasks to perform. In some mini-blocks, participants had to repeat the task that they performed in the previous mini-block (task repetition), whereas in other mini-blocks, they had to switch to the other task (task switch). The cue was displayed for 700ms and disappeared for another 600ms. On each trial of a miniblock, the RDK stimulus was shown for 1500ms, followed by an inter-trial interval of 700ms. Participants were asked to indicate the task-relevant response while the stimulus was on the screen. In the beginning of the experiment, we used a staircasing procedure to identify coherence levels (i.e. the percent of dots having the same motion or color) for each participant that standardized performance at around 85% accuracy for both tasks. After training participants to associate the task cues with each task, participants switched between tasks over a sequence of two larger blocks of 66 miniblocks each.

Design. Participants were divided into two experimental groups, one that switched tasks between mini-blocks 25% of the time (low switch rate) and one that switched tasks 75% of the time (high switch rate). For each task switching sequence, we counterbalanced seven factors with respect to the first trial of each mini-block: task (color or motion task), task transition (task switch or task repetition), task cue (first or second cue associated with a task), congruency (congruent or incongruent), dot motion (upward or downward), color (mostly blue or red) and correct response ('A' or 'L' key).

Data Analysis. We focused our analysis on the second block of the experiment, assuming that subjects take the first block to adjust to the frequency manipulation of the experiment. We were specifically interested in the performance costs associated with task switches. Prior work suggests that switch costs diminish after the first trial of a mini-block (Rogers & Monsell, 1995). We therefore analyzed reaction times (RTs) and error rates associated with the first trial of a miniblock. Furthermore, RT data was limited to correct trials that were preceded by at least one correct trial. For each group of participants, we computed switch costs as the difference in performance between switch trials and repetition trials for both RTs and error rates. We also computed incongruency costs on task repetitions[2] as the difference in performance between congruent and incongruent trials. Finally, we conducted two-tailed t-tests to assess whether participants in the low switch rate group exhibited different switch costs and different incongruency costs compared to the high switch rate group.

Model Fitting Procedure. Before fitting parameters of the model to behavior of human participants, we evaluated how well we can recover these parameters from simulated behavior generated by the model. Motivated by the formal analysis described above, we parameterized the control module with balanced recurrent and inhibitory weights, $w_{i,i} = 1, w_{i,j} = -1$,

[2]Incongruency costs have been shown to interact with task transition (Rogers & Monsell, 1995; Goschke, 2000; Wendt & Kiesel, 2008). To avoid confounding effects of congruency with the frequency of task switches we conditioned incongruency costs on task repetition trials.

Table 1: Fitted model parameters with prior distributions.

Parameter	Prior Distribution	Lower Bound	Upper Bound
g	$Gamma(2.5, 0.75)$	0	4
z	$Gamma(3, 0.02)$	0.01	0.25
c	$Gamma(3, 0.75)$	0.015	0.25
h	$Beta(1.2, 1.2)$	0	1
w_a	$Gamma(16, 0.05)$	0.1	0.5

and computed the activities of both processing units trial-by-trial, by numerically integrating Equation (2) with step size h. We set the input for the currently relevant task unit to $I_i = 0.8$ and the input for the task-irrelevant unit to $I_{j \neq i} = 0$. The stimulus dimension encoding the color feature was set to $S_1 = 0.1$ if the majority of the dots was red and set to $S_1 = -0.1$ if the majority of the dots was blue. Similarly, the stimulus dimension encoding the motion feature was set to $S_2 = 0.1$ if the dots were moving upward and set to $S_2 = -0.1$ if dots were moving downward. We fixed the non-decision time of the DDM to $T_0 = 0.2$ and fit five free parameters with priors shown in Table 1: network gain g, DDM response threshold z, DDM noise c, integration constant h and automaticity weight w_a. The number of free parameters was determined based on prior analyses of parameter identifiability, indicating that larger or different sets of free parameters may not be reliably recovered. To assess how well the five parameters can be recovered from the simulated behavior of the model, we first sampled 10 parameter configurations uniformly from the intervals shown in Table 1. We then generated distributions of response times for each trial of the second experiment block and identified parameters that maximized the likelihood of the model's responses given the data. The identifiability of each parameter was quantified by regressing the true parameter against the fitted parameter across all sampled parameter configurations. We used the same procedure to fit the model to each participant. Finally, we conducted a one-tailed t-test to assess whether fitted gain parameters of the participants in the low switch rate group were higher relative to fitted gain parameters in the high switch rate group.

Optimality Analysis. To evaluate whether participants adapt rationally to the stability-flexibility dilemma, we identified the optimal gain that maximizes accuracy across all trials in the experiment, given all other fitted parameters for a given participant[3]. For each participant group, we computed the difference between fitted gains and optimal gains, and performed a two-sided t-test to evaluate whether fitted gain parameters systematically deviate from their optimal gain.

Results

We found that participants who switched tasks less frequently took more time to switch tasks, $t(56) = 2.04, p < 0.05$, but found no significant differences in terms of error rates, $t(56) = 0.20, p = 0.84$. Participants showed no significant differences in incongruency costs between the two experimental groups in terms of both RTs, $t(56) = 0.93, p = 0.35$ and error rates, $t(56) = 1.30, p = 0.20$.

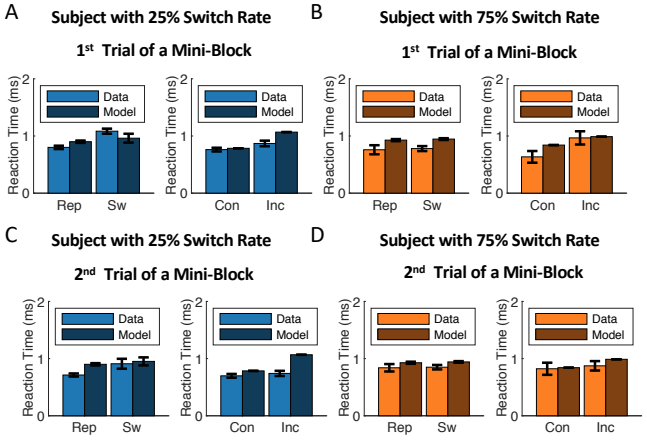

Figure 4: Examples of participant RTs and RTs generated by the fitted model. RTs are shown as a function of task transition (repetition, switch) and response congruency (congruent, incongruent) for the first (A, B) and second (C, D) trial of a mini-block. Data is shown for one participant from the low switch rate group (A, C) and one participant from the high switch rate group (B, D). Dark bars indicate average RTs generated by the fitted model. Error bars indicate the standard error of the mean across trials.

Overall, we were able to recover parameters from behavior generated by the model. The true parameter value significantly predicted the value estimated by the fitting procedure for network gain, $b = 0.97$, $t(9) = 4.44$, $p < 0.01$, DDM response threshold z, $b = 1.09$, $t(9) = 14.06$, $p < 0.001$, DDM noise c, $b = 0.69$, $t(9) = 9.03$, $p < 0.001$, integration constant h, $b = 0.87$, $t(9) = 5.02$, $p < 0.01$, and automaticity weight w_a, $b = 0.64$, $t(9) = 3.06$, $p < 0.05$. Figure 4 shows the behavior of two participants along with the behavior generated by the fitted model. In line with the prediction made by the model, we observed that the fitted gain parameters to behavior of human participants were significantly higher in the low switch rate group relative to the high switch rate group, $t(56) = 3.61, p < 0.001$ (Figure 5A). Note that Figure 3 depicts formal expressions of cognitive stability (Figure 3A) and cognitive flexbibility (Figure 3B) as a function of the average fitted gains for both groups. Interestingly, the fitted gains were significantly lower than the optimal gains, for both groups: low switch rates, $t(30) = 7.40, p < 0.001$, and high switch rates, $t(26) = 4.24, p < 0.001$, suggesting that, while participants adapt gain in the predicted way, overall they exert more constraint on control allocation (lower gain) than was predicted to be optimal.

General Discussion and Conclusion

A fundamental characteristic of control-dependent processing are constraints on the allocation of control (Shiffrin & Schneider, 1977; Posner & Snyder, 1975). Recent work sug-

[3]We chose to maximize accuracy over maximizing reward rate as the duration of each trial was independent of response time. However, we obtained identical results when optimizing for reward rate.

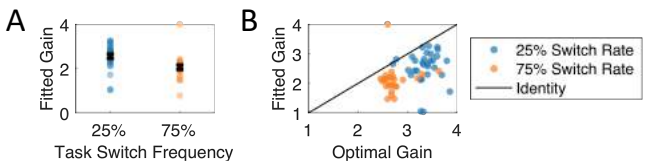

Figure 5: Model fitting results. (A) Fitted gains are shown for participants with a low (blue) and high (orange) switch rates. Each circle corresponds to the fitted gain of a participant. Vertical lines indicate the standard error of the mean fitted gain, centered around the mean. Mean gains for each group are also shown in Figure 3. (B) Fitted gain for each participant is plotted against the optimal gain that maximizes the overall accuracy of the model for a given participant.

gests that these limitations may origin from shared representations (Feng et al., 2014; Musslick et al., 2016; Salvucci & Taatgen, 2008), as well as persistence characteristics in neural systems (Musslick et al., 2018), and the resulting need to trade off the amount of control that can be allocated to a single task against the time required to switch from one task to another. In this work, we introduced a formal analysis of the latter — that is, the tradeoff between cognitive stability and cognitive flexibility.

Applying perturbation theory to the network model described by Musslick et al. (2018), we formally defined cognitive stability in terms of the distance between attractors for competing control states, and defined cognitive flexibility in terms of the time to converge from one control attractor to the other. We showed that the two measures trade off against each other, and that the balance of this tradeoff is determined by the gain of the network's activation function. We then examined whether human participants balance this tradeoff in a similar manner as a function of the demand for flexibility, by fitting the model to participants who were required to switch tasks at either a low or high frequency. We observed that participants who switched more frequently showed lower switch costs, suggesting that they became more cognitively flexible. Moreover, model fits showed that this could be explained by lower gain, and with it, higher constraints on control. Interestingly, fitted gains for all participants were lower compared to the gains that optimized accuracy in the face of the stability-flexibility tradeoff. This suggests that there may be other factors that limit control allocation.

Altogether, our analytic and empirical results provide a rationale for how participants should adapt to different demands for flexibility given a mechanistic model for how control is represented and allocated in a recurrent neural network model. A formal relationship between cognitive stability and cognitive flexibility may not only help interpret human behavior in terms of model fits but may also help identify neural correlates for both measures. For instance, the dynamics of steady-state visually evoked potentials (SSVEP) — used to index feature-specific attention (Müller et al., 2006) — may be characterized in terms of the evolving distance between attractors of competing attentional states. Finally, the behavioral results replicate earlier work, showing that participants' switch costs decrease as task switches become more frequent (Mayr, 2006; Monsell & Mizon, 2006). Furthermore, prior work suggests that participants trade off cognitive flexibility against higher incongruency costs in voluntary task switching scenarios when task switches are associated with a higher reward than task repetitions (Braem, 2017).

One interesting puzzle concerns the learning mechanisms that underlie rational adaptations to changing demands in cognitive flexibility. A computationally cheap, but inflexible approach is to learn the amount of control that should be exerted through model-free reinforcement (Lieder et al., 2018). Alternatively, humans may approximate the optimal tradeoff, by attaching a cost to the amount of control that can be allocated. From this perspective, the stability-flexibility tradeoff may provide a normative rationale for parameterizing the cost of cognitive control that is integral to recent theories of control allocation (Shenhav et al., 2013, 2017).

Abstract

Researchers have long been interested in using laboratory measures of cognitive control to predict a person's cognitive control/self control success outside the lab. We used a computational approach to identify which lab-based performance measures provide the most valid individual difference measures of one's ability and/or motivation to exert cognitive control. We simulated performance across an array of cognitive control tasks, and estimated the degree to which different performance metrics (e.g., congruency effects, conflict adaptation, and demand avoidance) could theoretically provide valid estimates of processes underlying control allocation. By performing dimension reduction on these performance metrics, we further revealed latent dimensions that can index separate mechanisms of control-demanding behavior. Our results suggest that individual differences in measures of cognitive control can originate from multiple factors, several of which are unrelated to *capacity* for cognitive control. We conclude by discussing implications of these analyses for assessing individual differences in cognitive control phenomena.

Keywords: individual differences; cognitive control; motivation; self-control

Introduction

Cognitive control refers to our ability to adapt mental processes to current task goals. Researchers have developed a variety of measures to index a given person's capacity to exert cognitive control, such as conflict-related interference, conflict adaption, and performance costs associated with task switching. It has often been assumed that individual differences in capacity and/or motivation for control should predict one's self-control success in the real world, and that performance on one cognitive control task should therefore correlate with indices of self-control. Unfortunately, however, such correlations have been inconsistent across the literature. For instance, whereas some individual studies find correlations between Stroop conflict-related interference (congruency costs) and real-world self-control outcomes (e.g., addiction treatment compliance, healthy diets; Streeter et al., 2008; Allan, Johnston, & Campbell, 2010), a large study (N=2,641) recently found no correlation between congruency costs and a well-validated index of real-world self-control (Saunders, Milyavskaya, Etz, Randles, & Inzlicht, 2017). The inconsistency in these findings has been taken to suggest that control mechanisms are highly context-specific and/or that self-control may not actually require cognitive control (Berkman, Hutcherson, Livingston, Kahn, & Inzlicht, 2017). Here we explore an alternative interpretation, that commonly used measures of control allocation may be ill-suited to indexing the control required of those tasks.

Converging evidence suggests that performance on cognitively demanding tasks reflects a combination of bottom-up stimulus processing and one's capacity and motivation to exert top-down control over such processing (Cohen, Dunbar, & McClelland, 1990; Shenhav, Botvinick, & Cohen, 2013; Shenhav et al., 2017). These insights have been integrated into a recent computational model of control allocation, which simulates an agent's performance on a cognitive task based on the parameters of that task (e.g., stimulus salience) and the incentives on offer (e.g., reward for correct response; Musslick, Shenhav, Botvinick, & Cohen, 2015). Control allocation is determined by comparing the expected reward (based on the incentives and the degree to which control increases the likelihood of a correct response) with an intrinsic cost of control, to determine the overall Expected Value of Control (EVC). The parameters of these simulated agents can be adjusted to vary how they process stimuli and incentives (e.g., their sensitivity to rewards), resulting in attendant changes to task performance. Theoretical analyses suggest that between-subject variability in some motivational parameters, such as reward sensitivity, can generally limit the ability to recover other motivational parameters, such as the cost of cognitive control, from task performance (Musslick, Cohen, & Shenhav, 2018; Caplin, Csaba, Leahy, & Nov, 2018). An important question that remains unaddressed, however, is whether individual differences in cognitive control phenomena provide a reliable index for one's capacity to exert cognitive control.

Here, we use the EVC model to simulate various phenomena that have been used to index one's capacity to exert cognitive control, including within-trial interference and cross-trial adaptation to response conflict; task-switching costs; and cognitive effort discounting. We then demonstrate that individual differences in these phenomena are influenced by parameters of the task and the agent, including variables related to bottom-up stimulus processing, the *ability* to exert control, and the *motivation* for doing so. Finally, we identify latent dimensions that explain individual differences across these simulated phenomena, and discuss implications of this work for the assessment of individual differences in cognitive control within and outside of the lab.

Expected Value of Control Model

The EVC theory is based on the premise that control allocation involves specifying the identity of candidate control signals, as well as the intensity of each (Shenhav et al., 2013). Increases in control signal intensity lead to improvements in performance on the corresponding task. However, it is also assumed that exercising cognitive control is costly and this cost increases monotonically with the intensity of the control signal. According to the EVC theory, the control system chooses to implement the configuration of control signals that yields the highest expected value of control, that is, the expected utility of implementing a configuration of control signals with specified intensities minus their associated costs. Critically, the expected value for each candidate control signal configuration is contingent on an internal model of the task environment that is updated based on experience.

The present implementation of the EVC model describes performance in the Stroop task (e.g., responding to the ink color of a color word, Stroop, 1935), in terms of an interaction between the control system and the task environment. The control signal is chosen optimally based on an internal model of the next trial which produces an estimate of the next trial (inferred state $\hat{\mathbf{S}}$). This signal is then used to interact with the environment (actual state $\mathbf{S}$), for example to commit one of the two possible responses[1] in the task. After each trial, the agent updates the internal model based on an observation of that trial following the response.

In order to generate reaction times (RTs) and responses on each trial, we use the drift diffusion model (DDM Ratcliff, 1978). Within the DDM framework, a response on the task can be conceptualized as a result of the noisy accumulation of evidence toward one of the two possible responses (e.g. one response indicating the color green and the other response indicating the color red; Musslick et al., 2015). Here, we assume that the rate of evidence accumulation toward one of the two responses is governed by a controlled and an automatic component

$$drift = \varepsilon \cdot drift_{\text{control}} + drift_{\text{automatic}} \tag{1}$$

where ε is a capacity parameter that scales the amount of control allocated. The automatic component reflects automatic processing of the color feature and word feature of the stimulus that is unaffected by control,

$$drift_{\text{automatic}} = a_{\text{color}} + a_{\text{word}}. \tag{2}$$

The absolute magnitude of the color-response association a_{color}, as well as the magnitude of the word-response association a_{word} depends on the strength of the association of each stimulus feature with a given response, and its sign depends on the response (e.g. $a_{\text{color}} < 0$ if the response is associated with the left button, $a_{\text{color}} > 0$ if response is associated with the right button). Thus, for congruent trials a_{color}, and a_{word} have the same sign, whereas the opposite sign for incongruent trials. The controlled component of the drift rate is the sum of the two stimulus values, as well as the intensity of the corresponding control signal, one for processing the color dimension of the stimulus u_{color} and one for processing the word dimension of the stimulus u_{word}:

$$drift_{\text{control}} = u_{\text{color}} \cdot a_{\text{color}} + u_{\text{word}} \cdot a_{\text{word}} \tag{3}$$

Thus, each control signal biases processing towards one of the two stimulus dimensions, both of which characterize the actual state on a given trial, $\mathbf{S} = \{a_{\text{color}}, a_{\text{word}}\}$. As a result, higher control signal intensity for processing the color dimension improves performance — speeds responses and lowers error rates — in a trial of the Stroop task. Mean RTs and response probabilities for a given parameterization of drift rate on trial t are derived from an analytical solution to the DDM (Navarro & Fuss, 2009).

In order to specify the optimal set of control signals $\mathbf{U} = \{u_{\text{color}}, u_{\text{word}}\}$ on a given trial t, the model estimates the expected value for each configuration of control signal intensities based on its internal model of the next trial $\hat{\mathbf{S}} = \{\hat{a}_{\text{color}}, \hat{a}_{\text{word}}\}$. This is done by weighting the expected reward for an outcome against the cost associated with the chosen control signal configuration:

$$EVC(\mathbf{U}, \hat{\mathbf{S}}) = P(\text{correct}|\mathbf{U}, \hat{\mathbf{S}})V(R) - Cost(\mathbf{U}) \tag{4}$$

where $P(\text{correct}|\mathbf{U}, \hat{\mathbf{S}})$ corresponds to the probability of reaching the decision threshold for the correct response and $V(R)$ corresponds to the subjective value of responding correctly. Here, the subjective value $V(R) = vR$ corresponds to the amount of reward offered for a correct response R weighted by the model's sensitivity to the reward v. The cost $Cost(\mathbf{U}) = Cost_{\text{impl}}(\mathbf{U}) + Cost_{\text{reconf}}(\mathbf{U})$ is composed of an implementation cost that increases with the amount of control being allocated (Shenhav et al., 2013; Manohar et al., 2015; Lieder, Shenhav, Musslick, & Griffiths, 2018),

$$Cost_{\text{impl}}(\mathbf{U}) = e^{c_{\text{I}} \cdot u_{\text{color}}} + e^{c_{\text{I}} \cdot u_{\text{word}}} \tag{5}$$

as well as a reconfiguration cost that scales with the degree to which control signals need to be changed relative to their previous state (Meiran, 1996; Rogers & Monsell, 1995)

$$Cost_{\text{reconf}}(\mathbf{U}) = e^{c_{\text{R}} \sqrt{(u_{\text{color},t} - u_{\text{color},t-1})^2 + (u_{\text{word},t} - u_{\text{word},t-1})^2}} \tag{6}$$

where the implementation cost is scaled by parameter c_{I} and the reconfiguration cost is scaled by parameter c_{R}. The model selects the control signal configuration with the maximum EVC within the inferred next trial $\hat{\mathbf{S}}$, out of all the configurations under consideration:

$$\mathbf{U}^* = \underset{\mathbf{U}}{\text{argmax}} EVC(\mathbf{U}, \hat{\mathbf{S}}) \tag{7}$$

Performance in the actual state $\mathbf{S}$ is determined by the influence of the chosen control signals on the true parameters

[1] A restriction to two response alternatives limits the scope of the model to paradigms with two-alternative forced choice but makes it amenable to tractable computation of mean reaction times and error rates.

a_{color} and a_{word}. After observing the actual state, the agent updates its inferred state $\hat{\mathbf{S}} = \{\hat{a}_{\text{color}}, \hat{a}_{\text{word}}\}$:

$$\hat{a}_{\text{color, new}} = \hat{a}_{\text{color, old}} + \alpha(\hat{a}_{\text{color, old}} - a_{\text{color}}) \quad (8)$$

$$\hat{a}_{\text{word, new}} = \hat{a}_{\text{word, old}} + \alpha(\hat{a}_{\text{word, old}} - a_{\text{word}}) \quad (9)$$

where α is the learning rate. Finally, the agent re-evaluates the optimal control policy for the next trial based on its revised model of the task environment.

Task Environments and Parameterization

We simulate behavior of the EVC agent across three different experimental paradigms that have been repeatedly used to index individual differences in cognitive control. Here, we describe each paradigm, the associated behavioral phenomena, as well as the corresponding parameterization[2] of the EVC model.

Stroop Task

In the Stroop paradigm, the agent is presented with a two-dimensional stimulus, one dimension representing an ink color and another dimension representing a color word (Stroop, 1935). On each trial, the EVC model is required to indicate the response associated with the ink color. In congruent trials, the word feature of the stimulus is associated with the same response as the ink color whereas in incongruent trials, the color and word features are associated with different responses. The experiment sequence encompassed 101 trials, and was fully balanced (excluding the first trial) with respect to congruent and incongruent stimuli, as well as with respect to all four transitions between the two trial types (congruent-congruent, congruent-incongruent, incongruent-congruent, incongruent-incongruent). As described below, we sampled a_{color} uniformly from $U(0.3, 0.4)$. To simulate congruent trials, we set $a_{\text{word}} = 0.4$ such that both stimuli dimensions promote the same response. On incongruent trials, we set $a_{\text{word}} = -0.4$ such that the word dimension is associated with a different response than the color dimension. Note that the absolute magnitude of a_{word} is higher than a_{color}, reflecting the assumption that word reading is a more automatic process than color naming (Cohen et al., 1990). We varied the range of control signal intensities from 0 to 10 in steps of 0.2 for the two control signals u_{color}, u_{word} and set the reward received for a correct response to $R = 100$. DDM parameters were set as follows: starting point = 0.0, noise coefficient = 0.7, non-decision time = 0.2s and threshold = 0.4.

We used this paradigm to simulate three different behavioral phenomena. One of the most reliable observations is that participants take more time and commit more errors when responding to incongruent stimuli as opposed to congruent stimuli (Stroop, 1935). Here, we assessed effects of stimulus congruency as the difference in RTs and error rates between incongruent and congruent trials. Another common observation is that participants exhibit a smaller performance cost for incongruent stimuli when the current stimulus was preceded by an incongruent stimulus as opposed to a congruent stimulus (Gratton, Coles, & Donchin, 1992; Egner, 2007). We assessed the congruency sequence effect as an interactive effect between the congruency of the current trial and the congruency of the previous trial on performance. Finally, participants tend to exert smaller congruency effects when the proportion of congruent stimuli is decreased (proportion congruency effect, Logan & Zbrodoff, 1979). We assessed this phenomenon by comparing the congruency effect in two different experiment sequences, one that contained 20% congruent trials, and one that contained 80% congruent trials.

Task Switching

The performance costs associated with switching from one task to another are often used to index cognitive flexibility (Koch, Poljac, Müller, & Kiesel, 2018; Rogers & Monsell, 1995). Here, we examined this effect in a cued task switching paradigm in which the model had to switch between categorizing the color of a stimulus (color naming) and categorizing its shape (shape naming). Similar to the Stroop task, stimuli were either congruent, $a_{\text{color}} = a_{\text{shape}}$, or incongruent, $a_{\text{color}} = -a_{\text{shape}}$. The trial sequence encompassed 100 trials that were randomly sampled with respect to stimulus congruency (congruent, incongruent), the currently relevant task (color naming, shape naming) and the task transition with respect to the previous trial (task switch, task repetition). On each trial, the model allocated control between the two control signals u_{color}, u_{shape}, using the same range of control intensities as described in the Stroop task. The model was cued with a baseline reward of $R = 100$, providing information about which feature is relevant for the task it has to perform on the current trial. DDM parameters were set as follows: starting point = 0.0, noise coefficient = 0.3, non-decision time = 0.2s and threshold = 0.15.

We assessed switch costs in terms of the difference in RTs and error rates between task switch trials and task repetition trials. Rogers and Monsell (1995) also demonstrated that congruency costs are higher on task switch trials compared to task repetition trials. To capture this effect, we also assessed the interaction between stimulus congruency and task transition.

Cognitive Effort Discounting

When given a choice between performing a task with low cognitive effort and a task with high cognitive effort, participants tend to select the former, even if it means to forgo a reward (Westbrook & Braver, 2015). Here, we simulated demand avoidance in the cognitive effort discounting (COGED) experiment described by Westbrook and Braver (2015). In this paradigm, subjects can choose on each trial whether they want to perform a baseline low-demand task for a low reward or a higher-demand alternative task for a higher reward. The amount of reward offered for the baseline task is adjusted to

[2]Note that fixed parameters for each paradigm were chosen such that the model performed with at least 55% accuracy for all combinations of individual difference parameters.

identify the point of indifference, that is, the reward at which subjects are indifferent between performing the low-demand baseline task and performing the high-demand task. To simulate this paradigm, we modeled both tasks as different types of trials that the model can choose between. Each trial encompassed a stimulus with a color dimension that mapped to one of two responses with $a_{\text{color}} > 0$. However, unlike in the Stroop task there was no word dimension, $a_{\text{word}} = 0$. The difficulty of the high-demand task was manipulated across experiment blocks, by varying the color-response association a_{color} from 1.0 to 0.2 in steps of 0.2, and the difficulty of the baseline task was fixed to $a_{\text{color}} = 1$ (higher color-response associations may reflect higher saturation values for a color patch). For each set of simulations, we fixed the reward for the high-demand task to $R = 200$ while steadily increasing the amount of reward offered for the low-demand task in steps of 1, beginning from an initial reward value of $R = 1$. On each trial, the EVC agent determined the highest EVC separately for each task and chose the task with the highest predicted EVC. We then assessed the amount of reward offered for the low-demand task for which the model would be indifferent between performing the low-demand task and the (more rewarding) high-demand task, and normalized this value by the amount of reward offered for the high-demand task. Following the notation by Westbrook and Braver (2015), we refer to this normalized value as the subjective value of completing the high-demand task. For instance, if the model would switch to performing the low-demand task at an offered reward of 120 then the (discounted) subjective value of the high-demand task would be 120/200. The range of control signal intensities was varied from 0 to 10 in steps of 0.2 and DDM parameters were set as follows: starting point = 0.0, noise coefficient = 1.5, non-decision time = 0.2s and threshold = 1. We assessed subjective value the high-demand task as a function of its difficulty, $1 - a_{\text{color}}$.

Simulation Procedure

We simulated behavior of 100 EVC agents in the three paradigms described above. For each agent, we uniformly sampled its control capacity $\varepsilon \sim U(0.5, 1.5)$, implementation cost $c_I \sim U(0.5, 1.5)$, reconfiguration cost $c_R \sim U(0, 3)$, reward sensitivity $v \sim U(0.5, 1)$, the stimulus-response association of the relevant task ($a_{\text{color}} \sim U(0.3, 0.4)$ in all paradigms[3], as well as a_{shape} in the task switching paradigm) and learning rate $\alpha \sim U(0, 0.5)$. Ranges for these parameters were chosen to warrant an accuracy above 55% across all simulated paradigms. Note that agents with a higher control capacity would effectively implement a higher amount of control. Therefore, control capacity can be taken as a proxy for the amount of control an agent exerts on average. The stimulus-response association determines the degree of task automaticity: The higher the stimulus-response association of a task-relevant feature, the easier the task, that is, the less cognitive control is needed to reach the correct outcome. Here, we assume that the stimulus-response association of a task feature reflects the task proficiency of an agent.

We first assessed average behavior across all agents with respect to seven dependent variables. In the Stroop task, we measured error rate effects of stimulus congruency, the congruency sequence effect, the proportion congruency effect, as well as overall error rate on the task. In the task switching paradigm, we assessed switch costs in error rates, as well as the congruency costs in error rates as a function of task transition. We also measured the subjective value of levels of task difficulty as determined by the COGED paradigm.

We restricted our analysis of individual differences to overall error rate in the Stroop task, congruency effects, congruency sequence effects, proportion congruency effects, switch costs, as well as the subjective value assigned to a task parameterized with a_{color} (effort discounting). We then took two different approaches to analyze individual differences in these measures. First, we used a multiple linear regression to assess the degree to which each of the six EVC parameters can explain each behavioral phenomenon. However, we did not include learning rate as a regressor in the task switching and COGED paradigms as the agent is provided full information about each trial. Second, we used principal component analysis (PCA) to explore whether individual differences can be explained by more complex latent factors. That is, we identified principal components that account for variance between agents (observations) across all dependent variables (dimensions), including overall error rate, congruency effect, congruency sequence effect, proportion congruency effect, switch cost and effort discounting. We then assigned a score to each agent that identifies its position on the axes spanned by either the first or the second principal component. These two components explain most of the variance in the space of behavioral phenomena, and can be best interpreted in terms of the behavioral effects that vary most along a given component. In addition, we sought to interpret each component in terms of individual difference parameters of the EVC model. That is, we identified the individual difference parameters that best explain each principal component, by regressing the component scores of all agents against their EVC parameters. Finally, we assessed which of the behavioral phenomena were most indicative of the amount of exerted control, by computing the Pearson correlation between each dependent variable (e.g. congruency effect) and the average intensity of control u that an agent exerts, across all agents.

Results

Behavioral Phenomena. The EVC model captured all of the cognitive control phenomena of interest[4] (Figure 1): 1) Responses were slower and more error-prone on incongruent versus congruent trials of a Stroop-like task (*congruency effect*), $F(1, 99) = 17.80$, $p < 0.001$. 2) When the stimuli on

[3] In the COGED task, we scaled the tested range of a_{color} by this value.

[4] We focused our analyses on error rates due to space constraints. However, we observed similar effects for RTs.

Table 1: Regression of behavioral phenomena against individual differences in EVC parameters. Significant regressors are ordered by standarized regression weight.

Model Parameter	β	t	p
Overall Error Rate, $df = 93$

Implementation Cost	0.139	17.44	< 0.001
Control Capacity	-0.051	-6.86	< 0.001
Reconfiguration Cost	-0.047	-17.48	< 0.001

the previous trial were incongruent, congruency effects were smaller on the current trial, relative to when the previous trial was congruent (*congruency sequence effect* or *conflict adaptation*), $t(99) = 4.22$, $p < 0.001$. 3) Congruency effects were higher when the trial sequence contained a high proportion of congruent trials versus a high proportion of incongruent trials (*proportion congruency effect*), $t(99) = 17.86$, $p < 0.001$. 4) Responses were less accurate when switching to a new task rather than repeating the same task (*switch costs*, Rogers & Monsell, 1995), $F(1,99) = 337.30$, $p < 0.001$. These switch costs were greater when transitioning to an incongruent trial (Rogers & Monsell, 1995), $F(1,99) = 214.96$, $p < 0.001$. 5) All else being equal, simulated agents assign less value to (and would therefore be less likely to engage with) tasks that are more rather than less difficult (*cognitive effort discounting*, see Figure 1D).

Individual Differences. We tested the degree to which each of the measures above were influenced by individual differences in factors related to bottom-up stimulus processing (task automaticity), cognitive control ability (control capacity), and motivational factors (e.g., reward sensitivity and control costs). Agents with a higher control capacity and lower implementation costs made fewer errors, had lower congruency effects, higher congruency sequence effects, adapted more to the proportion of congruent trials, had higher switch costs and discounted cognitive effort less (Table 1). Agents with higher reconfiguration costs and a lower sensitivity to reward adapted less to congruency of the previous stimulus or to the proportion of congruent trials. Both, a higher reconfiguration cost and a higher reward sensitivity were associated with higher switch costs. A higher reward sensitivity also yielded overall fewer errors while higher reconfiguration costs predicted less effort discounting. Agents with a higher learning rate and task automaticity performed overall better in the Stroop task, showing smaller congruency effects and smaller proportion congruency effects. Unsurprisingly, agents with a higher learning rate show greater sequential adaptations to response congruency whereas agents with a higher task automaticity discounted effort less.

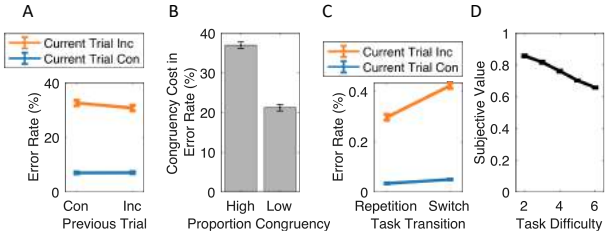

Figure 1: Average effects of simulated agents. (A) Error rates are shown as a function of congruency of the previous and the current trial. (B) Congruency effects (difference in error rates on incongruent and congruent trials) are shown for a sequence with a low (80%) and high (20%) proportion of congruent trials. (C) Error rates are shown as a function of congruency of the previous trial and task transition. (D) Subjective value of a task as a function of its difficulty. Error bars indicate the standard error of the mean across simulated agents.

Principal Components Analysis. After performing a PCA across our behavioral effects of interest, we found that individual differences across these are well captured by two orthogonal dimensions that explained more than 75% of between-agent variance (Figure 2). Regressing these phenomenon-driven components on the model parameters that we varied, we find that a high score on Component 1 is associated with higher task automaticity, lower implementation costs, higher control capacity and higher sensitivity to reward. Agents with a higher value for any of these parameters are expected to perform better on a task (Table 3). Component 2 appears to most reliably capture differences in reconfiguration costs, and to a lesser degree differences in task automaticity, reward sensitivity and implementation costs.

Correlation with control intensity. We found that each behavioral effect significantly correlated with the average amount of control exerted by an agent (Table 2). Interestingly, overall error rate in the Stroop task was most indicative of exerted control intensity, followed by incongruency costs.

General Discussion and Conclusion

People have varying degrees of success at adapting their thoughts and behaviors to meet their current goals. Failing

Table 2: Correlations between dependent behavioral measures and exerted control intensity across simulated agents ($df = 98$).

Dependent Measure	r	p
Overall Error Rate	-0.76	< 0.001
Congruency Effect	-0.67	< 0.001
Proportion Congruency Effect	0.58	< 0.001
Effort Discounting	0.46	< 0.001
Congruency. Sequence Effect	0.31	< 0.01
Switch Cost	0.20	< 0.05

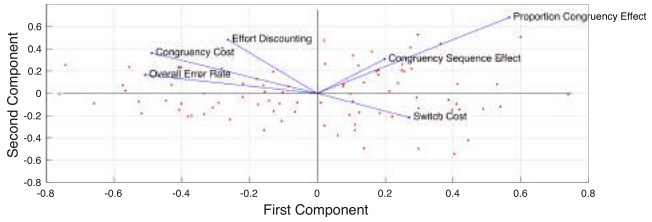

Figure 2: Principal Components Analysis. Each red dot summarizes the behavior of an agent in the space of the first and second principal component. The direction and length of the blue vectors indicates the score of each behavioral effect in terms of the two components. For instance, subjects with low scores on the first component appear to commit more errors but show lower costs of switching tasks.

to exert the appropriate level of control can have very negative consequences for one's health, career, and social status. It is therefore important to understand whether and how such real-world self-control can be predicted from lab-based measures of cognitive control. We used a computational model of control allocation to examine the degree to which different performance metrics from such tasks can theoretically index individual differences in processes related to stimulus processing, strength of control, and motivation for control.

We showed that the EVC model can account for a wide array of effects used to index cognitive control, including response interference, sequential adaptation to stimulus congruency, adaptation to the proportion of congruent stimuli, performance costs associated with task switching, and demand avoidance. Critically, we showed that individual differences in each of these measures can be accounted for by a multitude of factors, including motivational variables (e.g., reward sensitivity) and bottom-up stimulus processing (task automaticity), rather than only by one's *ability* to exert cognitive control (indexed by control capacity). This suggests that individual differences in cognitive control phenomena may not not be a reliable indicator of one's ability to exert control but may instead reflect individual differences in other variables. A PCA revealed a broad distinction between effects that vary as a function of how much control an agent is capable of allocating (overall performance, congruency costs, effort discounting) and effects that index how flexibly an agent can adapt to changing demands of the environment (switch costs, congruency sequence effects and proportion congruency effects). Finally, our analyses suggest that overall error rate and incongruency costs in the Stroop task best indexed the actual amount of control exerted by an agent whereas congruency sequence effect and switch costs were found to be least diagnostic.

Table 3: Regression of principal components (PC) against individual differences in EVC parameters.

Model Parameter	β	t	p
First PC, $df = 88$			
Task Automaticity	0.7867	3.58	< 0.001
Implementation Cost	-0.2582	-11.43	< 0.001
Control Capacity	0.2289	10.84	< 0.001
Reward Sensitivity	0.1870	4.53	< 0.001
Reconfiguration Cost	-0.0122	-1.61	0.111
Second PC, $df = 88$			
Task Automaticity	-0.8127	-4.10	< 0.001
Reward Sensitivity	0.0882	2.37	< 0.05
Reconfiguration Cost	-0.0586	-8.59	< 0.001
Implementation Cost	0.0435	2.14	< 0.05
Control Capacity	0.0033	0.17	0.862

Interestingly, we found that higher costs of *implementing* control were associated with lower costs of *switching* tasks. This finding is consistent with previously observed tradeoffs between cognitive stability and cognitive flexibility: higher amounts of control can reduce distractor interference but require larger reconfiguration of control signals when switching between tasks (Goschke, 2000; Musslick, Jang Jun, Shvartsman, Shenhav, & Cohen, 2018). Perhaps more surprisingly, we also found that participants with higher reconfiguration costs discounted cognitive effort *less* (i.e., were more willing to engage in demanding tasks). This finding reflects an approach-avoidance conflict inherent to demand avoidance paradigms: The more a person is engaged with a cognitively demanding task, the less they are willing to switch to an easier task (Kool, McGuire, Rosen, & Botvinick, 2010).

One limitation of the current implementation of the EVC model is its focus on 2-alternative forced choice tasks. We chose to focus on these tasks because they are amenable to analysis with the well-studied DDM (Bogacz, Brown, Moehlis, Holmes, & Cohen, 2006; Ratcliff, 1978). However, the DDM may be an over-simplified model for cognitive control tasks given that such tasks can involve a variety of response alternatives, as in traditional variants of the Stroop task (Stroop, 1935).

The set of relevant individual difference parameters heavily depends on the requirements of the task for cognitive control. For instance, the n-back task requires subjects to decide whether a stimulus matches the stimulus that was presented n steps before in a sequence, and has been hypothesized to involve processes of working memory updating, interference between representations held in working memory, and familiarity judgment (Chatham et al., 2011; Juvina & Taatgen, 2007). The study of individual differences in more complex tasks will require implementing more realistic process models of those tasks, such as a working memory gating model in the case of the n-back task (Chatham et al., 2011).

Altogether, these analyses suggest that individual differences in cognitive control phenomena do not necessarily re-

flect differences in someone's capacity to exert cognitive control but may as well reflect differences in task automaticity or sensitivity to reward. Accounting for differences in these variables is therefore crucial when indexing cognitive control through behavioral phenomena. However, the collinearity between simulation parameters in this analysis prevents us from teasing apart the effects of each parameter. More elaborate parameter sensitivity studies are necessary to provide more fine grained insights into the source of individual differences in cognitive control phenomena.

The Modularity of the Motor System

Myrto Mylopoulos
Carleton University, Ottawa, Ontario, Canada

Abstract

The extent to which the mind is modular is a foundational concern in cognitive science. Much of this debate has centered on the question of the degree to which input systems, i.e., sensory systems such as vision, are modular (see, e.g., Fodor 1983; Pylyshyn 1999; MacPherson 2012; Firestone & Scholl 201; Burnston 2017; Mandelbaum 2017). By contrast, researchers have paid far less attention to the question of the extent to which our main output system, i.e., the motor system, qualifies as such. I will argue that the motor system should be construed as quasi-modular, at best, in that it is informationally encapsulated only to a certain degree, and in a way that can be strategically modulated by the agent. I will explore the implications of this result for nearby philosophical puzzles relating to different aspects of action control.

Do round numbers always become reference points?: An examination by Japanese and Major League Baseball data

Kuninori Nakamura (nakamura.kuninori@gmail.com)
Faculty of Social Innovation, Seijo University, 6-1-20, Seijo, Setagayaku
Tokyo 152-0061, Japan

Abstract

The round number effect refers to discontinuity around round numbers ("0.300", "4 hours") in frequency distribution, indicating that people consider the round numbers as goals or reference points for their performances. This study aimed to examine the round number effect by exploring the following two issues: (1) examination of Japanese baseball data, and (2) comparison between batters who exceeded the regulation number of at-bat of season and those who did not. Results indicate the following three points; (1) the round number effect was found in Japanese baseball data, (2) but it was found only for the batters who exceeded provision bat number of season, and (3) magnitude of the effect was stronger in Japanese than Major League Baseball data. General discussion argued these results in terms of players' motivation and disposition.

Keywords: reference dependence, round number effect, discontinuity

Introduction

How people perceive values of objects depends not only on nature of the objects themselves but also the degree the objects are judged compared using a criterion. This tendency is known as reference dependency (Kahneman & Tversky, 1979; Rosch, 1978), and has been demonstrated through exploration for anomalies in human decision-making including studies on framing effect (Tversky & Kahneman, 1981) or anchoring effect (Tversky & Kahneman, 1974). According to these studies, people's judgments are affected by arbitrarily presented numbers (Tversky & Kahneman, 1973) or wordings of decision problems (Tversky & Kahneman, 1981) that are not themselves irrelevant to answers for the decision tasks, indicating that people make judgments according to the reference points that are considered as goals for their behavior rather than relying on their own beliefs or preferences.

The round number effect (Allen et al, 2016; Pope & Simonsohn, 2009) is a new example of reference dependency that refers to a discontinuity of distribution for continuous variables around the round numbers that can be considered goals for performance. When students take the SAT, they may say that they want to acquire 1100 points, but never 1098 or 1103 points. Marathon runners may try to finish the race within 4 hours, but never within 3 hours and 56 minutes. As these examples indicate, round numbers are often employed as goals for performances. As a result, people's behavior would change depending on whether they can perform just short of the round number or not, and density of the distribution for the performance would fluctuate around the round number (also see Heath et al., 1999; Kahneman & Miller, 1986; Medvec & Savitsky, 1997).

Pope and Simonsohn (2011) reported the round number effect in Major League Baseball (MLB) data. In their study, they analyzed data about batting averages of MLB players who had scored at least 200 at bats during the season from 1975 to 2007, and found that the relative frequency of baseball players whose batting averages at the end of the seasons were 0.300 was higher than those whose batting averages were 0.299. In addition to the discontinuity of frequency around 0.300, Pope and Simonsohn (2011) also found that performance or strategy of the batters who could achieve "0.300" by hit on their final bat differed from those of the batters who could not or already achieved "0.300": their probabilities for hitting at the final bat were higher than, and probabilities to choose the walks at the final bat were lower –in fact, 0- than the other batters. These results indicate that the batters used "0.300" as their goal for their batting performance, and tried to achieve this goal by any means, resulting in discontinuity around the round number. Beside the example of batting average data, the round number effect was reported in various domains including SAT score (Pope & Simonsohn, 2011) or marathon running time (Allen et al, 2011; also see Pope & Simonsohn, 2011 for an example of fictitious scenario).

Studies on round number effect suggest that people in some sense can do nothing without a concrete goal In other words, rather than trying as much as they can, people aim to exceed their criteria that are arbitrarily determined, and round numbers are often chosen as simple and definite goals. This study aimed to deepen the understanding of how round numbers become reference points by analyzing records of batting average data in the same way as Pope and Simonsohn (2011). However, this study explored the following two points that have not been examined in the previous studies.

One purpose of this study was to test the round number effect in Japanese baseball data. Although Pope and Simonson (2009) demonstrated the round number effect in MLB data, its replicability in other leagues is still unexplored. In Japan, baseball is the one of the most popular and major professional sports, and abundant data for batting records are available for this examination. Additionally, the round number "0.300" is often referred to the cutoff for top-ranking batters in Japanese baseball. Thus, Japanese professional baseball (Nippon Professional Baseball: NPB)

data is adequate to test whether the round number effect can be replicated in the same way as in MLB.

The other purpose of this study as to explore individual differences in the round number effect of "0.300." Although this study referred to the number "0.300" as cutoff for the top-ranking batters in professional baseball, it also recognizes that this number does not always become goals for all the players. In professional baseball, batting average itself cannot be proof of the top-ranking batters because values of the batting averages depend on number of plate appearance. For example, although batting averages of the batters who got three hits at ten bats or one hundred and fifty hits at five hundred bats are both the same at "0.300," meanings of "0.300" might be different between the batters. Though the former average might be considered as a result of chance, the latter average would be thought as reflecting real ability. In fact, both MLB and NPB determined the regulation number of at-bat, and averages cannot be recognized as formal records without achieving the regulation number. Thus, it is probable that whether batters consider "0.300" as reference points depend on their numbers of battings: while the batters who cannot achieve number of regulations at battings do not consider "0.300" as their goal, for ones who can achieve the number, it might be valuable goal. The second purpose of this study was to test this possibility.

To accomplish the above purposes, this study gathered data for batting averages both in MLB and NPB, and tested the round number effect by examining whether relative frequencies of the batters whose batting averages were "0.300" stick out in the frequency distribution. In doing so, this study employed statistical test used in Chetty, Friedman, Olsen, and Pistaferri (2011) that utilize a broader range of data than Pope and Simonsohn (2011). With this method, this study also analyzed data that were divided by the number of plate appearance and examined whether the round number effect depends on whether the batter achieved the number of regulations at bats or not. The theoretical meanings and scope of the round number effect were discussed as well..

Method

This study obtained batting average data of Japanese baseball from Nippon Professional Baseball Organization (http://npb.jp/). This website contains results for all players of Japanese professional baseball from 2005 to 2018. Similar to Pope and Simonsohn (2011), this paper restricted its sample to players who had at least 200 at bats during the season. As a result, data of 1436 players were analyzed.

This paper also obtained MLB data in the same time as NPB data from Retrosheet.com. This website has data that was used by Pope and Simonsohn (2011), and contains data of all players in MLB for the same periods as Japanese data. This paper collected data of MLB using the same criteria as Japanese data, resulting in analysis of data of 4630 players.

This study aimed to investigate whether the round number effect would vary according to the number of appearances at bats. To accomplish this, the study divided the data into two groups by whether the number of appearances at bats exceeded the regulation numbers at bats or not both in NPB and MLB data. In NPB data, the regulation numbers at bats differed depending on year and league. In 2005 and 2006 the regulation numbers were 452 at Central League and 426 at Pacific League, and during 2007 and 2014, the number in both leagues was 446, and after 2015, it was 443. As a result, this study considered 743 batters as exceeding the regulation number at bats and 818 batters as not exceeding the regulation number.

In MLB, the regulation number at bats was settled as 400 since 1957. Thus, this study considered 2561 batters as exceeding the regulation number at bats and 2081 batters as not exceeding the regulation number in MLB data.

Results and discussion

Analyses of fundamental statistics of the round number effect

Figure 1 shows distribution of relative frequencies of batting averages at the ends of season both for players who had at least 200 at bats in both NPB and MLB. Visual inspections to these distributions suggest the following three points. First, with regard to the players who had at least 200 at bats, relative frequency of the average "0.300" is higher than any other values of batting averages of NPB and MLB players. In fact, similar to Pope and Simonsohn (2011), the proportion of players ending the season with a 0.298 or 0.299 was lower than that with a 0.300 or 0.301 ($z=4.84$ and 3.99 for MLB and NPB, respectively) in both the leagues, indicating that this study replicated the round number effect with a dataset different from that of Pope and Simonsohn (2011).

However, trends of the frequency around 0.300 appear to be different between the batters who exceeded the regulation number of at-bat of season and those who did not: the density of frequency around 0.300 that occurred for the batters who exceeded the number disappeared for the batters who did not. The Z tests demonstrated a significant difference in the proportion between 0.298 or 0.299 and 0.300 or 0.301 ($z=4.87$ and 4.05 for MLB and NPB, respectively) for the batters who exceeded numbers of regulation at bat in season, but did not demonstrate significant differences for the batters who did not exceed the number ($z=1.48$ and 1.50 for MLB and NPB, respectively). These results indicate that the round number effect would vary according to the number of at bat.

Third, increases in the frequency around 0.300 were higher for the NPB than MLB players. With regard to the total data, though the ratio of the frequency between 0.300 and 0.299 was more than 9 (3 for 0.299, and 28 for 0.300) in NPB data, that in MLB data was less than 3 (22 for 0.299,

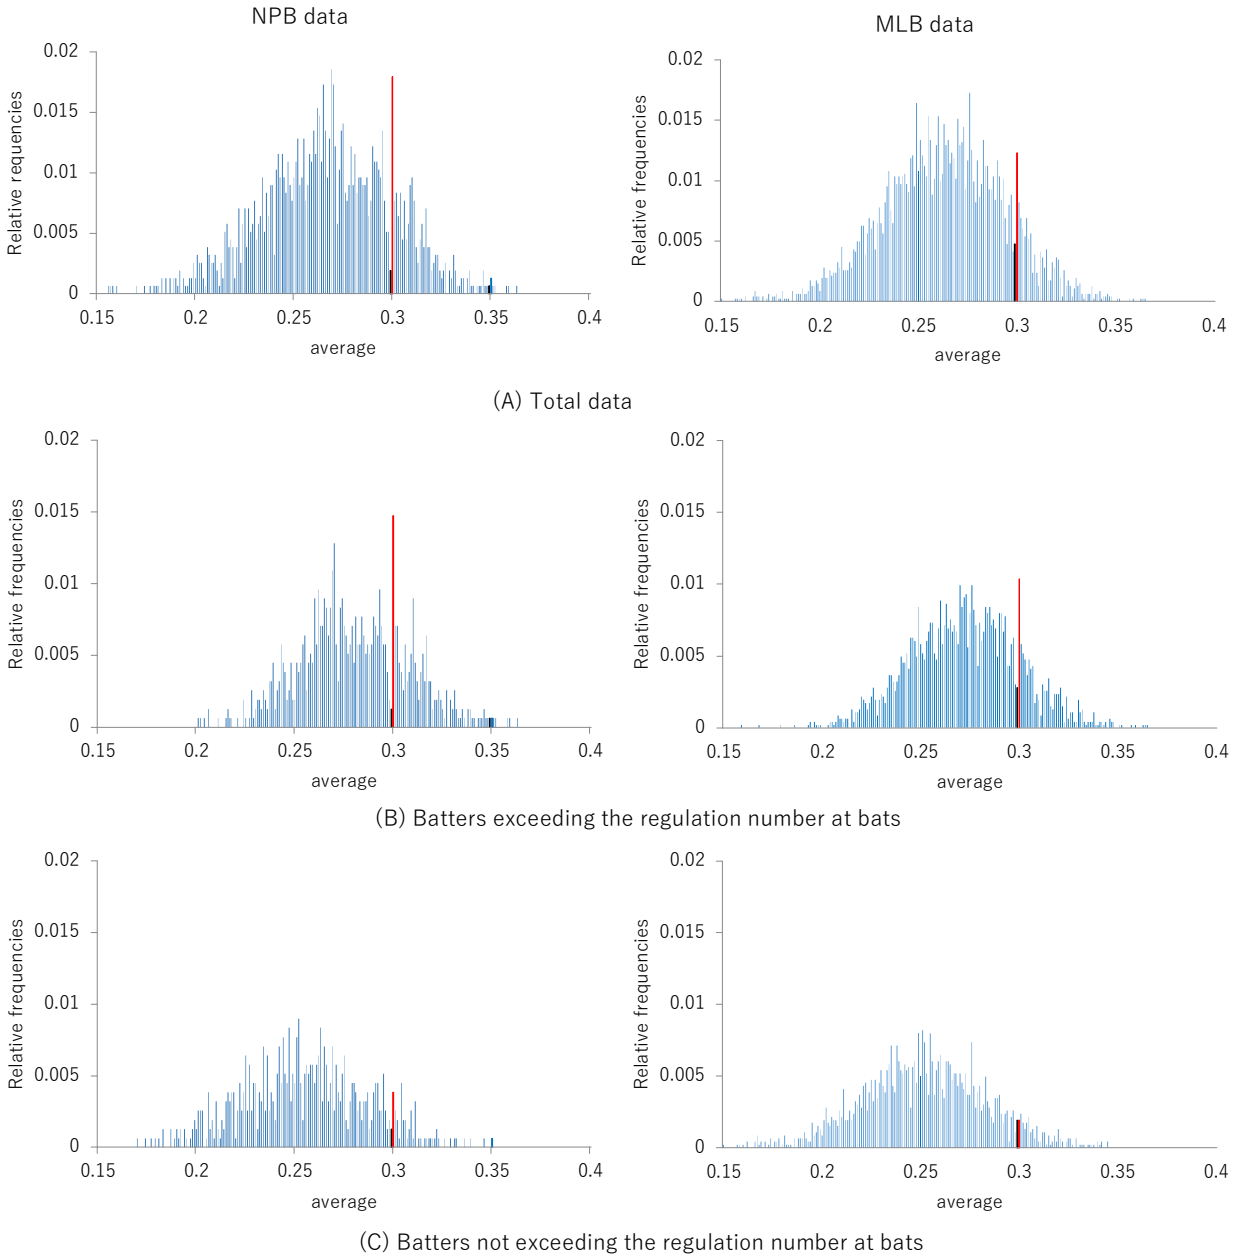

Figure 1 Distributions for batting averages of batters in NPB and MLB: Left and right column demonstrate distributions for NPB batters and MLB batters, respectively. Figures in the top, middle, and bottom row demonstrate distributions of the all batters, the batters who exceeded the number of regulation at bats, and batters who did not exceed the number of regulation at bat, respectively.

and 57 for 0.300). When data were limited only to the batters who achieved the provision bat number in the season, differences in the ratio became more salient (2 for 0.299 and 23 for 0.300 in NPB data, and 13 for 0.299 and 48 for 0.300 in MLB data). These results suggest that the round number effect would occur more strongly in NPB than MLB.

Quantitative estimation of the round number effect

One concern of the above discussion is that they solely consider data around the round number. However, as shapes of the distributions indicate, rise and drop around the round number in frequencies might be within probabilistic fluctuation. Thus, to explore this possibility, this study adapted a methodology proposed in Chetty et al. (2011) to quantify the extent of excess mass in an interval around a round number. This methodology enables examining

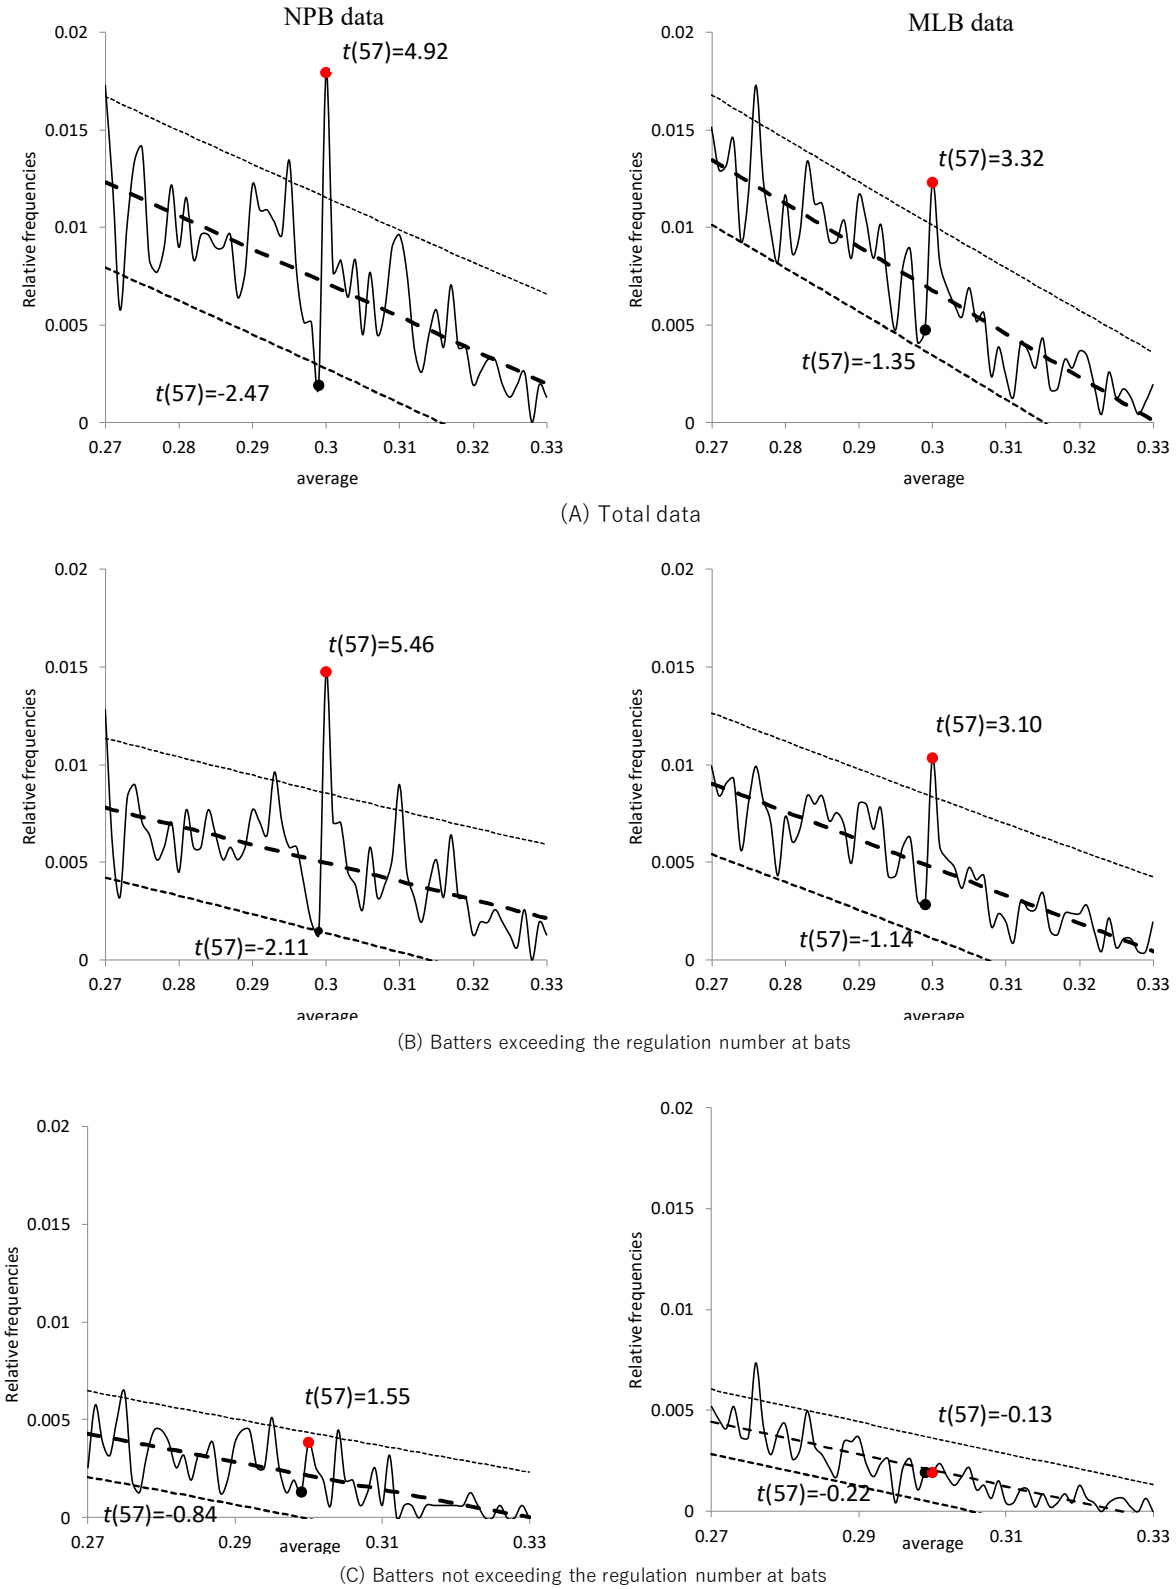

Figure 2 Result of Chetty's test: Left and right columns demonstrate distributions for NPB batters and MLB batters, respectively. Figures in the top, middle, and bottom row demonstrate distributions of the all batters, the batters who exceeded the number of regulation at bats, and batters who did not exceed the number of regulation at bat, respectively. Dotted lines in the graphs indicate regression line (bold) and 95% predictive intervals (thin). Red points indicate data of 0.300, and black points indicate data of 0.299.

whether discontinuity in distribution would occur around the reference point. The following section explains this methodology referring to the case of the round number effect in the batting average data.

This study aimed to examine whether discontinuity occurs between 0.299 and 0.300 because for the batters, "0.300" serves as reference point to be achieved. To address this issue, this study considered what would happen if "0.300" was not the reference point and the bunch around this number occurred in fact by chance. If so, frequencies of the batters around these values would follow trends that can be predicted through data from other domains. To test this consideration, this study first analyzed batting average data excluding frequencies of the batters whose averages were 0.299 and 0.300 with polynomial regression analysis where the batting average was the independent variable and the frequency of the batters was the dependent variable. Then, based on the results of this analysis, this study predicted frequencies of the batters whose averages were 0.299 and 0.300, and compared these predictions with the data. In sum, Chetty et al.'s (2011) method constructed "counterfactual" prediction from the data excluding values around the round numbers and examined the degree of deviation of the data from the counterfactual prediction by estimating prediction intervals of the polynomial regression models.

Using this methodology requires several inspections. First, the range of data used for this methodology must be selected in terms of research. For example, Allen et al. (2013) decided the range of data to be analyzed using Chetty et al.'s (2011) methodology through "visual inspection" of the data. Following Allen et al. (2013), this study also decided the range of data through visual inspection of the distribution. Thus, frequencies of the batters between 0.270 and 0.330 were used for the analysis. Second, the number of independent variables must be selected from results of polynomial regression analyses. This study adopted single regression model to approximate the data because only the effect of first order term in this model was significant throughout the six distributions.

Results of the analyses are shown in Figure 2. As the graphs shown in Figure 2 demonstrate, the frequencies of the batters whose averages were 0.300 were beyond 95% predictive intervals of the regression model both for NPB and MLB data. However, the frequencies of the batters who did not achieve the number of regulations at bat were within the 95% predictive interval from the regression models. Additionally, values of t-statistics for frequencies of the batters at 0.300 were larger in NPB than MLB, indicating that deviation from the predictions from the regression are more extreme in NPB than in MLB. In sum, these results support the findings in the previous section: the round number effect was replicated in NPB data, and depends on the number of plate appearance. Moreover, magnitude of the round number effect is more prominent in NPB than MLB.

Conclusion

Findings from the above analyses can be summarized as follows. First, this study demonstrated the round number effect using dataset other than that of Pope and Simonsohn (2011). The results indicate that the round number effect occurred in NPB data, and in doing so, this study analyzed MLB data collected using criteria different from those of Pope and Simonsohn (2011). This finding is also important in showing replicability of the round number effect in real situations with more strict methodology (Chetty et al., 2011) that was not adopted in the previous study (Pope & Simonsohn, 2011).

Second, this study found that the round number effect depends on people's incentives or motivation. Analyses of the data of the batters who did not exceed the number of regulations at bat indicated that increase in the frequencies of batters whose averages were 0.300 did not occur, indicating that 0.300 was not the reference point for performance for these batters. This finding indicates scpoe of the round number effect, which had not been explored in the existing studies (Allen et al., 2016; Pope & Simonsohn, 2011). Specifically, this finding is important in that the round number effect does not solely depend on people's preference for the round number.

In this vein, it is interesting that this study found difference in the round number effect between NPB and MLB data. Although NPB and MLB data are different in their sample size, discontinuities in the distributions around 0.300 in NPB data are more prominent than those in the MLB data, indicating that Japanese batters attach more weight to average 0.300 than Major League batters. This difference might be based on some cultural difference in professional baseball, suggesting that situational factor also affect the round number effect. In other words, Japanese baseball culture might attach greater importance on batting average to evaluate abilities of batters than in MLB. More precise analyses should be conducted to understand this difference in future research more profoundly.

According to Pope and Simonsohn (2011), the round number can serve as cognitive reference point in numerical scale in the same way as goals (Heath, Larrick, & Wu, 1999; Larrick, Heath, & Wu, 2009), expectations (Feather, 1969; Mellers, Schwartz, Ho, & Ritov, 1997), and counterfactual (Kahneman & Miller, 1986; Medvec, Gilovich, & Madey, 1995; Medvec & Savitsky, 1997). In contrast to this interpretation, this study revealed motivational and situational aspect of the round number effect. In other words, this study suggests that the round number cannot become reference point for performance solely by itself. Although for batters who exceed the number of regulations at bat the average of 0.300 can serve as proof for the top rank batter, for the batters who do not exceed the number, 0.300 itself might not be an important number. That is, for these batters, before achieving the average 0.300, it is important to exceed the number of regulation at bat. In addition, situational or cultural factor may also enhance the round number effect. This implication of the round number

suggests that meaning of the number depends on individual disposition. Thus, exploring conditions that enhance or inhibit the round number effect is an important future research question.

One methodological concern for this study was the arbitrariness of assumptions in analysis. This study performed the Chetty test (Chetty et al., 2011) using data from 0.270 to 0.330 through visual inspection of the distributions. However, it is possible to consider other criteria for data selection from the distribution to analyze the round number effect. Sophistication of methodology to test the round number effect is also necessary for future research.

Cultural Affordances in AI Perception

Zachariah A. Neemeh (zaneemeh@memphis.edu)
Department of Philosophy, University of Memphis, Memphis, TN 38152

Abstract

Affordances offer AI research an alternative from representations for linking perception to action in autonomous systems. Affordances are based in the informational structure of the environment and the somatic capacities of the agent and arise in their interaction. AI implementations of affordance perception typically utilize relatively basic, natural affordances such as the graspability of a handle. Culturally-scaffolded affordances, such as the letter-mailing capacity of a postbox, pose a more intractable problem for affordance-based robotics. This class of affordances requires acculturation and is highly culture-specific. AI implementations of affordance perception typically bypass this difficulty by making recourse to representations. I begin by reviewing affordance perception and the difference between natural and cultural affordances. I then critically discuss implementations of cultural affordance perception in autonomous agents. Finally, I argue that AI affordance perception does not require a robust representationalism in order to implement cultural affordances.

Keywords: affordances; AI perception; embodied cognition; philosophy of AI; representations

Introduction

The perpetually shifting nature of the environment poses a significant challenge to robotics research. Autonomous agents must negotiate and adapt to dynamically changing environments. Representational architectures limit autonomous agents' capacity to do so, however (Raubal & Moritz, 2008). Problems arise with the bandwidth, processing power, computational time, and programming time required to represent shifting environments (Rome et al., 2006). Nonrepresentational and affordance-based architectures have been proposed to overcome these difficulties (Braitenberg, 1984; Brooks, 1990, 1991; Horton, Chakraborty, & St. Amant, 2012). These architectures do not rely on separate layers for perception, action, and planning or reasoning. Instead, they offload part of the computational process onto the environment. As Rodney Brooks, the pioneer of embodied robotics and the inventor of the Roomba, said, "the world is its own best model" (1990, p. 4).

Many nonrepresentational architectures utilize affordances to replace otherwise separate perceptual and actional layers. Natural affordances, like the graspability of a handle, are embedded in the basic informational structure of the immediate environment (Gibson, 1979/2015). The agent picks up on information available in the environment, such as the light waves and pressure feedback of the handle. The affordance arises as the agent interacts with the object and is an opportunity for action that is highly constrained by the agent's form of embodiment.

Implementations of affordance perception are beset by a difficulty, however, once they encounter cultural affordances, or affordances that implicate background knowledge that is culturally mediated. Few AI implementations of affordance perception have attempted to incorporate such higher-order affordances (see Awaad, Kraetzschmar, and Hertzberg, 2015; Chu, Fitzgerald, and Thomaz, 2016; Raubal & Moritz, 2008). While the graspability of a handle can be modeled as an online, dynamical interaction unfolding between the agent's sensorimotor processes and the object's properties, the mail-ability of a letter implicates a vast background knowledge of letters, the postal service, postboxes, writing, and interpersonal communication. This background knowledge poses a significant problem. If all the rules and background knowledge pertinent to the mail-ability affordance must be represented, then affordance-based robotics offers little advantage over traditional architectures.

In this paper, I critically review extant AI implementations of cultural affordance perception and sketch a framework for perceiving cultural affordances with minimal recourse to representations. My aim is to show that a robust representationalism is not *conceptually* necessary for cultural affordance perception.

Affordance Perception

In classical computational models, the perception of the environment involves the creation of an inner, representational model (Fodor, 1985; Marr, 1982/2010).[1] The agent is decoupled from its environment and interacts with it through the medium of representations, which are processed computationally. The term 'representation' is used in a wide variety of senses, from a minimal sense of a covariation between an internal and external state, to a more robust internal mapping of an external state. To avoid the deep complexities involved in this term, I here use it to pick out any internal state that tracks an external state in the world, when that state is decoupled from perception and action. In autonomous agents, typically representations are instantiated in a planning or reasoning layer mediating between perceptual and actional layers. Processing can be

[1] While computationalism and representationalism do not necessarily entail one another (see Dennett, 1969), in practice they usually work in tandem.

through classical, serial processing architectures (as in Turing machines), or they can be massively parallel (as in connectionist, neural network, and similar architectures).

Autonomous agents in the real world encounter a wide variety of environments, no two of which will exactly be the same. Even the same environment often shifts in content through time. This creates a significant computational challenge, in addition to being resource- and energy-intensive. The existence of an inner representational layer places all the computational burden on the agent itself. Affordances, however, arise in the agent-environment interaction, offloading part of the processing burden onto the environment. Introducing affordance perception into autonomous agents enables them to continuously and dynamically adapt to shifting and changing environments.

Traditional autonomous agents separated sensing, planning/reasoning, and acting into different processes that would only link up at a later stage (Gat, 1998; Maes, 1991). The perceptual process sends information to the planning process, which in turn sends instructions for action (Horton, Chakraborty, & Amant, 2012). However, "[e]ven if an agent has perfect segmentation and feature recognition capabilities, this new form of information may be hard to translate into appropriate actions" (Nye & Silverman, 2012, p. 184). Affordance perception dispenses with the intermediary planning layer, instead generating affordances within a tight perception-action loop. What planning there may be is performed online through the perception-action loop, instead of offline between perception and action. This does not mean that the agent does no planning whatsoever; rather, it means there is often no representational layer mediating between perceptual and actional processes—at least, not at the level of basic perceptual processes (see Şahin et al., 2007). What planning there may be is performed online through the perception-action loop, instead of offline between perception and action. Furthermore, machine learning alone is insufficient; a robotic body is *required* for an affordance to be perceived. This is because affordances are not merely perceptual processes—they are perception-action processes and require dynamic engagement with the environment.

Natural and Cultural Affordances

Affordance perception in AI is complicated by the fact there are two very different types of affordances: natural and cultural. Natural affordances involve very basic cognitive processes. Cultural affordances are comparatively richer and involve culturally- and intersubjectively-mediated processes in order to be perceived and acted upon.[2] Cultural affordances, however, pose a particularly intractable problem. While natural affordances arise from the informational structure of the environment, cultural affordances require that the percipient be acculturated. There seems, *prima facie*, to be a level of decoupled, even representational, processing required to perceive a cultural affordance (Ramstead, Veissière, & Kirmayer, 2016).

Natural affordances are possibilities in the environment available for action (Dotov, Nie, & de Wit, 2012). Different agents can perceive different affordances based on their embodied capacities and species-typical behaviors. For example, a twig affords different actions to a cat, a finch, and a human. To the cat, the twig affords bite-ability and play-ability. To the finch, it affords graspability by the beak and build-ability for a nest. Finally, to the human, it affords manual manipulation. In each case, the embodied capacities and species-typical behaviors of the agent shape what kind of action the twig affords.

Affordances are based on the real information (light, pressure, scent) available in the environment. However, they do not themselves exist in the environment. They are generated in the agent-environment interaction. Affordance-perception occurs because the agent and environment form a complex, emergent system (Favela & Chemero, 2016; Thompson, Varela, & Rosch, 1991/2016; Gallagher, 2017; Thompson, 2007). That is, the agent is dynamically coupled with the environment. This coupling is modeled in ecological psychology and embodied cognition research using dynamical systems theory (Beer, 2014; Chemero, 2009; Turvey, 2019).

Several formalizations of affordances have been proposed (see Chemero, 2003; Stoffregen, 2003; Turvey, 1992). Stoffregen's (2003) formalization, which has been successfully utilized in AI affordance perception research (Nye & Silverman, 2012), is:

> "Let W_{pq} (e.g., a person-climbing-stairs system) = (X_p, Z_q) be composed of different things Z (e.g., person) and X (e.g., stairs). Let p be a property of X and q be a property of Z. The relation between p and q, p/q, defines a higher order property (i.e., a property of the animal−environment system), h. Then h is said to be an affordance of W_{pq} if and only if
>
> - W_{pq} = (X_p, Z_q) possesses h.
> - Neither Z nor X possesses h" (Stoffregen, 2003, p. 123).

Cultural affordances require the agent to utilize "explicit or implicit expectations, norms, conventions, and cooperative social practices" (Ramstead, Veissière, & Kirmayer, 2016, p. 3). It is precisely these elements that seem, *prima facie*, to require a representational layer decoupled from perception-action processes. For example, Gibson (1979/2015) remarks that a buyer and a seller each afford one another opportunities for action (viz., buying and selling). However, he goes on to say,

> "The perceiving of these mutual affordances is enormously complex, but it is nonetheless lawful, and it is based on the pickup of the information in touch, sound, odor, taste, and ambient light" (p. 127).

The information, in this case, is directly out there in the environment, and the agent perceives it. The affordances for

[2] Although affordances may differ regarding their basicness or their cultural scaffolding, in practice it is difficult to disentangle these two (see Wagman, Caputo, & Stoffregen, 2016). Indeed, for human agents, even basic perception-action processes like picking up an apple are culturally mediated.

action, however, arise in the interaction of the agent with its environment. It is the information, not the affordance, that is objectively embedded in the immediate environment. However, how could a buyer be perceived *as such* merely based on light waves, sound pressure waves, and other ecological information?

Gibson also claims that "the real postbox…affords letter-mailing to a letter-writing human in a community with a postal system" (1979/2015, p. 130). In this example, we have a culturally-scaffolded process of perception and action that functions only within a highly-specific cultural framework. It is not clear, however, how these culturally-scaffolded processes could be "directly" perceived based on the immediate information available in the environment. Memory and background knowledge are required for the postbox to be perceived with a letter-mailing affordance. However, there is little in the postbox's shape, color, and size that informs the agent of the postal system, letter-writing culture, and letter-reading agents enabling it to have mail-ability. Either cultural affordances are representational (see Ramstead, Veissière, & Kirmayer, 2016), or they must somehow be generated in a cultural milieu and for an acculturated agent by utilizing nonrepresentational, memory-based processes (see Rietveld & Kiverstein, 2014).

AI Cultural Affordance Perception

Most AI implementations of affordance perception have focused on natural affordances. These are, no doubt, relatively easier to implement because they do not require background knowledge of culture or a process of enculturation in order to perceive and act upon them. They are based only on the informational structure of the immediate environment. The true challenge for AI affordance perception is to achieve the perception of *cultural* affordances. If, however, cultural affordance perception turns out to require a robust representationalism, it is not clear that it has any advantage over non-affordance-based AI.

Raubal and Moratz (2008) provide an AI implementation of cultural affordance perception whereby cultural affordances are scaffolded onto natural affordances by representations of cultural knowledge. Their target agent is the Bremen Autonomous Wheelchair *Rolland*, which interprets linguistic commands by its human occupant and navigates across the environment. The need for cultural affordance perception arises because the wheelchair does not blindly perform actions commanded by their users. For example, the user may request to visit a center outside of operational hours. In this case, the AI utilizes cultural affordances integrating knowledge of the institution and its operating hours when selecting for action outputs.

Cultural affordances arise in their system by a system of constraints upon natural affordances. A natural affordance is constrained within a given social and institutional context. For example, the mailbox affords a multiplicity of actions, including smashing, opening, inserting objects, and touching. In their model, it is the social and institutional context of the postal system, letter-readers, and letter-writing that constrain the possible natural affordances into a smaller subset of cultural affordances. The agent then performs internal actions on these cultural affordances—essentially, planning or reasoning processes—in order to act upon the more basic natural affordance of opening and inserting.

The cultural affordances utilized by Raubal and Moratz' (2008) agent are representational. A separate planning layer is retained by their AI wheelchair. Their conception of cultural affordances is simply a subset of natural affordances that are given social and institutional constraints. Knowledge such as closing and opening hours is certainly representational and linguistically-based. The problem with their implementation of cultural affordances is that there is little that distinguishes them from classical representations. The construct of 'cultural affordance' is not doing any work that the construct of 'representation' does not already do. Their agent is essentially a hybrid system incorporating affordance perception for low-level navigation and symbolic representations for higher-level constraints upon that navigation.

Furthermore, some forms of social and institutional knowledge that Raubal and Moratz (2008) discuss, such as navigating across a city, are not necessarily fully representational processes. Unwritten norms such as walking on the right side of the sidewalk in many Western countries could be conceived of as representational rules. However, spontaneous pedestrian patterns can emerge without any specific intention (Moussaid et al., 2009).

Socialization and Supervised Learning

Awaad, Kraetzschmar, and Hertzberg (2015) provide an affordance-based model for AI agents that can "socialize" by learning expected uses of objects. The practical applications of this are in producing service robots that perform actions commanded by humans without being "robotic." When humans perform service tasks, an entire body of knowledge is brought to bear. Take the example of sweeping the floor. The human agent needs to know how to use a broom. However, the possibility space for utilizing a broom to sweep in *deviant* ways is quite large: one could sweep under the feet of others, sweep at the wrong times (e.g., while others are cooking), or sweep with furious movements and kick up dust. All these behaviors accomplish the task of sweeping but are social nuisances and perhaps even physically dangerous. There is an entire network of social expectations and etiquette surrounding the tool use in question. There is, in short, a "right way to do things." Furthermore, humans

> "effortlessly adapt our actions to unexpected situations, especially given the dynamic nature of our environment and the amount of uncertainty about it" (p. 422).

While moving a broom back and forth can be largely explained with natural affordances, these cultural constraints cannot. The broom affords more actions than are socially acceptable or considered appropriate to the task. Awaad,

Kraetzschmar, and Hertzberg (2015) attempt to integrate them within an affordance-perception paradigm, however. They note that programming procedural knowledge is insufficient to cover these cases of "the right way to do things" because the agent will always encounter novel situations. They implement Hierarchical Task Network to decompose tasks into a set of individual tasks in order to accomplish a goal.

In order to reduce the possibility space for action to one for socially-appropriate action, Awaad, Kraetzschmar, and Hertzberg (2015) store information about the object, the commanding agent, and the intended uses of the object. These constraints are scaffolded on the natural affordance of the object. The broom, for example, is defined by its socially-intended purpose of cleaning. The commanding agent, the human who demands cleaning, would have a set of preferences and expectations as to how that task is accomplished. The authors implement this cultural scaffolding through coded representations. Like Raubal and Moratz (2008), they conceive of cultural affordances simply as subsets of natural affordances that arise through representational cultural constraints.

Although the authors use representations to implement the socially-scaffolded constraints on the object's affordances, their broader proposal shows how a nonrepresentational framework could be used to do the same work. While they programmed the constraint knowledge into their agents, they suggest that this would be better done by supervised learning, particularly learning by demonstration. In the following section, I argue such supervised learning by demonstration of affordances does not require a strong concept of representations for its implementation.

Joint Interaction and Cultural Affordances: Unsupervised and Supervised Learning

Chu, Fitzgerald, and Thomaz (2016) develop autonomous agents that learn to perceive and use affordances through a combination of unsupervised and supervised learning through interaction with a human. A human teacher physically guides the robot to certain affordances. For example, a robot is taught that drawers have an openable affordance by guiding its hand. The robot learns to mimic this movement and perceive the openability affordance of the drawer's handle.

While the openability of the drawer *prima facie* appears to be a natural affordance provided by the structure of the robot's hand and the drawer's handle, there is a large possibility space for socially-deviant drawer-opening behavior. Although Chu, Fitzgerald, and Thomaz (2016) do not note this, the human teacher is not merely teaching the autonomous agent how to perceive and act upon the openability affordance of the drawer. They are simultaneously teaching the AI agent the *acceptable* way to perform this action. The drawer is not to be forcefully opened or rapidly opened and closed in succession (as a small child may annoyingly do), for example. The process of supervised learning allows the AI agent to learn the socially-acceptable affordances. This makes the drawer's openability affordance not simply natural, but also culturally-scaffolded.

Ramstead, Veissière, and Kirmayer (2016) invoke Gricean norms to understand these contexts. Grice (1975) articulated a set of rules governing conversation. These rules are ancillary to the communicative and phatic functions of language and facilitate nondeviant interactions. For example, one ought to convey as much detail as the topic requires without divulging too much detail. If one fails to do the former, one is perceived as terse, reticent, or uncommunicative. If one fails to do the latter, one is perceived as a windbag. In either case, deviation from the unwritten norm has the effect of interrupting the communicative act itself. Likewise, mundane actions have ancillary but unwritten norms guiding how they ought to be performed. These norms can only be learned by actual practice and observation of these actions in a social context. They are not symbolic rules because there may be no explicit representation of their content. They are merely habitual patterns of behavior used to accomplish certain tasks—e.g., opening a drawer slowly rather than forcefully.

While the robot may not develop shared intentions with the human teacher, in this case, it is significant that the robot only learns to perceive and act upon affordances through a process of interaction with a human (who is a "native" affordance perceiver-actor). In this case, representations are not necessary to explain how the AI agent learns to perceive and act upon the drawer's openability affordance in a socially-nondeviant way. While Awaad, Kraetzschmar, and Hertzberg (2015) programmed in cultural knowledge through representations, this supervised learning process does not specifically require the agent to store representations of cultural constraints, expectations, and other social rules. Rather than storing social rules and using them to constrain the agent's affordance perception and action, supervised learning allows the agent to learn to perceive and act upon the affordance in certain typical ways. Instead of inducing a rule based on the multiple supervised learning instances of opening the drawer—e.g., if drawer, then constraint *x*, *y*, *z*—the agent can simply follow the typical range of paths that have been learned.

One objection is that human agents are conscious of not deviating from socially-accepted norms of tool usage. These norms may be at a higher level than "not kicking up dust." One may be aware that one ought not to bother or annoy anyone. Nonetheless, even that does not require a specific rule. Even if the human agent has such a rule in mind, it is generally not the cause of their socially-nondeviant behavior. We do not walk around constantly thinking "I ought not to annoy *x*." If we can formulate such a rule, and even implement it in some cases, it is the exception (perhaps applying to a highly novel situation) rather than the norm. There is nothing here that cannot also be explained through processes of social learning, acculturation, and operant conditioning. These parallel the supervised learning trials in

AI affordance perception (Awaad, Kraetzschmar, & Hertzberg, 2015; Chu, Fitzgerald, & Thomaz, 2016).

AI Perception of Cultural Affordances without Representations: Learning and Habit

Representations such as rules can be used to constrain behavior in highly novel situations. Indeed, these kinds of rules may be part of the learning process itself. However, programming a database of representational cultural constraints for autonomous agents is a task just as formidable as that of traditional, non-affordance-based AI and computer vision. It is not clear that utilizing affordances in AI perception gains us anything. The problem, however, is that implementations of cultural affordance perception have generally been representational. The supervised learning in Chu, Fitzgerald, and Thomaz (2016) provides a way of thinking about what partially-nonrepresentational cultural affordances may look like in autonomous agents. Their autonomous agent learned how to open cabinet drawers in nondeviant and socially-acceptable ways. The drawer's handle information could afford multiple possibilities for action that are deviant, such as forcefully opening or rapidly opening and closing. During its supervised learning trials, the autonomous agent only learns the socially-acceptable way of opening the drawer. The agent does not perceive a natural affordance of open-ability. It perceives a cultural affordance of gentle-open-ability, one that is only salient within a given social structure and context.

Their autonomous agent does not have to learn or be preprogrammed with a *rule* about acceptable ways to open drawers. It is through multiple supervised learning trials that the cultural affordance begins to emerge—it is, in short, a *habit*. By habit, I mean a pattern of behavior that develops through supervised and unsupervised learning. The agent's habitual patterns of behavior are not representational in the sense that they are not primarily guided by symbolic rules, although the latter may constrain habits in actual behavior. Habit emerges from a set of previous behaviors and continues to guide future ones without necessarily having any explicit formulation. Surely some affordances must be constrained by symbolic representations. The closing time of a building or institution is something that could be learned by habit. The agent could develop a sense of when it closes by a long process of trial and error. However, that would be far less efficient than simply having a rule representing its closing time. In many cases, though, the work being done by representations can just as well be done by supervised and unsupervised learning or habit.

Returning to the example of sweeping, when the AI agent learns how to sweep from a human teacher, the latter will only teach the socially-accepted ways to sweep. The teacher will not teach how to sweep under people's feet, around them while walking, vigorously so as to kick up dust, or any other socially-deviant manner. The agent would learn these patterns of use of the object. Inducting a specific representational rule to cover these cases is supernumerary and fails to add explanatory value. The agent does not need a representational rule ("do not kick up dust"), because they have been taught to use the broom in a set of patterns that do not include kicking up dust. Following Ockham's razor, if the explanation can be had without representations, then we ought to dispense with them as an *explanans* in those cases.

One of the challenges for robustly-representationalist implementations of cultural affordance perception is that they require just as thorough programming with rules as traditional representational architectures. Habit, however, could greatly reduce the set of background knowledge that needs to be programmed. This is also a primary way that human agents develop habits during development. Children do not learn about their culture's interpersonal distance—the typical distance people stand from one another during communication—by learning a rule about how many centimeters away from another person to stand. They merely develop a habit of standing a certain distance away from another person. This habit is reinforced by observation of others and by violations of the norm (e.g., standing too close to someone can be perceived as aggressive). They may not even be aware that there is such a social norm guiding their behavior. If a representational rule happens to be extracted by a reflecting agent, it is still habit and not that rule that continues to guide its behavior. A humanoid autonomous agent could likewise learn to communicate using nondeviant interpersonal distance without any representational rules dictating how many centimeters away to stand by recourse to supervised learning (observation and mimicry) and unsupervised learning (violations).

Conclusion

Affordance perception offers a new paradigm for perception and action in autonomous agents. While traditional three-level systems dissociate perception, planning or reason, and action into separate layers, nonrepresentational affordances involve a dynamic and bidirectional perception-action loop with online planning. Many implementations of affordance perception in AI research have retained the representationalist paradigm even as they seek to integrate affordances. While this is certainly feasible from a technical standpoint, the construct of 'affordance' loses much of its power. An affordance-based robotics that remains largely representationalist has no clear advantage over traditional architectures.

Examining several implementations of cultural affordance perception in AI research, I argue that representations are not *necessary* for cultural affordances. I sketched a possible way for autonomous agents to implement cultural affordance perception by habit gained through supervised and unsupervised learning. AI implementations of affordance perception do not conceptually require a robust representationalism. If affordance-based robotics is to have any advantage over traditional architectures, it may need to reconsider the role of representations in cultural affordance perception.

Neighborhood in Decay: Working Memory Modulates Effect of Phonological Similarity on Lexical Access

Abstract

A mainstay of models that account for the access of lexical knowledge is that auditory words compete for selection based on form similarity, commonly seen in an inhibitory effect to greater phonological neighborhood density (PND). PND is a metric that states that two words are neighbors if they differ by the addition, deletion or substitution of a single phoneme. A drawback to this account is that there is competing evidence even among the European languages investigated thus far. We sought to verify whether the inhibitory effect of greater PND would hold for Mandarin Chinese in two auditory word repetition tasks with monosyllabic and disyllabic Mandarin words. Results of Experiment 1 showed a facilitative effect to greater PND. Experiment 2 added a non-verbal distractor task to lessen the putative effect of working memory load during the task. The facilitative effect to greater PND was confirmed along with a significant post-hoc interaction with memory decay, operationalized as the duration spent on the distractor tasks. The facilitative effects extend previous reports of differential behavior due to linguistic typology.

Keywords: Lexical access; phonological neighborhood density; memory decay; Mandarin Chinese

Introduction

Essential to the current models of lexical processing is that target words interact during selection with items in long-term memory based on their shared semantic, orthographic, and phonological similarity. Both orthographic and phonological similarity are most commonly calculated through the addition, deletion or substitution of a single letter or phoneme (Landauer & Streeter, 1973). According to this metric, known as neighborhood density, a target stimulus with many similar words in the lexicon, i.e., neighbors, resides in a dense neighborhood, while a word with few similar words in the lexicon resides in a sparse neighborhood. The contrasting of dense and sparse words has been used to model the structural organization of lexical knowledge. For example, in the recognition of orthography, according to both the orthographic and phonological metrics, words from dense neighborhoods have been shown to facilitate recognition (Orthographic; e.g., Coltheart, Davelaar, Jonasson, & Besnar, 1977; Phonological: e.g., Yates, Locker, & Simpson, 2004). This facilitation has motivated the claim that greater density results in greater overall activation, a defining feature that was later implemented in several computational models (Coltheart, Rastle, Perry, Langdon, & Ziegler, 2001; Grainger & Jacobs, 1996; Wagenmakers et al., 2004). However, when tasks are performed in the auditory modality, greater density has been reported to inhibit recognition (e.g., Luce & Pisoni, 1998; Vitevitch & Luce, 1998; Ziegler et al., 2003), motivating the construction of modality specific models of speech processing (Luce, Goldinger, Auer, & Vitevitch, 2000; McClelland & Elman, 1986; Norris, 1994). In response, Chen & Mirman (2012) constructed a connectionist model in an attempt to give a unified account of both facilitative and inhibitory neighborhood effects across both visual and auditory modalities, perception and production tasks, and orthographic, phonological and semantic neighborhood interactions. Their innovative approach, unfortunately, rests on the false assumption that there is a consensus in the literature for modality and task specific neighborhood effects.

To limit the discussion, we will consider only the effects known for phonological neighborhood density (PND). Two hypotheses of note have been advanced concerning differences in polarity from the body of behavioral evidence: psychotypology, and methodology.

The psychotypological argument holds that cognitive processes differ due to the linguistic differences between the languages being tested. The case, as it regards lexical access (Vitevitch & Rodríguez, 2004; Vitevitch & Stamer, 2006, 2009), was made based on evidence from both auditory recognition, and speech production. Dense phonological neighborhoods were inhibitory to speech recognition for English speakers (e.g., Luce & Pisoni, 1998), yet were facilitative for Spanish speakers (Vitevitch & Rodríguez, 2004), whereas, dense words were facilitative for English speakers in picture naming (Vitevitch, 2002), yet inhibitory for Spanish speakers (Vitevitch & Stamer, 2006, 2009). Vitevitch and colleagues speculated that the differences between the English and Spanish lexicons led to differences in polarity. Whereas English words have on average a greater number of shorter words with more phonological neighbors, the sparser Spanish vocabulary features words that are

neighbors both phonologically and semantically, e.g., *niño/niña* (boy/girl).

The methodological argument to account for differences in polarity points towards the design and methods employed in PND related studies. Sadat, Martin, Costa, and Alario, (2014) posited that the contradictory findings could be amended through testing with larger stimulus sets and the use of mixed effects models. The re-analyses of PND studies done by Sadat and colleagues clarified important differences between F tests and mixed effects models in the analysis of a variable that is continuous in nature and thus best fit for regression rather than factorial designs.

A third possibility to account for the differences in polarity in PND studies is to investigate working memory, specifically as it concerns the size of the stimuli sets used. As a participant recognizes or names a word, that lexical item is temporarily stored in working memory. If participants are exposed to multiple words, memory load increases and with it reaction times (Cohen et al., 1997; Jha & McCarthy, 2000). If the participant sustains attention on one task then memory decay does not happen at the same rate compared to if they were given a pause or a distractor task that does not interfere with the domain or modality of the main task (Rae & Perfect, 2014). In the case of phonological information, Baddeley (1986) found that phonological memory decayed within roughly 2 seconds. This does not differ greatly from the recall of orthographic letters after doing simple math problems (Brown, 1958; Peterson & Peterson, 1959). Given that during PND related tasks the inter-stimulus pause tends to be between 500-1500ms, i.e., under the rate of decay known to exist for phonological information, it is feasible that words are subject to cumulative activation, i.e., that activations of multiple word representations overlap and contribute to participant performance.

The studies that have investigated neighborhood effects amongst adults have utilized a large range of different sized stimulus sets. In studies implementing auditory word repetition tasks the story is quite straightforward, wherein large stimulus sets (Luce & Pisoni, 1998: 400 words; Vitevitch & Luce, 1998: 240 words) led to an inhibitory PND effect. In lexical decision tasks, two experiments using large stimulus sets showed inhibitory PND effects (Luce & Pisoni, 1998: 610 words; Vitevitch, Stamer, & Sereno, 2008: 112 words) while one with a small set of stimuli showed a facilitative PND effect (Vitevitch & Rodríguez, 2004: 80 words). The picture naming literature is where we see inhibitory results with large and small stimulus sets (e.g., Sadat, et al., 2014: 533 pictures; Vitevitch & Stamer, 2006: 48 pictures), facilitative results with small stimulus sets (Baus, Costa, & Carreiras, 2008: 48 pictures; Marian, Blumenfeld, & Boukrina, 2008: 57 pictures; Pérez, 2007: 89 pictures; Vitevitch, 2002: 48 pictures; Vitevitch & Stamer, 2009: 48 pictures), and non-significant PND effects (Jescheniak & Levelt, 1994: 96 pictures repeated 3 times; Vitevitch et al., 2004: 44 pictures). Note that non-significant results might also have been due to issues unrelated to stimuli number, such as mixing photographic and hand-drawn stimuli or due to naming pictures that represent conceptual processes such as verbs (Newman & Bernstein Ratner, 2007; Tabak, Schreuder, & Baayen, 2010).

The role of PND in working memory has not been fully explored. The only studies to test their interaction found a facilitation of greater density in serial recall tasks with English speakers (Oberauer, 2009; Roodenrys, Hulme, Lethbridge, Hinton, & Nimmo, 2002). The facilitative effect was said to be due to redintegration, which can be described as the restoration of short-term memory traces due to long-term memory representations. In order to test cumulative activation, however, it is necessary to account for overall memory load rather than that of isolated words.

To test the possibility that cumulative working memory influences the directional effect of PND, we performed two experiments with a large number of stimuli. In Experiment 1 we presented the full stimuli set to our participants without sufficient time for decay in memory load. In Experiment 2 we inserted three nonverbal distractor tasks in order to introduce memory decay. In both experiments we implemented the auditory word repetition task due to it being the only task thus far without contradictory findings. The cumulative memory hypotheses, allows for the prediction of an inhibitory effect to greater PND in Experiment 1 and a facilitative or null effect in Experiment 2.

In the current study we also incorporate concerns brought by both previous hypotheses concerning methodology and psychotypology on differing PND effects. Through the use of a large stimuli set and mixed effects models we treated PND as a continuous variable. Meanwhile, our target language, Mandarin Chinese, was chosen due to its typological distinctness to either English or Spanish, allowing for a unique view on how the dimensions of the lexicon affects lexical access.

The Mandarin vocabulary differs from both English and Spanish in critical ways. Its syllable inventory, when including lexical tone, has roughly 1,300 items, which is a number far less than the 10,000+ English syllables. Unlike Spanish that boasts of a large proportion of multisyllabic words rich in morphological variation (Arbesman, Strogatz, & Vitevitch, 2010), roughly 72% of Mandarin's phonological words (i.e., in which all homophones are collapsed to one item) are disyllabic, and only 3.8% monosyllabic (Neergaard & Huang, 2019). Meanwhile, Mandarin words have little to no morphology. For instance, unlike Spanish, Mandarin verbs do not conjugate, and nouns do not note gender nor number.

To date, no results have been reported in the auditory word repetition task with Mandarin speakers. Despite this lack of prior evidence, the psychotypology account allows for certain predictions. Given the greater distance lexically from Spanish, particularly in relation to its on average longer word length and inflectional morphology, Mandarin shares greater similarity with English. English has shown inhibitory PND effects in both auditory lexical decision and word repetition, making it likely that lexical competition best accounts for the selection of dense phonological words in Mandarin.

Experiment 1

Methods

Participants Thirty-three native-Mandarin speakers participated in this experiment (Female: 21; Ages 18-35, M: 12, SD: 3.64). None of the participants reported speech, hearing, or visual disorders. All participants reported native-level proficiency in Mandarin.

The current study design was approved by The Hong Kong Polytechnic University's Human Subjects Ethics Sub-committee (reference number: HSEARS20140908002). The participants gave their informed consent and were compensated with 50HKD for their participation.

Stimuli The auditory stimuli for this experiment consisted of 154 Mandarin words (10 practice; 144 test). A female native-speaker of Mandarin from Fujian province produced all of the stimuli by speaking at a normal speaking rate into a high-quality microphone. Stimuli fell into 4 categories according to their syllable or segment length: 36 3-segment monosyllables with a CVN syllable structure (e.g., *san1*); 36 4-segment monosyllables with a CGVN syllable structure (e.g., *bian3*); 36 3-segment disyllables with a CV V syllable structure (e.g., *da4 yi1*); 36 4-segment disyllables with a CV CV syllable structure (e.g., *li4 shi3*). The 144 test stimuli were made from 20 syllable onsets, whose distributions were not significantly different in syllable length ($p=1$) or segment length ($p=1$). Eleven stimuli sets were constructed, each where stimuli were pseudo-randomized such that there were no consecutive presentations of items with the same onset or lexical tone (first syllables for disyllabic words). The stimuli list can be seen in Appendix 1.

Because the current stimuli consist of monosyllables and disyllables of both 3 and 4 segments in length, it was not possible to control for their durations along all 4 dimensions. Instead, stimuli were chosen in order to minimize durational differences between 3-Segment words (CV V, M: 609.25; SD: 11.59; CVN, M: 609.00; SD: 11.01) and between 4-Segment words (CVCV, M: 784.67; SD: 9.25; CVVN, M: 784.17; SD: 11.02). Stimuli did not differ within their respective segment length groups, but were significantly different across segment lengths ($F=9433$, $p<0.001$). Thus, while a significant difference in reaction times is expected between 3- and 4-Segment words, the same cannot be said between monosyllable and disyllables belonging to their respective segment lengths, which is critical in identifying whether monosyllables and disyllables are processed in an equivalent manner.

Lexical statistics for the stimuli were taken from the Database of Mandarin Neighborhood Statistics (Neergaard, Xu, & Huang, 2016), in which lexical frequency is derived from the wordlist of Subtlex-CH (Cai & Brysbaert, 2010) according to the summed subtitle frequency for each phonological word. All relevant statistics were calculated from 30,000 phonological words. In order to test the hypothesis that words of varying unit sizes are subject to the effect of phonological similarity during speech processing, it was necessary to use the fully segmented Mandarin syllable schema (C_G_V_X_T) because it allowed us to control for both segment and syllable length while distinguishing between words according to lexical tone. Stimuli did not differ in log10 lexical frequency for either 3-segment words (CVN, M: 3.08, SD: 0.40; CV V, M: 2.75, SD: 0.46) or 4-segment words (CGVN, M: 2.98, SD: 0.49; CV CV, M: 3.33; SD: 0.21) according to both segment length ($p=0.869$) and syllable length ($p=0.981$).

The remaining variables are of the density variety and include PND, log10 neighborhood frequency (NF, M: 3.11; SD: 1.06), and homophone density (HD, M: 1.67; SD: 1.26).

The goal in choosing stimuli according to PND, knowing that greater length negatively correlates with higher density, was to assure that there was sufficient spread for each group. For the syllable length group, disyllabic words had a spread of 0-11 neighbors (M: 3.71, SD: 2.45), while monosyllabic words had a spread of 4-25 neighbors (M: 13.29, SD: 5.05). For the segment length group, 3-segment words had a spread of 0-25 neighbors (M: 10.10, SD: 7.03), while 4-segment words had a spread of 0-17 neighbors (M: 6.90, SD: 4.85).

Procedure Participants sat in a quiet room in front of a computer running E-Prime 2.0 (Psychology Software Tools, 2012). They were instructed to repeat the words they heard over headphones into an attached microphone as fast as possible. Each trial began with a cross '+', in the center of the screen for 1000ms. Next, the onset of the target audio was presented concurrent with the exposure of a blank screen. A PST Serial Response Box was activated by the participants' voice, dependent on their response, which then led to a pause of 1000ms and the end of a trial. Stimuli were pseudo-randomized such that no two items were presented sequentially with the same onset or lexical tone. The entire experiment lasted roughly 10 minutes. Participants were given a practice set of 10 words prior to beginning the experiment.

Results and discussion

Reaction times were measured offline using SayWhen (Jansen & Watter, 2008). No participants were excluded due to excessive error rates, or deviant reaction times. Three stimuli were removed for error rates higher than 25% (*guang4, qing3, san4*). From the new total of 4,653 trials, 102 were removed due to production errors, accounting for 2.19%. A further 238 trials (5.23%) were removed for values below the duration of our shortest stimuli (577ms), and for values 2.5 standard deviations above the group mean. The final number of trials to be analyzed were 4,313 (M: 917ms; SD: 144ms).

As can be seen in Table 1, Subject and Item were placed in the random effects, while each of the density variables (PND, HD, and NF) were analyzed according to the two levels of segment length (SegLen: 3-seg, 4-seg). We also place syllable length (SyLen) into the fixed effects structure to evaluate whether there was a processing cost despite stimulus durations not being different between monosyllables and disyllables in each segment group.

Table 1. Model estimates for Experiment 1

Random effects	Var.	SD			
Subject	0.003	0.057			
Item	0.012	0.111			
Residual	0.007	0.086			
Fixed effects	**β**	**SE**	**df**	**t**	**p**
Intercept	9.4^{e-1}	2.2^{e-2}	54	42.21	< 0.001
SyLen (di)	-5.2^{e-2}	1.9^{e-2}	132	-2.73	0.007
3-seg:PND	-3.3^{e-2}	9.4^{e-3}	132	-3.48	< 0.001
4-seg:PND	-5.2^{e-2}	1.4^{e-2}	132	-3.63	< 0.001
3-seg:HD	6.5^{e-3}	6.1^{e-3}	132	1.07	0.287
4-seg:HD	7.0^{e-4}	1.1^{e-2}	132	0.06	0.950
3-seg:NF	-1.6^{e-2}	1.1^{e-2}	132	-1.51	0.133
4-seg:NF	-7.8^{e-3}	1.1^{e-2}	132	-0.70	0.483

Results revealed that monosyllables (M: 903ms; SD: 15ms) were produced significantly faster than disyllables (M: 928ms; SD: 14ms). Greater PND was facilitative for both 3-segment (M: 867ms; SD: 138ms) and 4-segment (M: 965ms; SD: 137ms) items. No effects were found for either SegLen:HD or SegLen:NF. An estimate of r^2, using the 'r2glmm' package in R (Jaeger, Edwards, Das, & Sen, 2016), revealed that the model had a marginal r^2 of 0.224, and semi-partial r^2 of 0.145 for SegLen:PND, and 0.053 for SyLen.

The facilitative effect to greater PND for both monosyllabic and disyllabic words, rather than supporting a cumulative memory account, is suggestive that typological differences between English (majority inhibitory findings to greater PND) and Mandarin led to the differential performance.

Experiment 2

The premise of the cumulative memory account is that shorter stimulus sets in a naming task result in facilitative PND effects due to there being fewer lexical items stored in working memory when compared to a task with a large stimulus set. It is possible that working memory builds cumulatively leading to increased activation, but that due to the particular psychotypological features of Mandarin, a facilitative effect to greater PND is the outcome. The only way to verify the status of a facilitative effect, while also nullifying the cumulative account, is to provide participants with sufficient time for memory decay during naming.

Methods

Participants Forty-seven native-Mandarin speakers participated in this experiment (Female: 29; Ages 19-38, M: 24, SD: 4). None of the participants reported speech, hearing, or visual disorders.

Stimuli The same auditory stimuli from Experiment 1 were used in this experiment.

Procedure The current design differed from Experiment 1 in that the experiment was partitioned into 4 blocks of 36 trials each with three interleaved distractor tasks. Each distractor task included four basic math questions: e.g., "20*2=__". The distractor task was self-paced. Participants had to press a button to return to the following test block. The entire experiment took less than 15 minutes.

Results and discussion

Reaction times were again measured offline using SayWhen (Jansen & Watter, 2008). Three participants were excluded from the analysis; two for reaction times 2.5 standard deviations above the group mean, and one due to experimenter error in data acquisition. No participants were excluded due to excessive error rates; however, three stimuli were removed for error rates higher than 25% (*qing3, san4, sang1*). From the new total of 6,203 trials, 142 were removed due to production errors, accounting for 2.24%. A further 103 trials (1.66%) were removed for values below 577ms and above 1446ms, leaving our final number of trials to be analyzed at 6,100 (M: 1010ms; SD: 148ms).

The same model configuration from Experiment 1, as shown in Table 2, again found a significant SyLen effect between monosyllables (M: 995ms; SD: 148ms) and disyllables (M: 1027ms; SD: 148ms), and a significant facilitative effect to greater PND for both 3-segment (M: 951ms; SD: 139ms) and 4-segment (M: 1069ms; SD: 134ms) items, with no significant effects for SegLen:HD or SegLen:NF. The model's marginal r^2 was 0.202, with a semi-partial r^2 of 0.121 for SegLen:PND, and 0.042 for SyLen.

Table 2. Model estimates for Experiment 2

Random effects	Var.	SD			
Subject	0.004	0.065			
Item	0.009	0.094			
Residual	0.008	0.091			
Fixed effects	**β**	**SE**	**df**	**t**	**p**
Intercept	1.04	1.9^{e-2}	115	55.22	< 0.001
SyLen (di)	-5.1^{e-2}	2.1^{e-2}	133	-2.41	0.017

4-seg:PND	-5.2^{e-2}	1.6^{e-2}	133	-3.25	0.001
3-seg:HD	6.1^{e-4}	7.0^{e-3}	133	0.09	0.931
4-seg:HD	-5.8^{e-3}	1.2^{e-2}	133	-0.46	0.643
3-seg:NF	-1.9^{e-2}	1.2^{e-2}	133	-1.57	0.118
4-seg:NF	-5.4^{e-3}	1.3^{e-2}	133	-0.43	0.667

In this experiment we confirmed the facilitative effect to greater PND for Mandarin. We have also shown that stimulus set sizes are not the likely candidates in the variability found in PND studies. We did not however account for how PND and working memory interact.

To investigate whether decay modulates the effect of PND, in a post-hoc analysis we operationalized memory decay as the time spent on the three interleaved distractor tasks. While each participant received the same basic math questions, they were given as much time as they saw fit to complete each task before returning to the repetition task. For the following analysis, it was necessary to exclude the trials belonging to the experiment's first block. In this way, each block under examination entailed auditory lexical processing after having received a limited time for memory decay from a previous session of auditory lexical processing.

The values for Decay ranged from as short as 3 seconds (3100ms) to as long as 41 seconds (41373ms). Visual inspection of Decay's token values revealed that it was not linearly distributed. We rescaled the variable using a Box Cox transformation (Tukey, 1977) to evenly distribute duration length of non-lexical processing during the distractor task.

Using the 'mcgv' package in R (Wood, Scheipl, & Faraway, 2013), a generalized additive model using tensor product smooths was constructed (with Subject and Item as random effects) in which Decay was added as an interaction to each level of PND, SegLen, and SyLen. With an adjusted r^2 of 0.651, Decay interacted significantly with PND ($F=23.94$; $p<0.001$); 3-segment ($F=28.75$; $p<0.001$) and 4-segment items ($F=15.62$; $p<0.001$); and both monosyllables ($F=6.32$; $p<0.001$) and disyllables ($F=8.28$; $p<0.001$). As can be seen in Figure 1, when Decay was shortest, the effect of PND was strongest, providing clear evidence that working memory is a determining factor of phonological neighborhood effects.

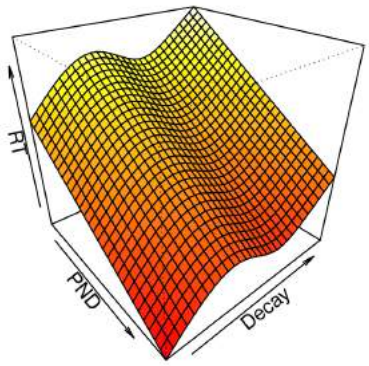

Figure 1: Interaction effect of phonological neighborhood density (PND) and time spent on the distractor task (Decay)

General Discussion

The purpose of the current study was to examine multiple hypotheses on the directional effect of PND through Mandarin Chinese, a language typologically distinct from the languages tested to date. We incorporated the methodological concerns brought by Sadat et al. (2014), through the testing of a large number of stimuli with mixed effects models wherein PND was treated as a continuous variable. We performed two auditory word repetition tasks, the only task to date that has not shown contradictory PND effects, in which our participants' rate of memory decay was manipulated to test whether differences in PND polarity have been due to cumulative memory. Finally, the testing of Mandarin participants allowed us to join the debate on psychotypology, i.e., whether the dimensions of a speaker's lexicon can result in differential behavioral outcomes.

In Experiment 1 we exposed our participants to the full stimuli set under the assumption that by not allowing for memory decay to occur our participants would produce an inhibitory effect to greater PND. Opposite our expectations, and in contrast to the previous English results, we found a facilitative effect to PND. In Experiment 2 we manipulated the task through the introduction of interleaved nonverbal distractor tasks. Changes in modality through distractor tasks have been shown to increase memory decay of the main task material (Rae & Perfect, 2014). The facilitative effect to greater PND was confirmed despite providing our participants with time for memory decay. A further post-hoc analysis illustrated that while working memory indeed modulates the phonological neighborhood effect, it can do so without lexical competition.

Under the assumptions of the psychotypology account of PND (Vitevitch & Rodríguez, 2004; Vitevitch & Stamer, 2006, 2009), we predicted that our Mandarin participants would experience lexical competition due to greater PND, in line with previous English results and contrary to previous Spanish results. This assumption was built on the greater difference between the Spanish and Mandarin vocabularies compared to the differences between the English and Mandarin lexicons. While Spanish is rich in morphology and on average has longer words, Mandarin has on average shorter words and no inflectional morphology. Contrary to our prediction, our Mandarin speakers were facilitated by greater PND, revealing that word length and inflectional morphology are likely not a reason for why Spanish speakers also experienced facilitation by words from dense phonological neighborhoods.

Given our current negation of the cumulative memory account, further work would benefit from delving deeper into the psychotypology of lexical access. Evidence has been mounting for differences in brain areas during language process between English and Mandarin speakers, at the level of whole-brain maps (Wu et al., 2015), and targeting language processing areas during tasks such as rhyming judgments (Brennan, Cao, Pedroarena-Leal, McNorgan, & Booth, 2013). A comparison of the Spanish and Mandarin lexicons might reveal how similarities between typologically distinct languages can lead to outcomes that defy the current models of speech production and perception.

It is also possible that an influence other than phonological neighborhoods is responsible for the facilitative effects in Spanish and Mandarin. The work of Vitevitch and colleagues pointed to a possible candidate other than word length and inflectional morphology, namely, neighbors of target words that are of both phonological and semantic relations (i.e., 'boy/girl, *niño/niña*). Our search of the literature found evidence concerning possible effects of semantic neighbors during auditory lexical decision, but only for English (Goh, Yap, Lau, Ng, & Tan, 2016; Tucker et al., 2018). In line with the current predictions, semantic neighbors did not significantly predict reaction times. In contrast to English, it is possible that both Spanish and Mandarin feature a sufficient number of phono/semantic neighbors to lead to facilitation during an auditory task. While Mandarin does feature phono/semantic word pairs such as *bian1* ('side' 边) / *pian1* ('one-sided' 偏), it also entertains a uniquely high level of homophony (*bian1* = 9 homophones; *pian1* = 3

homophones), making future comparisons between the two languages challenging.

Abstract

The purpose of this paper is to determine whether a particular context factor among the variables that a researcher is interested in causally affects the route-choice behavior of drivers. To our knowledge, there is limited literature that consider the effects of various factors on route choice based on causal inference.Yet, collecting data sets that are sensitive to the aforementioned factors are challenging and the existing approaches usually take into account only the general factors motivating drivers route choice behavior. To fill these gaps, we carried out a study using Immersive Virtual Environment (IVE) tools to elicit drivers route choice behavioral data, covering drivers' network familiarity, education level, financial-concern, etc, apart from conventional measurement variables. Having context-aware, high-fidelity properties, IVE data affords the opportunity to incorporate the impacts of human-related factors into the route choice causal analysis and advance a more customizable research tool for investigating causal factors on path selection in network routing. This causal analysis provides quantitative evidence to support drivers diversion decision. The study also provides academic suggestion and reference for investing in public infrastructure and developing efficient strategies and policies to mitigate traffic congestion.

Keywords: Causal and Counterfactual Explanation

Introduction

Route choice refers to the choices of roads among a set of possible alternatives made by human drivers while navigating through an urban area. Route Choice Models estimate the route choices of drivers in an urban setting. Most route choice models connect characteristics of alternate routes to those selected by the drivers. These models help in estimating traffic levels on different routes and thus enable development of effective traffic management strategies that can reduce traffic delays and allow maximum utilization of transportation systems. Existing route choice models use revealed preference behavior to model route choice. The use of revealed choice data limits the accuracy of the prediction as it fails to capture subjective context factors of drivers at individual level. Therefore, it is essential to use a data collection methodology that incorporates the importance of contextual factors in route choice.

As commuters we all make choices on which route to use when traveling to work, school, or shopping mall. Most of the times we pick a route that is familiar and also minimizes travel time. However, there is plenty of evidence that as commuters we take routes that do not minimize travel time (Ben-Akiva, Ramming, & Bekhor, 2004). In order to try and explain this route choice behavior, transportation engineers have been studying the route choice behavior of drivers for the past three decades to try and explain it. Transportation researchers have adopted econometric based approaches and used two types of data to mathematically model and rationalize the route choice behavior (Prato, 2009).

The data used in modeling route choices is collected by using two approaches. The first approach is based on actual observed route choice behavior that is often labeled as Revealed Preference data. The second approach is based on collecting data from hypothetical choice experiments that is often called as State Choice data (Ben-Elia & Shiftan, 2010). There are times when both types of data are combined to model and explain route choice behavior. However, the combination of econometric approaches and different data collection methods have yielded mixed results in explaining route choice behavior.

Based on the literature reviewed we believe that there is not much research that have tried to apply causal analysis methods to explain route choice behavior. We believe that by applying causal analysis techniques we can identify root causes that influence route choice and will subsequently allow us to enhance Route Choice models that will better forecast traffic levels on transportation networks and also to better comprehend drivers response to route guidance and dynamic message signs.

The main objective of this paper is to conduct causal analysis of route choice behavior using data collected from a Stated Choice Experiment in an Immersive Virtual Environment (IVE). We carried out a study using IVE tools to elicit drivers route choice behavioral data, covering drivers network familiarity, education level, financial- concern, etc, other than conventional measurement variables. Having context-aware, high-fidelity properties, IVE data affords the opportunity to incorporate the impacts of human-related factors into the route choice causal analysis and advance a more customizable research tool for investigating causal factors on path selection in network routing. This causal analysis provides quantitative evidence to support drivers diversion decision. The study also provides academic suggestion and reference for investing in public infrastructure and developing efficient strategies and policies to mitigate traffic congestion.

This paper makes the following contribution:

- To the best of our knowledge, the paper presents the first causal analysis of route choice behavior of drivers using data collected from a Stated Choice Experiment in an Immersive Virtual Environment (IVE).

Related Work

Transportation engineers have been studying commuter route choice behavior for four decades now. Engineers developing route choice models theorized that travel time plays a crucial and important role in the selection of a route. Route choice behavior theories began to evolve in the late eighties and early nineties as engineers' understanding of route choice behavior improved by studying data about empirical route choice behavior. Pursula and Talvite (Pursula & Talvitie, 1993) developed a mathematical route model by postulating that drivers do consider other factors apart from travel time in making a route choice. In (Khattak, Schofer, & Koppelman, 1993), the authors discovered that commuters prefer to use habitual routes when traveling in familiar areas as opposed to choosing a route that provides them with maximum utility. Other researchers such as Doherty and Miller (Doherty & Miller, 2000) investigating route choice found that apart from travel time, factors such as residential location, familiarity with the route, and employment locations are significant in the route choice process. Deep learning techniques (Basu et al., 2018, 2015; LeCun, Bengio, & Hinton, 2015; Liu et al., 2019; Lv, Duan, Kang, Li, & Wang, 2015; Song, Kanasugi, & Shibasaki, 2016) can be used to predict traffic congestion and route choice. However, deep learning models, being opaque, cannot be used to causally explain drivers' route choice.

In reviewing the existing research it can be gleaned that transportation researchers have employed two different types of empirical data collection in studying route choice behavior. First, collecting route choice data using observed actual choices and second, collecting route choice data in hypothetical experiments. Researchers have for the majority of cases used utility maximizing theory to explain route choice behavior that is rooted in econometrics (Ben-Akiva, Lerman, & Lerman, 1985).

Constructing Graphical Causal Models

In causal inference, we need a way of formally representing our assumptions about causal relationship within data. Graphical models comes in handy for this purpose. There are a variety of ways to depict causal relationship using graphical causal models (Spiegelhalter, Dawid, Lauritzen, & Cowell, 1993; Glymour & Cooper, 1999; Neapolitan et al., 2004; Pearl, 2009). A graphical model provides a clear way to represent and better understand the causal relationships within a data set (Pearl, 2014; Pearl & Mackenzie, 2018). A Causal graph is useful in determining the cause-effects from data by identifying confounding and endogenous selection bias. We also can derive a testable implications from the graph to test our assumptions (Elwert, 2013). To construct a graphical model requires subject-matter understanding (Hernan & Robins, 2018).

In our study, to model causal assumptions we carried out an iterative procedure following three steps. We identified the related variables and constructed our pilot causal graph via one-to-one discussions with experts in the field of transportation. In the second step, since a casual graph reveals testable implications, we tested our assumption to some extent using graphical criteria. In the final step, we evaluated the pilot model discussing with experts again. We modified our graph according to the discussion with experts and results obtained by testing the model against data. After proper adjustments, we finalized the causal model for further causal inference procedure.

Data Collection

Route choice can be influenced by factors, such as, road condition and human-related factors (i.e., driving experience, driver's socio-economic characteristics, and driving behavior and attitudes (de Oa, de Oa, Eboli, Forciniti, & Mazzulla, 2014)). The current route choice models are calibrated using static contextual conditions and are not generally able to account for accessibility to the nearest freeway, traffic incidents, and road closures due to emergency. Collecting dataset including dynamic contextual factors are challenging and the existing approaches usually take into account the general factors motivating drivers route choice behavior. In causal inference of route choice, it is preferable to have as much as data related to contextual factors which have potential influence on drivers' route choice decision. This study conducts experimental scenarios in which specific contextual factors are added in the testing design, using Virtual Reality (VR) platform and a driving simulator.The study, in particular, examines individuals diversion tendency onto alternate routes that are induced by traffic condition, journey type, and the impact of social influence while driving in the Interstate 10 (I-10) freeway in Baton Rouge, between the Mississippi River Bridge and College Drive exit. Collecting route choice data in hypothetical experiments facilitated our study by providing various factors information for causal analysis.

IVE Experimental Setting In this study, we used a driving environment that is designed based on the I-10, starting off the Mississippi River bridge all the way to the College Dr. Along the way, five alternate routes were introduced to the participants Exits A, B, C, D, and E, the latter of which would be College Drive. Ten experimental scenarios were conducted to produce initial data about drivers dynamic route choice behavior, given emerging contextual factors. See Table 1.

Forty-one individuals (20 male and 21 females; age: 31.44 ± 7.97) volunteered to participate in the experiment. Prior to the experiment, participants were presented with a questionnaire asking the following items: 1) demographic characteristics (age, gender, race, education, employment status); 2) top concerns while they stuck in the traffic conges-

Table 1: Contextual Factors Description

Contextual Factors	Scale
Traffic Condition	Normal
	Medium
	Heavy
Journey Type	Urgent
	Non-Urgent
Social Impact	Yes
	No

tion. Their choices included hours of extra travel time, speed reduction, monetized value of delay; 3) familiarity with the area; 4) socio-economic status (having concerns about spending less money on your gas). After answering the questionnaires, participants were asked to sit on a stationary chair at a desk with a driving wheel which was placed in front of a flat screen monitor where the driving simulation would run. Next, they were invited to practice for a few minutes to get acquainted with driving the simulator. After enough practicing with the driving simulator and becoming comfortable with its environment the research team would assign the participant to the scenarios. See Table 2.

Table 2: Experimental Scenarios of the Study

Traffic Condition	Journey Type	Social Impact
Normal	Urgent	No
Medium	Urgent	No
Heavy	Urgent	No
Medium	Urgent	Yes
Heavy	Urgent	Yes
Normal	Non-Urgent	No
Medium	Non-Urgent	No
Heavy	Non-Urgent	No
Medium	Non-Urgent	Yes
Heavy	Non-Urgent	Yes

The origin and the destination in all the scenarios were same and each scenario took about two minutes to finish. In each scenario different contextual factor(s) were presented and participants were required to choose their preferred route.

Each participant was exposed to all the driving scenarios including a baseline scenario. The baseline scenario would collect information about participants route choice pattern in a normal traffic and non-urgent bound condition. Each scenario contained 1, 2, or 3 contextual factors. The first contextual factor was the traffic flow which was varied over three levels, i.e., normal, medium, and heavy density. The next factor was the purpose of the trip (journey type) which consisted of a work-bound and home-bound trips; on the work-bound trip, participants were told to consider how important was it to meet the time of arrival commitment, while the home-bound posed no rush to reach the destination. The third factor considered is the impact of other drivers route choice, exploring the idea of social influence, that is whether the driver would be influenced by watching other drivers take an exit.

Dynamic route guidance was presented to the participants where a driver is guided on to routes that will minimize travel time for the overall road network. The scenarios were counterbalanced and played out in a random fashion to avoid behavioral biases due to order effect.

DAGs, D-Separation, Testable Implication

DAGs Directed Acyclic Graphs (DAGs) can represent probability distributions of the data and can be considered as causal graphical models under three important assumptions (Hernan & Robins, 2018). First, we assume that direct causal effect exists between pairs of variables connected by directed edges. Second, we assume that DAGs satisfy the Causal Markov condition (Hernan & Robins, 2018). The Causal Markov condition states that a variable is independent of every other variable except its effects conditioned on all of its direct causes (Hernan & Robins, 2018; Anderson & Lenz, 2001). Mathematically, this is expressed as:

$$f(V) = \prod_{i=1}^{n} f(x_i|pa_i)) \tag{1}$$

where $f(V)$ denotes joint probability mass function over the set of nodes V. The variables pa_i denote the values of the direct causes of variables x_i, and i takes values from 1 to n.

The third condition is Faithfulness. By assuming that a causal graph satisfies Causal Markov condition, we assume that any population produced by this causal graph has the conditional independence relations obtained by applying d-separation. (Scheines, 1997).

We can test the assumption (the pilot causal model) by applying d-separation (Pearl, 2014). This allows us to verify if the model fits the data. If the conditional independence test based on data violates the d-separation rule, we can modify original model. Fortunately, d-separation rules spot the flaws locally so we can fix the problems without much effort. We don't need to throw away the model and start the whole process from scratch.

D-SEPARATION: It is a criterion for identifying, from a given causal graph, which variables in the graph must be independent conditional on which other variables. D-separation rule needs to consider three basic causal structures in a DAG (Pearl, Glymour, & Jewell, 2016; Pearl, 2014). These structures correspond to causation, endogenous selection (Elwert & Winship, 2014; Pearl & Mackenzie, 2018), and confounding. We shall use a shorthand notation for conditional independence (Dawid, 1979). These structures are chains (i.e, $e \to d \to f$, the path is d-separated when $e \perp\!\!\!\perp f|d$), forks (i.e, $e \leftarrow d \to f$, the path is d-separated when $e \perp\!\!\!\perp f|d$), and inverted forks (i.e, $e \to d \leftarrow f$ the path is d-connected when $e \not\perp\!\!\!\perp f|d$, so to be d-separated we can not condition on d which is a collider).

We identified the D-separation conditions implied by the causal model and tested the implications to some extent using the dataset. The results are shown in Table 3.

In the conditional independence test, our null hypothesis states that two variables are independent conditional on the other variable. So, if the *p*-value is greater than the significance level $\alpha = 0.01$, we will accept our null hypothesis; otherwise we will reject it. After the test, it showed that some of the conditional independences implied by causal model were not consistent with the probability distribution underlying the dataset. For example, the result of conditional independence test against the dataset suggests that the variable of 1st concern while stuck in the traffic and the variable of route choice are independent conditioned on the variable of traffic. However, in the DAG, there is a direct edge between the variable of 1st concern while stuck in the traffic and the variable of route choice which is an indication of dependency. So we will eliminate this edge to make D-separation condition in the model match the conditional independence in the data.

Table 3: Some of the Conditional Independence Test

Conditional Independence	P-value (α=0.01)
1stConcernWhileStuckInTraffic and RouteChoice given Traffic	p=0.037
RouteChoice and 1stConcernWhileStuckInTraffic given Age	p=0.043
1stConcernWhileStuckInTraffic and Education given Race	p=3.57E-10
Education and 1stConcernWhileStuckInTraffic given Gender	p<2.2E-16
1stConcernWhileStuckInTraffic and RouteChoice given SocialImpact	p=0.504
RouteChoice and Traffic given SocialImpact	p<2.2E-16
1stConcernWhileStuckInTraffic and RouteChoice given Urgency	p=0.481
Traffic and 1stConcernWhileStuckInTraffic given Urgency	p=1
Education and EmploymentStatus given Gender	p<2.2E-16
Education and EmploymentStatus given Age	p<2.2E-16
Education and EmploymentStatus given Race	p<2.2E-16
FinancialConcern and EmploymentStatus given Age	p<2.2E-16

We concluded that the pilot model is not a good fit for the data set. To modify the pilot model, we could introduce new variables, remove redundant variables, or modify the relationship between variables by adding or eliminating nodes and edges. Based on the test results, we modified the pilot model by merely eliminating edges from the node of Traffic to the node of 1st concern while stuck in the traffic, and from the node of 1st concern while stuck in the traffic to the node of Route Choice. In the pilot DAG, there were 12 nodes (variables) and 26 directed edges. In the final causal DAG, the number of nodes remain the same as in the pilot model, but 24 directed edges remain. The pilot and final casual models are shown in Figure 1.

Causal effect estimation

The causal graph shows that between treatment-outcome pairs there is a direct path and an indirect (back-door) path (i.e, traffic $\rightarrow$ route choice is direct path; traffic $\leftarrow$ social impact $\rightarrow$ route choice is an indirect path). The back-door path is confounding. When trying to estimate causal effect, we want to block any back-door paths by conditioning on some variables, because such paths are not transmitting causal influences, and if we don't block the back-door path, it confounds the effect that a node has on another node. For instance, as shown in Figure 2 (we boxed the collider with the dashed line and similarly presented the confounder's arrows with dashed line), when trying to calculate the causal effect of employment status on route choice, there exists back-door paths: 1) employment status $\leftarrow$ education $\leftarrow$ gender $\rightarrow$ route choice; the blockage of this path can be ensured by conditioning on gender which is a confounder; 2) employment status $\leftarrow$ age $\rightarrow$ route choice; the blockage of this path can be ensured by conditioning on the confounder age; 3) employment status $\leftarrow$ race $\rightarrow$ 1st concern while stuck in the traffic $\leftarrow$ social impact $\rightarrow$ route choice; within the path there is a collider which is the variable of 1st concern while stuck in the traffic. So the back-door path is already blocked without conditioning on any variables. However, if we try to condition on the collider we make the path open instead. There are other back-door paths: we haven't listed all of them. After identifying every back-door path between these two variables, we selected age and gender thereby blocking the back-door paths between employment status and route choice.

To select the variables that entail blockage of the the back-door paths, we carried out graph-surgery as described above. Then, we adjusted these variables to calculate the pure causal effect. We paired every treatment with the outcome variable, identified back-door paths between them, and selected the confounding variables using the Back-door criterion. Between the variables of Urgency, Gender, Race, Age, SocialImpact, FamiliarityWiththeEnvironment, and the RouteChoice there doesn't exist any back-door path. In addition to that, from the variables of 1stConcernWhileStuckInTheTraffic, and FinancialConcern, there doesn't exist any direct causal path to the variable of RouteChoice. So, there is no casual effect of these two variables on the variable of RouteChoice. The relationship between them can be interpreted as association instead of causation. Hence, there is no need to estimate the causal effect of these two variables. We listed the confounders in the the back-door paths between the variables of Traffic, Urgency, Education, EmploymentStatus

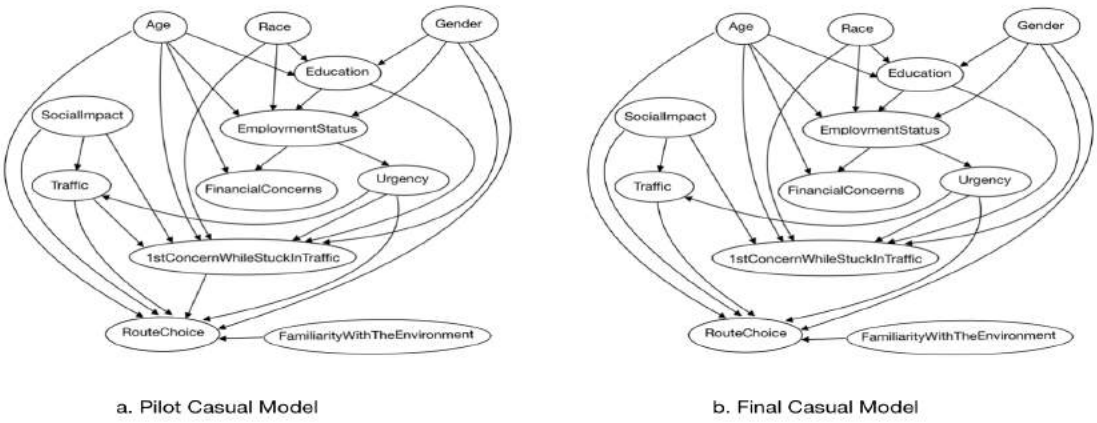

Figure 1: Casual Models

and RouteChoice (Shown in Table 4). Normally, the strategy of putting in all possible confounders is usually used. However, this strategy may end up adjusting for colliders and mediators that can introduce bias. For example, employment status → urgency → route choice. In this direct path, urgency is mediator. if we condition on the mediator, we will bias our estimate.

Table 4: Confounder in Backdoor Paths

Variables	Confounder
Traffic	Urgency, SocialImpact
Urgency	Gender, Age
Education	Race, Gender, Age
EmploymentStatus	Gender, Age

We applied Inverse Probability(IP) weighting method to adjust the variables Z, which are the confounders. The purpose of using IP weighting is to break the association between the covariates Z and treatment X to estimate true causal effect on outcome variable y (Hernán & Robins, 2006; Robins, Rotnitzky, & Zhao, 1994). By predicting Z based on X, we can estimate the propensity score $\Pr(X = x|Z)$. We can get a propensity score using non-parametric (i.e, probability) or parametric methods (i.e, regression model). If the data is high-dimensional with many covariates and some of them with multiple levels, it is desirable to use a parametric method. In our study, we have 12 variables and some variables have more than two levels. To find propensity score, we applied logistic regression model. The equation is given below:

$$\Pr(X_i = x|Z_i) = \frac{1}{1 + e^{-(\alpha+\beta Z_i)}} \tag{2}$$

After getting propensity scores, we used them to obtain the weights W to create a pseudo-sample in which there is no association between the covariates and treatment. The IP weighting formula is given below:

$$W_i = \frac{X_i}{\Pr(X|Z_i)} + \frac{1 - X_i}{1 - \Pr(X|Z_i)} \tag{3}$$

where X_i indicates if the ith subject was treated.

We started our approach of calculating the causal effect by training a model with covariates Z to predict X. Our treatments X are categorical variables, so we calculated the propensity scores $\Pr(X|Z)$ by applying equation 2.

After estimating the propensity scores, we applied equation 3 to obtain the IP weight. We used stabilizing factor $\Pr(X)$ in the numerator to narrow the range of the $\Pr(X)/W$. After we obtained stabilized IP weights as $SW = \Pr(x)/W$, we trained new model with treatment variables X as features and outcome Y by using SW_i as sample weight for the ith observation. Then, we used this model to predict the causal effect. In this study, outcome variable is categorical data, so we used logistic regression again to obtain the casual odds ratio as a casual effect measure.

Based on our determination of average causal effect (shown in Table 5), the result suggests that when heavy and medium traffic conditions are compared with the normal condition separately, their effects have significant magnitude. It implies that changes in traffic conditions impact drivers route choice. More specifically, when the traffic is heavy, proportion of drivers who choose the nearest exit is about 6 times greater than that when traffic is normal. However, when the traffic is medium, proportion of drivers who choose the nearest exit is about 3 times greater than that when traffic is normal. So, we can conclude that when the traffic is normal, the drivers are more likely to stay on the high way. Considering social impact, a driver would be influenced by watching other drivers take the exit. The proportion of drivers who choose the nearest exit is about 5 times greater when they get influenced than they don't. Considering familiarity with environment, proportion of drivers, who are not familiar with the road, choosing the nearest exit is about 3 times greater than those who are familiar with the road. Considering race, white

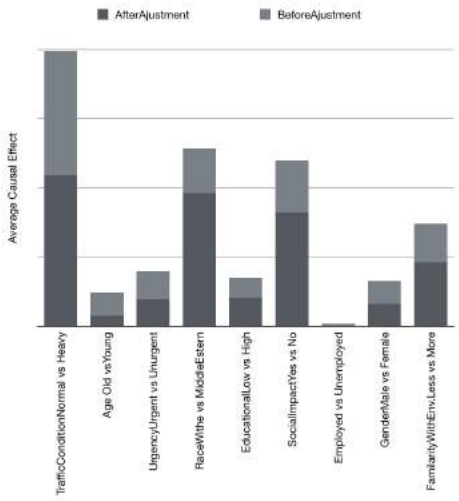

Figure 3: Average Causal Effects Of Variables Computed by Adjusted and Un-Adjusted Regression Model

people are more likely to stay on the highway than middle eastern people or others. Age and Urgency also have significant effect on drivers route choice. We also conducted another experiment in which we built an estimator for route choice without adjusting for confounding factors, and compared the results with the one of causal inference (shown in Figure 3). The results suggest that on the un-adjusted estimator, the effect of age and employment status are overestimated, race, social impact, and familiarity with the environment are under estimated. This is because there are confounding and collider sources between the path of these variables and the outcome. Based on causal inference, the effect of traffic, race, social impact, and familiarity with the environment are more significant than others.

Conclusions

This paper described a causal analysis of route choice behavior of drivers using data collected from a Stated Choice Experiment in an Immersive Virtual Environment (IVE). This work will not only fill in the lack of causality based approaches in the transportation field, but it also showed that without adjustment on treatment, causal effect results will be affected by spurious correlation as well.

Investigating the Intrinsic Integration Hypothesis for the Design of Game-Based Learning Activities

Abstract

The intrinsic integration hypothesis proposes that using core game mechanisms to teach learning material makes educational games more fun to play and better for learning. Our study tests the intrinsic integration hypothesis with two educational versions of Battleship that were designed for this experiment, in the domain of complex numbers. We examine the learning gains and motivation of 58 participants who interacted with either the intrinsically-integrated or extrinsically-integrated version of the game. Our results contradict previous findings supporting the intrinsic integration hypothesis: participants reported similar levels of motivation from both versions of the game and participants who interacted with the extrinsically-integrated version learned significantly more as measured by pretest to posttest gains. This work contributes empirical data to the debate concerning intrinsic integration, and it highlights the need for additional studies exploring the integration of learning material into educational games.

Keywords: Intrinsic integration; games; student learning

Games and Student Learning

Educational games aim to make learning fun by incorporating game elements, such as fantasy, challenge, and competition, into instructional activities (Malone & Lepper, 1987). Three recent meta-analyses found that overall, students learn more from educational games than from traditional activities like standard classroom instruction (Sitzmann, 2011; Wouters, van Nimwegen, van Oostendorp, & van der Spek, 2013; Clark, Tanner-Smith, & Killingsworth, 2016). While this result is encouraging, there are two caveats: (1) not all studies found a positive effect of games, and (2) comparing games to other activities does not inform on how to best design games to maximize learning and engagement from them. Thus, there have been calls to test the effect of various design factors on student outcomes, referred to as the *value-added* approach to educational game research (Mayer, 2011). This approach involves comparing student learning and/or motivation with a basic version of a game to the outcome of one that includes an additional design feature.

As an example of the value-added approach, studies have examined the effects of cooperation and competition in educational games (Ke & Grabowski, 2007; Plass et al., 2013). Ke and Grabowski (2007) compared the impact of games involving cooperative competition, individual competition, and a non-game control condition on math learning and attitudes among fifth-grade students. Participants in both game conditions learned more than those in the non-game control condition. Moreover, attitudes regarding math were significantly better in the cooperative game condition than in the other two conditions. Plass et al. (2013) also examined the effects of cooperation and competition on learning outcomes. Learning, assessed by pretest and posttest scores, was only significantly higher in the competitive condition compared to the control condition that did not include competition or cooperation. While the collaborative condition had the lowest in-game performance of all three conditions, it produced the most positive affect as measured by intention to play the game again and to recommend it to others.

As another example of the value-added approach, Conati and Manske (2009) assessed the value of adding an agent delivering adaptive hints in an educational game. The hints were generated based on a user model of student knowledge. No difference was found between the agent version of the game and a control version without the agent. Conati and Manske (2009) speculated that the reason for the lack of an effect may have been due to an inaccurate user model, the challenge of fostering learning in the target domain, and/or the hints interrupting the flow of the game.

An area within the value-added approach that has not received much attention is the integration of a game's motivating elements with the learning material. A recent meta-analysis by Clark et al. (2016) found only one experiment that investigated this factor, involving a game that completely separated the learning mechanisms from those designed for engagement with the game – this experiment will be described in the next section.

Extrinsic and Intrinsic Integration

How should game elements be integrated with the learning elements? Kafai (1996) anecdotally observed that students tasked with designing educational games took one of two distinct approaches. He called this dichotomy *extrinsic* vs. *intrinsic* integration. The extrinsic approach used the game as a form of 'sugar-coating:' players in the game were rewarded for answering questions on the learning material with the opportunity to continue playing the game. Thus, the game play was clearly separated from the instructional activities. The alternative to this approach is the intrinsic approach, which involves using the game's core mechanisms to present the learning material, thereby integrating the learning activities with game play. Thus, in contrast to the extrinsic approach, with the intrinsic approach there is no distinct separation between game activities and learning activities.

Habgood and Ainsworth (2011) proposed that students would learn more from intrinsically-integrated games than extrinsically-integrated games (referred to as the *intrinsic integration hypothesis*). Their experiment compared two versions of an educational game called Zombie Division, designed for middle-school children. In the intrinsically-integrated version, players navigated their character around a dungeon and used division to defeat computer-controlled opponents represented by skeletons. Importantly, while this version required students to practice division, doing so was the primary way to progress through the game. In contrast, in the extrinsic version the learning material was removed from the game portion and isolated to quizzes presented between game sessions. Results indicated that students who played the intrinsically-integrated version improved significantly more from pretest to posttest and reported higher engagement.

While the Habgood and Ainsworth (2011) results are encouraging, they warrant replication. Because the math activities were moved to quizzes in the extrinsic version of the game, the gameplay in that version became less challenging, as acknowledged by the authors and reported by the students who played the game. Lack of challenge may have diminished learning outcomes from this version. Additionally, interleaving the questions with gameplay sessions changed the instructional sequence of the extrinsic condition. Thus, the decreased challenge and different instructional sequence could have biased the results.

While intrinsic integration does have the benefit of not interrupting players during game play to have them complete educational tasks, it also has potential downsides. One is related to transfer. The learning material in an intrinsically-integrated game is often presented in a context different from the one in which it will later be applied and tested. Students find it difficult to transfer knowledge learned in one context to a different one even when the fundamental concepts are the same (Kaminski, Sloutsky, & Heckler 2009). Intrinsic integration could also be disadvantageous because it requires the player to simultaneously cope with two competing sets of demands, stemming from the educational and game elements, which could increase extraneous cognitive load.

Given the above considerations, the goal of the present work was to test the intrinsic integration hypothesis through an empirical study.

The Present Study

To test the intrinsic integration hypothesis, we created a paper-and-pencil educational game designed to help students practice concepts in our target domain of complex numbers. The game was based on *Battleship*. To play Battleship, each player secretly plots their ships onto a two-dimensional plane and then fires upon their opponent's ships. The first player to correctly guess every coordinate containing a ship wins the game. While the original Battleship was not explicitly educational, the two-dimensional nature of complex numbers makes them particularly suited for intrinsic integration into Battleship, as the coordinates on the two-dimensional board can be substituted with complex numbers.

Participants

The participants (N = 66, 35 females) were undergraduate students at a Canadian University recruited via Sona and posters displayed around campus. As the game in our study was played in pairs, participants were asked to come to the study with a friend or classmate, instead of being paired with a stranger. This was done to facilitate interaction during gameplay, as both participants would already know each other. Each participant was compensated with their choice of either course credit or $20.

Materials

Intrinsic and Extrinsic Versions of Battleship We created two versions of Battleship; both were played with pencil and paper materials. In each version, participants had two game boards, printed on paper, also referred to here as "planes". One game plane was private as it was positioned behind a screen and players were instructed to keep it hidden from their opponent. They were asked to draw their ships on this private plane at the start of the game. The second plane was public and was used during the game to indicate players' shots on their opponents' ships (done by drawing the shot on the public game plane). Because our goal was to only vary the intrinsic/extrinsic dimension while keeping other aspects of the two game versions as similar as possible, the game play was almost identical in both versions.

In the intrinsic version, the game board corresponded to a complex plane (see Figure 1, left). A turn began with each of the two players selecting where they would place their next shot on the public plane. To do so, they indicated the chosen location by writing down the rectangular form of a complex number corresponding to that location on the '*shot list*,' which was a second piece of paper labeled with turns (see Figure 1, right). For example, if a participant thought their opponent's ship was in the top-left of the plane, then

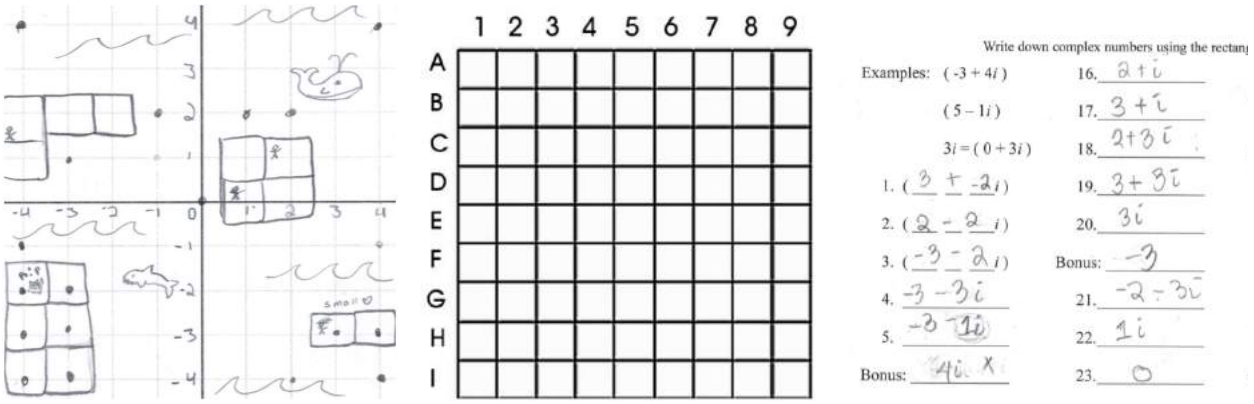

Figure 1: The complex plane used in the intrinsic condition (left), marked with a participant's game moves, the plane used in the extrinsic condition (centre), shown without any entries, and the response sheet used in both conditions (right), shown with a player's entries.

they would write (-4 + 4*i*). When both shots were written down, the players checked each other's entries for the correct format. The participants could not continue playing until the correctness of their entry was confirmed by their opponent. However, the experimenter did not verify the answers and, if asked, referred participants to the examples provided by the game material (the screen hiding the private game planes had a recap of the instructional material and another sheet provided examples of complex number problems). Thus, the responsibility was on the participants to verify their entries, and they had resources to help them do so. This did not take away from the competitive aspect of the game as the competition came from locating the opponent's ships, like in the original Battleship. Once both players were satisfied their opponents had written a complex number in the correct format, they checked if their opponent's shot struck one of their ships, and they indicated the result on their public game board. Note that "a shot" corresponded to the complex number that they had written down. Thus, the learning material was intrinsically integrated with the game mechanisms: to play the game, participants had to apply complex number knowledge.

The extrinsic version was identical except for two key differences. First, the game board was based on the standard *Battleship* game and so corresponded to a coordinate plane where the axes were labeled with letters in the left margin and numbers on the top margin (see Figure 1, center). Second, at the start of a turn, participants first randomly chose a coordinate on the complex plane from a deck of cards. Thus, in this version, the coordinate did not represent a shot on the opponent. Like in the intrinsic version, the players translated that coordinate to a complex number and had their opponent check it. In contrast to the intrinsic version, however, they then specified the shot on their opponent using a letter-number pair corresponding to the axes' labels on their planes (e.g., A-2). This was done to create a divide between the learning material and the game material, thereby making the game extrinsically integrated.

After every five shots participants in both game versions were asked to multiply the previous complex number by the imaginary unit, writing their answer on the shot list. This was considered a bonus question and a correct answer was rewarded with an extra shot.

The game and study materials were refined via pilots.

Complex numbers lesson To provide the domain background needed to play the educational game, participants were given a paper-based lesson we developed on the complex number system. The lesson consisted of a two-page description with accompanying illustrations.

Test Materials A pretest and posttest were used to measure participants' complex numbers knowledge before and after they played the game. Each test consisted of twenty questions.

Instruments An online survey was used to collect motivational and affective data, in addition to basic demographics. The motivational and affective survey used a Likert scale and included: (1) the Intrinsic Motivation Inventory (Deci & Ryan, 2003) based on four sub-constructs, including interest, competency, choice, and pressure; (2) some custom questions measuring participants' willingness to re-engage with the instructional material in the future (e.g., "I would use the game to teach complex numbers"). Several other instruments were used to measure mindset and math attitudes but results from their analysis are not included here, so they are not described.

Design

We used a two-factor (2 x 2) mixed design. The first factor, *condition*, was a between-groups variable with two levels (intrinsic and extrinsic, corresponding to intrinsically-integrated and extrinsically-integrated game versions, respectively). The second factor, *time*, was a within-groups variable with two levels (pre and post, referring to pre-game

play and post-game play, respectively). Participants were assigned to a given condition in a round-robin fashion.

Procedure

Each session was conducted individually and included a pair of participants. Each dyad spent approximately 90 minutes in the study, with the exact duration varying based upon the amount of time participants spent on the instructional material as well as the pretest and posttest. The procedure for the two conditions was the same. After providing consent, participants were seated back to back and (1) read the complex numbers lesson, and (2) filled in the complex numbers pretest. Once both participants had finished the pretest, they were asked to move to the game table positioned in the centre of the room where they sat across from each other, and the gameplay phase began.

Participants were provided with all the game materials and instructions on how to how to play the game (for details, see Nidd, 2018). After both participants had plotted their ships according to the game rules, they were given 35 minutes to play the game. Any questions relating to complex numbers were answered by referring the participants to the examples in the instructional materials that were provided as well as the recap of the lesson on each of their game screens. When the time was up, participants were given the choice to play for another five minutes if they wanted. This was done as an additional measure of motivation.

Directly after the game phase, participants were moved back to their initial seats where they were seated back-to-back and completed the (1) posttest and (2) the study questionnaires.

Results

The analysis is based on 58 participants (eight participants were not included either because they were at ceiling on pretest, i.e., 90% or higher or because their performance decreased from pretest to posttest). The analyses, which were conducted with the statistical software *R*, used inferential statistics that assume independence between participants. Since participants worked together during the game, there was a potential concern that their learning-related data might be dependent. To check for this, a correlation between pretest to posttest difference scores of both individuals in a pair was conducted. The correlation between the learning outcomes of paired participants was not significant and corresponded to a very small effect, $r(31) = .05$, $p = 0.78$, suggesting that the independence assumption was not violated. Thus, we continued with our analysis testing the conditional effect on (1) learning outcomes and (2) motivation.

Are Intrinsically-integrated Games Better for Learning?

To check for equivalence between the two conditions on *a priori* knowledge, participants' pretest scores were compared. The scores were distributed fairly evenly between the two conditions and while they were slightly positively skewed (skewness of 0.90 and 0.60 respectively), this was within the bounds of normality. As shown in Table 1, the mean pretest scores were similar between the two conditions, with no significant difference between them as indicated by an independent samples t-test, $t(54.05) = 0.11$, $p = .91$.

Table 1: Descriptive statistics for the test scores.

	Extrinsic		Intrinsic	
	M	*SD*	*M*	*SD*
Pretest (/20)	4.93	2.85	4.83	3.71
Posttest (/20)	10.39	3.79	8.73	4.38
Difference (post - pre)	5.46	2.43	3.90	2.64

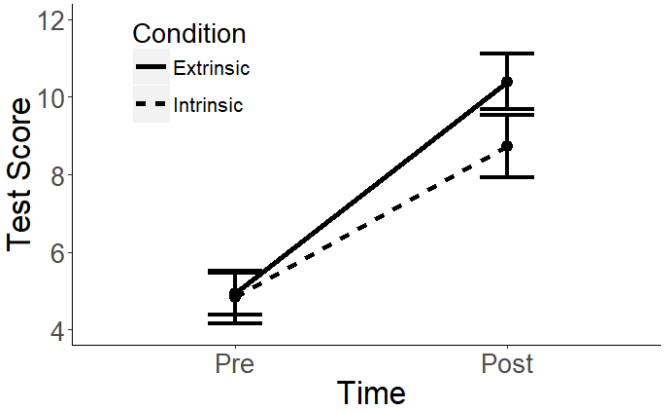

Figure 2: Interaction between time and test score, indicating higher pre to posttest learning in the extrinsic condition.

As is standard, learning was measured by the difference between a participant's performance on the pretest, completed after they read the instructional material but before they played the educational game, and their performance on the posttest. The descriptive statistics are shown in Table 1. The higher mean difference in the extrinsic condition suggests that participants who played the extrinsic version of the game learned more, because they improved more from pretest to posttest.

To analyze the impact of the extrinsically- and intrinsically-integrated versions of the game on learning, a two-way mixed ANOVA was conducted with test scores as the dependent variables, condition (extrinsic vs. intrinsic) as the between-subjects independent variable, and time (before and after the experimental intervention, i.e. game play) as the within-subjects independent variable.

In general, collapsed across conditions, participants improved from the pretest to posttest as indicated by the

significant main effect of time on participants' test scores, $F(1, 56) = 194.62$, $p < .001$, $\eta_p^2 = .78$. While this demonstrates that the instructional material improved learning overall (collapsed across the two conditions), of primary interest is the time by condition interaction, which examines the effect of condition on learning (i.e., pretest to posttest differences). This interaction was significant, $F(1, 56) = 5.49$, $p = .02$, $\eta_p^2 = .09$. As shown in Figure 2 this interaction indicates that participants who played the extrinsic version of the game learned significantly more than those who played the intrinsically-integrated game.

Are Intrinsically-integrated Games More Motivating?

The effect of game version on participants' motivation was measured by (1) Intrinsic Motivation Inventory (Deci & Ryan, 2003), (2) the custom questionnaire measuring self-reported re-engagement, and (3) the behavioral data on whether participants chose to continue playing the game for an additional five minutes after they were told they could stop. Like the Intrinsic Motivation Inventory, this additional measure was derived by averaging a participant's answers to the custom set of questions that asked them to report their willingness to re-engage with the instructional material using a 7-point Likert scale.

Descriptive statistics for this analysis are in Table 2. There was little difference between the two conditions in terms of the motivational variables. This was confirmed by a series of independent-samples t-tests comparing the five measures of participants' motivation in the two conditions. As shown in Table 3, none of the analyses were significant (while this analysis did not control for familywise error rate, doing so would not have changed the results, as none of the findings were significant). A chi-squared test of independence was performed to examine the relationship between the game version and participants' decision to continue playing for an additional five minutes. Like the other measures of motivation, the difference between the two conditions was not significant, $X^2(1, 29) = 0.016$, $p = .90$.

In summary, there was no evidence that the version of the game, intrinsic versus extrinsic, impacted participants' motivation. However, collapsed across condition, participants had fun playing the game. Participants reported that they were interested in the instructional material as indicated by high scores on the motivational questionnaire, and a third of them chose to stay longer than they needed to. Anecdotally, these measures are further supported by the verbal reactions of participants. One person remarked that the experiment was "really fun actually. If math was like this, I'd enjoy it a lot more." Another exclaimed upon receiving the post-test, "Battleship actually helped with this!" When the same participant – who was vocally anxious about math – forgot to take their shot upon the opponent's ships and immediately drew another complex number question, they joked: "Sorry, I just love math." Additionally, some participants asked if they could keep their game sheets to finish the game at home, and one participant even asked if they could buy the extrinsic version as they thought it was an improvement on the original Battleship. These measures and anecdotal reactions suggest that the educational game was motivating for participants.

Table 2: Descriptives for the five motivation subscales in each condition.

	Extrinsic		Intrinsic	
Subscale	*M*	*SD*	*M*	*SD*
Interest	5.00	1.64	5.01	1.48
Competency	4.27	1.41	4.62	1.44
Choice	5.03	1.42	5.13	1.40
Pressure	2.66	1.37	2.99	1.22
Re-engagement	4.17	1.27	3.95	1.44

Note. The maximum score for each subscale is 7

Table 3: Results for the conditional effect on each subscale of the motivational questionnaire.

Subscale	*df*	*t*	*p*	*d*
Interest	54.35	0.03	.98	.01
Competency	55.89	0.94	.35	.25
Choice	55.57	0.28	.78	.07
Pressure	54.20	0.96	.34	.25
Re-engagement	55.82	0.61	.54	.16

Discussion

Our results do not support the intrinsic integration hypothesis, as participants who played the intrinsically-integrated version of the game were not more motivated and did not learn more than those who played the extrinsic version. On the contrary, those who played the extrinsically-integrated version of the game learned significantly more.

Why did extrinsic integration result in more learning than intrinsic integration? As we already noted, one of the potential disadvantages of intrinsic integration is the need for transfer. In the intrinsic game version, the complex numbers corresponded to the coordinates of players' ships. Consequently, the numbers represented two constructs: they were concrete representations of a location on the game board, and they were the abstract representations that would later be tested. By having participants play and interact with these representations, intrinsic integration potentially made it more difficult for participants to see the complex numbers they were using as being important in themselves (Brown, McNeil, & Glenberg, 2009; Uttal, O'Doherty, Newland,

Hand, & DeLoache, 2009). Importantly, this potential disadvantage of intrinsic integration is not an artifact of our game design but rather a requirement of intrinsically integrated games. In contrast, the extrinsic version may have made it easier for participants to focus on and learn the mathematical principles by separating the abstract target knowledge from the more concrete interactions between the player and the game state (Uttal et al., 2009).

A second potential explanation for our findings pertains to cognitive load. The intrinsically-integrated game may have increased participants' extraneous cognitive load, as the tasks related to game play and complex numbers were integrated. In other words, the intrinsic version had players pick a shot, practice the learning material, and then resolve the shot. In contrast, the extrinsic version separated these tasks. These competing demands imposed by the intrinsic game and the domain questions may have diminished players' learning by increasing the load on their working memory (Clark, Nguyen, Sweller, & Baddeley, 2006). Similarly, the extrinsic version could have made working memory available for the mental processing that is required for learning. Since we did not measure cognitive load, this conjecture awaits future research.

Our results are not aligned with those from Habgood and Ainsworth's (2011) experiment. A potential explanation for these differences relates to control of the instructional sequence and challenge levels in the two versions of the game. Our experiment maintained similar instructional sequences between conditions by incorporating the extrinsic learning material throughout gameplay. In contrast, the prior study divided the learning material and game into lengthy blocks that may have disrupted user engagement more than is necessitated by extrinsic game design. This separation in the prior study also reduced challenge, a factor known to impact engagement with games (Garris, Ahlers, & Driskell, 2002). By removing the learning material from the game mechanism, players no longer had to solve a problem to progress through the game. This was reported by participants as they remarked, "it just tells you what to use" and "it's not a challenge" (Habgood & Ainsworth, 2011, p. 28). This difference was not present in the two game versions used in our experiment.

Another potential reason that our results do not support the intrinsic integration hypothesis relates to an interaction between the type of integration and cooperation/ competition. Specifically, adding a second player may have 'gamified' the non-game elements. For instance, participants answering the non-game domain questions in the extrinsic version of Battleship were still competing against their opponent to get the right answer. This aspect of the extrinsic game is comparable to a trivia game, as a correct answer was required to take a shot in the game of Battleship. Indeed, an educational game could consist of just this competitive quiz aspect (as in Ke & Grabowski). In Habgood and Ainsworth's (2011) game, completing the domain questions in the extrinsic version was likewise necessary to play the game, as participants needed to repeat the quiz if they did not get a passing score; however, this requirement could seem like a prerequisite in a single-player game, whereas it could seem like an element of the game when another player is involved.

There are also several methodological differences worth noting between our experiment and the previous work that did support of the intrinsic integration hypothesis (Habgood & Ainsworth, 2011). Our experiment used undergraduate students as opposed to primary school students between the ages of 7 and 9. Additionally, we recruited these participants in pairs instead of recruiting entire classes. Although similar domains were used, the target knowledge was more advanced in our experiment to match the participants' education level. The games in the two experiments differed in fundamental ways: our game was implemented as a board game rather than a video game, another human player was involved in our game, and the narrative elements were more pronounced in Habgood and Ainsworth's game. The measure of motivation also differed as Habgood and Ainsworth used qualitative interview data paired with a second experiment that measured the amount of time spent in the intrinsic and extrinsic versions when given a choice. In lieu of this, our experiment used the established Intrinsic Motivation Inventory to measure participants motivation to engage with the educational game.

In conclusion, our experiment contributes empirical data to the debate concerning intrinsic integration and educational game design. Our findings indicate that extrinsically-integrated games are better for learning and similarly motivating as intrinsically-integrated games. Ultimately, given the relatively few studies in this area and the lack of agreement between findings from the ones that do exist, our work highlights the need to further explore factors related to educational game design and their impact on student learning and motivation.

To be or not to be: Examining the role of language in a concept of negation

Ann E. Nordmeyer (a.nordmeyer@snhu.edu)
Department of Psychology, Southern New Hampshire University

Jill G. de Villiers (jdevilli@smith.edu)
Department of Psychology, Smith College

Abstract

Negation is a complex, abstract concept, despite the ubiquity of words like "no" and "not" in even young children's speech. One challenging aspect to words like "no" and "not" is that these words can serve many functions in speech, giving us tools to express an array of concepts such as denial, refusal, and nonexistence. Is there a single concept of "negation" that unites these separate negative functions – and if so, does understanding this concept require the structure of human language? In this paper we present a study demonstrating that adults spontaneously identify a concept of negation in the absence of explicit verbal instructions, even when the exemplars of negation are perceptually varied and represent many different functions of negation. Furthermore, tying up participants' language ability using verbal shadowing impairs participants' ability to identify a concept of negation, but does not impair participants' ability to identify an equally complex control concept (natural kinds). We discuss our findings in light of theories regarding the representation of negation and the relationship between language and thought.

Keywords: negation; philosophy of language; language and thought

Introduction

Due to the early emergence of words such as "no" and "not" in children, and their frequent use in human discourse, it is tempting to dismiss negation as a simple concept. However, the concept of negation has long been a puzzle to philosophers, psychologists, and cognitive scientists. In order to understand the complexity of this phenomenon, consider the following thought experiment:

> Consider, for example, negation. It's easy to tell somebody that it's not going to rain. Try drawing them a picture of it's not going to rain…Think about trying to draw a picture of "there's not a giraffe standing beside me" (Fodor, 1994).

The inherent difficulty in finding a way to depict negation raises questions about the nature of the representation of negation. Is language necessary to understand an abstract concept of negation?

One challenging aspect of negation is that the words ``no'' and ``not'' play many different functions in human speech (see Bloom, 1970; Pea, 1980; Choi, 1988 for discussions of several taxonomies of negation and their trajectory in children's language acquisition). For example, you can use negation to express the *nonexistence* of an object, e.g., "There is no food in the dog's bowl." You can also use negation to express *refusal,* e.g., "No, I don't want to read." And you can express *denial* or truth-functional negation by making statements about falsehoods, e.g. "The light is not on" [*i.e., it is not true that the light is on*]. It is possible to imagine ways to represent each of these statements perceptually or through simple positive concepts, e.g., an empty bowl, a girl looking away from a book on a table, a lamp that is off. Without the language of negation, however, there is nothing perceptually or conceptually similar about these concepts. One important goal of this study is to examine whether adults can spontaneously identify the similarity of these events (i.e., a unified concept of negation) in the absence of explicit language explaining the similarity between the events.

Under a propositional account of the representation of negation, negative sentences are represented as a negative operator acting over a proposition (Clark & Chase, 1972; Carpenter & Just, 1975; Just & Carpenter, 1971, 1976). That is, all of the sentences in the previous example are "unified" by the presence of a negative operator in their representations. Where, then, does this negative operator come from – or any of the structures that underlie human thought? Fodor (1975, 2008) proposed that there must be a "language of thought", which is language-*like* in the sense that it must contain an innate "lexicon" of concepts, as well as a syntax to organize those concepts. According to Fodor, concepts are learned through a process of linking one's experiences in the world with innate concepts. Without such an underlying system, Fodor argues, concept learning (and ultimately word learning) would not be possible. Under this hypothesis, the negative operator that creates a unified concept of negation exists in the lexicon of the language of thought.

Another possibility is that natural language itself is the vehicle for representing and structuring thought. According to Hinzen (2007), there is a conceptual framework that underlies human thought, and language is necessary to organize these concepts into complex propositions. If natural language can provide the same kind of structure that Fodor (1975) argues is necessary for complex thoughts to arise, then the existence of a separate Language of Thought becomes redundant (deVilliers, 2010; Collins, 2000). Under this hypothesis, the development of human language is required to understand a unified concept of negation.

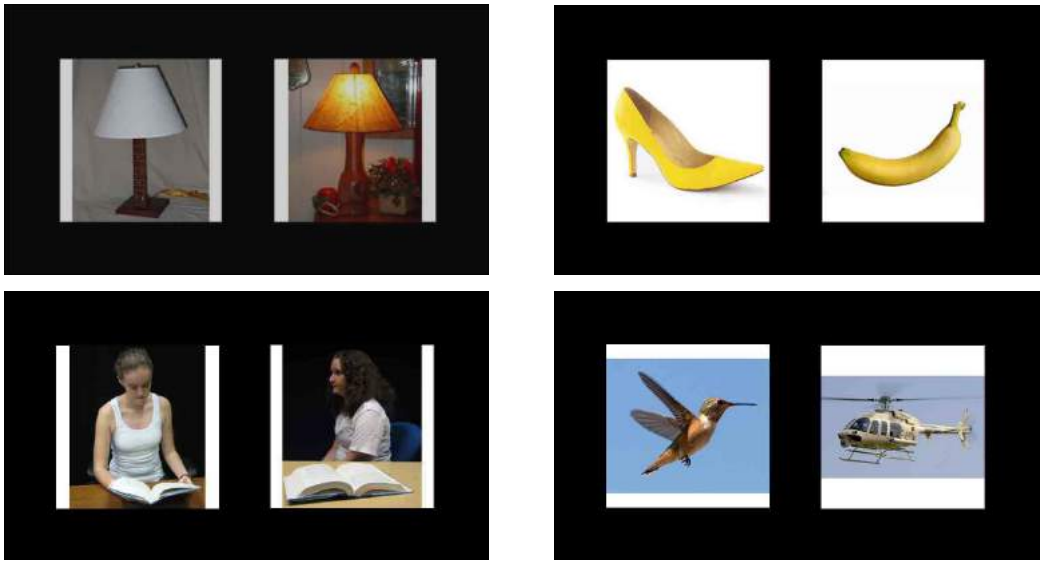

Figure 1: Examples of Negation stimuli (left) and Natural Kind stimuli (right).

The purpose of the present study is to examine, first, whether people have a general concept of negation – that is, a concept of negation that unifies a variety of negated events, actions, objects, and states of being, despite these all having very different perceptual features. That is, do adults recognize the similarity between an empty food bowl, a person refusing to read, and a lamp that is off, without someone explicitly describing these scenes using negation? Second, the study will examine the role that language plays in forming and understanding this concept. If negations are represented as propositions, in an organized and structured way, there must be some mechanism for representing them as such. We propose that natural language can provide an individual with the necessary structures to represent thoughts propositionally, and that natural language might be required to hold a generalized concept of negation.

Method

To test our first question of whether people can identify an abstract concept of negation in the absence of verbal descriptions, we created a non-verbal anticipatory looking task. Participants viewed pairs of photographs in which one image represented an affirmative event and the other image represented the negated version of that event; after several seconds, an animation occurred around the negative event. These stimuli were designed to create a "context of plausible denial" – that is, a context in which the formation of a negative proposition would be a likely response (Wason, 1965). This allowed us to test whether participants would spontaneously identify an abstract concept of negation when looking at pictures without hearing language, allowing the role of language to be manipulated and evaluated separately.

To manipulate participants' ability to use language during this task, half of our participants engaged in a language interference/verbal shadowing task, in which participants listened to a story through headphones and repeated what they heard out loud simultaneously. This task has been shown to interfere with adults' ability to utilize language in abstract cognitive tasks (Hermer-Vazquez, Spelke, & Katsnelson, 1999, Newton & de Villiers, 2007). We hypothesized that participants would be able to identify the negative event in the absence of verbal interference, but would perform at chance when shadowing language.

To test whether the effects of verbal interference are specific to an abstract concept like negation, as opposed to simply distracting participants from the task, we developed a control task to test participants' ability to form a different concept – one that was equally varied but that potentially would not require language to understand. We selected "natural kind objects" as a control concept because it is a broad, complex concept, which cannot be organized around single perceptual cues alone, but which we believed would not require language. For example, young children (Gelman, 1988; Gelman & O'Reilly, 1988) and pre-verbal infants (Booth & Waxman, 2002; Shutts, Markson, & Spelke, 2009) appear to be sensitive to the distinction between natural kinds vs. artifacts. This work suggests that it may be possible to represent the natural kind concept without requiring propositions with a language-like structure.

Participants

Participants were recruited through two psychology courses. The participants were all undergraduate students and all but one of the participants were female (due to the nature of the institution's population). Participants received credit towards their final grades for participation. After excluding participants for lack of attention to the task (see "Data Processing"), our final sample included 84 participants (negation, no shadowing: n=18; negation, shadowing: n=17;

natural kind, no shadowing: n=27; natural kind, shadowing: 20).

Stimuli

Stimuli consisted of pairs of photographs that portrayed either an affirmative or negated event (in the experimental condition) or a natural kind or an artifact object (in the control condition). To ensure that the photographs in each pair were equally salient, we conducted a pilot test in which adults (N = 12) viewed a total of 72 pairs of photographs for three seconds. Paired-samples t-tests were conducted to determine if the total looking time was greater for one picture more than the other in each pair using a conservative alpha level of .1. This resulted in the removal of 9 pairs from the negation condition and 8 pairs from the natural kind condition. One additional pair was randomly selected to be removed from the natural kind group, in order to have an equal number of pairs in each group. This left 22 pairs of photographs in each group for the final study. Figure 1 shows examples of the stimuli used in each task.

One of our primary hypotheses for the study was to examine whether participants would be able to identify a unified concept of negation from perceptually varied stimuli, without explicit verbal descriptions. To do this, we needed to be sure that the negative stimuli were sufficiently varied (i.e. drawing from many different types/functions of negation) and could not be united by some other concept. To do this, we created four different categories of negation: non-functional (4 exemplars, e.g., affirmative = a digital alarm clock that is showing the time, and negative = a digital alarm clock that is not showing the time), nonexistence (5 exemplars, e.g., affirmative = a dog with food in its bowl, and negative = a dog with an empty food bowl), unexpected state (6 exemplars, e.g., affirmative = a lamp that is on, and negative = a lamp that is off), and refusal (7 exemplars, e.g., affirmative = a girl who is reading, and negative = a girl sitting next to but looking away from an open book).

During the experiment, the pairs of photographs were animated so that each pair of photographs would be presented as still photographs for three seconds, after which the target photo (the negated photograph in the experimental condition, and the natural kind photograph in the control condition) would animate. The animation consisted of a cartoon foot emerging and moving down to squish the target photo to 20% of its original height. The foot then moved back up and the photograph returned to its original height as the foot receded. The animation, from the emergence of the foot to its disappearance, took a total of three seconds. Thus, each pair of photographs was on the screen for a total of six seconds, half of which consisted of the animation phase. Five seconds of black screen separated each animation.

The experiment was constructed in Tobii Studio. Two pseudo-random lists were created, specifying the order in which the participants would see the stimuli, and participants in all of the conditions were randomly assigned to one of the two lists. In both conditions, four photographs were selected as "example photographs". In the negation task, the four example photos included one from each negation type. Participants were not told that these were example photographs, but the examples differed in that each was displayed twice, once with the target picture on the left and once with the target picture on the right. This was done to draw participants' attention to the content of the photographs themselves (as opposed to simply the position on the screen), and to familiarize them to the kinds of stimuli and animation that they would be seeing.

Procedure

This experiment used a 2x2 between-subjects design. Half of the adults were tested on the negation task, and half were tested on the natural kind task. Within each of these conditions, half of the participants were tested with verbal shadowing and half were tested without verbal shadowing.

The experiment was run on a Tobii 1750 eye tracker. Participants were told that they would see pairs of photos on the screen in front of them, and that their job was to watch the pictures and pay attention to what they saw on the screen. Participants in the verbal shadowing condition were told that they would listen to an audio book through a pair of headphones (a passage from 1984 by George Orwell), and would have to repeat what they heard out loud as they listened. Participants were told to speak as simultaneously as possible with the speech they heard, and to be as accurate as possible, but to continue speaking if they made any mistakes, as the most important thing was that they spoke as continuously and fluidly as possible. Participants were then reminded that as they listened and spoke, they would have to keep their attention on the pictures they saw on the screen in front of them.

After the tasks were explained, the experimenter asked the participants in the shadowing condition to practice the verbal shadowing for 30 seconds. Participants in the verbal shadowing condition were videotaped throughout the duration of the experiment so that their performance on the shadowing task could be evaluated at a later point. After 30 seconds of practice, the experimenter started the videocamera and began the experiment. Participants who were not in the shadowing condition were not videotaped, and the experiment was started immediately after explaining the eyetracking task. In both conditions, the experimenter stepped out of the room as soon as the experiment began.

Data Processing

Areas of Interest (AOIs) were created around each photograph in each pair, with the negated event or the natural kind image designated the "target" photograph. The Total Fixation Duration (a measure of the durations of all fixations within an AOI in seconds) within each AOI was collected for the three seconds prior to the start of the animation began. The AOIs were constructed so that the computer would only record a fixation if a person's gaze fixated within the boundaries of the photograph. Thus, although the combined total fixation time possible between

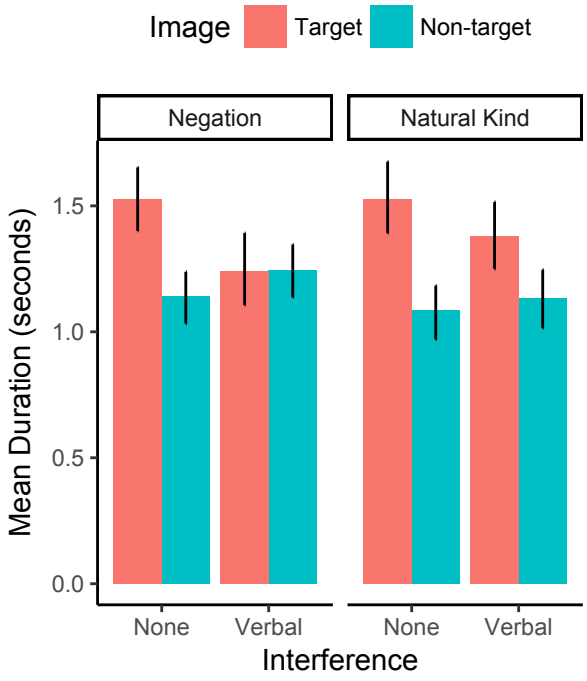

Figure 2: Mean Total Fixation Duration for each condition. Mean looks to the target image (negative event, natural kind) are shown in red and mean looks to the non-target image (affirmative event, artifact) are shown in green. Error bars portray 95% confidence intervals.

the target and non-target AOI was 3 seconds, it is possible that the combined total fixation time would be less than that if participants were fixating their gaze anywhere on the black screen outside of the pictures. The percentage of time that a person's gaze was anywhere on the screen throughout the experiment was also noted, and participants whose total gaze dropped below 60% were excluded from the analysis. This resulted in the exclusion of 18 participants from analysis.

The videotapes of the participants in the shadowing condition were analyzed to determine that the participants had continued speaking throughout the duration of the experiment. Any participant who stopped shadowing for more than 2 seconds was excluded from the analysis. This analysis resulted in the exclusion of three participants, two from the negation group and one from the natural kind group.

Results

Can participants spontaneously identify a unified concept of negation?

First, we asked whether adults would be capable of spontaneously identifying the negative concept in the negation task. To do this, we looked only at the negation/no interference condition to determine if participants looked more to the target picture compared to the non-target picture when they were not subject to verbal interference.

Mean looking times to the target and non-target picture for all conditions are shown in Figure 2. In the negation/no shadowing condition (left-most bars of Figure 2), mean looking time towards the target picture was greater than the mean looking time to the non-target picture (M_{target} = 1.53 s, $M_{non\text{-}target}$ = 1.14 s). A paired-sample t-test showed that this difference was significant, t(17) = -3.82, p<.01, suggesting that participants were able to spontaneously identify the negative concept and look to the correct picture in anticipation of the animation.

To make sure that participants were truly responding to the general concept of negation, and not a simpler sub-concept such as "refusal" or "failure", we examined each of the four subtypes of negation separately. Participants looked more to the target image compared to the non-target image in the non-functional subtype (t(17) = -2.20, p <.05), the nonexistence subtype (t(17) = -3.23, p < .01), and the refusal subtype (t(17) = -4.47, p<.001), but not the unexpected state subtype (t(17) = -1.47, p = .16). The fact that participants spontaneously looked towards the target picture for a wide range of subtypes (i.e., many perceptually different types of images and events) suggests that participants were identifying and responding to a general concept of negation.

Does verbal interference impair participants' ability to identify a concept of negation?

The previous analysis indicated that participants were able to spontaneously identify the negative concept, looking significantly more to the target (negative event) picture compared to the non-target (affirmative event) picture prior to the animation (t(17) = -3.82, p<.01). In the negation/verbal shadowing condition, however, mean looking time was nearly identical between the target and non-target images (M_{target} = 1.239 s, $M_{non\text{-}target}$ = 1.243 s, t(16) = 0.04, p = .97), suggesting that participants' ability to identify the negative concept was impaired under verbal interference. In the natural kind task, mean looking time to the target picture was greater than the mean looking time to the non-target picture in both the no shadowing condition (M_{target} = 1.53, $M_{non\text{-}target}$ = 1.08 s, t(26) = -3.66 s, p < .01) and the shadowing condition (M_{target} = 1.38 s, $M_{non\text{-}target}$ = 1.13 s, t(19) = -2.22, p < .05).

To examine the effect of the interference condition on whether participants looked more to the target or the non-target photograph, separate two-way ANOVAs were conducted for the negation condition and the natural kind condition. In the negation condition, there was a significant interaction between the target image and verbal interference (F(1,66) = 9.39, p<.01), suggesting that participants' ability to spontaneously identify the negative concept was significantly impaired by verbal interference. In the natural kind condition, there was a significant effect of target image (F(1, 90) = 26.12, p < .001) but no effect of verbal interference (F(1, 90) = 0.56, p = .46) and no interaction

between target image and verbal interference ($F(1.90) = 2.09$, $p = 0.15$), suggesting that participants' ability to spontaneously recognize the natural kind concept was not impaired under verbal interference.

To examine the interaction between task (negation vs. natural kind) and verbal interference (shadowing vs. no shadowing), we fit a linear mixed effects model[1]. For this analysis we calculated Differential Looking Scores (DLS) for each trial by dividing the difference between target and nontarget fixation duration by the total fixation duration to either picture, giving us a measure of the proportion of looks to target relative to the overall looking time for a given participant on a given trial. However, this model did not produce any significant effects (main effect of task: $\beta = -0.016$, $p = .81$; main effect of verbal interference: $\beta = -0.078$, $p = .19$; interaction between task and verbal interference: $\beta = -0.084$, $p = .35$). Because the two tasks used an entirely different set of stimuli, it is possible the variability in items makes it difficult to compare the two tasks in this way. In the General Discussion we discuss alternative possibilities for control tasks to test whether the effect of verbal interference is specific to negation.

General Discussion

We hypothesized that language is necessary for adults to implicitly recognize a unified concept of negation. We expected participants in the non-interference negation condition would implicitly learn to look towards the target picture in the seconds before it animated; that is, with implicit language abilities intact the resemblance across the items as negatives would be evident. Under conditions of verbal interference, where participants cannot implicitly use language to understand the concept, we predicted that participants would be unable to identify the resemblance across the diverse instances of negation. Conversely, we predicted that participants in the natural kind condition (a concept that would not necessarily require propositional structure) would look to the target picture regardless of verbal interference.

These results offer support for our hypotheses. First, participants in the negation condition without verbal interference *were* able to spontaneously identify exemplars of the negative concept despite a lack of verbal instructions telling them what concept to look for. The fact that participants, who were not told anything about the images they would see and were simply told to look at the pictures, were able to look at the negative event in anticipation of the animation suggests that there is some concept of negation that unites these very different exemplars.

Second, participants' ability to identify the tested concept was impaired by verbal interference in the negation condition, but not the natural kind condition. Non-shadowing participants in the negation group looked significantly more to the negation picture than the affirmative picture, while shadowing participants did not look significantly more to one photograph more than the other. In the natural kind group, participants looked more to the natural kind photograph than the artifact photograph, and, critically, this difference was not affected at all in the shadowing condition. This provides support for the hypothesis that language is required to understand a concept of negation, but not to understand other concepts, such as natural kinds.

One possible limitation of this study is that participants may have "passed" the negation task by identifying a simpler concept, rather than truly identifying a general concept of negation. We attempted to address this in our design by creating stimuli that represented a wide range of types of negation. In our analysis of the data, we found that participants were significantly more likely to look to the target picture in three of the four subtypes of negation that we included in our stimuli, suggesting that participants were responding to a general concept of negation rather than succeeding on only a small subset of trials.

Another possible limitation of this study is that the control task (natural kinds) may have simply been easier than the negation task. Although we do not think this is the case (overall looking time to the target picture in the no interference condition was identical across the two conditions, M = 1.53 seconds), this could be addressed in future work by using additional control tasks. One possibility would be to use the negation task stimuli with *affirmative* pictures as the target image, with the prediction that verbal interference should not affect looks to the affirmative picture. A downside to this option is that it isn't clear whether there is an underlying unifying concept of affirmation that would be spontaneously identified by participants – that is, participants might find the affirmation condition challenging even in the *absence* of verbal interference. Other possible control conditions could include a wider range of control concepts thought to not require propositional structure, or using an attentional control task such as rhythmic tapping, which has been used in past verbal shadowing studies (Hermer-Vazquez, Spelke, & Katsnelson, 1999, Newton & de Villiers, 2007).

Our results suggest that some kind of linguistic structure is necessary to understand a general concept of negation. The language-like structure that is required to support propositional thinking could come from a "language of thought" (e.g. Fodor, 1975), or it could come from the structure of natural language (e.g., Hinzen, 2007). One way to tease apart these possibilities would be to examine whether pre-verbal children or non-verbal animals can understand a general concept of negation. Many "language of thought" hypotheses propose that the LOT exists preverbally in children (and facilitate the development of natural language), and perhaps to some extent in non-verbal animals as well (Fodor, 1975, 2008). In the domain of animal research, Premack (1980) attempted to teach three chimpanzees a symbolic system based on plastic tokens that included a token for the word "not." The attempt was only

[1] Model specification: `DLS ~ task x interference + (1 | subject) + (interference | item)`

partially successful for one chimp, and unsuccessful for the other two. This would suggest that chimpanzees, at least, are unlikely to be able to represent an abstract concept of negation.

Research on children's acquisition of negation suggests that children begin producing the word "no" to express refusal as early as 12 months (Pea, 1980), and that children as young as 26 months understand denial negation (Austin, Theakston, Lieven, & Tomasello, 2014; Feiman, Mody, Sanborn, & Carey, 2017), though this may be task or context-dependent (Nordmeyer & Frank, 2014; 2018; Reuter, Feiman, & Snedeker, 2017). Under a "language of thought" hypothesis, children should be able to identify and understand a general, non-verbal concept of negation even if they cannot yet articulate this concept in natural language, and therefore children would perhaps be capable of passing a task similar to ours. If natural language is providing the structure to represent propositional negation, however, we would expect to see developmental changes in whether children are capable of understanding a general concept of negation, with pre-verbal (or pre-negation) children failing and older children succeeding.

Future work could examine the role of language in understanding other logical operators, such as "and" and "or", or quantifiers such as "some" and "all". Many philosophers of language have suggested that an important role of language is linking and connecting simple concepts into an infinite number of thoughts and combinatorial, complex concepts (Fodor, 1975, 2008; Carruthers, 2002; Hinzen, 2007). If this is true, words such as "and" and "or" would be vital to a system of thought, and conversely, it is possible that language is again necessary to form thoughts that require these logical connectives. These logical connectives and quantifiers are necessary aspects of human reasoning, and studying the role that language plays in understanding them could push our understanding beyond simply how we *perceive* the world, providing insight as well into how we reason about the world around us.

Neural Substrates Mediating the Utility of Instrumental Divergence

Abstract

We assessed the neural substrates mediating a recently demonstrated preference for environments with high levels of instrumental divergence – a formal index of flexible operant control. Across choice scenarios, participants chose between gambling environments that differed in terms of both instrumental divergence and expected monetary pay-offs. Using model-based fMRI, we found that activity in the ventromedial prefrontal cortex scaled with a divergence-based measure of expected utility that reflected the value of both divergence and monetary reward. Implications for a neural common currency for information theoretic and economic variables are discussed.

Keywords: instrumental divergence; flexible control; utility; model-based fMRI

Introduction

A series of recent studies (Mistry & Liljeholm, 2016; Liljeholm et al., 2018) have demonstrated that individuals strongly prefer environments in which instrumental divergence – the degree to which alternative actions differ with respect to their outcome probability distributions – is relatively high. A high level of instrumental divergence is a necessary feature of flexible control: If all available action alternatives have identical, or very similar, outcome distributions, such that selecting one action over another does not significantly alter the probability of any given outcome state, an agent's ability to exert flexible control over its environment is considerably impaired. Conversely, when available action alternatives produce distinct outcomes, discrimination and selection between actions allow an agent to flexibly obtain the currently most desired outcome. Since subjective outcome utilities often change from one moment to the next, flexible instrumental control is essential for reward maximization and, as such, may have intrinsic value, serving to reinforce and motivate decisions that guide the organism towards high-agency environments (Liljeholm, 2018). In the current study, we investigate the neural substrates mediating the apparent preference for high instrumental divergence.

Previous work suggests that the ventromedial prefrontal cortex (vmPFC) retrieves and ranks the values of decision outcomes, and that these value signals are subsequently used to compute decision values (see O'doherty, 2011 for review). Intriguingly, activity in the vmPFC scales with the values of a wide variety of goods, including food, money, books DVDs, and clothes, suggesting a common neural value-scale for distinct stimulus categories (Chib et al., 2009; McNamee et al., 2013). It is unknown, however, whether this common value-scale might also extend to more abstract, cognitive, commodities, such as instrumental divergence. Here, using a task in which participants choose between gambling environments based on differences in both instrumental divergence and monetary pay-offs, we combine computational cognitive modeling with functional MRI to investigate neural representations of the utility of instrumental divergence.

Method

Participants

Twenty undergraduates at the University of California, Irvine (11 females; mean age = 21.2 ± 4.65) participated in the study for monetary compensation. The sample size was determined based on an a priori power analysis of data from a previously published study (Mistry & Liljeholm, 2016), indicating that 18 subjects were required to demonstrate a clear behavioral preference for high instrumental divergence at a power of 90% given a 0.05 threshold for statistical significance. All participants gave informed consent and the Institutional Review Board of the University of California, Irvine, approved the study.

Task & Procedure

The task is illustrated in Figure 1. At the start of the experiment, participants were instructed that they would assume the role of a gambler in a casino, playing a set of four slot machines (i.e., actions, respectively labeled A1, A2, A3, and A4) that yielded three different colored tokens (blue, green and red), each worth a particular amount of money, with different probabilities. They were further told that, in each of several blocks, they would be required to first select a room in which only two slot-machines were available, and that they could only choose between the two machines in the selected room on subsequent trials in that block. Finally, participants were instructed that, while the outcome probabilities would remain constant throughout the

study, the values of the tokens would change at various times, and these changes might occur after the participant had already committed to a particular pair of machines in a given block. Consequently, although changes in value were explicitly announced, and the current values of tokens were always printed on their surface, a participant might find themselves in a room in which the values of the two available actions had suddenly been altered.

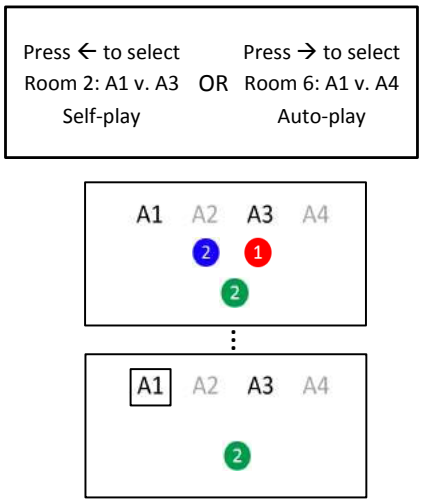

Figure 1: Task illustration showing the room-choice screen at the beginning of a block (top), and the choice (middle) and feedback (bottom) screens on a trial in the selected room.

Two distinct probability distributions over the three possible token outcomes were used and the assignment of outcome distributions to slot machines was such that two of the machines (either A1 and A2 or A1 and A3, counterbalanced across subjects) always shared one distribution, while the other two machines shared the other distribution. This yielded a low (zero) divergence for rooms in which the two available slot machines shared the same probability distribution, and a relatively high divergence for rooms in which slot machines had different outcome probability distribution. The unpredictability (i.e., Shannon entropy) of outcomes given a particular machine was held constant for all machines. Three token-reward distributions were used, changing intermittently across blocks, such that expected monetary pay-offs were either the same across rooms, or differed across rooms in either the same or opposite direction of instrumental divergence. In addition to mimicking dynamic changes in the utilities of natural rewards, the sporadic changes in token reward values across blocks allowed us to pit the value of instrumental divergence against that of monetary reward.

Given a constant outcome entropy level, increases in instrumental divergence are accompanied by increases in the perceptual diversity of obtainable outcomes – a variable previously shown to elicit preferences in economic tasks (Ayal & Zakay, 2009). To rule out perceptual diversity as an explanation for any effects of instrumental divergence, gambling rooms differed in terms of whether the participant was allowed to chose freely between slot machines in the room (self-play) or a computer algorithm alternated between machines across trials in that room (auto-play). In auto-play rooms, participants were still required to press a key corresponding to the slot machine indicated by the computer, to control for movement execution. Critically, in the absence of voluntary choice, high-divergence no longer yields flexible instrumental control. However, the alternating computer algorithm still yields greater perceptual diversity in high- than in low-divergence rooms. Consequently, if choices were driven by a desire to maximize perceptual diversity, rather than instrumental divergence, they should not differ depending on whether the participant or an alternating computer algorithm choose between the slot machines in a room. In addition to controlling for perceptual diversity, this self- vs. auto-play manipulation relates the preference for instrumental divergence to a well-established preference for free over forced choice (e.g., Leotti & Delgado, 2011).

There were a total of 44 blocks, with participants choosing between two gambling rooms at the start of each block (the decision of interest), followed by 3-5 gambling trials within the selected room. The order different reward distributions, and of room choice scenarios, was counterbalanced across subjects. Before starting the gambling task participants were given a practice session in order to learn the probabilities with which each slot machine produced the different colored tokens. If a participants' estimate of any given probability deviated by more than 0.2 from the programmed probability, they were returned to the beginning of the practice phase, and this continued until all rated probabilities were within 0.2 points of programmed probabilities. At the end of the study, participants again provided estimates of the action-token probabilities.

Computational Models

Instrumental divergence is formalized as the Jensen-Shannon divergence of instrumental sensory-specific outcome probability distributions (Liljeholm et al., 2013). Let P_1 and P_2 be the respective outcome probability distributions for two available actions, let O be the set of possible outcomes, and $P(o)$ the probability of a particular outcome, o. The instrumental divergence (ID) is:

$$ID = \frac{1}{2}\sum_{o\in O}\log\left(\frac{P_1(o)}{P_*(o)}\right)P_1(o) + \frac{1}{2}\sum_{o\in O}\log\left(\frac{P_2(o)}{P_*(o)}\right)P_2(o),$$

where

$$P_* = \frac{1}{2}(P_1 + P_2)$$

We defined the *expected value* (EV) of each slot machine as the sum over the products of its transition probabilities and token utilities. In turn, the expected *monetary* value of a gambling room is simply the mean of the EVs of slot machines in that room. To model the utility of instrumental divergence, a second variant of EV was specified by adding the term *w*ID* to the expected monetary value of a room, where the free parameter *w* represents the subjective utility of instrumental divergence and *ID* is the divergence of the particular room. Thus, in this variant, the EV of a room reflects *both* the monetary pay-off and the instrumental divergence associated with that room. For both models, a softmax distribution with a noise parameter, τ, was used to translate expected room values into choice probabilities, and free parameters were fit to behavioral data by minimizing the negative log likelihood of observed choices. Choice scenarios in which at least one room option was both high divergence and self-play (HDSP), yielding high *instrumental* divergence, and those in which the high-divergence room option was auto-play, or both rooms had zero divergence (HDAP), were modeled separately. The corrected Akaike Information Criterion (AICc) was used for behavioral model comparisons.

Neuroimaging Acquisition & Analyses

All MR images were obtained in a 3T Siemens Prisma Scanner, fitted with a 32-channel RF receiver head coil, padded to minimize head motion, at the facility for imaging and brain research (FIBRE) at the University of California, Irvine. Functional images covered the whole brain with 48 continuous 3-mm thick axial slices with T2*-weighted gradient echoplanar imaging (TR=2.65s, TE=28ms, 3-mm^2 in-plane voxel size, 64 x 64 matrix). All participants had a high-resolution structural image taken before functional scanning commenced (T1-weighted FSPGR sequence: 208 continuous 0.8-mm axial slices 0.4-mm^2 in-plane voxel size; 640 x 640 matrix). All stimulus materials were presented, and all responses recorded, using MATLAB. All imaging data was preprocessed with MATLAB and SPM12. Functional images were preprocessed with standard parameters, including slice timing correction, spatial realignment, coregistration of the high-resolution structural image to functional images, segmentation of the structural image into tissue types, spatial normalization of functional images into MNI space, and spatial smoothing with an 8mm FWHM kernel.

All imaging data was analyzed using MATLAB and SPM12. At the first level, two general linear models (GLMs) were specified for each participant. In both GLMs, two regressors respectively specified the onsets of room choice screens for HDSP and HDAP choice scenarios. In the first GLM, these onsets were parametrically modulated by the absolute difference between rooms in their expected monetary pay-offs; in the second GLM these onsets were parametrically modulated by the absolute difference between rooms in their divergence-based utility, which reflected both the monetary pay-off and the level of divergence associated with each room. In addition, in both GLMs, two regressors indicated the onsets of choice screens on each trial within a selected room, for self-play and auto-play rooms respectively, and each of these were parametrically modulated by the expected monetary value of the chosen slot machine. Finally, both GLMs included a single regressor indicating the onsets of trial feedback screens, modulated by the monetary reward obtained on each trial, as well as regressors indicating separate scanning runs and accounting for the residual effects of head motion.

Fixed effects models were estimated using restricted maximum likelihood and an AR(1) model for temporal autocorrelation. Group-level statistics were generated by entering contrasts of first level parameter estimates into between-subject analyses. All effects are reported at a whole brain corrected $p < 0.05$ level, using cluster size thresholding (CST) to adjust for multiple comparisons. AlphaSim, a Monte Carlo simulation, was used to determine cluster size and significance. For an individual voxel probability threshold of p=0.005, a minimum cluster size of 148 MNI transformed voxels resulted in an overall significance of $p < 0.05$.

Results

Behavioral Results

Participants required on average 2.1 (*SD*=0.3) cycles of practice on the action-token probabilities. Mean probability ratings, obtained right before and right after the gambling phase, are shown in Table 1.

Table 1: Mean probability ratings with standard deviations. Programmed probabilities are shown in the top row. Mean ratings, obtained before and after the gambling task, are averaged across identical objective probabilities, yielding three unique values.

	0.7	**0.0**	**0.3**
Before	0.69 ± 0.06	0.00 ± 0.00	0.31 ± 0.05
After	0.67 ± 0.10	0.00 ± 0.00	0.32 ± 0.05

The decision of interest was that at the beginning of each block, when participants choose between rooms that differed in terms of their divergence, expected monetary pay-offs and self- vs. auto-play. Model-derived choice probabilities and AICc scores for these decisions are listed in Table 2.

Table 2: Mean room-choice probabilities derived using the divergence-based and conventional models of expected value (EV), and associated AICc scores, for HDSP and HDAP choice scenarios, with standard deviations.

	Choice Probabilities		AICc Scores	
	HDSP	HDAP	HDSP	HDAP
Divergence EV	0.65 ± 0.13	0.58 ± 0.07	19.5 ± 2.7	38.3 ± 7.4
Conventional EV	0.55 ± 0.05	0.57 ± 0.07	21.6 ± 5.6	36.8 ± 7.5

A repeated measures analysis of variance (ANOVA) revealed that the model-derived probabilities of observed behavioral choice preferences were significantly greater for the divergence-based utility algorithm than for the conventional utility model, and this difference was significantly greater for HDSP choice scenarios than for HDAP choice scenarios, yielding a significant main effect of EV model, $F(1,19)=12.40$, $p<0.005$, as well as a model by choice scenario interaction, $F(1,19)=9.52$, $p<0.01$. Accordingly, there was also a significant interaction for the AICc scores, $F(1,19)=7.71$, $p<0.05$, such that scores were significantly lower, indicating a better fit, for the conventional than for the divergence-based utility model in HDAP blocks ($t(19)=5.2$, $p<0.001$) while being lower for the divergence-based utility model, albeit with only marginal significance ($p=0.14$) in HDSP blocks.

Neuroimaging Results

As with the behavioral data, the period of interest was the choice made at the beginning of each block, between two gambling rooms that differed in terms of divergence, monetary pay-offs and free choice. As illustrated in Figure 2, neural activity in the ventromedial prefrontal cortex (vmPFC) was parametrically modulated by the absolute difference in divergence-based EV between rooms, when at least one room option was both high-divergence and self-play (HDSP) but not when the high divergence room was auto-play, or both room options had zero divergence (HDAP). No significant effects of the difference between room options in expected monetary pay-offs emerged in this region. A similar pattern of results, with activity scaling selectively with the absolute difference in divergence-based EV between rooms options in HDSP choice scenarios, was found in the middle frontal gyrus, as well as the premotor cortex. Once a room had been selected, activity in a more dorsal aspect of the vmPFC, extending into the dorsal medial prefrontal cortex scaled with the expected monetary pay-off of the chosen slot machine, in self-play but not in auto-play rooms, as did activity in the lateral orbitofrontal cortex, posterior right middle temporal gyrus and right dorsolateral prefrontal cortex.

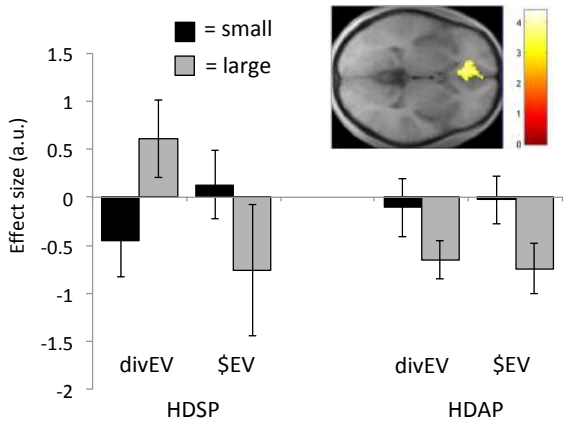

Figure 3: Map of the t-statistics for a test of differential parametric modulation by the difference across rooms in divergence-based expected value (divEV) for choice scenarios in which at least one high-divergence room option was self-play (HDSP) versus those in which the high-divergence room option was auto-play, or both options had zero-divergence (HDAP), showing significant effects in the vmPFC. Bar plots show effect sizes (y-axis) extracted from 4 mm spheres centered on the peak coordinate (x, y, z = -4, 34, -4), for small and large differences in divEV and monetary expected values ($EV), in HDSP and HDAP choice scenarios. Error bars=SEM.

Discussion

Countless studies on motivated behavior have investigated the neural representation of primary and monetary rewards (Abe & Lee, 2011; Abler et al., 2009; Belova et al., 2007; Cador e al., 1989). Here, having previously demonstrated a behavioral preference for instrumental divergence – a formal index of flexible operant control – we explored neural substrates mediating the influence of this information theoretic variable on economic choice. Specifically, participants were scanned with fMRI as they chose between gambling rooms that differed with respect to both instrumental divergence and expected monetary pay-offs. Using a model-based analysis, we found that activity in the ventromedial prefrontal cortex (vmPFC) scaled with a divergence-based measure of expected utility that reflected both instrumental divergence and monetary pay-offs.

Considerable evidence from neurophysiological and neuroimaging studies suggest that the vmPFC encodes the subjective values of primary rewards, such as tastes and odors (Rolls et al., 2003; Anderson et al., 2003; Small et al., 2003), as well as visual stimuli, including the attractiveness of faces or pictorial scenes (O'Doherty et al., 2003; Kirk et al., 2009), and more abstract goods, like social praise (Elliot et al., 1997) and monetary gain (O'Doherty et al., 2001).

Two notable features of the vmPFC shed important light on the current results: First, value encoding in the vmPFC appears to be relative, such that the value signal for a particular stimulus depends on the values of other, proximal, stimuli (O'Doherty, 2011). One might expect, thus, that the vmPFC signal would respond most clearly to a *difference in value* between concurrently available stimuli. Second, recent findings suggest that the vmPFC encodes stimulus values that are independent of the particular stimulus category, essentially implementing a common neural value scale for different types of goods (Chib et al., 2009; McNamee et al., 2013). The currently demonstrated value signal in the vmPFC, corresponding to a difference between options in divergence-based utility, suggest that this common value scale can be extended to a relative analysis of exceedingly abstract concepts.

Our previous work has implicated the right supramarginal gyrus (rSMG) of the inferior parietal lobule in encoding instrumental divergence. Specifically, using a simple value-based decision-making task, Liljeholm et al. (2013) found that activity in the rSMG scaled parametrically with trial-by-trial estimates of instrumental divergence, and that this signal was dissociable from other information theoretic and motivational variables, including outcome entropy and expected utility. In a subsequent task, aimed at assessing neural substrates mediating the acquisition of goal-directed vs. habitual instrumental behavior, Liljeholm et al., (2015) found that activity in the rSMG increased across blocks of instrumental acquisition in a high-divergence, but not in a zero-divergence, condition. In contrast, we did not find any effects of instrumental divergence in the rSMG in the current study. There are several possible reasons for this discrepancy: First, none of the previous studies assessed the motivational significance of instrumental divergence, in terms of a behavioral preference for environments with relatively high divergence. Second, in the current study, outcome probability distributions were trained to criterion prior to scanning (eliminating acquisition effects), and instrumental divergence remained constant within a room (eliminating responses to trial-by-trial fluctuations in divergence). Further work is needed to determine how these differences may account for a differential engagement of the rSMG.

A fundamental property of stimuli that possess intrinsic value is their ability to transfer that valence to neutral stimuli with which they are paired – a phenomenon termed *conditioned reinforcement,* that has been studied extensively using a wide range of stimuli, species and procedures (e.g., Arroyo et al., 1998; Williams, 1994). This large body of research has demonstrated that conditioned reinforcers are powerful behavioral determinants, maintaining instrumental responding in the absence of primary rewards, such as food and sex, and even serving as goals in themselves. Moreover, once established, previously neutral conditioned reinforcers can pass on their motivational significance to other neutral stimuli; For example, casino chips maintain gambling based on their association with monetary reward, which in turn obtains valence from its usefulness in acquiring primary rewards. One might expect, therefore, that any sufficiently valuable stimulus, no matter how abstract, should be able to induce conditioned reinforcement in associated arbitrary, and initially neutral, stimuli. Another important question, thus, is whether the affective properties of instrumental divergence may transfer to concomitant stimuli, and what brain regions might mediate such a processes.

Formal theories of goal-directed decisions postulate that the agent generates a "cognitive map" of stochastic relationships between actions and states such that, for each action in a given state, a probability distribution is specified over possible outcome states. These transition probabilities are then combined with current estimates of outcome utilities in order to generate action values – the basis of goal-directed choice (Doya et al., 2002). Although computationally expensive (Otto et al., 2013), the dynamic binding of outcome probabilities with utilities offers adaptive advantage over more automatic action selection, which uses cached values based on reinforcement history. However, when instrumental divergence is zero, or very low, the processing cost of goal-directed computations does not yield the return of flexible control, suggesting that a less resource-intense automatic decision strategy might be optimal. As noted, in a previous study we found evidence implicating instrumental divergence in the deployment of goal-directed and habitual behavior, and this is an important avenue for future work.

In summary, we have used model-based fMRI to investigate the neural computations mediating a behavioral preference for instrumental divergence. We found that activity in the vmPFC was significantly modulated by a variant of expected value that reflected both instrumental divergence an monetary pay-offs, but not by a conventional model of expected value, based solely on monetary gain. Our results complement previous work on the role of the vmPFC in value-based choice.

Causal intervention strategies change across adolescence

Abstract

Intervening on causal systems can illuminate their underlying structures. Past work has shown that, relative to adults, young children often make intervention decisions that confirm single hypotheses rather than those that discriminate alternative hypotheses. Here, we investigated how the ability to make informative intervention decisions changes across development. Ninety participants between the ages of 7 and 25 completed 40 different puzzles in which they had to intervene on various causal systems to determine their underlying structures. We found that the use of discriminatory strategies increased through adolescence and plateaued into adulthood. Our results identify a clear developmental trend in causal reasoning, and highlight the need to expand research on causal learning mechanisms in adolescence.

Keywords: cognitive development; information-seeking; hypothesis testing; causal learning

Introduction

We frequently take actions to manipulate the causal systems that make up our environments. Critically, these causal interventions often vary in the information they reveal (Bramley, Lagnado, & Speekenbrink, 2014; Tong & Koller, 2001; Coenen, Rehder, & Gureckis, 2015).

Imagine, for example, a child tending to a plant. She might believe that the plant requires sunlight, water, and fertilizer to grow. The child might intervene to confirm this hypothesis by placing her plant on a sunny window sill, watering it daily, and fertilizing it. If the plant blooms, she will take this as evidence confirming her initial hypothesis. However, if she were to consider a competing hypothesis – that the plant needs only water and sun but not fertilizer to flourish – she could instead provide the plant with water and sunlight, and critically, withhold fertilizer. If the plant were to wither, she would gain evidence in favor of her first hypothesis, but if it were to grow, she would gain evidence in favor of the second. In this way, different intervention decisions bring about different sets of evidence that help to discriminate competing ideas.

Consistent with this example, previous research has identified two broad classes of decision strategies for making interventions: Confirmatory interventions seek evidence consistent with a particular hypothesis, while discriminatory interventions seek information that can disambiguate competing alternatives (Coenen et al., 2015). It is unclear, however, how causal intervention strategies change with age. Previous work suggests that children as young as 2 years old can derive sophisticated causal knowledge about the structure of their environment by updating their prior assumptions about cause and effect as they encounter new evidence (Gopnik et al., 2004). This evidence is often self-generated – children perform their own "experiments" during play by intervening on causal systems to resolve their uncertainty about how they work (Gopnik, 2012).

Though children are capable of making informative interventions to drive their own learning (Bonawitz, van Schijndel, Friel, & Schulz, 2012; Schulz & Bonawitz, 2007; Sobel & Sommerville, 2010), their information gathering strategies may be sub-optimal. For example, early work in children's hypothesis testing suggests that the ability to systematically test competing alternatives improved from age 5 to age 11, but that even 11-year-olds often failed to make interventions that would enable them to learn underlying causal rules (Rieber, 1969). In a different experiment, when 9- to 11-year-olds were tasked with determining the cause of a specific chemical reaction, the majority of children failed to design systematic experiments that would enable them to efficiently isolate the causal agent (Kuhn & Phelps, 1982).

Characterizing developmental change in causal reasoning

While this work hints that there may be changes in causal intervention strategy across development, no prior work has systematically characterized these changes from childhood to adulthood, perhaps due to the inherent difficulty in measuring developmental change in this complex ability. Multiple strategies can promote effective inference, so studies that have examined only the accuracy of causal judgments, or that have allowed children to freely manipulate causal systems by performing many different actions, may not effectively capture subtle changes in strategy use across development.

A recent study of adults (Coenen et al., 2015) developed a Bayesian measurement model for determining the extent to which confirmatory vs. discriminatory intervention strategies are invoked during decision-making. In this study, adults' intervention decisions were best characterized by a model that combined the discriminatory Expected Information Gain (EIG) strategy with a Positive Testing Strategy (PTS) that assigned "value" to intervention decisions based on the proportion of causal links they would activate. This intervention strategy is generally less cognitively effortful than more discriminatory strategies and can yield informative outcomes in some contexts (Austerweil & Griffiths, 2011), but can also hinder learning by failing to rule out alternative causal models (Nickerson, 1998). Further, adults increased their use of a discriminatory strategy after attempting to solve problems in which confirmatory interventions were systematically less effective, but decreased their discriminatory strategy use under time pressure (Coenen et al., 2015).

The task and modeling approach used by Coenen et al. (2015) has several key properties that make them particularly well-suited to characterize changes in causal intervention strategy across development. First, the task itself is easy to understand but challenging to perform optimally, such that it can be understood by young children while remaining sensitive to changes in causal learning that may occur throughout late childhood, adolescence, and early adulthood. Second, the modeling approach can effectively capture both discriminatory intervention decisions, but also the more cognitively simple, confirmatory strategy that may be adopted by resource-constrained learners. Finally, the model enables estimation of continuous strategy mixture weights for each participant, which can characterize the extent to which their choices reflect confirmatory or discriminatory strategies. By leveraging this measure, we can both account for heterogeneity in strategy use across individuals and examine how strategy use may change across development.

Two previous studies have taken a similar approach but have only examined the choices made by young children, between the ages of 5 and 8 (McCormack, Bramley, Frosch, Patrick, & Lagnado, 2016; Meng, Bramley, & Xu, 2018). In both these studies, rather than selecting interventions that maximized their ability to disambiguate multiple competing possibilities, children often made choices that maximized positive evidence in favor of a *single* hypothesis. However, these studies used only a small number of trials, potentially leading to unreliable estimates of strategy use and preventing the examination of learning over time.

Further, selecting interventions that maximize information gain may require multiple cognitive mechanisms that continue to develop throughout late childhood and adolescence. When faced with intervention decisions, individuals must prospectively imagine the outcomes that different actions are likely to bring about (Sloman & Lagnado, 2015). Then, they must evaluate whether these outcomes provide evidence for one causal hypothesis over another to ultimately choose which action to take (Coenen & Gureckis, 2015). Finally, individuals need to recognize that this cognitive process is "worth it" – that considering possible outcomes of different interventions promotes more accurate hypothesis evaluation relative to other less effortful cognitive strategies. Each of these component mechanisms undergoes marked change throughout development. The ability to use mental models of the environment to prospectively compare decisions (Decker, Otto, Daw, & Hartley, 2016), the ability to infer causal relations based on observed outcomes (Gopnik et al., 2017), and metacognitive sensitivity to the efficacy of different cognitive strategies (Weil et al., 2013) all improve not just in early childhood – a focal point of many studies of causal learning – but continuously across late childhood, adolescence, and early adulthood.

Here, we leveraged the approach introduced by Coenen et al. (2015) – and its key measurement characteristics – to determine the developmental trajectories of causal learning strategies across late childhood, adolescence and early adulthood. Though these developmental periods have been largely neglected in the causal intervention literature, research focused on related cognitive mechanisms suggest these periods may be characterized by robust change in learning and decision-making strategies. Beyond characterizing the general trajectory of change in the use of different intervention strategies, we sought to illuminate interactions between different cognitive mechanisms that may support the emergence of discriminatory hypothesis testing.

Methods

Participants

Ninety 7-to-25-year-olds ($M_{age} = 15.87$ years, $SD_{age} = 5.26$ years, range = 7.04 - 25.74 years, 46 females) participated in the study. All participants completed the matrix-reasoning and vocabulary section of the Wechsler Abbreviated Scale of Intelligence, from which age-normed IQ scores were derived. There was not a significant relation between age and IQ in our sample, $F(1,88) < .001, p > .99, \eta_p < .001$.

Task

Participants completed a computerized task in which they were told they were employees at a computer chip factory, whose job was to sort 3- and 4-node computer chips based on the configuration of their hidden wires. On each trial, participants first viewed two causal graphs for 2 seconds, each of which displayed a different possible configuration of the chip's hidden wires (Figure 1). Then, a computer chip appeared, with all of its nodes turned "off." Participants had as much time as they wanted to make one intervention decision – that is, to click on one node. The node that was clicked *always* turned on. After a brief delay (200 ms) during which the chip turned grey and beeped, the chip reached its final state, indicating outcome of the intervention. The activation of a parent node turned on its direct descendants with a probability of .8. There were no background causes - nodes could only turn on if they were directly clicked or activated by a parent node. After viewing the outcome of their intervention, participants had unlimited time to click on whichever of the two causal graphs they believed indicated the true configuration of the chip's hidden wires. Participants then used a continuous slider to rate their confidence that they selected the correct configuration. Participants were told that they would be paid a bonus based on how many chips they sorted correctly.

Prior to beginning the experimental trials, all participants completed an extensive tutorial in which they were trained on the probabilistic nature of the wires, the directionality of the wires, the correspondence between the causal graph diagrams and the actual chip on which they intervened, and the overall trial procedure.

Participants completed 40 experimental trials. Trial order was pseudo-randomized such that in each block of 10 trials, participants always completed five 3-node puzzles and five 4-node puzzles. The specific puzzles were selected such that the

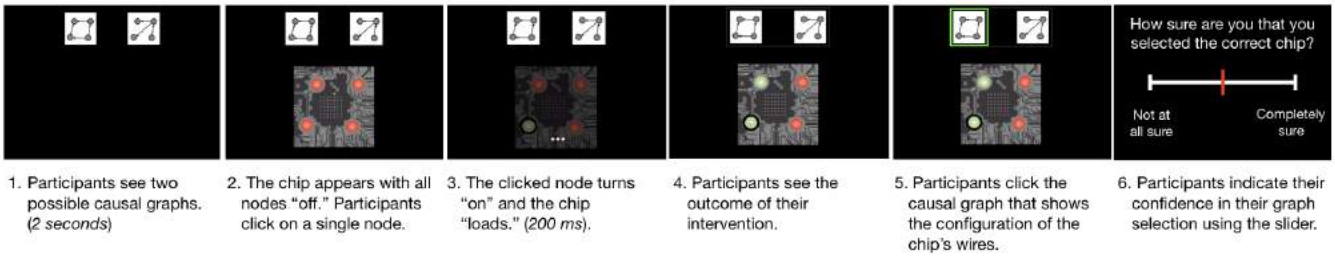

Figure 1: Participants completed 40 intervention trials, in which they had to select a node to determine the configuration of a computer chip's hidden wires.

discriminatory and confirmatory strategy we modeled (more details below) made divergent predictions about the probability of selecting different nodes. The side of the screen on which each graph appeared was randomized. On each trial for each participant, one graph was randomly selected to be the chip's "true" underlying structure. Participants only learned how many chips they sorted correctly at the end of the task; they did not receive trial-by-trial feedback.

Strategies

To model participant intervention choices, we focused on one specific discriminatory intervention strategy - Expected Information Gain - and one specific confirmatory strategy - Positive Testing Strategy. The models differ in how they assign value to possible interventions.

Expected Information Gain (EIG) EIG assumes that individuals have a set of hypotheses about the structure of a particular causal system, with each system represented as a causal Bayesian graph. A learner's uncertainty about which graph (g) is most likely the source of their current observations is represented as the Shannon entropy over the graphs within their hypothesis set (G):

$$H(G) = \sum_{g \in G} P(g) log_2 \frac{1}{P(g)}$$

Learners maximizing information gain should select the information that will cause the largest reduction in their uncertainty. This can be computed by considering the amount of information gained by each possible outcome (o) of each action (a), weighted by their probability:

$$EIG(a) = H(G) - \sum_{o \in O} P(o|a) H(G|a,o)$$

where $H(G|a,o)$ is the new uncertainty after an intervention:

$$H(G|a,o) = \sum_{g \in G} P(g|a,o) log_2 \frac{1}{P(g|a,o)}$$

Positive Testing Strategy (PTS) PTS assumes that participants seek positive evidence to confirm a single hypothesis. We use the formalization introduced in Coenen et al. (2015) which assumes that participants consider each graph in turn, and choose the intervention that will activate the largest proportion of nodes within a single causal graph:

$$PTS(a) = \max_g \left(\frac{DescendantLinks_{n,g}}{TotalLinks_g}\right)$$

Results

Age-related change in strategy use

To characterize participants' intervention choices, we fit a single Bayesian model in which we assumed participants were linearly combining EIG and PTS with weight θ, where $\theta = 0$ indicates a pure PTS strategy and $\theta = 1$ indicates a pure EIG strategy. We further assumed that participants' choices were noisy, such that the expected value of each choice probabilistically influenced intervention decisions. We used a softmax choice function to represent this process, with a free parameter, τ, to capture each participant's decision noise.

The two previous studies using this modeling approach employed a hierarchical model in which group-level hyper-parameters were also estimated (Coenen et al., 2015; Meng et al., 2018), but given our broad age range, we did not want to assume that the participants in our sample comprised a single group. Rather than estimating group-level hyper-parameters, we estimated the model separately for each participant.

We estimated posterior distributions over the parameters using Markov chain Monte Carlo (MCMC) sampling via the NUTS algorithm implemented in STAN (4 chains of 2000 iterations, 1000 per chain discarded as warmup; 4000 total samples per parameter) (Stan Development Team, n.d.; Team, 2013). We used uniform priors over the parameter space ($\tau \sim U(0,\infty); \theta \sim U(0,1)$). Rhat values for all parameter estimates were less than 1.1, indicating convergence across chains (Brooks & Gelman, 1998).

To characterize how strategy use changed with age, we extracted the posterior mean estimates of strategy mixture weights (θ) and examined their relation with age. We tested two linear regression models to examine linear and nonlinear trajectories of developmental change: One included linear z-scored age as a predictor, and one included both linear z-scored age and quadratic z-scored age as predictors (Somerville et al., 2012). We followed this approach for all subsequent models described in the paper.

The model with the quadratic age term provided a significantly better fit to the data, $F(1,87) = 9.95, p = .002$. Both age ($\beta = .12, p < .001$) and age^2 ($\beta = -.06, p = .002$) significantly predicted strategy mixture weight (Figure 3), suggesting that through early adolescence, participants decreased their use of PTS in favor of EIG. Even within age groups,

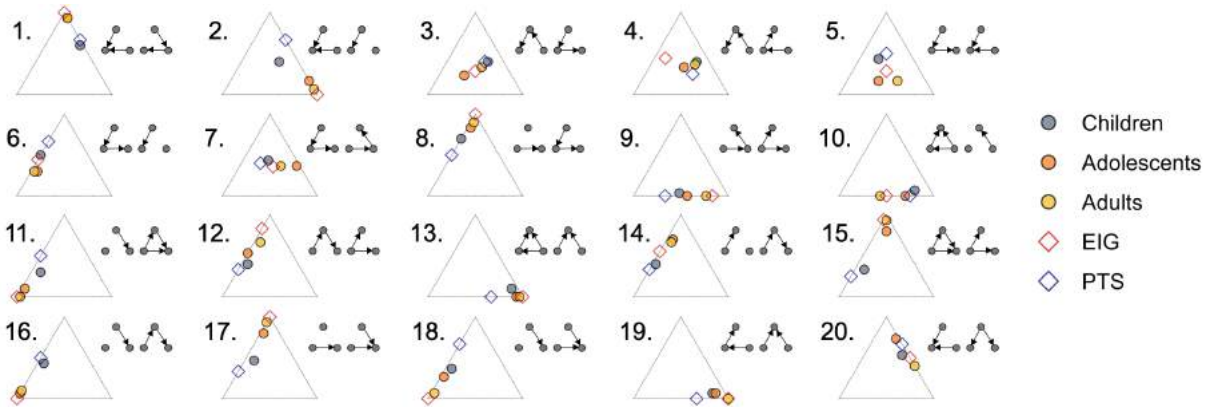

Figure 2: Intervention choices for the 20 three-node puzzles presented in the experiment. The corners of each simplex represent nodes on which participants intervened. The circles represent the average choice for each age group (Children: 7 - 12 years old, Adolescents: 13 - 17, Adults: 18 - 25), while the diamonds represent the "value" of each node as determined by EIG and PTS.

strategy use varied across problems (Figure 2); adolescent choices, for example, sometimes resembled those of adults (16) and sometimes were more like those of children (10).

We also examined how decision noise (τ) changed with age. Decision noise decreased linearly with age ($\beta = -.576, p = .048$), indicating that the choices of older relative to younger participants were more fully captured by the predictions of the two intervention strategies (Figure 3). There was not, however, a significant relation between θ and τ ($p = .271$), suggesting that age-related change in strategy mixture weight can not be attributed to age-related differences in decision noise.

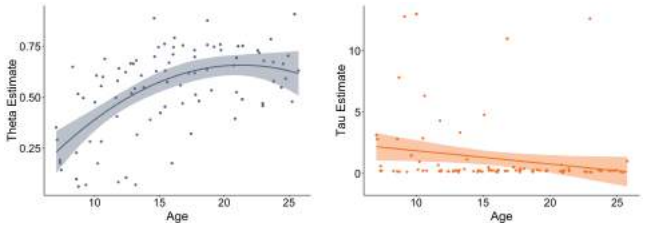

Figure 3: Model-derived estimates of participants' strategy mixture weights (θ) show that participants became more discriminatory with increasing age through late adolescence. Decision noise estimates (τ) show that intervention decisions became more value-based with increasing age. Best-fitting regression lines illustrating the effects of age and age^2 on θ and age on τ are plotted.

In line with previous findings (Meng et al., 2018; Coenen et al., 2015), our modeling results suggest that children and adults use a combination of confirmatory and discriminatory strategies to test causal hypotheses. Further, they demonstrate that this combination systematically differs across children, adolescents, and adults.

Inference-intervention interactions

Why did the use of a discriminatory intervention strategy increase across development? One possibility is that when presented with the novel task, participants explored different intervention strategies until finding one they believed was most effective. Older participants may have been more sensitive to the relative efficacy of different intervention strategies. For EIG to be a useful strategy, however, individuals needed to be able to make accurate causal inferences based on the outcomes of their interventions. Gaining information to disambiguate competing hypotheses was only useful if individuals could correctly updated their beliefs based on that new evidence (Coenen & Gureckis, 2015).

To examine whether causal inference changed with age, we computed the posterior probabilities of each of the two possible causal graphs based on the selected node and the final states of the other nodes on each trial. We then ran a linear mixed-effects model to determine whether there was a relation between age and the posterior probability of the structure selected. Older participants selected more probable causal structures, $F(1,88) = 10.44, p = .002$. This suggests that with increasing age, individuals became better at evaluating the outcomes of their interventions to disambiguate competing hypotheses. However, this metric is inherently confounded with intervention decisions – by definition, interventions with higher EIG scores were more likely to lead to greater increases in the posterior probability of one structure over another. Thus, it is difficult to determine the direction of the relationship between causal intervention and inference – were older participants selecting more informative interventions because they could more effectively prospectively evaluate how that information would enable them to update their beliefs? Or were they updating their beliefs more effectively because they chose interventions that provided stronger evidence in favor of one hypothesis over another?

Participant confidence in the structure they selected can provide insight into developmental change in causal infer-

ence – and metacognitive sensitivity to causal evidence – without being confounded by intervention choice. If participants were sensitive to the extent to which the information they gained allowed resolution of competing hypotheses, then their confidence in the structures they selected should track their posterior probabilities. To determine how these posterior probabilities and age influenced confidence ratings, we ran a linear mixed-effects model. Our best-fitting model included both a linear and quadratic effect of age. Participants were more confident in their selection when the posterior probability of the structure they selected was higher, $F(1,3535.17) = 353.69, p < .001$ However, this effect was qualified by an age x posterior probability interaction ($F(1,3529.67) = 21.75, p < .001$) as well as by an age^2 x posterior probability interaction ($F(1,3529.76) = 12.83, p < .001$), such that the influence of posterior probabilities on confidence ratings increased throughout childhood and early adolescence. These results indicate that the ability to evaluate the extent to which new information supported causal hypotheses improved non-linearly across development. Importantly, they suggest developmental improvements in causal inference that are separable from improvements in intervention strategy.

We next examined whether developmental change in causal inference influenced intervention strategy. Specifically, we computed the correlation between the posterior probability of the structure selected and confidence ratings for each participant and ran a linear regression to determine whether these values, which we will refer to as "evidence sensitivity," predicted strategy mixture weight (θ). We found a positive relationship between evidence sensitivity and θ ($\beta = .09, p < .001$), even when controlling for age and age^2. In other words, participants with stronger sensitivity to the strength of the evidence on which to base their inferences also demonstrated greater use of EIG.

Within-task learning effects

Beyond examining how causal intervention strategy changed with age, our use of 40 trials enabled us to examine learning over the course of the task. We hypothesized that older participants' greater use of a discriminatory strategy might in part be driven by faster learning, such that age would more strongly influence estimated values of θ in the second half of the experiment, after participants had the opportunity to learn to adjust their strategy based on their evaluations of their earlier decisions.

To examine whether participants used a different mixture of strategies throughout the course of the task, we fit our Bayesian model separately to the first and second half of trial data for each participant. We then ran a linear mixed-effects model to determine how experiment half and age influenced strategy mixture weight. As before, both linear and quadratic age predicted strategy mixture weight ($ps < .02$). Furthermore, strategy mixture weight increased from the first half to the second half of the experiment, $F(1,87) = 11.4, p < .001$ (Figure 4), indicating that participants may have learned to use a more discriminatory strategy over the course of the task. Contrary to our prediction, however, experiment half did not interact with age or age^2 ($ps > .20$).

Decision noise also decreased over the course of the experiment, $F(1,88) = 5.18, p = .03$. This effect was qualified by an age x experiment half interaction, such that younger participants demonstrated a greater decrease in decision noise from the first to the second half of trials, $F(1,88) = 4.72, p = .03$ (Figure 4). This suggests that younger participants may have learned to use their estimates of the value of each intervention to more strongly guide their decisions over the course of the task. While the change in their strategy mixture weight did not statistically differ from that of older participants, younger participants may have learned that *both* strategies were more effective than randomly selecting nodes.

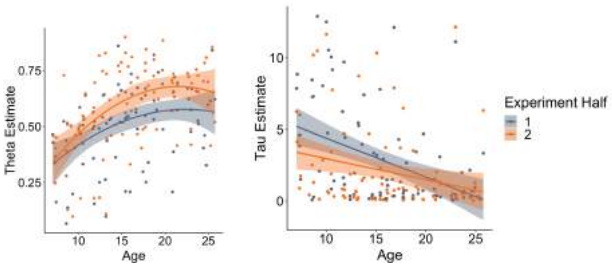

Figure 4: In the second half of the experiment, participants relied more on EIG over PTS, and their choices were less noisy.

Finally, we examined whether evidence sensitivity related to participants' change in strategy use over the course of the task. We computed $\Delta\theta$ for each participant by subtracting their estimated θ value over the first half of the experiment from their estimated θ value over the second half of the experiment. We then ran a regression examining the effects of age and evidence sensitivity on $\Delta\theta$. We found a significant effect of evidence sensitivity on $\Delta\theta$, $\beta = .049, p = .019$, such that participants who were most sensitive to their ability to correctly identify underlying causal structures demonstrated increased use of EIG over the course of the experiment. Mirroring our previously reported results, there was not a significant effect of age on $\Delta\theta$, nor was there an age x evidence sensitivity interaction effect ($ps > .61$).

Discussion

Our results and modeling analyses demonstrate robust changes in causal intervention strategy from middle childhood to adulthood. In sum, interventions become more discriminatory with increasing age until reaching a plateau in late adolescence. What causes this developmental shift?

One possibility is that improvements in intervention strategy are due to increased exposure to scientific reasoning strategies through formal schooling. Future work could test participants at multiple time-points and examine the extent to which increases in EIG use align with exposure to curricular units focused on concepts like controlling variables to

effectively discriminate hypotheses (Kuhn, Arvidsson, Lesperance, & Corprew, 2017).

However, several aspects of our data suggest that formal schooling can not account for all age-related change in strategy use that we observed. First, almost all participants demonstrated a mixture of strategies throughout the experiment, and this mixture appears to change *gradually* with increasing age (as opposed to a sharp shift corresponding to the introduction of specific concepts during formal schooling). We also found that individual and developmental differences in more basic learning mechanisms, like sensitivity to the informativeness of intervention outcomes, predicted strategy use. Additionally, individuals across our age range increased their use of a discriminatory strategy throughout the course of the task, without any explicit instruction or feedback.

It may also be the case that with increasing age, individuals become better at prospectively planning their intervention decisions. Though evidence sensitivity correlated with strategy mixture weight in our data, it did not fully account for developmental change in strategy use. Importantly, we hypothesized that the ability to make accurate causal judgments may enable individuals to select the best intervention only if they prospectively simulate and sample the outcomes of potential choices in the first place (Bonawitz, Denison, Griffiths, & Gopnik, 2014). On some trials, participants may not have attempted to think through the possible outcomes of their decisions, in which case the ability to evaluate those outcomes would not affect the intervention choice. Future studies should probe the role of other cognitive mechanisms in supporting the use of EIG, like model-based decision-making, which may support or similarly rely on simulating probabilistic outcomes of multi-stage decisions (Decker et al., 2016; Doll, Duncan, Simon, Shohamy, & Daw, 2015).

Another possibility is that younger people are equally *capable* of implementing a more discriminatory intervention strategy, but perform a different cost-benefit analysis when determining which strategy to use. As mentioned previously, the confirmatory PTS strategy often reveals diagnostic information in environments in which causal links are sparse or deterministic (Austerweil & Griffiths, 2011). Additionally, confirmatory hypothesis testing may be adaptive when individuals have the opportunity to make multiple interventions at low cost. It may be the case that rather than spending time and cognitive effort to make the single best intervention, children prefer to make multiple, easier, intervention decisions, which together provide the information they need. Future studies could isolate changes in *ability* from changes in effort allocation, by raising the cost of making an uninformative intervention or forcing all participants to spend a long time deliberating prior to allowing them to perform their intervention.

Finally, though few studies have examined causal learning in adolescence, our results demonstrate that causal learning and decision-making continue to change during this period. Future work probing the cognitive mechanisms that drive these changes will inform how to best support adolescents as they interact with their environments with increasing independence and shape their own learning opportunities.

Abstract

Children often fail to control variables when conducting tests of hypotheses, yielding confounded evidence. We propose that getting children to think of alternative possibilities through counterfactual prompts may scaffold their ability to control variables, by engaging them in an imagined intervention that is structurally similar to controlled actions in scientific experiments. Findings provide preliminary support for this hypothesis. Seven- to 10-year-olds who were prompted to think counterfactually showed better performance on post-test control of variables tasks than children who were given control prompts. These results inform debates about the contribution of counterfactual reasoning to scientific reasoning, and suggest that counterfactual prompts may be useful in science learning contexts.

Scientific Reasoning in Development

Equipping children with scientific inquiry skills is a core objective of elementary science education, allowing children to collect evidence and draw inferences about the world around them. However, extensive research has found that children are relatively unequipped to engage in many aspects of scientific inquiry in the absence of direct instruction and frequent scaffolding (Klahr, Fay, & Dunbar, 1993; Klahr & Nigam, 2004; Kuhn & Franklin, 2006; Schauble, 1996). In the present study, drawing from research and theory in cognitive development, science education, and philosophy, we investigate the use of a novel pedagogical tool – counterfactual reasoning prompts – to scaffold children's scientific reasoning skills.

An important sub-skill of scientific inquiry is the ability to control variables. This skill, termed the control-of-variables strategy (CVS) has received a great deal of attention in research on scientific reasoning over the past four decades (for a review, see Zimmerman, 2007). To properly execute this skill, the learner should isolate a single variable at a time, while holding all else constant.

Consider a common task used in studies investigating CVS (e.g., Chen & Klahr, 1999; Klahr & Nigam, 2004). Children are presented with a set of ramps that can be varied along a number of dimensions (e.g., ramp height, surface, run length, ball size) and their task is to manipulate the ramps to determine the effect of different variables on where a ball stops after rolling down the ramp. To make warranted inferences about individual variables, the learner should change the values of a single variable (e.g., compare a high ramp to a low ramp), keeping all other variables constant (e.g., smooth surface, same-size balls).

Although children are able to *recognize* a conclusive test of a hypothesis as young as age 6 (Sodian, Zaitchik, & Carey, 1991), they typically fail to *produce* one themselves in the absence of scaffolding through middle childhood (Klahr, Zimmerman, & Jirout, 2011; Zimmerman, 2007). However, with direct instruction, children often show improvement in their ability to design controlled experiments (Chen & Klahr, 1999; Klahr & Nigam, 2004; for a meta-analysis, see Schwichow, Croker, Zimmerman, Hoffler, & Hartig, 2016). For instance, Chen and Klahr (1999) found that 7- to 10-years-old who were given explicit instruction on CVS were better able to transfer this strategy to both similar and dissimilar problems than those who engaged in self-guided inquiry. Younger children frequently failed to design unconfounded tests.

Although past studies have found that children are able to learn the control of variables strategy through direct instruction or demonstrations, science curricula and educational guidelines often recommend teaching scientific inquiry skills through *inquiry-based learning* instead (e.g., US National Research Council, 2000). That is, children's scientific inquiry skills are thought to be best supported by having children explore science concepts based on their own

observations and experiences with phenomena of interest, with little explicit instruction from educators. Thus, there is significant educational value to identifying methods for scaffolding children's hypothesis testing abilities that not only fit within these curricular guidelines, but also harness children's intuitive reasoning skills.

Causal and Counterfactual Reasoning

Whereas the work reviewed above suggests that older children are poor at testing and revising hypotheses, another body of research shows that children are adept at parallel skills when engaging in causal learning tasks.

From a young age, children form, test, and revise hypotheses in building informal theories in various domains (Carey, 1985; Gopnik, Meltzoff, & Bryant, 1997; Keil, 1992;). For instance, toddlers are able to infer higher-order relational causes (Walker & Gopnik, 2014). Preschoolers are able to draw appropriate causal inferences from patterns of dependence, even when evidence conflicts with their prior knowledge (Schulz & Gopnik, 2004), and use evidence from interventions to make inferences about causal structure (Schulz, Glymour, & Gopnik, 2007).

Why do older children (and even adults) fail when applying this skill-set in scientific reasoning contexts? We suggest a few possible explanations for this discrepancy. First, studies of intuitive causal reasoning with toddlers and preschoolers use tasks that are typically decontextualized, placing relatively few demands on children's prior knowledge. Many of these studies rely on a "blicket detector" paradigm, in which children are familiarized with a novel machine, and their task is to determine what makes it switch on (Gopnik & Sobel, 2000). In contrast, scientific reasoning tasks given to older children typically use knowledge-laden tasks that rely heavily on children's existing (and often incorrect) knowledge and theories (e.g., Chen & Klahr, 1999). Second, causal reasoning tasks typically measure children's abilities implicitly, whereas scientific reasoning tasks ask children to explicitly plan and often verbally demonstrate their abilities. Despite these differences, both classes of studies rely on a common set of domain-general inferential skills, including the ability to form and revise hypotheses on the basis of available evidence.

How do we connect the parallel mechanisms children successfully apply in causal reasoning tasks to scientific reasoning contexts? In the current study, we explore the claim that counterfactual reasoning is fundamental to causal and scientific reasoning, and suggest that counterfactual prompts may help to connect these abilities. When we think counterfactually, we compare the way things are to the way things *could have been*. Counterfactual reasoning therefore necessarily involves thinking about causes: As one considers how an event could have turned out differently, one reasons about the causal relationship between an antecedent and outcome. If the event X had not happened, would event Y still have happened? If the answer to this is "no", one can conclude that event X is a cause of event Y (Lewis, 1986).

However, the utility of counterfactual reasoning may not be limited to drawing *specific* causal inferences. Several researchers have drawn theoretical parallels between the *mechanisms* underlying counterfactual reasoning and scientific reasoning (e.g., Buchsbaum, Bridgers, Weisberg, & Gopnik, 2012; Erb & Sobel, 2014; Gopnik & Walker, 2013; Sloman, 2005; Rafetseder & Perner, 2014; Walker & Gopnik, 2013). If a learner believes that X caused Y, they can mentally intervene on X by imagining that it did not occur, follow the causal implications of this change, and then reason about whether it would have led to a change in Y (Gopnik & Walker, 2013; Walker & Gopnik, 2013). We follow an identical process in *scientific* reasoning. We hypothesize that X causes Y, and then make plans to systematically manipulate X in order to investigate its impact on Y. In both counterfactual and scientific reasoning, the learner adjusts a causal system by (mentally or physically) intervening on one event and considering the effects of this change.

Despite the proposed contribution of counterfactual reasoning to science learning, there is relatively little research connecting the two (Engle & Walker, 2018; Frosch, McCormack, Lagnado, & Burns, 2012; Schulz, et al., 2007) and no work linking these capacities to hypothesis testing in children. Only two previous studies to our knowledge have investigated the relationship between counterfactual reasoning and scientific inquiry. Adults primed with counterfactuals were better able to conduct a disconfirming test of a hypothesis than those given neutral primes (Galinsky & Moskowitz, 2000). In another study, counterfactual prompts scaffolded children's ability to detect anomalies to an existing hypothesis in a causal learning task (Engle and Walker, 2018).

Given that counterfactual and scientific reasoning both involve intervening on a single variable to investigate its causal role in an outcome of interest, we propose that engaging children in counterfactual reasoning during a control-of-variables task will scaffold their ability to conduct a controlled test of a hypothesis by activating a parallel underlying cognitive mechanism.

That said, it is worth first considering whether children of the age we tested in the current study (7 to 10 years) are capable of counterfactual reasoning, given the lively debate about its developmental trajectory. Previous research has been mixed, with some findings indicating that children *can* reason counterfactually as young as 3-½ years (Harris, German, & Mills, 1996), and other work suggesting that this ability does not reach maturity until adolescence (e.g., Rafetseder, Schwitalla, & Perner, 2013). However, more recent work suggests that studies showing counterfactual reasoning to be late-developing may have underestimated children's ability by presenting opaque causal structures and by placing large demands on children's memory (McCormack, Ho, Gribben, O'Connor, & Hoerl (2018; Nyhout, Henke, & Ganea, 2019). A recent set of studies demonstrates that children reason counterfactually by age 4 when given a clear and novel causal structure that does not

rely on their background knowledge (Nyhout & Ganea, 2019). Thus, we conclude from these findings that children have the requisite abilities to engage in counterfactual reasoning well before the age of those in the current study.

Current Study

In contrast to previous research (Chen & Klahr, 1999; Klahr & Nigam, 2004), we investigated whether children's ability to control variables could be scaffolded in non-school settings. We also reduced task demands by including a smaller number of variables (2 variables, rather than 4).

Children in the present study were assigned to either a counterfactual or control condition. After watching a video of an actor conducting a controlled test of a hypothesis, children were given either a *counterfactual* prompt, asking them to consider what would happen if the actor had conducted her test differently, or a *control* prompt, in which children were asked to recall what had happened. We predicted that children given counterfactual prompts would be more likely to improve from pre-test to post-test than children given control prompts. We tested a range of ages typically used in CVS research (7 to 10 years), but did not have prior predictions about age-related differences in performance.

Method

Participants

Participants aged 7 to 10 years of age were recruited and tested at a museum in a large urban area. The final sample included 88 children (M = 8.91, SD = 1.13, range = 7.00 to 10.97, 45 girls) whose data are reported below. Participants were placed in two categories, based on their age. The *younger* age category included children between the ages of 7.00 and 8.99 (n = 46, M = 8.00, SD = 0.63) and the *older* age category included children between the ages of 9.00 to 10.99 (n = 42, M = 9.90, SD = 0.59), with categories selected on the basis of similar previous studies (e.g., Chen & Klahr, 1999; Klahr & Nigam, 2004). Participants who passed the pre-test phase (n = 24) were excluded as they were determined to be already competent with CVS. Three additional participants were excluded due to experimenter error (n = 2) or language barriers (n = 1).

Materials

For the pre- and post-test phases described below, participants were given two identical ramps with both a down- and up-ramp side. The ramps were ridged on the up-ramp where the ball could stop (Figure 1). Each ridge was painted a different color to allow for unambiguous reference and measurement. There were four binary variables, but participants received only two of the four variables at a time, and the remaining two variables were "fixed". The variables were paired as follows: (1) height (high or low) and ball size (large or small), or (2) starting place (top or middle), and surface (rough or smooth). For instance, at one time-point, participants were given a large and small ball for each ramp, and pieces to adjust the steepness of each ramp ("high" or "low"). At the other time-point, participants were given a rough surface and smooth surface for each ramp, and a piece of cardboard to adjust where the ball started for each.

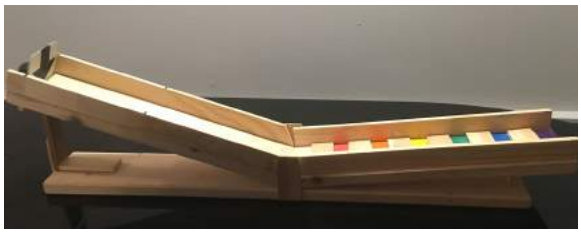

Figure 1: One of two identical ramps used in the study. A ball is launched from the down-ramp (left) and stops on one of the coloured ridges on the up-ramp (right). The apparatus can be adjusted for height, surface type, where the ball starts on the down-ramp, and ball size.

The same set of ramps were used in a video in the scaffolding phase, displayed for participants on a laptop.

Procedure

The study included a warm-up activity (uncertainty training) followed by pre-test, scaffolding, and two post-test phases. Participants were assigned to one of two conditions for the scaffolding phase: counterfactual (n = 45, M age = 8.47, 23 girls) or control (n = 43, M age = 8.44, 22 female girls). The order of all variables and variable sets were counterbalanced between participants.

Uncertainty Training. Given that some of the prompts in the intervention phase required children to acknowledge their uncertainty about an outcome, we included an uncertainty training phase to ensure children were able to recognize and acknowledge their uncertainty. All children, regardless of condition, received the same uncertainty training. Using cards with various colors and suits, the experimenter placed a pair of cards face down, and turned over one card. Before revealing the second card, she asked the participant if they could be "sure or not sure" if the face-down card was the same or different as the face-up card. Regardless of the participant's response, the experimenter instructed children that they cannot be sure if the two cards are the same, and that it is okay to answer the question in this way. The process repeated until the participants answered that they could not be sure three times.

Pre-test. The experimenter placed the two ramps next to each other, directly in front of the participant, and explained that the two ramps were similar and worked the same way. She then showed participants how to operate and adjust the ramps along two of the variables (e.g. height of ramp and size of ball). The other two variables (e.g. ramp surface and run length) were fixed and not introduced until the *post-test transfer phase*. Participants were asked to demonstrate how to manipulate the ramps. If they did not set up the ramp correctly, the experimenter showed them again. All

demonstrations were performed with one ramp, and participants were reminded that the ramps were the same.

To measure children's ability to execute CVS, the experimenter asked them to show how they would find out if one variable plays a role in how far the ball travels down the ramp (e.g., "Can you show me how you would find out if *the size of ball* matters for how far the ball goes down the ramp?"). She told participants they had one chance to set up both ramps at the same time, and then repeated the question a second time. Participants were required to set up both ramps before launching the balls down each ramp one at a time. After each ball was launched, the experimenter labeled the outcome (e.g., "Look! The ball stopped on the yellow line.") but did not compare between the two ramps.

Using the same procedure, the experimenter then asked participants to determine if a second variable mattered for how far the ball would travel down a ramp (e.g., "Can you show me how you would find out if *the height of the ramp* matters for how far the ball goes down the ramp?").

Participants who controlled the correct variable received 1 point for each question for a maximum score of 2. Participants who received a score of 2/2 at pre-test were excluded from the study (and the study was terminated at this point), because they already possessed an understanding of CVS ($n = 24$). Participants who received scores of 0 or 1 went on to the scaffolding phase.

Scaffolding. Participants in this phase watched two videos of an actor exploring the ramps and were told that they would be asked about what they saw after each video. The actor in the videos manipulated the same two variables that participants were asked to isolate during the pre-test, using the same ramps. The video started with the actor stating that she was going to find out if a variable (e.g., height of the ramp) played a role in how far the ball travelled down the ramps. The actor then proceeded to set-up the ramps and labelled the set-up as she went along (e.g., "I'm going to set Ramp 1 to high"). After she set-up both ramps, she launched the balls one at a time and labeled the outcome by stating the color the ball landed on. At the end of the video she stated which ball (on Ramp 1 or Ramp 2) travelled farther. The experimenter then paused the video so that the participants could see the outcome of both ramps at the same time. The videos were identical across conditions; the only difference was in the question prompts children were asked after.

In the *counterfactual condition*, participants were asked to imagine a change to the value of a variable (e.g., "Let's imagine that she set Ramp 1 to low. Would the ball have travelled down the ramp farther on Ramp 1, farther on Ramp 2, or you can't be sure?"). This imagined change would create a confounded (or uncontrolled) test. In the *control condition*, participants were asked to recall what had happened (e.g., "Let's imagine again what happened to the ball on Ramp 1? Did the ball travel farther on Ramp 1, farther on Ramp 2, or you can't be sure?"). Children did not receive feedback on their responses during the scaffolding phase in either condition.

In both conditions, a second video was shown highlighting the other variable (e.g., size of ball). In the counterfactual condition, the experimenter asked the participants to imagine a change to the value of this new variable (e.g., size of ball), creating another confounded test. In the control condition, the experimenter asked the participants the same question as before, but highlighted the other ramp (e.g., Ramp 2).

Post-Test Same. The experimenter removed the laptop and placed the ramps side-by-side in front of the participant. This phase was identical to the pre-test, except participants were not asked to demonstrate how the ramps worked. Responses were coded in the same way, with participants receiving a maximum score of 2.

Post-Test Transfer. The experimenter then told participants that the ramps can work in a different way. The two original variables were fixed (e.g., ramps could only be set to high, and only the big balls could be used) and two new variables were introduced (e.g., surface of the ramp and starting position for the ball). As in the pre-test, the experimenter showed participants how the new variables worked on the ramps and asked participants to demonstrate how to manipulate each new variable.

The procedure was the same as the pre-test and post-test same phases except participants were asked two new questions about each of the new variables (e.g. "Can you show me how you would find out if *the surface of the ramp*/*where the ball starts on the ramp* matters for how far the ball goes down the ramp?"). Again, participants could receive a score up to 2 across the two test questions.

In sum, participants were asked two questions each at pre-test, post-test same, and post-test transfer, and received a score between 0 and 2 for the number of controlled tests they conducted in each phase. In each counterbalancing order, the pre-test and post-test same phases were identical, whereas the post-test transfer phase used two previously unencountered variables. The experimenter live-recorded with paper-and-pencil, and later checked videos for accuracy. A second researcher coded 34% of videos, and inter-rater reliability was excellent (96.6% agreement, Fleiss' $\kappa = 0.93$, $p < .001$).

Results

We first tested whether there were differences between the two conditions at pre-test using a Chi-Square test of independence, and found no significant differences across conditions in pre-test score, $p = .206$. We also found no significant differences between genders ($U = 926$, $p = .687$) or the variable set participants received at pre-test ($U = 902$, $p = .522$), thus we do not consider these variables further.

To investigate the change in children's score (CVS score out of 2) from pre-test to *(1) post-test same* and *(2) post-test transfer*, we conducted two generalized estimating equation (GEE) analyses with multinomial distributions and cumulative logit-log link functions with condition (counterfactual or control) and age group (younger or older) as predictor variables.

For the GEE of pre-test vs. *post-test same* performance, there was a main effect of test, B = -2.56, SE = 0.56, Wald $\chi2(1) = 20.84$, $p < .001$, such that children were 12.82 times more likely to receive a higher score at *post-test same* than at pre-test, Exp(B) = 0.78, 95% CI = [0.03, 0.23]. There was also a main effect of age, B = -1.66, SE = 0.76, Wald $\chi2(1) = 4.78.$, $p = .029$, such that older children were 5.26 times more likely to receive a higher score than younger children, Exp(B) = 0.19 95% CI = [0.04, 0.84]. The main effect of condition was not significant, $p = .436$. The test phase by age category interaction was significant, B = 1.59, SE = 0.72, Wald $\chi2(1) = 4.85.$, $p = .028$, such that older children in the post-test same phase were 4.90 times more likely to receive a higher score than younger children in the post-test same phase, Exp(B) = 4.90, 95% CI = 1.19, 20.13] All other interactions were non-significant.

For the GEE of pre-test vs. *post-test transfer*, there was again a main effect of test, B = -1.59, SE = 0.51, Wald $\chi2(1) = 9.70$, $p = .002$, such that children were 4.90 times more likely to receive a higher score on the *post-test transfer* phase than the pre-test phase, Exp(B) = .204, 95% CI [0.08, 0.55]. There was also a main effect of age, B= -1.35, SE = 0.68, Wald $\chi2(1) = 3.92$, $p = .048$, such that older children were 3.85 times more likely to receive a higher score than younger children, Exp(B) = 0.26, 95% CI = [0.069, 0.987]. The main effect of condition was marginally significant, B = 1.31, SE = 0.67, Wald $\chi2(1) = 3.819$, $p = .051$. Children in the counterfactual condition were 3.71 times more likely to receive a higher score than those in the control condition, Exp(B) = 3.71, 95% CI = [1.00, 13.78]. All interactions were non-significant.

We conducted planned post-hoc comparisons to further investigate performance between groups at each test-phase using Chi-square tests of independence. Performance differed significantly between children in the counterfactual and control conditions at both *post-test same* $\chi^2(2) = 7.28$, $p = .026$ and *post-test transfer* $\chi^2(2) = 6.04$, $p = .049$. Table 1 presents the relevant proportions of children who conducted 0, 1, and 2 controlled tests in each test phase entered into the Chi-square analyses.

Table 1: Proportion of children who conducted 0, 1, or 2 controlled tests in each post-test phase (CVS Score).

		CVS Score (/2)		
Post-test	Condition	*0*	*1*	*2*
Same	Counterfactual	11.1	33.3	55.6
	Control	34.9	20.9	44.2
Transfer	Counterfactual	24.4	22.2	53.3
	Control	41.9	30.2	27.9

Finally, we considered the relation between children's responses to counterfactual prompts in the scaffolding phase and their CVS scores, although we did not make predictions about any such relation. Recall that the correct answer to the counterfactual prompts was "can't be sure", because the counterfactual intervention created a confounded test. Of the 45 children in the counterfactual condition, 13 (29%) answered "can't be sure" to both prompts, 19 (42%) answered "can't be sure" to 1/2, and 13 (29%) did not answer "can't be sure" to either prompt. Children's "can't be sure" responses did not significantly correlate with their performance on any of the CVS tests, Spearman's rho = -.121 to -.231, $p = .127$ to .430.

Discussion

We proposed that prompting children to think counterfactually during a control-of-variables task would scaffold their performance by capitalizing on their underlying causal reasoning skills. The results of this study provide initial support for this proposal. Children given counterfactual prompts showed better performance on the post-test phases than those given control prompts, though these differences were non-significant on post-test same and marginally significant on post-test transfer in the omnibus analyses. Critically, when considering condition differences alone, children in the counterfactual condition performed significantly better than those in the control condition at both post-tests. The largest proportion of control group children scored 0/2 on both post-tests, whereas the largest proportion of counterfactual group children scored 2/2, as displayed in Table 1.

Along with these condition differences, there was also an indication that the video demonstration alone improved children's ability to control variables, given that we found significant main effects of test phase, but no condition by test-phase interaction. The actor did not explicitly comment on the strategies she was using, and the demonstration was devoid of ostensive pedagogical signals (Csibra & Gergely, 2009) that were present in many previous CVS studies (Schwichow et al., 2016). Future work may consider the role of similar demonstrations and counterfactual prompts separately to identify the extent to which they may yield different benefits.

Our findings are surprising in light of previous studies, which found that children required more intensive instruction and scaffolding in order to improve, with some of these interventions even taking place over the course of several sessions (e.g., Schauble, 1996). Even with a subtle manipulation in the form of two counterfactual questions following a demonstration, children showed improvement in their ability to conduct a controlled test of a hypothesis.

Children in the counterfactual condition were able to conduct a controlled test both on the variables they had already encountered and on two new variables, with more than half of children in the counterfactual condition scoring 2/2 on both post-tests. In contrast, children in the control condition showed less evidence of transfer, with a minority of children scoring 2/2 in the post-test transfer phase.

These findings provide preliminary evidence that counterfactual prompts may be a promising pedagogical tool for supporting CVS. However, these results do not allow us to pinpoint the precise mechanism by which counterfactuals may confer this benefit. We have suggested that

counterfactuals may serve as *imagined interventions*, helping learners to connect their intuitive causal reasoning abilities to the current task. This suggestion is in line with previous work emphasizing the relation between causal and counterfactual reasoning (e.g., Gopnik & Schulz, 2007; Sloman 2005; Gopnik & Walker, 2013).

However, other work suggests that counterfactuals may have a *general* effect on reasoning by activating a "mindset" that is open to alternatives. Previous research shows that prompts to consider alternatives in the form of counterfactuals (Galinsky & Moskowitz, 2000) or multiple explanations (Hirt & Markman, 1995) have wide-reaching effects, with individuals showing generally debiased reasoning across a range of settings. Researchers studying these effects have suggested that counterfactuals activate a *mental simulation mindset* that breaks the reasoner free of a singular viewpoint or hypothesis and incites consideration of alternative, and potentially contrasting possibilities. In ongoing research, we are currently investigating whether children prompted with counterfactuals on one task (e.g., ramps) show improvement on a far-transfer task (e.g., pendulums) to better understand the potential mechanisms by which counterfactual prompts may support performance. In the present study, our counterfactual questions were about the experimental design and specifically pertained to the control-of-variables process. It is an open question whether counterfactual questions about a peripheral or irrelevant feature of the task (e.g., the color of the ball) would scaffold performance. An alternative "mindset" account would predict that counterfactuals should be beneficial regardless of their focus.

Our counterfactual prompts not only focused on the control of variables process, but also specifically invited children to imagine a *confounded test*. An alternate explanation for children's success in the counterfactual condition may therefore be that by engaging children in imagining a confounded test, our prompts led them to recognize that such tests were inconclusive and that they should avoid producing such tests themselves. However, the lack of a relation between children's "can't be sure" responses and their ability to control variables suggests that children did not need to explicitly recognize the inconclusiveness of a confounded test in order to benefit from the process of thinking counterfactually. In other words, the effect of the counterfactual prompts appears to be distinct from the specific response they elicit. This finding aligns with research on children's self-explanation showing that the *process* of generating explanations benefits children's causal reasoning, regardless of the specific explanations they produce (e.g., Walker, Lombrozo, Legare, & Gopnik, 2014).

Another possibility is that our counterfactual prompts drew children's attention to both values of the variable that was held constant (e.g., "Let's imagine that she set Ramp 1 to low" when she had set both ramps to high), whereas the control prompts did not (e.g., "Let's imagine again what happened to the ball on Ramp 1"). This may have made children more likely to consider and control the alternate variable. In a follow-up study, we have adapted our control prompt to highlight both levels of the alternate variable to investigate whether this accounts for children's better performance in the counterfactual condition.

Although we are not yet able to identify the precise mechanism by which counterfactuals confer the benefits observed, these findings connect to a wider body of results that suggest that drawing children's attention to alternatives benefits their scientific inquiry (e.g., Sodian et al, 1991; Engle & Walker, 2018). For instance, children in Sodian et al. (1991) were able to recognize a conclusive test of a hypothesis when presented with two contrasting hypotheses, and, as mentioned above, Engle and Walker (2018) found that counterfactual prompts scaffolded children's ability to detect anomalies during causal learning. These results suggest that thinking of counterfactuals and alternatives may benefit a range of scientific inquiry skills.

Conclusion

Children prompted to think counterfactually showed improvements in their ability to conduct controlled tests of a hypothesis – an ability previous studies have suggested requires direct instruction or intensive scaffolding. These results support theoretical proposals about the role of counterfactuals in scientific reasoning, and suggest that counterfactuals may have educational utility. The prompts used in the current study are short and simple, and could easily be implemented in a range of formal and informal learning contexts.

Abstract

People make decisions based on probabilistic information every day and often use inaccurate, heuristic decision rules. Although a great deal of research has investigated the developmental trajectory of accurate probability judgments, very little research has investigated how the learning process unfolds. In the current study a microgenetic experimental design was deployed to investigate the influence of feedback on children's probabilistic decision making strategies. Seven- to ten-year-old children (N = 50) first performed a computer-based task to assess the type of strategy they use in a probabilistic judgment task. Next, children receive feedback on a series of 24 trials and then perform a post-test consisting of the same computer-based strategy assessment. Findings revealed that some strategies may benefit from feedback more than others. These results suggest that children can learn about the proportional nature of probability from feedback alone and that the amount and type of feedback influence the learning process.

Keywords: probabilistic reasoning; numerical cognition

Introduction

Every day, children and adults are presented with decisions involving probabilistic information and decades of research has shown that their decisions are often influenced by heuristic biases (Kahneman, 2011; Kahneman & Tversky, 1973; Tversky & Kahneman, 1983). Even on tasks involving simple random draws in which a decision maker is asked to choose between two different options with known probabilities both children and adults have been observed using heuristic decision rules (Falk, Yudilevich-Assouline, & Elstein, 2012; O'Grady & Xu, 2019; Pacini & Epstein, 1999). Although these studies have reported a wealth of data on the factors which promote and inhibit biased decision making, and developmental research has reported a large number of experiments on the developmental trajectory of probabilistic reasoning, very little research has investigated the role of outcome feedback (i.e. the result of a random draw) on children's use of heuristics in probabilistic decision making tasks. In the current paper, a microgenetic experimental design is used to assess the influence of feedback on children's decision making strategies in a simple random draw task.

Developmental trajectory of probabilistic reasoning

Developmental research originally devised by Piaget & Inhelder (1975) studied children's choices in a 2-alternative forced-choice (2AFC) random draw task in which they are presented with two groups of marbles, each contain both red and white marbles in different amounts and are asked to choose the group that is best for getting a target color marble. Piaget and Inhelder (1955) found that young children rely on heuristic decision rules, such as 'pick the group with the greatest number of target outcomes' when making these simple probability judgments and argued that these decision biases suggest children have difficulty with part-whole reasoning, often making comparisons of parts (i.e. making a simple comparison about the number of favorable marbles in each group) without taking into account the relation between the part and the whole (i.e. calculating the proportion of favorable to total outcomes). Although decades of research led to incremental improvements in Piagetian methods in this subfield of developmental psychology (Chapman, 1975; Falk, Falk, & Levin, 1980; Fischbein, Pampu, & Mnzat, 1970), the most thorough and recent experiment conducted by Falk et al. (2012) provides the greatest insight into children's probabilistic reasoning abilities.

Falk et al. (2012) devised a 2AFC random draw task involving a series of 24 trials in which 4- to 11-year-old children were presented with a choice between two groups of marbles each containing a number of favored and unfavored marbles. Children were then asked to choose the group with the best chance of yielding their favored color marble from a single random draw. The 24 trials were designed to discern between four of the most common strategies children have been shown to use in similar tasks. These strategies are (1) 'pick the group with more favorable marbles' ('more favorable') or (2) 'pick the group with the least unfavorable marbles' ('less unfavorable') (3) 'pick the group with the largest difference between favorable and unfavorable marbles' ('greater difference') and (4) the formally correct strategy of 'pick the group with the highest proportion of favorable marbles' ('greater proportion'). Findings from a series of experiments revealed that children progress from 1-dimensional strategies in which they focus on either favorable or unfavorable outcomes (strategies 1 & 2) to more complicated, 2-dimensional strategies in which they attend to both favorable and unfavorable outcomes (strategies 3 & 4). Results revealed that children begin to use the formally correct, proportional strategy around 8 years of age.

Children's difficulties with fraction representations of rational number are notorious and the errors are so common that they are often termed the 'whole number bias' (Ni & Zhou, 2005; Siegler, 2016). This bias presents itself in several different ways across many types of tasks and is very similar to the errors children make in part-whole reasoning during 2AFC random draw tasks. For example, when children are asked to choose the greater of two fractions (say, 1/3 or 2/7) they often choose incorrectly based on comparisons of either the numerator or the denominator (in the above example, choosing 2/7 because the numbers are larger).

Teaching Children Probability Concepts

In a review of the research on statistical edcuation, Garfield & Ahlgren (1988) argue that school-age children have difficulty developing an intuitive understanding of fundamental topics in probabiltiy and statistics for three reasons. First, students have difficulty reasoning about rational number and proportions. Second, probability concepts often conflict with students' real-world experience. Finally, Garfield & Ahlgren (1988) argue that students often develop an aversion to statistics and probability because they learn about these concepts at a very abstract and formal level. Previous research has addressed several of these concerns in their attempts to improve children's understanding of probability.

In formal mathematics, probability is represented as a rational number between 0 and 1, and in the 2AFC random draw task these probabilities are computed as proportions of favorable outcomes. Several groups of researchers have attempted to teach children strategies for calculating and reasoning about probability. Fischbein & Gazit (1984) investigated the effect of teaching probability on 10-13 year olds' predictions of probabilistic outcomes using survey questions about the results of rolling two dice. Students in the experimental group received 12 lessons in which they were taught computational strategies and conceptual relationships in probability. Interestingly, the results revealed that while the experimental group outperformed the control group on computational questions (i.e. questions in which children needed to apply a specific algorithm to identify the correct answer), there was no significant difference in performance on conceptual questions (i.e. questions in which children needed to generalize a concept to a novel context). Although Fischbein & Gazit (1984) report the use of a successful intervention, it is possible that the children in the experimental group merely learned the computational algorithms for solving probability problems without changing their prior concepts about part-whole relations in probability.

Using a didactic approach, Castro (1998) taught young high-school students (14-15 year olds) formal probability. This method encouraged the teachers to incorporate student's intuitive understanding of probability into lessons by allowing students to reflect on their experiences. The experimental group demonstrated significantly more improvement from pre-test to post-test on both probability-reasoning and probability calculation tests. An analysis of the amount of children who changed their answers on similar questions from pre-test to post-test revealed that there were more students who switched their answers in the conceptual change group than in the traditional teaching method group. However, since this study included older teens who may have had experience with formal probability, it is impossible to tell if the conceptual change was a result of the teaching method alone or the interaction of prior conceptual understanding and instruction.

In an intervention study, Nunes, Bryant, Evans, Gottardis, & Terlektsi (2014) attempted to teach 10-year-old children about the importance of understanding the sample space when calculating probability. Participants in the experimental group participated in seven, 50-minute lessons on sample space and probability led by a researcher. Another condition received lessons in mathematical problem solving while a control group of children stayed in the classroom and received regular lessons from their teachers. All three groups received four assessments on understanding sample space, a pre-test, and three post-tests given at various points throughout the program. The experimental group outperformed the two control groups on all three post-tests.

Calculating probability based on proportion of outcomes in the sample space can be accomplished through the use of several cultural forms such as absolute number, ratios, fractions, proportions and percentages. The function of calculating probability is not inherent in any one of these forms and the decision to use one form over another entails a complex interaction of social and individual factors as well as aspects of the problem for which the chosen form is recruited. Nunes and colleagues (2014) argue that ratio representations may be better suited for teaching probability to 9-11 year olds because children understand ratios earlier than proportions and most probability problems are based on proportional judgments. However, since ratio judgments only provide part-part comparisons they may prime children to make correspondences between two different quantities rather than integrating the two quantities by using proportions.

Prior knowledge and instructional context

Discordant assumptions about communicative exchanges can be problematic during instruction if a teacher and a learner view the same forms as supporting different functions (Saxe, 2004). Using a quasi-experimental design, Saxe, Gearhart, & Seltzer (1999) investigated the influence of children's prior understanding of fractions and classroom practices on mathematics learning. Children were categorized as either having or not having a rudimentary part-whole understanding of fractions and classrooms were rated on a scale of alignment with reform standards. High alignment was characterized by the degree to which a teacher draws out and expands upon a student's mathematical knowledge as well as the extent to which conceptual issues are highlighted during problem solving tasks. Importantly, classrooms that espouse either self-discovery or procedural memorization would be considered low in alignment with reform policies. Results revealed that high classroom alignment with reform standards predicted greater performance on a post-test requiring a conceptual understanding of fractions and this effect was stronger for children without a rudimentary understanding of fractions. Interestingly, there was no clear relationship between classroom alignment with reform standards and performance on computational problems regardless of students' prior understanding of fractions. With low levels of alignment to reform principles students without a rudimentary understanding had no basis with which to structure their goals and may have relied on their prior conceptual understanding of integers. However, with supportive classroom environments in which teachers

seek to draw-out and build upon a learner's prior knowledge, children can more easily engage with mathematical goals and stand a better chance of learning.

These findings highlight the importance of both prior knowledge and instructional context on a child's ability to learn mathematics. Educators have long understood the importance of providing children with specific feedback based on their prior conceptual knowledge. Indeed, Saxe et al. (1999) found that fraction learning outcomes are a function of a learner's prior understanding (whole number vs rudimentary fraction understanding) and instructional context. Teachers who are able to identify a child's prior conceptual understanding of fractions can construct a learning environment that either confirms accurate conceptualization or scaffolds the learner towards a more thorough conceptualization.

Rationale for the current study

Can children learn to avoid whole number biased choices in probability tasks when they are provided with feedback about the outcomes of their choices? What features of the instructional context allow them to override their non-proportional strategies? We hypothesize that children require consistent feedback on problems which conflict with their prior knowledge and we predict that children who are provided with such feedback will be more likely to reject their incorrect strategy compared to children who are provided with a mix of conflicting and non-conflicting examples.

Methods

Participants

The current experiment was pre-registered (`http://aspredicted.org/blind.php?x=mp6gc9`) with a target sample of 80 children between the ages of 7 and 10 (20 children in each age group: 7-year-olds, 8-year-olds, 9-year-olds, and 10-year-olds), which was determined based on previous research using a similar task (Falk et al., 2012). Currently, data have been collected from N = 50 children (19 7-year-olds, Mean age = 7.5, SD = 0.26; 13 8-year-olds, Mean age = 8.45, SD = 0.23; 9 9-year-olds, Mean age = 9.28, SD = 0.2; and 9 10-year-olds, Mean age = 10.2, SD = 0.2). All fifty children participated in the first session and three children declined to participate in the follow-up session 1 week later (1 7-year-old, 1 8-year-old, and 1 10-year-old).

Material

Images depicting two gumball machines and two groups of green and purple marbles were rendered using Blender (Version 2.78) 3D animation software. Following Falk et al. (2012), each trial image was internally labeled with the trial type designators 'GGGG', 'GGGS', 'SSSG', and 'SSSS' with each letter representing the dimension of comparison and the letter itself relating the correct choice (higher probability of yielding the child's favored color marble) to the incorrect choice (lower probability of yielding the child's favored color). For each target color (i.e. green or purple), two sets of 24 images were created using the same distributions used by Falk et al. (2012) for a total of 96 images.

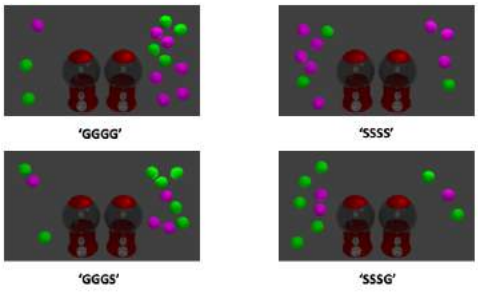

Figure 1: Example images for each of the 4 trial types. In all 4 images, the correct choice for obtaining a purple marble is located on the right side of the image.

Figure 1 presents an example image for each trial type. Note that the correct choice in the figure on the top left (labeled 'GGGG') has a greater amount of favored marbles (1st G), a greater amount of non-favored marbles (2nd G), a greater total of favored and non-favored marbles (3rd G) and a greater difference between favored and non-favored marbles (4th G). In contrast, the correct choice for the image on the top right (labeled 'SSSS') has a smaller amount of marbles in each of these categories compared to the incorrect choice. Children using a strict 'more favorable' strategy would make a correct choice on all 12 'GGGG' and 'GGGS' trials but would choose incorrectly on all 12 'SSSS' and 'SSSG' trials. A child using a strict 'less unfavorable' strategy would make a correct choice on all 12 'SSSS' and 'SSSG' trials but would choose incorrectly on all 12 'GGGG' and 'GGGS' trials. Children using a strict, 'greater difference' would make a correct choice on all 12 'GGGG' and 'SSSG' trials but would choose incorrectly on all 12 'SSSS' and 'GGGS' trials. Finally, a child using the formally correct proportional strategy would choose correctly on all 24 trials.

Procedure

Children were seated approximately 60 cm away from a MacBook Pro laptop (OSX; Screen resolution 1280 x 800) and told they would play a game in which they would try to collect green or purple marbles from one of two different gumball machines. The task consisted of a self-paced game automated using the psychophysics toolbox written for the MatLab programming language (Brainard, 1997; Kleiner, Brainard, & Pelli, 2007; Pelli, 1997). In order to maintain an average testing time of 20 minutes, the experiment was split into 2 testing sessions spaced 1 week apart. Children completed the *assessment phase* during session 1 and then completed the *conflict phase* and *post-test phase* during session 2.

Assessment Phase During the first testing session, the experimenter explained the task and children were prompted to choose their favorite of the two colors, either purple or green.

For each of the 24 images, the computer presented the image at random along with 4 counting prompts, one for each group of marbles (i.e. "How many (green/purple) marbles are on this side (left/right)?"). The child responded by pressing the appropriate number key on the keyboard. An error message was presented if the child chose the wrong number and the game did not progress until the child pressed the correct number key. Counting prompts for each color and side were randomized for each image. Once children completed the counting prompts, they were prompted with the question "Which would you pick to get a (green/purple) marble?". Importantly, the position of the marbles on the screen were randomized to prevent children from choosing based on the positions of their favorite color marble. However, in order to ensure that children did not rely on the placement of the marbles on the screen they were told to "Pretend that the marbles will go into the machines and that the machines will be shaken up so you don't know what's going to come out next."

Following the methods outlined by Falk et al. (2012), the MatLab program discerned which strategy the child used based on their performance on each of the four trial types. After children completed the *assessment phase*, the MatLab program calculated point scores for each strategy based on the choices that the child made. Whichever strategy had the highest point score was deemed to be that child's strategy. Point scores could range from 0 to 24 with 0 indicating no strategy-consistent responses and 24 indicating perfect strategy use. Participants using the 'more favorable' strategy provided about 21 (M = 21.6; SD = 3.5) out of 24 strategy-consistent responses, while those using the 'less unfavorable' strategy provided 16 (M = 16; SD = 1.79) out of 24 strategy-consistent responses, participants using the 'greater difference' strategy provided 20 (M = 20.2; SD = 20.2) out of 24 strategy-consistent responses, and participants using the 'greater proportion' strategy provided 19 (M = 19.78; SD = 19.78) out of 24 strategy-consistent responses.

Conflict Phase Children were semi-randomly assigned to one of two different conditions ensuring that an equal number of children using each strategy were assigned to both conditions. In the 'half-conflict' condition, children viewed all 24 trials, 12 of which conflicted with the child's strategy and 12 of which did not conflict. Children in the 'high-conflict' condition viewed 24 trials that conflicted with their strategy.

In the 'high conflict' condition, feedback trials were assigned as follows. Children designated as using the 'more favorable' strategy viewed 12 'SSSS' trials and 12 'SSSG' trials. Children using the 'less favorable' strategy viewed 12 'GGGG' trials and 12 'GGGS' trials. A child using the 'greater difference' strategy viewed 12 'SSSS' trials and 12 'GGGS' trials while children using the proportional strategy were simply assigned to the 'half-conflict' condition as none of the trials conflicted with their strategy. In all conditions and for all trials, children received feedback in the form of either a favored or unfavored color marble returned in the dispenser of the machine they chose. Importantly, all feedback was provided deterministically, meaning that if a child chose strictly according to their non-proportional strategy in the 'high-conflict' condition, they would receive 24 unfavored marbles and a child in the 'half-conflict' condition would receive 12 favored and 12 unfavored marbles. Children in the 'half-conflict' condition received a mix of confirmatory and dis-confirmatory feedback with respect to their strategy while children in the 'high-conflict' condition received only dis-confirmatory feedback.

Post-test phase After completing the *conflict phase*, each child received the same 24 trials they viewed in the *assessment phase* one week prior in a randomized order. Importantly, the *post-test phase* is an immediate post-test because it occurred directly following the *conflict phase*.

Results

The results of each phase of the experiment are reported separately below along with a brief discussion section. For all three phases, analyses consisted of comparisons of Generalized Linear Regression Models with Mixed effects (GLMMs) using the lme4 package written for the R statistical programming language (Bates, Maechler, Bolker, & Walker, 2015). All models predicted the binary response variable while holding participant ID as a random effect. Nested models were compared using Chi Squared tests for model fits while non-nested models were compared using the Akaike Information Criterion (AIC), a measure of model fit in which models with smaller AICs are preferred over models with higher AICs. For all three phases of the experiment, modeling results revealed no influence of participant gender, favored color, on performance. Model coefficients for GLMMs are reported as log-odds, that is, the log of the odds ratio of correct to incorrect responses.

Assessment Phase Results

In order to investigate the influence of age on strategy use we used a Chi Squared test to assess the independence of age group and strategy. Results of the χ^2 test revealed that older children were significantly more likely to use the correct proportional strategy ($\chi^2(9, n = 50) = 18.11$, $p = .034$). Figure 2 presents the proportions of children using each strategy by age. Note that the two younger age groups (7-year-olds and 8-year-olds) are predominantly relying on the, 'more favorable' strategy whereas children in the two older age groups (9-year-olds and 10-year-olds) have a more equal spread across the four different strategies.

Comparisons of GLMMs revealed that the model with the best fit to the assessment phase data was the model predicting performance from strategy alone ($AIC_{Strategy}$ =1562.96). This model outperformed the null model (AIC_{null} = 1613.55; χ^2= 56.6; df = 3; $p < .001$), as well as the model predicting performance from age (AIC_{Age} =1609.59). More complex models predicting performance from age and strategy ($AIC_{Strat+Age}$ = 1561.79; χ^2= 3.17; df = 1; p = .07) and the interaction of age and strategy ($AIC_{Strat*Age}$ = 1564.95; χ^2= 6.01; df =

4; p = .20) did not perform better than the model for strategy alone. Thus, the simpler model is preferred since it can predict the same amount of variance with fewer model parameters. There was no effect of trial number indicating that children's performance did not improve with time during the *assessment phase*.

Inspection of model coefficients reveals that the log-odds of a correct reponse increased for children using the 'greater difference' ($\beta_{>F-U}$ = 0.53; SE = 0.2; 95% CI [0.13, 0.93]), and 'less unfavorable' strategies ($\beta_{<U}$ = 0.17; SE = 0.18; 95% CI [-0.19, 0.53]), as well as those using formally correct proportional strategy ($\beta_{>F/F+U}$ = 1.49; SE = 0.19; 95% CI [1.11, 1.87]) compared to children using the 'more favorable' ($\beta_{>F(Intercept)}$ = 4.003^{-16}; SE = 0.07; 95% CI [-0.09, 0.2]). However, only the coefficients for 'greater difference' and 'greater proportion' strategies reached statistical significance (Wald test: 'greater difference': $p < .01$; 'greater proportion': $p < .001$).

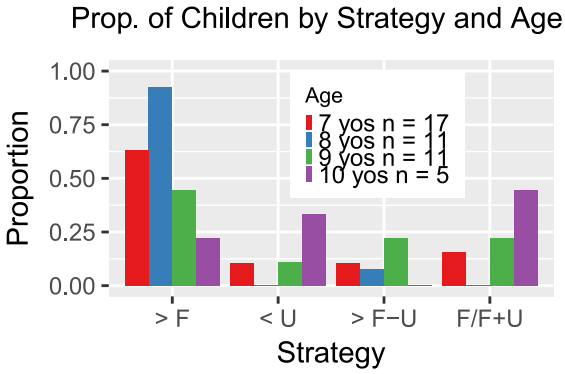

Figure 2: Proportion of children using each strategy by age group. Strategies are designated as follows: '> F': more favorable; < U: less unfavorable ; > F-U: greater difference; > F/F+U: greater proportion.

Assessment Phase Discussion

Results of the current study converge with those of previous reports indicating that children's use of the correct proportional strategy improves with age (Falk et al., 2012; O'Grady & Xu, 2018). Importantly, results of the GLMM comparisons revealed an effect of strategy on performance indicating that children who attended to the number both of favorable and unfavorable marbles in each choice performed better than children who made their choices based on one single dimension (i.e. choosing based solely on the number of favorable or unfavorable marbles).

Conflict Phase Results

Nine children were found to be using the formally correct proportional strategy during the assessment phase the previous week. Since there are no trials that conflict with this strategy, data from these children were excluded from the conflict phase analyses resulting in a sample size of N = 38. Comparisons of GLMMs for this subsample revealed that the model with the best fit to the data predicted performance from the conflict condition and the trial number as well as the interaction between the two variables ($AIC_{Condition*Trial}$ =1143.09). This model outperformed the null model (AIC_{null} = 1613.55; χ^2= 29.74; df = 3; $p < .001$) as well as the simpler models predicting performance from conflict condition ($AIC_{Condition}$ = 1158.39; χ^2= 19.3; df = 2; $p < .001$) and trial number alone (AIC_{Trial} = 1162.96; χ^2= 23.87; df = 2; $p < .001$) and the more complex model accounting for both the conflict condition and trial number without an interaction ($AIC_{Condition+Trial}$ = 1154.51; χ^2= 13.43; df = 1; $p < .001$). There were no significant effects of the three non-proportional strategies, nor was there an interaction between conflict condition.

Inspection of the model coefficients revealed that the log-odds of a correct decreased for children in the 'high-conflict' condition ($\beta_{High-Conflict}$ = -0.13; SE = 0.35; 95% CI [-0.81, 0.55]) compared to children in the 'half-conflict' condition ($\beta_{Half-Conflict}$ = 0.32; SE = 0.25; 95% CI [-0.18, 0.81]), which is not surprising considering that all of the trials in the 'high-conflict' condition conflicted with the children's strategies whereas only 12 of the 24 trials in the 'half-conflict' condition conflicted with the children's strategies. While the model coefficient for trial number was slightly negative (β_{Trial} = -0.01; SE = 0.01; 95% CI [-0.04, 0.02]) indicating a decrease in the log-odds of a correct response, the interaction between trial number and condition revealed that in the 'high-conflict' condition, trial number had a positive effect on the log-odds ($\beta_{Trial*High-Conflict}$ = 0.08; SE = 0.02; 95% CI [0.04, 0.12]). The interaction between trial order and the 'high-conflict' condition was the only model coefficient to reach statistical significance (Wald test: $p < .001$) indicating that performance improved over time in the 'high-conflict' condition suggesting that children in this condition may have learned from feedback on earlier trials.

Conflict Phase Discussion

Results revealed that both conflict condition and trial order had an effect on performance. Importantly, the interaction between conflict condition and trial number produced the greatest positive effect on performance while the coefficient for the 'high-conflict' condition alone had a negative effect on performance. This set of results suggests that children in the 'high-conflict' condition began by choosing according to their strategy but then switched to another strategy after several trials in which they received negative feedback.

Post-Test Phase Results

Of the 9 children who used the correct proportional strategy during the *assessment phase* only one child (a 10-year-old) did not continue to use the correct proportional strategy. Interestingly, this child used the 'more favorable' strategy and reported that they switched to a simpler strategy because "the game was boring and I wanted to finish it faster" suggesting that this child understood the time-accuracy tradeoff among

the various potential strategies. Table 1 presents the number of children using each of strategy in the *post-test phase* ('Post-test' column) based on the child's *assessment phase* strategy ('Assessment' column) and condition ('half-conflict' and 'high-conflict' columns).

Assessment	Post-test	Half-Conflict	High-Conflict
>F	>F	9	3
>F	<U	1	7
>F	>F-U	1	1
>F	>F/F+U	2	4
<U	>F	2	1
<U	<U	0	1
<U	>F-U	0	0
<U	>F/F+U	0	1
>F-U	>F	0	0
>F-U	<U	0	0
>F-U	>F-U	2	0
>F-U	>F/F+U	0	3

Table 1: This table presents the number of children using each strategy listed in the Post-test column during the post-test phase after using the strategy in the Assessment column during the assessment phase.

Comparisons of GLMMs revealed that the model with the best fit to the data predicted *post-test phase* performance based on the interaction between conflict condition and *assessment phase* strategy ($AIC_{Condition*Strategy}$ =1182.6). This model outperformed the null model (AIC_{null} = 1613.55; χ^2= 19.41; df = 5; $p < .001$), the models for conflict condition alone ($AIC_{Condition}$ = 1189.82; χ^2= 15.22; df = 4; $p < .001$) and *assessment phase* strategy alone ($AIC_{Strategy}$ = 1188.48; χ^2= 11.88; df = 3; p = .01) as well as the model for conflict condition and *assessment phase* without any interactions ($AIC_{Condition+Strategy}$ = 1185.81; χ^2= 7.21; df = 2; p = .03).

Inspection of model coefficients revealed that the only model coefficient to reach statistical significance was the interaction between 'greater difference' strategy and the 'high-conflict' condition which increased the log-odds of a correct reponse ($\beta'_{>F-U'*High-Conflict}$ = 1.74; SE = 0.65; 95% CI [0.46, 3.01]; Wald test: $p < 0.01$) compared to the children using the 'more favorable' strategy in the 'half-conflict' condition ($\beta_{Intercept}$ = 0.05; SE = 0.35; 95% CI [-0.64, 0.73]). All remaining coefficients did not reach statistical significance. Figure 3 presents the proportion of correct responses by conflict condition and *assessment phase* strategy.

Post-Test Phase Discussion

The interaction between conflict condition and *assessment phase* strategy indicates that children using the 'greater difference' strategy benefited more from the 'high-conflict' condition compared to children using the other 2 strategies. Although these findings are promising, there were only three children using the 'greater difference' and three children using the 'less unfavorable' assigned to the 'high-conflict' condition thus more data will be needed to make any firm conclusions. However, it is interesting to view the differences between the 'half-conflict' and 'high-conflict' condition for children using the 'more favorable' strategy. Note from table 1 that only 3 of the 15 children using this strategy in the 'high-conflict' condition (20%) continued using their strategy after the feedback condition while 9 of the 13 assigned to the 'half-conflict' condition (69.2%) continued to use the strategy.

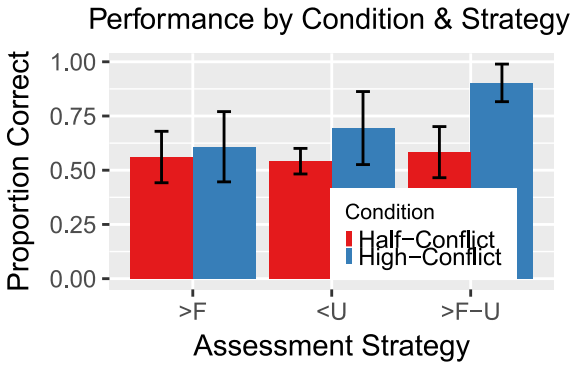

Figure 3: Proportion of correct responses in the post-test phase by conflict condition and assessment phase strategy. Error bars indicate standard deviation.

General Discussion

The current findings provide three important insights into the development of proportional reasoning in probability judgments. First, during the *assessment phase*, children using the correct proportional strategy performed better than children using non-proportional strategies and there was no effect of trial order indicating that children relied on the same strategy throughout the task. These findings provide an important replication of previous research (Falk et al., 2012; O'Grady & Xu, 2018). Second, during the *conflict phase*, results revealed an interaction between trial order and conflict condition indicating that children in the 'high-conflict' condition performed better on later trials compared to earlier trials while this effect was not found in the 'half-conflict' condition. Previous research investigating the influence of feedback in similar decision making tasks have observed the effect of feedback on a single trial (Falk et al., 2012) or presented feedback on a limited number of trials (O'Grady & Xu, 2018). In contrast, the current approach allows for the observation of a comprehensive set of trials allowing for a more thorough understanding of how feedback influences strategy change. Finally, results from the *post-test phase* revealed that while children in the 'high-conflict' condition were more likely to abandon their strategy, children using the 'greater difference' strategy seemed to have gained the most from this feedback. Although more data need to be collected, these preliminary results suggest that strategy-specific feedback can help children overcome 'whole number bias' in probability tasks.

Our findings shed new light on how children learn about probability. In the 'half-conflict' condition, we attempted to mimic the experience a child would gain from actively exploring the environment. In contrast, the 'high-conflict' condition was meant to provide a learning context tailored to the child's prior understanding of proportional relations in probability.

Constructivist theories of cognitive development highlight the interaction between a learner's prior knowledge and new information gained through their own active exploration as well as through socio-cultural processes like education (Piaget & Inhelder, 1975; Vygotsky, 1962). By assessing the child's prior understanding and then presenting examples which conflict with that understanding, the computer program in the 'high-conlfict' condition is acting much like a constructivist teacher, identifying the learner's prior knowledge, providing them with conflicting evidence, and allowing the child to construct a new conceptual understanding.

Why do children benefit from feedback in the 'high-conflict' condition but not from the feedback on the 12 conflicting trials in the 'half-conflict' condition? Children understand the uncertain nature of probability, that is, they understand that they may receieve their non-favored marble even though they chose the 'best' option for getting their favorite color. In the 'half-conflict' condition this prior understanding of uncertainty allows children to continue to believe their inaccurate strategy is correct because the negative feedback can be chalked up to chance. However, children in the 'high-conflict' condition are forced to reconcile their inacurate strategy with the evidence at hand. Thus they must reject their prior conceptualization of probability and construct a more accurate representation. Although the current evidence suggests that children in the 'high-conflict' condition reject their prior conceptualization of probability, future research will be necessary to uncover the new representations that children construct as well as the process through which this transition ocurrs.

Abstract

This study investigated direct and indirect effects of executive functions (EF) on reading comprehension in 87 adolescents (*mean age* = 14.0 years, *SD* = 1.5). The operation span task was used to measure the *updating* aspect of working memory, the plus-minus task to measure *task-switching*, and the numerical Stroop task to measure *inhibitory control*. Literacy skills tasks assessed nonword decoding, text recall/inference, and passage comprehension. Regression models indicated that EF measures accounted for significant variance in literacy skills after controlling for age and fluid intelligence. Working memory was associated with passage comprehension, task-switching with nonword decoding, and inhibitory control with nonword decoding as well as text recall/inference. Parallel mediation models tested for indirect effects of EF constructs via decoding and text recall/inference. Working memory showed direct and indirect effects on passage comprehension, the latter mediated by text recall/inference. Task-switching was associated with decoding, but its relation to passage comprehension was not significant. Inhibitory control showed indirect effects on passage comprehension via decoding and text recall/inference. Results indicate overlapping but distinct contributions of EF to literacy skills.

Keywords: reading comprehension, literacy skills, decoding, text recall/inference, executive functions, working memory, task-switching, inhibitory control

Introduction

Reading comprehension is an active process that involves weaving together information contained within a text to construct a coherent, accurate representation of its meaning (Kintsch, 1994). Various theoretical models have proposed that reading comprehension relies on the interplay of literacy subskills, including *decoding* (i.e., mapping orthographic units onto phonological units), *recall* (i.e., activation of previously encountered information), and *inference* (i.e., drawing conclusions to make sense of information). These subskills, in turn, rely on sustained attention and other manifestations of executive functions (EF). The goal of the current study was to explore direct and indirect associations between EF, literacy subskills, and reading comprehension. Our purpose was to shed light on sources of individual differences in reading ability, which in turn inform theoretical models of reading.

The *simple view of reading* identifies decoding and linguistic comprehension as two critical skills supporting readers in constructing meaning from text (Gough & Tunmer, 1986; Hoover & Gough, 1990). Decoding involves the utilization of spelling-to-sound (grapheme-to-phoneme) rules to translate printed text into spoken language. Through decoding, readers are able to sound out words quickly and accurately, and thus gain fluency in recognizing letters in words and words in text.

The *dual route model* (Coltheart, 2006) further distinguishes the processes involved in decoding words. According to this model, word reading occurs either through a lexical route, which involves accessing lexical representations through familiar spelling patterns, or through a non-lexical (phonological) route, which utilizes knowledge of letter-sound associations (i.e., phoneme-to-grapheme correspondence rules) to sound out words. Although the two routes are thought to be separable, readers utilize both routes in parallel, which may place considerable demands on EF.

In addition to decoding, models of the development of reading emphasize the importance of text recall and inference skills (Cain, Oakhill, & Lemmon, 2004; García & Cain, 2014). The *construction-integration model* outlines the process by which readers construct meaning from text (Kintsch & Mangalath, 2011): Readers achieve coherence by organizing information across sentences and linking it with broader contextual and background knowledge (Graesser, Singer, & Trabasso, 1994; Kintsch & Mangalath, 2011). Text representations may encode information verbatim or may encode the gist (Reyna, Corbin, Weldon, & Brainerd, 2016). In constructing such representations, readers rely on recall and inferential processes that bridge information (e.g., to resolve ambiguities, identify pronominal referents, establish causal relations), bring together verbatim and gist representations, and subsequently validate inferences against general knowledge (Singer, Harkness, & Stewart, 1997). Such operations are demanding of cognitive resources, especially working memory (Peng et al., 2018).

EF and the Development of Literacy Skills

EF broadly refers to a constellation of cognitive skills thought to be essential in the planning, monitoring, and control of cognitive processes. According to the unity and diversity framework, EF has three main components: working memory (also referred to as updating), task-switching, and inhibitory control (Miyake et al., 2000). The current study focused on individual differences in these three EF components and how they each influence decoding, text

recall/inference, and reading comprehension in adolescents. As children become more fluent readers capable of recognizing familiar words with automaticity, less cognitive effort needs to be exerted to decode text, thus freeing up cognitive resources to better comprehend and critically understand the meaning behind the text (Kuhn et al., 2010; LaBerge & Samuels, 1974).

Working memory involves maintaining and/or updating information in response to task demands (Baddeley, 2012). As shown in a recent meta-analysis (Follmer, 2018), working memory appears to have a moderate positive association with reading comprehension (r = .38, 95% CI [.34 : .43]). It is less clear whether working memory bears an equally strong relation to decoding skill. In a study with 7- to 8-year-olds, Oakhill, Cain, and Bryant (2003) found that measures of working memory, text integration, and metacognitive monitoring accounted for individual differences in reading comprehension, whereas performance on phoneme deletion, a phonological awareness task, explained variance in word reading. Their findings suggest that working memory may have a limited association with decoding, and a more direct association with reading comprehension.

Task-switching, or the ability to shift between different conceptual representations and rule sets, supports a wide variety of academic tasks including reading (Best, Miller, & Jones, 2009). Meta-analyses have reported a significant, albeit weak, association (r = .21, 95% CI [.11 : .31]) between task-switching and reading achievement in children (Yeniad, Malda, Mesman, van Ijzendoorn, & Pieper, 2013) and a moderate correlation (r = .39, 95% CI [.20 : .56]) between task-switching and reading comprehension in participants ranging from age 6 years to adults (Follmer, 2018). In a study involving 1st and 2nd graders, Cartwright et al. (2017) found that variation in reading comprehension was associated with performance on a color-shape cognitive flexibility task (a measure of task-switching), even after accounting for decoding ability. To date, few studies have examined direct associations between decoding and task-switching, though there is some evidence of a significant, albeit weak, association (Kieffer, Vukovic, & Berry, 2013).

To construct accurate text representations, readers also need to suppress competing sources of information and interpretations that may be concurrently activated (Gernsbacher & Faust, 1991). The mechanism of suppression is thought to stem from inhibitory control processes. An association between reading comprehension and inhibitory control has been reported in various studies with children (e.g., Kieffer et al., 2013), although a recent meta-analysis (Follmer, 2018), spanning ages from 6 years to adults, reported that the association between reading comprehension and inhibitory control was relatively weak (r = .21, 95% CI [.13 : .30]). The strength of this association in decoding is not well established.

Control Variables: Fluid Intelligence and Age

Over childhood and adolescence, reading ability typically improves. This age-related trend likely stems from accumulated experience with oral and written language in the context of formal education (Stanovich, 1986), as well as maturation of linguistic and cognitive abilities, such as improved lexical access (Logan, Schatschneider, & Wagner, 2011) and EF (Christopher et al., 2012). Prior research also suggests that fluid intelligence, i.e., the ability to solve novel reasoning problems, may correlate with specific EF components (Brydges, Reid, Fox, & Anderson, 2012), as well as early literacy skills (Blair & Razza, 2007). However, other studies suggest that individual differences in EF, most notably in working memory, largely account for the contribution of fluid intelligence to literacy skills in children and adolescents (Alloway & Alloway, 2010). In addition, not all EF components appear to be equally correlated with measures of fluid intelligence. Some prior research has reported a strong association between fluid intelligence and working memory (Unsworth, Fukuda, Awh, & Vogel, 2014), but not between fluid intelligence and task-switching or inhibitory control (Friedman et al., 2006). Taken together, previous research suggests the need to control for age and fluid intelligence in efforts to elucidate the unique contribution of EF components to reading skills, including decoding, text recall/inference, and reading comprehension.

Research Objectives

The current study used a battery of assessments to explore relations between components of EF (working memory, task-switching, inhibitory control) and literacy skills (decoding, text recall/inference, and passage comprehension). First, we sought to determine the extent to which the three components of EF were uniquely and directly associated with each literacy skill after controlling for other factors known to be related to reading ability (i.e., fluid intelligence and age). Second, we examined indirect associations between each EF component in relation to passage comprehension as mediated by nonword decoding and text recall/inference. We hypothesized that: (1) some aspects of EF would account for variation in the reading subskills of nonword decoding and text recall/inference; (2) some aspects of EF would account for variance in reading comprehension; and that (3) indirect associations between aspects of EF and reading comprehension would emerge by way of the reading subskills of nonword decoding and text recall/inference.

Method

Participants

Teachers from partnering schools (two middle schools and two high schools in New York City) brought their classes to a university research lab where their students were invited to participate in various computer-based studies including the current study. Only students whose parents had provided written consent were eligible to participate. The sample comprised of 87 students in grades 6 to 12 (49 females, 35 males, and 3 who did not disclose gender), ranging in age from 12 to 17 years (*mean* = 14.0, *SD* = 1.5).

Tasks and Measures

Working Memory. *The operation span task*, a complex span measure shown to correlate with moderately challenging to difficult arithmetic and reading tasks (Unsworth, Heitz, Schrock, & Engle, 2005), was used to assess working memory. Reliability on operation span tasks has been found to range between .70 to .80, depending on scoring methods (Conway et al., 2005), or approximately .77 using split-half reliability coefficient alphas (Kane et al., 2004). In the task used here, participants were instructed to perform simple arithmetic operations (e.g., (3 x 4) + 11 = ?) and indicate whether an answer was correct or incorrect. Between each arithmetic problem, participants were shown a letter to remember. The task presented three blocks of trials, with each trial consisting of an arithmetic problem followed by a letter. At the end of each block, the participant was asked to recall the letters in that block in the order presented. As an index of working memory, we calculated the proportion of correctly ordered letters across the three blocks of trials.

Task-switching. *The plus-minus task* was given as a measure of task-switching (Miyake et al., 2000); reliability of scores on this task has been estimated as approximately .60 using split-half reliability (Del Missier, Mäntylä, & Bruine de Bruin, 2010). In our version of the task, participants were shown three lists of 30 two-digit numbers and asked to perform numerical computations as quickly as possible on each number in the list. For List 1, participants were instructed to add 3 to each two-digit number; for List 2, they were instructed to subtract 3 from each number; for List 3, they were instructed to alternate between adding or subtracting 3 from each number. Standardized mix cost scores (z-scores) were used as an index of task-switching, based on prior studies (e.g., Miyake et al., 2000).

Inhibitory Control. We administered a shortened version of the *numerical Stroop task* (McVay & Kane, 2012) as a measure of inhibitory control. Reliability estimates of the numerical Stroop task indicate sufficient reliability **(**Cronbach α = .71; McVay & Kane, 2012). Our numerical Stroop task presented three blocks of trials in which participants were asked to identify the number of figures shown in an image on the computer screen. In Block 1 (five trials), the participant was shown a series of Xs (ranging from 1 to 9) and instructed to indicate the number of Xs presented (e.g., 5 in response to X X X X X). In Block 2 (five trials), they were shown a series consisting of a repeated digit (ranging from 1 to 9), with the length of the series also varying between 1 and 9 and consistent with the number of digits present (e.g., 4 4 4 4). In Block 3 (five trials), the digit and the number of digits in the series was never the same (e.g., 5 5 5) with the participant instructed to indicate the number of digits while ignoring the digit value. We calculated the number of correct responses in Block 3 as an index of inhibitory control.

Decoding Ability. We used a *nonword decoding task* to assess participants' ability to apply knowledge of grapheme-phoneme correspondences to pronounce letter strings. The nonword decoding task was based on an orally administered task, previously developed for research purposes (Hogan, Catts, & Little, 2005). It used five nonwords that followed phonotactic constraints of standard American English: *bos*, *bune*, *cim*, *gep*, *phoncher*. Participants were shown each nonword along with five options for a phonetically equivalent alternate spelling, with instructions stating, "Select the spelling that most closely matches the pronunciation of the word provided." For the item where the target nonword was *bos*, options included *bose, boz, doz, pose*, and *doze* (correct response is *boz*). Scores were calculated as the proportion of items answered correctly.

Text Recall and Inference. The *component reading processes task* is a multicomponent assessment of the ability to integrate knowledge while comprehending text (Hannon & Daneman, 2001). We used a modified computerized version that assessed participants' ability to recall information and make inferences across statements. Participants were given two three-sentence paragraphs describing relations between three nonwords (nouns), with each sentence relating a pair of nonwords (e.g., *A RILI resembles a DARF but is slower and larger.*) and appearing on a separate line. Participants read the first paragraph and answered four questions, then read the second paragraph and answered four additional questions. Participants were given up to 40 seconds to read each paragraph before being prompted with a set of questions that were presented without the paragraph in view.

Subscores (proportions of correct responses) calculated for each question type (i.e., recall and inference) were highly correlated, $r_p(85) = .49$, $p < .001$, after controlling for age. Subsequently, scores for text recall/inference were computed as the average between the two subscores.

Passage Comprehension. We administered a practice test from the New York State 12th grade English Language Arts Regents Exam (NYSED, 2012). The test presented two passages (one expository, one narrative) of equivalent length (i.e., 38 and 41 sentences; 551 and 559 words). Each passage had an accompanying 7-item multiple-choice test, with four response options per item. Accuracy (percentage correct) was used as the measure of reading passage comprehension.

Fluid Intelligence. A set of *Raven's progressive matrices* (Raven, 2000) was used to assess nonverbal fluid intelligence. The task consisted of five incomplete visual matrices, each with 5 to 8 possible options from which to choose a pattern to complete the matrix. The task has been shown to have robust indicators of reliability, with a test-retest Pearson correlation coefficient of .93 (Burke, 1972). Scores were computed as the proportion of correct responses.

Background Variables. A demographics questionnaire was administered following the research tasks. It included questions about the participant's gender, age, and first language learned (coded as English or not English). These variables were included as possible control variables in preliminary regression models predicting literacy skills.

Procedure

Upon arrival to the lab, students were provided with information about the study. After assenting to participate

they were seated at computer stations to complete the computer-based tasks, administered via Qualtrics software. Students completed the reading passage comprehension test either before or after the computer-based tasks; this was randomized across participants.

Results

Table 1 presents descriptive statistics for the assessments of literacy skills and EF tasks.

Table 1. Descriptive statistics (*N*=87).

Measure	*M* (*SD*)
Raven's Progressive Matrices	61.6% (18.1%)
Executive Functions	
Operation Span Average	47.4% (28.4%)
Plus-Minus Mix Cost (*z*)	0.00 (1.00)
Numerical Stroop	48.5% (38.7%)
Literacy Skills	
Nonword Decoding	52.4% (28.4%)
Text Recall/Inference	52.7% (22.6%)
Reading Passage Comprehension	68.4 % (20.9%)

Preliminary Correlational Analyses

We examined partial correlations (controlling for age) across measures of literacy skills. After adjustment for multiple comparisons (Bonferroni-controlled $\alpha = .0167$), significant correlations were observed between the scores on the passage comprehension test and both nonword decoding, $r_p(85) = .37$, $p < .001$, and text recall/inference, $r_p(85) = .44$, $p < .001$. Nonword decoding and recall/inference were not significantly associated, $r_p(85) = .19$, $p = .084$.

We also examined partial correlations (controlling for age) between measures of EF (operation span for working memory, mix costs on the plus-minus task for task-switching, and numerical Stroop for inhibitory control) and fluid intelligence (Raven's progressive matrices). After adjustment for multiple comparisons (Bonferroni-corrected $\alpha = .0083$), none of the partial correlations were statistically significant, see Table 2. There was a trend towards an association between fluid intelligence and working memory, $r_p(85) = .27$, $p = .012$.

Table 2. *Descriptive Statistics and Age-controlled Partial Correlations for EF Variables (N=87)*

	WM	TS	IC
Working Memory			
Task-switching	–.03		
Inhibitory Control	–.02	.07	
Fluid Intelligence	.27	–.12	.18

WM: Operation Span, TS: Plus-Minus Mix Cost (z-score), IC: Numerical Stroop

Regression Analyses of Reading Subskills

Regression models were used to assess whether EF components accounted for variation in literacy skills.

Nonword Decoding. The overall model was significant, $F(6, 80) = 6.59$, $p < .001$, $R^2 = 33$. Task-switching and inhibitory control were significantly associated with nonword decoding, see Table 3.

Table 3. Multiple regression with nonword decoding as the outcome measure (*N*=87).

Variable	*β*	*SE*	*t*	*p*
Age	.18	.02	†1.68	.098
Fluid Intelligence	.19	.16	†1.81	.074
Recall-Inference	.00	.15	–.03	.974
Working Memory	.08	.11	.73	.468
Task-switching	.27	.03	**2.87	.005
Inhibitory Control	.31	.08	**3.06	.003

***$p < .001$, **$p < .01$, *$p < .05$, †$p < .10$

Component Reading Processes: Recall/Inference. The overall model was significant, $F(6, 80) = 8.81$, $p < .001$, $R^2 = .40$. Age, working memory, and inhibitory were significantly associated with text recall/inference, see Table 4.

Table 4. Multiple regression with text recall/inference as the outcome measure (*N*=87).

Variable	*β*	*SE*	*t*	*p*
Age	.32	.01	**3.22	.002
Fluid Intelligence	.13	.12	1.32	.190
Nonword Decoding	.00	.08	–.03	.974
Working Memory	.21	.08	*2.14	.035
Task-switching	.07	.02	.70	.483
Inhibitory Control	.27	.06	**2.78	.007

***$p < .001$, **$p < .01$, *$p < .05$

Reading Passage Comprehension. The overall model was significant, $F(7, 79) = 10.34$, $p < .001$, $R^2 = .48$. Fluid intelligence, nonword decoding, text recall/inference, and working memory were significantly associated with scores on the reading passage comprehension test, see Table 5.

Table 5. Multiple regression with reading passage comprehension as the outcome measure (*N*=87).

Variable	*β*	*SE*	*t*	*p*
Age	–.03	.01	–.29	.776
Fluid Intelligence	.21	.11	*2.25	.027
Nonword Decoding	.21	.07	*2.11	.038
Recall-Inference	.29	.10	**2.77	.007

Task-switching	.08	.02	.98	.332
Inhibitory Control	–.00	.05	–.02	.987

***$p < .001$, **$p < .01$, *$p < .05$

Mediation Analyses

Mediation analyses were run to test whether EF components had indirect associations with reading passage comprehension via nonword or text recall/inference skills. Constraints due to the number of observations and free parameters prevented a single model from being analyzed lest it be under-identified (Kline, 2015). Thus, three separate

parallel mediation models tested for direct and indirect effects of EF measures on reading passage comprehension; see Figure 1 for the analytic model. Note that in the models for each EF construct, age and fluid intelligence were added as covariates associated with passage comprehension.

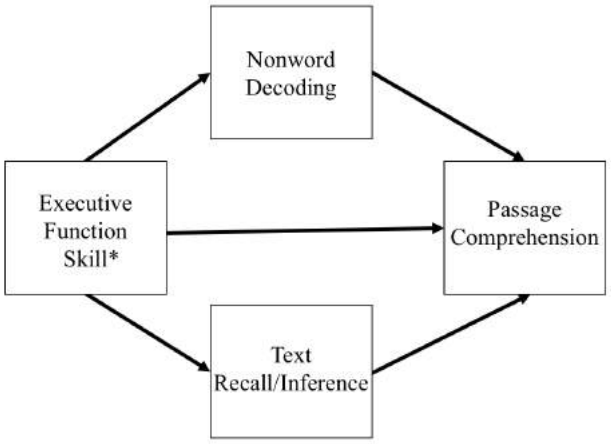

Figure 1. Parallel mediation model showing a direct path from EF skill to reading passage comprehension, and indirect paths through nonword decoding and text recall/inference. Each EF skill was entered as a predictor into one of three separate models with this form.

Indirect Effects of Working Memory. The first mediation analysis confirmed a statistically significant association between working memory and reading passage comprehension, total effect: β = .46, 95% CI [.45, .48], *SE* = .07, z = 4.71, p < .001; direct effect: β = .29, 95% CI [.28, .31], *SE* = .07, z = 2.97, p = .003. Tests of indirect effects indicated significant mediation via text recall/inference, β = .12, 95% CI [.11, .13], *SE* = .03, z = 2.62, p = .009. The indirect effect by way of nonword decoding was not significant, β = .05, 95% CI [.05, .06], *SE* = .02, z = 1.72, p = .087. These results suggest the association between working memory and passage comprehension is direct; however, text recall/inference partially mediates the association.

Indirect Effects of Task-switching. The mediation analysis failed to provide evidence that task-switching ability was associated with passage comprehension, total effect: β = .16, 95% CI [.15, .16], *SE* = .02, z = 1.56, p = .12, direct effect: β = .09, 95% CI [.08, .09], *SE* = .02, z < .01, p = .36.

Indirect Effects of Inhibitory Control. The mediation analysis indicated that inhibitory control was associated with reading passage comprehension, but the effect was indirect; for the total effect: β = .22, 95% CI [.21, .23], *SE* = .05, z = 2.14, p =.032; for the direct effect: β = –.06, 95% CI [–.07, –.04], *SE* = .06, z = –.39, p = .60. Tests of mediation indicated a significant indirect effect of inhibitory control on passage comprehension via nonword decoding, β = .12, 95% CI [.11, .12], *SE* = .03, z =2.41, p = .016, and a significant indirect effect of inhibitory control on passage comprehension via text recall/inference, β = .16, 95% CI [.15, .17], *SE* = .03, z = 2.93, p = .003. These results suggest that inhibitory control influences passage comprehension through its associations with both decoding and text recall/inference abilities.

Discussion

The current study aimed to identify relations between specific EF components (working memory, task-switching, inhibitory control) and literacy skills (nonword decoding, text recall/inference, and reading passage comprehension) in adolescents. Understanding sources of individual differences in literacy skills has implications for developing interventions and refining theoretical models of reading. Such research is urgent given estimates that 1 out of every 10 children in the United States experiences reading difficulties, even among children with average or above average levels of intelligence (National Institutes of Health, 2010).

As a preliminary step in modeling effects of EF on literacy skills, we ran correlational analyses. These indicated a lack of unity across EF measures; hence the EF constructs were treated as separable in subsequent models. After accounting for influences of age and fluid intelligence, regression analyses identified a direct relation between working memory and reading passage comprehension. This result implicating working memory in performance of a complex and integrative reading comprehension task is in line with previous literature (Peng et al., 2018). Working memory also exhibited an indirect association with reading passage comprehension by way of text recall/inference, such that the higher one's operation span, the better one is able to read text fluently and make inferences based on its meaning, and subsequently construct accurate text representations.

Part of the novelty of our findings is in showing that working memory may play a lesser role in lower-level literacy skills, such as nonword decoding, than in higher-level skills, such as text recall/inference processes and reading passage comprehension. Our results corroborate Oakhill et al. (2003) in finding a significant direct association between measures of working memory and reading comprehension, but not between working memory and decoding. However, such an association has been reported by others (Christopher et al., 2012; Kieffer et al., 2013). In light of these mixed findings, a meta-analysis may be warranted to ascertain the relation of working memory to decoding.

Unlike working memory, task-switching was significantly associated only with nonword decoding. This is consistent with prior work that found an association between task-switching and word reading (e.g., Cartwright, 2012), and suggests that the ability to shift attention is instrumental for retrieving and applying letter-sound associations. Although the current study focused only on nonword decoding, we expect task-switching to impact decoding more generally. In relation to the dual-route model (Coltheart, 2006), readers must flexibly alternate between reliance on the lexical and nonlexical routes as they encounter both familiar and unfamiliar words. Within the more transparent French orthography, task-switching has been found to correlate with decoding (Colé, Duncan, & Blaye, 2014), suggesting an association independent of orthographic depth.

Inhibitory control was associated with nonword decoding and with text recall/inference abilities. In contrast to working memory, inhibitory control did not show a direct relation to

passage comprehension. These findings are consistent with a previous large-scale study of adolescents that also found inhibitory control to be associated with decoding ability, but not with reading comprehension (Arrington, Kulesz, Francis, Fletcher, & Barnes, 2014). Thus, as in the current study, the effect of inhibitory control on reading comprehension appeared to be indirect and mediated by decoding ability.

Limitations

The simple view distinguishes decoding ability and linguistic comprehension as factors underlying reading comprehension. However, as we did not assess linguistic comprehension (e.g., receptive vocabulary and grammar) independently of text, it is difficult to apply the current findings to this framework. We also recognize that some cognitive assessments may be poorly suited for individual differences research (Hedge, Powell, & Sumner, 2017); hence future work should not rely on single measures to assess underlying EF constructs (see Denckla, 1994).

Conclusions

Our findings indicate that different components of EF have distinct relations with literacy skills in adolescents, which were evident after accounting for a number of control variables previously shown to influence reading abilities. We did not find evidence in support of unity across EF constructs. Given the complexity inherent to both reading and EF, it is perhaps not surprising that the relation between these cognitive processes is multifaceted. Our findings suggest that problems with a number of different EF skills may underlie reading difficulties in adolescents. Prior research has found a paucity of evidence that EF may be targeted to improve overall academic skills such as reading (Jacob, & Parkinson, 2015), and that it has limited potential in identifying responsiveness to targeted academic skills interventions (Miciak, Cirino, Ahmed, Reid, & Vaughn, 2019). Nevertheless, as the current study indicates, there is evidence of associations between EF and reading skills. Translating these findings into interventions to support reading comprehension will require further work.

Abstract

We examined whether probability weighting in decisions made under risk changed depending on the difference in evaluation methods. In particular, we focused on two methods, joint evaluation (JE) and separate evaluation (SE). We conducted a behavioral experiment and found that participants put more probability weight on small probability when using the SE method than when using JE, and that for large probabilities, the inverse was observed (i.e., participants put more weight in JE). We analyzed these results using a cognitive model and found that participants' subjective value of money does not change owing to differences in evaluation methods. However, beliefs concerning uncertain events shifted depending on evaluation methods, which led to the differences in probability weight. In this paper, we also discuss psychological mechanisms that produce different judgments or evaluations between SE and JE.

Keywords: probability weight; separate evaluation; joint evaluation; computer simulation; cognitive model of decision making

Introduction

It is well known that judgments change greatly depending on the difference in the evaluation methods. In the present study, we focused on one of the most studied topics, the difference between separate evaluation (hereafter, SE) and joint evaluation (hereafter, JE; Hsee, 1996; Hsee, Loewenstein, Blount, & Bazerman, 1999). Hsee (1996) showed that preference reversals by SE and JE occur in several contexts. Imagine people evaluating the worth of the following two dictionaries:

Dictionary A: Number of entries, 10,000
Dictionary B: Number of entries, 20,000 (cover is broken)

When they evaluate dictionaries A and B at the same time (i.e., JE), they may easily spot that there is a difference in the number of entries, and they may be attracted by the number of entries in Dictionary B. Thus, they may evaluate Dictionary B as having a higher price than Dictionary A. However, if people evaluate these dictionaries separately (i.e., SE), they may not notice the difference in the total number of entries (they may feel that either is enough), but they may mind the broken cover of Dictionary B. Thus, they may value Dictionary A as having a higher price than Dictionary B.

We predicted that shifts in evaluations by JE and SE might occur in the evaluation of probabilistic information. Previous studies on decisions under risk have shown that people put unique weights (i.e., non-linear weight) on probabilistic information in making decisions (Kahneman & Tversky, 1979; Tversky & Kahneman, 1992). For example, in decisions under risk, although people tend to be highly sensitive to differences in the end point (e.g., the difference between 0% and 10%, or differences between 90% and 100%), they tend to be less sensitive to differences in the middle degree (e.g., the difference between 30% and 40%). This finding suggests that sensitivity to differences is not constant. Recent studies have also showed that probability weighting is constructed through experimental procedures. In particular, different sets of probabilistic values presented in experimental tasks induce different probability weighting (e.g., Stewart, Reimers, & Harris, 2014; Walasek & Stewart, 2015).

Based on these previous findings, we predicted that differences in evaluation between JE and SE would change the probability weighting. If so, then what differences will be generated between JE and SE? In evaluating a certain probability value, people may refer to their probabilistic beliefs. For example, in evaluating 30% in a probabilistic event, people may refer to their probabilistic beliefs (i.e., how likely is the event to occur) and compare 30% with that belief. If they believe that the event usually occurs with high probability,

they may judge 30% as "not enough." In contrast, if they believe that the event usually occurs with low probability, they may judge 30% as "enough." Then, what is the nature of people's belief about probabilistic events? Stewart, Chater, and Brown (2006) showed that when people communicate probabilistic information using verbal expressions such as "likely" or "impossible," they tend to use highly extreme expressions such as "never" (representing 0%) or "always" (representing 100%). This finding suggests that people tend to easily imagine event occurrences or non-occurrences. In other words, people may refer to "black and white" probabilistic beliefs when evaluating probability.

We predicted that this would be true in evaluations using the SE method, but that it may not be true in evaluations using the JE method. In JE, people are presented with some probabilistic values at the same time, and they can compare these values. Thus, people may refer to probabilistic information in a continuous way. To the best of our knowledge, no previous studies have examined the above issue. In the present study, using a behavioral experiment and cognitive modeling, we examined whether probability weighting would shift depending on differences in the evaluation method between SE and JE. In the following section, we report the results of our behavioral experiment. We then report our analyses based on cognitive modeling.

Behavioral experiment

We examined whether probability weighting would shift due to using different evaluation methods—specifically, JE or SE—in a gambling task.

Method

Participants. We recruited 682 students as participants.

Task, stimulus, and procedure. We followed the method in Gonzalez and Wu (1999) to conduct the following task: Participants were asked to make a choice between a gamble that gets 10,000 yen (around $100) with certain probability p or sure gain. Figure 1 shows an example of the task. For example, participants choose one of two options: 100% chance of winning 5,000yen or a 30% chance of winning 10,000 yen. When they choose to a sure option, the monetary value of the option decreased: "you can get 4,500 yen." Amounts of sure gain ranged from 9,500 yen to 500 yen. As seen in Figure 1, the choice should change from a sure option to a gamble, and in the change point, we can assume that there is an amount of money to which a person is indifferent about getting a sure gain or playing the gamble (i.e., certainty equivalent, hereafter, CE). We assumed that CE was the median of the change point (in Figure 1, CE was assumed to be 1,750 yen). For the probability of the gambles, we set 11 values: 1%, 10%, 20%, 30%, 40%, 50%, 60%, 70%, 80%, 90%, and 99%.

In the JE group (n = 47), participants were asked to answer the choices for the 11 probabilities. At first, they were instructed to answer the choices for 11 probabilities and then check their choices for each while answering the questions. In the SE group (n = 635), they were presented with one of

Table 1. Results of statistical analyses about the difference in CE between the two groups.

Probability	t-test		Effect size (d)
1	t (99) = 4.00	p = .001	0.80
10	t (106) = 4.23	p < .001	0.82
20	t (109) = 2.45	p = .174	0.47
30	t (118) = 0.68	p = .999	0.13
40	t (95) = 0.01	p = .999	0.00
50	t (93) = 2.58	p = .125	0.53
60	t (111) = 0.80	p = .999	0.15
70	t (101) = 0.19	p = .999	0.04
80	t (98) = 1.28	p = .999	0.26
90	t (99) = 2.13	p = .392	0.42
99	t (101) = 3.99	p = .001	0.79

Note. p-value was adjusted with *Bonferroni's* method.

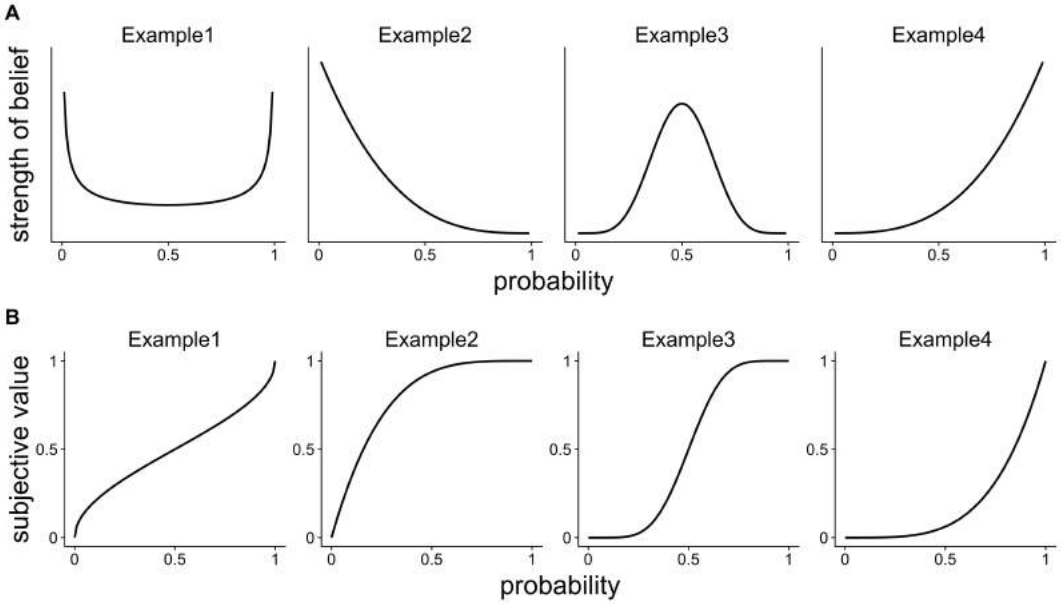

Figure 3. Summaries of DbBS. (a) Probabilistic belief regarding an uncertain event. (b) Subjective value in DbBS. This is represented with the cumulative distribution function (CDF) of the beta distribution.

the 11 probability gambles and answered the choices for the probability.

Results

Figure 2 shows mean CEs for 11 probabilities in the two groups. We found that the CEs differed between the two groups. In particular, in the low-probability range (1–20), the CE was higher for the SE group than in the JE group, suggesting that participants in the SE group applied more probability weight than those in the JE group. However, this trend reversed in the high-probability range (80–99), suggesting that participants in the JE group applied more probability weight than those in the SE group (as to the statistical analyses of CEs, see Table 1).

Taken together, the difference in evaluations between the JE and SE groups induced different probability weighting. In the following sections, we report the analyses of cognitive processes using a cognitive model.

Analyses of cognitive processes based on the cognitive model

Cognitive model of decision making: Decision by Belief Sampling (DbBS)

In this section, we introduce the decision model, called the *decision by belief-sampling model* (hereafter, DbBS; Honda, Matsuka, & Ueda, 2017). This model was proposed based on the *decision by sampling* model (*DbS*; Stewart, Chater, & Brown, 2006; Stewart, 2009). In the DbS model, subjective attribute values are constructed by a series of binary, ordinal comparisons to a sample of attribute values that reflect the immediate decision context and real-world distribution. The subjective value for a target is calculated as follows:

$$r = \frac{R-1}{N-1} \quad (1)$$

where r ($0 \leq r \leq 1$) denotes the subjective value for a target, and R denotes the rank of the target within the decision sample of N items. In this model, if the decision sample differs, r varies in the relationship between R and the decision sample. For example, imagine the subjective value for 60%. When decision samples are 10%, 20%, 30%, 30%, and 70%, the subjective value is r = (5-1)/(6-1) = 0.8. In contrast, in decision samples of 20%, 30%, 70%, 80%, and 90%, the subjective value is r = (3-1)/(6-1) = 0.4. That is, even when the target has the same attribute value, the subjective value varies depending on the decision samples. Previous studies have shown that this model can explain evaluations that vary depending on the samples (e.g., Stewart, Chater, Stott, & Reimers, 2003; Stewart, Reimers, & Harris, 2014).

DbBS is a model representing the subjective evaluation of probability. DbBS has two assumptions. First, the decision maker (DM) refers to the probabilistic belief samples in making decisions, and these samples represent the DM's probabilistic belief of an event's occurrence. For example, imagine the probable success rates of medical procedures for a serious disease and for appendicitis, respectively. Generally, people believe that the probability of success in treating a serious disease is low compared to the probable success of treating something simple, like appendicitis (Honda & Matsuka, 2014). We assume that the DMs refer to belief samples according to their probabilistic beliefs. We represent these beliefs using beta distributions (see the four examples

of DMs' subjective beliefs in Figure 3[a]). Example 1 represents the belief such that an event will occur or not (people refer to event occurrence and nonoccurrence). Likewise, in Examples 2 and 4, the DMs have the belief such that the event will happen with a low or high probability. Example 3 represents the belief that an event has a 50% chance of occurring. Thus, beta distributions can represent extensive kinds of beliefs about uncertain events. As a second assumption, a subjective value for a target is constructed by the comparison between the target value and the belief samples. Figure 3(b) shows subjective values calculated by the DbBS model. Given that beta distributions represent beliefs about uncertain events, subjective values correspond to values in the cumulative distribution functions (CDF) of beta distributions.

Using DbBS, we estimated the beliefs participants had in answering the gambling task in the behavioral experiment. In particular, we focused on the difference in beliefs produced between participants in the JE and SE groups.

Parameter estimation

In the gambling task of the behavioral experiment, when CE is y yen for the gamble that can win 10,000 yen with probability p, we assumed that the following relation:

$$v(y) = v(10000)w(p) \quad (2)$$

where v is a value function, represented with $v(x) = x^{\alpha}$, and $w(p)$ is a subjective weight for probability p. In this study, $w(p)$ is represented by subjective value according to DbBS.

With the above assumptions, we estimated parameters for value function (i.e., α) and two parameters of the beta distribution whose CDF best explains the choice patterns in gambling task.

In the JE group, we estimated the best parameters based on the choice patterns for the 11 probabilities. In this estimation, we conducted a grid search; for α, from 0.04 to 1 with increments of 0.04 (i.e., 25 values); and for each of the two parameters of beta distributions, from 0.01 to 1 with increments of 0.01 (i.e., 100 values). Thus, in total, from 250,000 combinations of parameters, we searched the combinations of parameters, which explained the observed choice pattern best for every participant in the JE group.

For participants in the SE group, it was impossible to estimate their beliefs on uncertainty because they answered choices only for one gamble. Thus, we constructed a hypothetical participant who responded to 11 gambles (i.e., gambles for 11 probabilities), by the "SE" method with the following procedure. CEs for the 11 probabilities were constructed based on the data of the behavioral experiment. In particular, the CE at one probability was randomly sampled from normal distribution. Here, mean and standard deviation were determined by the data of the behavioral experiment (i.e., the data demonstrated in Figure 2). In these random samplings for 11 probabilities, we assumed that the hypothetical participant showed consistent choice patterns such that when $p_1 < p_2$, CE for p_1 (CE_1) and p_2 (CE_2) always satisfied $CE_{p1} \leqq CE_{p2}$. Thus, we estimated the response for 11 gambles using the SE method by the "identical person." With these procedures, we constructed 1,000 hypothetical participants. For the data of the hypothetical participants, we estimate the best parameters for value function and beta distribution using a grid search as we did for the JE group.

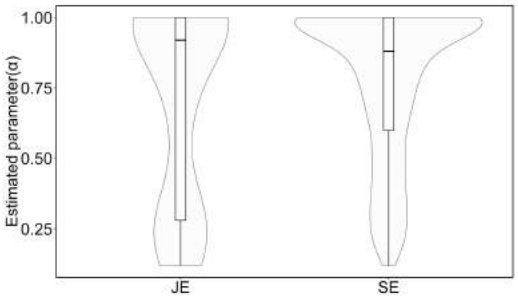

Figure 4. Distribution of estimated parameter for value function (α)

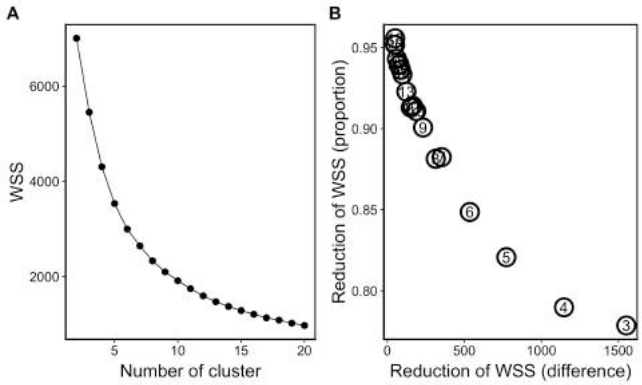

Figure 5. Results of clustering analysis. (a) Scree plot for within-cluster sum of squares (WSS) in K-means clustering. (b) Relationship between reduction of WSS (difference) and that in proportion. The number in the circle (e.g., n) indicates the reductions in WSS when the number of clusters increased from (n-1) to n.

In our parameter estimation, we evaluated the model fit using R^2. In the following analyses, we used the data wherein the model showed a good fit. Here, we set the criterion of "goodness" as $R^2 > 0.5$ (44 out of 47 data in the JE group and 787 out of 1000 data in the SE group satisfied this criterion).

Results of parameter estimations

Value function

Figure 4 shows the distribution of the estimated parameter of α for the JE and SE groups. As shown in the figure, the distributions were similar between the two group, and there was no significant difference ($w = 16328$, $p = .516$, Wilcoxon rank sum test). Thus, this result suggests that the different evaluations did not affect valuation of money.

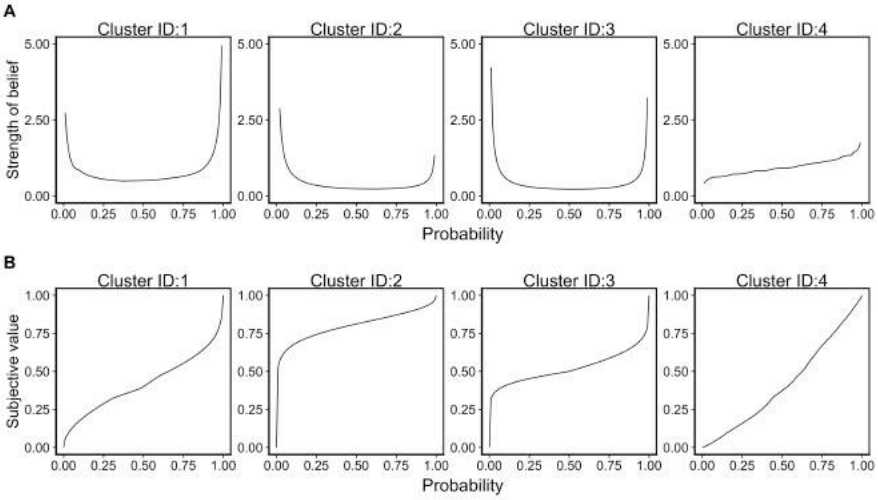

Figure 6. Median of strength of probabilistic belief (A) and subjective value (B) for the four clusters.

Table 2. Proportion of data categorized into the four clusters.

Group	Cluster 1	Cluster 2	Cluster 3	Cluster 4
JE	0.295	0.364	0.068	0.273
SE	0.287	0.159	0.475	0.079

Beliefs on uncertainty

Next, we examined participants' beliefs (i.e., estimated beta distribution) in detail with the following procedure. First, we clustered beliefs (i.e., shape of beta distribution) using probability densities. For the 831 data sets, the patterns of probability densities for 99 probabilities (1%, 2%, 3%,..., 97%, 98%, 99%) were clustered using the K-means method. We determined the number of clusters by considering the tradeoff between parsimony (i.e., as least clusters possible) and informativeness (i.e., as many clusters as required). Here, we calculated the within-cluster sum of squares (WSS) for each cluster and examined reductions in the WSS in terms of the difference and proportion of increasing numbers of clusters. Figure 5 shows the scree plot (a) and the relationship between the reduction in WSS in difference and proportion (b). We adopted four clusters based on their parsimony and informativeness.

We examined features of each cluster: median strengths of belief and median subjective values for 99 probabilities for each cluster. Figure 6 shows these results. The four clusters can be summarized as follows: For the clusters 1, 2, and 3, the probabilistic belief is "black and white" (i.e., deterministic). That suggests that a person refers to "winning" and "losing" gambles. The differences among the three clusters lie in whether a person is more optimistic (i.e., the belief in "winning" is stronger than that for "losing," Cluster 1), more pessimistic (i.e., the belief in "losing" is stronger than that for "winning," Cluster 2), or neutral (i.e., the belief in "losing" is as strong as that for "winning," Cluster 3). Cluster 4 has a different feature: the strength of belief is almost constant, suggesting that a person believes that the probability of winning gamble takes any probability (i.e., referring wide range of probability).

Then, we examined the proportions of data categorized into the four clusters for the two evaluation methods. Table 1 shows those results. Most data were categorized into Clusters 1, 2, or 3, which represented "black and white" belief. Those findings were generally consistent with the previous findings in Stewart et al. (2006) showing that people tend to often use extreme probabilistic expressions representing 0% and 100%. However, the most notable point was the proportion that was categorized into Cluster 4: more data from the JE group were categorized into Cluster 4 than from the SE group (p <.001, Fisher's exact test), suggesting that the participants (though "hypothetical participants") in SE referred to probabilistic information in a continuous way. These findings corroborated our prediction.

Discussion

In this study, we examined whether probability weighting shifts according to which evaluation method, JE or SE, was used in a gambling task. We found that the different evaluation methods induced different weighting. Furthermore, we analyzed our results using a cognitive model. The analyses indicated that differences in probability weighting for JE and SE were derived from a difference in probabilistic beliefs that people refer to in making decisions.

Previous studies have discussed changed preferences based on evaluation methods (JE, SE) but there has been little discussion about the process of making decisions under risk. One reason may be the difficulty of examining decision processes since researchers can obtain only one datum for each participant in an SE group, making model-based analysis highly difficult. In the present study, we proposed a new method to overcome such difficulties by constructing hypothetical participants using behavioral data. We believe that the proposed method makes a substantial contribution

that helps clarify the difference in cognitive processes between JE and SE methods.

A proverb is worth a thousand words: Learning to associate images with proverbs

Abstract

We describe a system that can associate images with English proverbs. We start from a corpus of proverbs, harvest related images from the web and use this data to train two variants of a convolutional neural network. We then collect a small set of annotations, and use these to combine the outputs of the two networks into a single prediction for each input image. We carry out feature selection experiments on a set of features derived from the images and from the predicted proverbs, and demonstrate that the metaphoricity of the proverbs plays a significant role in classification accuracy. An empirical evaluation with human raters confirms the system's ability to abstract from the raw bits in the images and to learn meaningful, non-trivial associations.

Introduction

Meaningful associations between visual information and short texts are a staple of effective and powerful communication. Instances of this form of communication can be found almost anywhere: on t-shirts, covers of books, records and magazines, social media posts, and ad campaigns, just to name a few. The empirical evidence, in agreement with our common sense and everyday experience, shows that meaningful image-text associations are very good predictors of the success of an online post (Hessel et al., 2017). To add to the value of an image, the caption must convey some information that is not already obvious. For example, consider two possible captions for the image in Figure 1. A purely descriptive caption like (a) is very accurate, but it does not add value to the image. By associating it with a proverb, a caption like (b) radically changes our perception of the image, from a collection of visual elements to an abstract representation of a familiar feeling (i.e., envy).

Recent advances in neural networks and computer vision have made it possible to generate high-quality descriptive captions such as (a) in Figure 1 automatically (Vinyals et al., 2017). Such captions are certainly remarkable from an artificial vision stand point, and very useful when it comes to organizing and accessing large databases of images. However, they do not make an image more memorable or compelling.

In this paper, we focus on the task of producing captions like (b), in which an image is associated with a memorable expression that emphasizes non trivial, suggestive aspects of the image. In particular, we leverage an existing corpus of English proverbs (Özbal et al., 2016) to learn a model that can associate any image to the most appropriate proverb in the repository. The resulting system can have many potential applications, e.g.: suggesting evocative and compelling taglines when posting an image on social media; proposing headlines for news, based on photos of an event; selecting the visual content of ad campaigns so as to evoke specific moods.

Figure 1: Different captions affect our perception of the same image: (a) "A half-barren, half-green field." (b) "The grass is always greener on the other side."

To the best of our knowledge, this is the first attempt to prove that existing models for object recognition can be successfully adapted to associate images to linguistically complex and semantically rich data such as proverbs. We demonstrate that the existing networks have enough capacity to abstract away from the mere graphical content of an image and learn original and surprising associations.

Note that we do not claim that our model can understand the language used in the proverbs. This is a complex problem per se, given the non-literal nature of most proverbs. In addition, from the point of view of our model a proverb is just a class label. Instead, we observe that by using the proverbs to retrieve related images allows the model to learn that some combinations of objects appearing in the pictures are relevant with respect to the meanings commonly attached to the proverbs, also when their meaning is far from literal.

The approach that we propose is simple and scalable, it relies on the availability of large amounts of noisy data and can be tuned using minimal supervision.

Related work

A growing body of literature, including Yamaguchi et al. (2014) and Gelli et al. (2015), has shown that image features do not contribute as much as textual features to the social popularity of multimedia content. In particular, Hessel et al. (2017) study the effect of visual and textual features on the popularity of Internet posts, and conclude that the right combination of visual and textual features plays a very important role. They also note that the cleverness of the accompanying captions can result in a very different response to pictures of very similar subjects, and make a less attractive subject more

popular than a better subject with a less remarkable caption.

Concerning the automatic captioning of images, Hall et al. (2015) propose to automatically generate natural language captions that describe the geographical context of georeferenced photos, such as "Rijksmuseum photographed at 2.15 pm at the corner of Stadhouderskade and Museumstraat near Spiegelgracht in Amsterdam, Netherlands.". Chen et al. (2015) present a large dataset consisting of groups of images observed with the same caption. The associative structure of the data is exploited to retrieve captions for query images. The retrieved captions can be further classified to select the more creative ones. Vinyals et al. (2017) present a generative model based on a deep recurrent architecture that can generate natural sentences describing an image. The model builds on recent advances in machine translation and computer vision. Szegedy et al. (2016) describe Inception-V3, a convolutional neural network that can be used to detect the main objects that appear in an image with very high accuracy.

Pertaining to the association of content with familiar expressions, (Tan et al., 2016) use neural networks to recommend quotes in writing and to make statements more compelling. They point out how computational methods can help writers select the most appropriate quote for a given context from a large repository of alternatives.

Regarding the appropriateness of proverbs as image captions, B. Mieder and Mieder (1977) analyze the reasons behind the common usage of proverbs in advertisement. Proverbs have a "familiar ring" that adds reliability, trustworthyness and a sense of timelessness to a brand or product. More recently, Qing-fang (2004) observes that proverbs are especially suitable for advertisement as they are short and concise, and they are associated with wisdom and moral guidance. To say it in the words of the author, "one proverb may say more than a thousand words".

Associating proverbs to images

In this section, we describe the architecture of a system that, given an image and a set of proverbs, decides whether the image is evocative of one of the proverbs. In particular, we use PROMETHEUS (Özbal et al., 2016) as a proverb repository, but a different set of proverbs or other types of memorable expressions (such as slogans or quotations) could be used in alternative. The resource consists of 1,054 proverbs, grouped into categories (such as "love and hate" or "fate") and annotated with metaphors at the word and sentence level. More than in other genres, such as news, fiction and essays, in proverbs metaphors can resolve a significant amount of the figurative meaning (Faycel, 2012). The richness of proverbs in terms of metaphors and their pervasiveness in all cultures makes them especially suitable for being used as evocative captions (W. Mieder, 1978).

We first use the proverbs to retrieve a large set of noisy data from the web. Then, we use this data to train two convolutional neural networks to associate proverbs to images. The two classifiers use the same architecture, but one is trained to directly associate images to proverbs, while the other builds associations between the objects that it recognizes in the images and the proverbs. Then, we use a small sample of the predictions of the two models to crowd source golden image-proverb associations. Finally, we use the noisy data and the golden labels to combine the output of the two classifiers into a unified model that decides whether it should select the proverb suggested by any of the two classifiers.

Noisy data collection

For each proverb in PROMETHEUS, we used the Flickr API to retrieve a set of candidate images. We included the full text of the proverb as part of the query string, forcing the API to only return images that mention the complete proverb in their title, description or tags. In our experiments we focus on the 98 proverbs for which we could retrieve at least 500 images.

To keep the data set reasonably balanced, we also limit the maximum number of images retrieved for each proverb to 1,000. The resulting data set consists of 83,895 images, each of which is associated with exactly one of 98 distinct proverbs. We then randomly split the data into a training (80,000 images) and a development (3,895 images) set. For the purpose of training and testing the classifiers, we used Flickr API to download 150×150 pixel versions of the images. These are obtained by cropping to a square around the main subject and then scaling to the final size, thus preventing warping or distortions of the elements of the images. As we reckon that color plays an important role with respect to the mood and perceived message of a picture, we did not convert the images to black and white.

Image classification

In this section, we describe the training of two classifiers that, given an image, predict the most likely proverb association. Both classifiers are based on Inception-V3, a convolutional neural network which has been shown to be very accurate in image classification tasks with a large number (1,000) of output classes (Szegedy et al., 2016). For each input image, the model outputs a probability distribution over all the output classes. The predicted label is the class with the highest probability density. For all our experiments, we use the Inception-V3 implementation included in the TensorFlow-Slim image classification model library[1].

Inception from scratch (I-FS) The first model is trained to establish a direct association between the visual clues present in the image and the output proverbs. It is an Inception-V3 network trained *from scratch* (I-FS) on the available training data. We use all the default settings of Slim's Inception implementation and we select the model after 669,923 iterations.

Inception fine-tuned (I-FT) We fine-tune the model starting from the Inception-V3 model[2] trained by Szegedy et al. (2016). This model was trained from the 1.2 million images of the 2012 ImageNet Large Scale Visual Recognition

(a)

(b)

Figure 2: Examples of reasonable predictions that differ from the noisy label. (a) Label: "Look before you leap". I-FS: "Rules are made to be broken.". (b) Label: "Beggars can't be choosers.". I-FS and I-FT: "Time and tide wait for no man".

Challenge (ILSVRC-12) (Russakovsky et al., 2015). We refer to the resulting proverb classifier as I-FT, for *Inception fine-tuned*. As the proverb classification task has a different number of output classes from ImageNet (i.e., 98 vs. 1,000), we do not restore the weights of the final layer of the network[3]. In addition, we only allow the weights of the classification layer to be updated during fine-tuning. In doing so, we expect the classifier to retain the object recognition capabilities of the internal layers of the pre-trained model and to establish meaningful association between the target proverb and the dominant objects in an image. Concerning I-FT, we select the model after 1,955,892 iterations[4].

Evaluation of I-FS and I-FT We measured the performance of the two classifiers on the 3,895 images in the development split of the noisy data. I-FT's recall is consistently higher than I-FS's (Recall@1: 0.20 vs. 0.15; Recall@5: 0.39 vs. 0.28). This is an expected result, as the inner layers of I-FT encode classification clues learned from a very large data set. While recall is relatively low for both classifiers, we should consider that each image can possibly evoke more than one proverb, whereas in our data set we only have one label for each image. Therefore, we regard these figures as very conservative lower bounds. For example, Figure 2 shows two images for which the decisions of the classifiers are quite reasonable, yet they do not agree with the noisy label.

It is also important to observe that the two classifiers learn very different models, as exemplified in Table 1. I-FS ans I-FT output a different label in the large majority of the cases (85%), and 27% of the times at least one of the two classifiers can reconstruct the correct association according to the noisy labels. In the next sections, we will explain how we leverage the different "personalities" of the two classifiers and combine them into a unified model that can predict a golden (i.e., human validated) proverb with an accuracy of 74.59%.

[3] https://goo.gl/tfHxzs

[4] We let both I-FS and I-FT learn for ≈1 week. Then, among the last 5 checkpoints, we selected the one having the smallest loss on the training data. Since there is no previous work to compare against, we are not trying to maximize accuracy at all costs. Instead, we aim to demonstrate that our pipeline produces results that are adequate for a range of user facing applications, as those mentioned in the introduction.

Statistics on development data	Count	%
Same prediction	579	14.87
Same prediction, both incorrect	226	5.80
Same predictions, both correct	353	9.06
Different predictions	3,316	85.13
Different predictions, both incorrect	2,604	66.85
I-FS correct, I-FT not correct	276	7.09
I-FT correct, I-FS not correct	436	11.19
I-FT or I-FS prediction correct	1,065	27.34

Table 1: Comparison of I-FS and I-FT. Correct and incorrect counts refer to the noisy development labels.

Gold standard collection

In the previous section, we observed that there is a number of cases in which the output of I-FS or I-FT are more suitable captions for a given image than its noisy label. To quantify this phenomenon, we set-up a crowd-sourced annotation in which we showed the raters an image and four proverbs, and asked the raters to select the most appropriate caption. To maximize the utility of the annotation, we included only the cases in which both models disagree with the noisy label. We decided to crowd-source the annotation of 500 images on the Figure-Eight platform[5].

We first included all the 226 development examples for which the two models predict the same label and the prediction is incorrect (2nd row in Table 1). We refer to these as *Type1* examples. We regard these examples as especially relevant, as we have seen before that the two models do not agree very often. Our hypothesis is that, in many such cases, the models are actually converging to a meaningful interpretation. Then, we added 274 randomly sampled images for which the predictions of the two models differ, and both predictions differ from the noisy label (*Type2*).

For Type1 examples, the raters could choose among: (1) the noisy label, (2) the proverb selected by I-FS and I-FT, and (3 and 4) two random proverbs. For Type2 examples, the raters could choose among: (1) the noisy label, (2) I-FS prediction, (3) I-FT prediction, and (4) a random proverb. In both cases, the random proverbs were selected among the 98 proverbs used to train the models. The raters were instructed to select all the relevant associations, and they also had the option to mark none of the proposed alternatives as relevant.

Due to the inherent subjectivity of the task, we decided to elicit 10 judgments for each image, for a total of 5,000 ratings. The agreement on the ratings, as reported by Figure-Eight, is 64.47%. The aggregated results of the annotation based on majority voting[6] are shown in Table 2. We can see that, overall, raters tend to prefer the decisions of I-FT over the noisy label (27.21% vs. 24.87%), and the noisy label over I-FS (20.70%). It is quite remarkable that I-FT's predictions are rated to be more accurate than the data on

[5] https://www.figure-eight.com/

[6] Even though raters could select multiple options, the majority decision has never included more than one.

	Times selected (%)		
Selected label	Overall	Type1	Type2
Noisy label	24.87	17.85	33.21
Random	3.84	3.69	4.01
None	23.37	17.54	30.29
I-FS	20.70	30.46	9.12
I-FT	27.21	30.46	23.36
I-FS or I-FT	31.39	30.46	32.48

Table 2: Results of the crowd-sourced annotation.

Label	Annotated data	Noisy data	Total
Either	99	353	452
None	312	-	312
I-FS	25	276	301
I-FT	64	436	500
Total	500	1,065	1,565

Table 3: Data distribution of the combined classifier. Note that we only annotated 500 examples out of 2,830 for which both I-FS and I-FT fail to predict the noisy label. As a consequence, 2,330 development examples are not included in this experiment.

which the model has been trained. When the two classifiers make the same decision (Type1), there is a marked preference of the raters for the predicted proverb over the noisy label (30.46% vs. 17.85%), whereas when the two classifiers do not agree (Type2) the raters generally find the noisy label preferable, even though the cases in which either I-FS or I-FT are chosen are almost the same with the noisy label (32.48% vs. 33.21%). Even though I-FS is not as accurate as I-FT to predict the noisy labels, there is a non negligible number of cases in which its decision is considered to be appropriate by the raters, and when the decisions of the two classifiers differ (Type2), I-FS selects a good option in 9.12% of the cases. There are very few cases (3.84% overall) in which a random proverb is preferred to any of the more principled alternatives, whereas there is a very significant number of cases (23.37% overall) in which none of the proposed alternatives, including the noisy label, is considered to be good.

Model combination

In this section, we describe a classifier that, given an image and the output of I-FS and I-FT, classifies the image into one of the following four classes: (a) *I*-FS, if the prediction of I-FS should be selected; (b) *I*-FT, if I-FT should be preferred instead; (c) *None*, for the cases in which neither of the two classifiers predicted an appropriate class; and (d) *Either*, if both the predictions of I-FS and I-FT are appropriate. We introduce the last class *Either* specifically to model the cases in which I-FS and I-FT output the same prediction.

Data set All the annotated examples for which the raters did not select either I-FS or I-FT predictions were mapped to the *None* class. These are all the images annotated as "Noisy label", "None" or "Random". Type1 examples where the prediction of the models was preferred by the raters were mapped to *Either*, whereas Type2 examples where I-FS or I-FT were preferred were mapped to the corresponding label. The distribution of the labels of the annotated data is summarized on the left side of Table 3. By construction, the annotated data contains only cases in which I-FS's and I-FT's predictions differ from the noisy label, and the *None* label is significantly over-represented. In order to come up with a more balanced data set, we also include the non-annotated examples in which either classifier agreed with the noisy label. If both classifiers agree with the noisy label, then we map the example to the *Either* label. If only I-FS (or I-FT) agrees, then we map the example to the I-FS (or I-FT) class. The column labeled "Noisy data" in Table 3 shows the distribution of the data added in this fashion. We regard these examples as highly accurate, given the low chance of random agreement between the noisy label and the classifiers (the output space of I-FS and I-FT consists of 98 proverbs).

Features From each example we extract 12 simple features,which we group into six sets to simplify the feature selection experiments. The set labeled "Base" (***b***) only accounts for the decisions of I-FT and I-FS. To avoid overfitting, we only include the prediction scores, and not the actual predicted classes. The set labeled "Metaphoricity" (***m***) makes use of the proverb-level metaphoricity annotations in PROMETHEUS. The metaphoricity can have one of three values: 0 (literal); 1 (slightly metaphorical); 2 (highly metaphorical). We expect proverbs which are metaphorical to be a good fit for a broader set of images. The feature set "Inception" (***i***) encodes the highest prediction score of the Inception-V3 model for the image. The intuition here is that a high prediction score, regardless of the class, means that the Inception-V3 model is confident that it can recognize a known object in the image. We use this measure as a proxy for the "concreteness" of the image, as a counterpart for the data encoded by *m*. The set "Category similarity" (***cs***) attempts to measure the compatibility between the category of the proverb (e.g., "love and hate" or "fate") and the object recognized in the picture by the Inception-V3 model. We use the DISCO (Kolb, 2009) library together with the provided English word space[7] and encode as feature the maximum cosine similarity between any synonym in the synset predicted by Inception-V3 and any content word in the predicted proverb categories. The feature set "Proverb similarity" (***ps***) is conceptually very similar, but we use the lemmas in the predicted proverb instead of its category. Finally the feature set "Difference" (***d***) encodes the difference in magnitude between the values of the feature in *b* and *m* computed for I-FS and I-FT. These features are meant to help the classifier reason more comparatively about I-FS and I-FT predictions.

Set-up To make the most of the available training data, we evaluate the combination of the two models in a leave-one-out setting, i.e., a cross-fold where the number of folds equals

[7] https://goo.gl/Rc45PW

F1	b	b+ m†‡	b+ d†	b+ ps	b+ i	b+ cs	b,m+ d†‡	b,m+ i	b,m+ ps	b,m+ cs
Macro	53.81	59.90	54.40	54.24	54.06	53.99	60.25	58.00	56.69	56.11
Micro	66.52	68.56	67.09	66.90	66.84	66.77	68.88	67.92	67.22	67.03

Table 4: Feature ablation results for the best learning algorithm. †: Significantly better than *b*. ‡: Significantly better than *b,d*. The difference between *b,m,d* and *b,m* is not significant.

the number of test examples. Please note that none of the images in the test set of the combined classifier is included in the traning of I-FS or I-FT. We compare different groupings of feature sets (always including *b*). As a learning algorithm, we use an SVM with a polynomial kernel of degree 2. We use the implementations provided by SciKit-Learn (Pedregosa et al., 2011). To compare the different feature combinations, we use McNemar's significance test (McNemar, 1947) with a 95% confidence interval ($p < 0.05$).

Results In Table 4 we report the detailed results of the feature inclusion experiments. The set of base features *b* alone achieves a micro F1 measure of 66.52. If we try to add another set of features on top of *b*, only *b,m* and *b,d* achieve a significant improvement, with *b,m* being significantly more accurate than *b,d* (68.56 vs. 67.09). If we try to add another feature set on top of *b,m*, we observe that only *b,m,d* achieves a higher accuracy (i.e., 68.88 vs. 68.56), even though the improvement is not significant. Adding any other feature set yields a negative contribution (micro F1 < 68).

As a further comparison between *b,m* and *b,d,m*, Table 5 shows the difference between the confusion matrices of the two configurations. We can observe that the error distribution of the two models is very similar, with the former being slightly more accurate on the examples labeled I-FS and *Either*, and the latter on *None* and I-FT. Interestingly, both models make very few mistakes on examples labeled *Either*, confirming that the convergence of I-FS and I-FT predictions is a strong signal of the accuracy of the predicted proverb. The error distribution also reflects the fact that I-FT, being a more accurate predictor than I-FS, is more represented in the training data. In fact, there are many more examples labeled I-FS which are predicted as I-FT than the other way round. For the same reason, the model also tends to predict I-FT when the actual label is *None*. All in all, this error analysis suggests that the best way to improve the classifier might be to introduce more data points for the classes *None* and I-FS, which are under-represented in the data (see Table 3).

From all the evidence above, we can conclude that the information about the metaphoricity of the predicted proverb provides very useful clues to the learning algorithm.[8] Contrary to our expectations, the features that account for the similarity between the objects in the pictures and the predicted proverbs (*i*, *ps* and *cs*) do not improve the classification accuracy.

Label	Predicted label: None		I-FS		I-FT		Either	
None	38	(**41**)	33	(37)	151	(148)	90	(86)
I-FS	0	(0)	**167**	(161)	134	(140)	0	(0)
I-FT	3	(1)	69	(61)	428	(**438**)	0	(0)
Either	12	(14)	0	(0)	0	(0)	**440**	(438)

Table 5: Confusion matrices for the combined model with feature groups *b,m* and *b,m.d* (in parentheses).

Finally, in Figure 3 we show 10 examples of system outputs (for the configuration using feature sets *b,m,d*), which we believe are quite representative of what the model has learned. Not all outputs are correct according to the golden labels, and we invite the readers to figure out which examples are correct and which are not before continuing reading (the answer is at the end of the paragraph). Looking at the outputs, we can see that in some cases (e.g., (d) and (i)) the associations are quite literal (hay, detergents). In other cases, the association is less obvious. These are the most interesting cases, in which the predictions showcase the ability of the model to abstract away from concrete objects, or to reproduce the cultural biases observed in the training data . In (a) there is a sense of frugality that is resolved to "every little helps". Concerning (b), in the training data "slow but sure" is very often associated with religious symbols, churches in particular. In (f), the model associates the flooded land with "storm" and the ships with "port". In (g), the model recognized the quietness of situation and the golden tones of the scenes. Concerning (h), a crowded school of fish evokes the association with "first come, first served". According to the golden labels, examples (a) to (e) are classified correctly, whereas the ones from (f) to (j) are incorrect. Nevertheless, for the applications that we have in mind all examples seem appropriate. This fact can be confirmed by restricting the evaluation to the examples annotated by the raters and by considering all the proverbs that have been selected by at least one human rater as good predictions. Under these conditions, the model selects an appropriate proverb in 74.59% of the cases.

Conclusion and future work

In this paper, we presented a model that can associate images to proverbs. It combines two variants of a high-performance convolutional neural network in a simple voting scheme, it is easily scalable and it requires very minimal supervision. By leveraging high volumes of noisy training data, the model can learn compelling associations at surprising levels of abstraction, such as "Misery loves company." for a sweaty bunch of skaters. To our best knowledge, we are the first ones to

[12] https://creativecommons.org/licenses/by-nc-sa/2.0/

use existing object recognition models to associate images to semantically rich, non-descriptive captions such as proverbs.

Our approach can easily be extended to cover more proverbs as well as other kinds of memorable and familiar expressions, such as slogans, citations or titles of famous works of art that have already been the focus of previous work on creative language generation (Gatti, Özbal, Guerini, Stock, & Strapparava, 2015; Özbal, Pighin, & Strapparava, 2013; Stock, Strapparava, & Valitutti, 2007). We have shown that knowledge about the metaphoricity degree of proverbs plays a significant role with respect to the classification accuracy. While PROMETHEUS already provides this information, this might not be the case for other sources of familiar expressions. On the other hand, it should be possible to automatically assess metaphoricity by leveraging recent state-of-the-art advancements in the field of metaphor detection (Özbal, Strapparava, Tekiroglu, & Pighin, 2016; Veale, Shutova, & Klebanov, 2016). In addition, we would like to generate more captivating captions, by injecting humor into the predicted proverbs through incongruity (Raskin, 1979) or other rhetorical devices. As Veale (2012) suggests, linguistic creativity can be utilized to "re-invent and re-imagine the familiar, so that everything old can be made new again".

Investigating the exploration-exploitation trade-off in dynamic environments with multiple agents

Denis Omar Palencia
Queen Mary University of London, London, United Kingdom

Magda Osman
Queen Mary University, London, United Kingdom

Abstract

Exploration and Exploitation represent two mutually exclusive goals associated with choices within an environment: search too little and the lack of information will make it difficult to distinguish good options penalizing the agent in the long run (exploiting) or search too much and suffer sub-optimal performance in the short term (exploring). Striking a balance between exploiting and exploring requires the learner to behave optimally in different environments. Managing this trade-off is an important process of our lives but isnt completely understood from a cognitive science perspective. To this end we present the findings from an experiment where the main objective was to examine how much the presence of competition and threats affects both behaviors: the presence of competition directs greater exploration and the presence of threats reduces this behavior, suggesting that learners prioritize their learning behavior in response to the presence of different types of agents in the environment.

Interference in Language Processing Reflects Direct-Access Memory Retrieval: Evidence from Drift-Diffusion Modeling

Dan Parker (dparker@wm.edu)
Department of English, Linguistics Program, College of William & Mary

Adam An (zan@email.wm.edu)
Linguistics Program, College of William & Mary

Abstract

Many studies on memory retrieval in language processing have identified similarity-based interference as a key determinant of comprehension. The broad consensus is that similarity-based interference reflects erroneous retrieval of a non-target item that matches some of the retrieval cues. However, the mechanisms responsible for such effects remain debated. Activation-based models of retrieval (e.g., Lewis & Vasishth, 2005) claim that any differences in processing difficulty due to interference in standard RT measures and judgments reflect differences in the *speed* of retrieval (i.e., the amount of time it takes to retrieve a memory item). But this claim is inconsistent with empirical data showing that retrieval time is constant due to the use of a direct-access procedure (e.g., McElree, 2000, 2006). According to direct-access accounts, differences in judgments or RTs due to interference arise from differences in the *quality* or *availability* of the candidate memory representations, rather than differences in retrieval speed. To adjudicate between these accounts, we employed a novel methodology that combined a high-powered (N = 200) two-alternative forced-choice study on interference effects with drift diffusion modeling to disassociate the effects of retrieval speed and representation quality. Results showed that the presence of a distractor that matched some of the retrieval cues lowered asymptotic accuracy, reflecting an effect of representation quality, but did not affect retrieval speed, consistent with a direct-access procedure. These results suggest that the differences observed in RTs and judgment studies reflect differences in the ease of integrating the retrieved item back into the current processing stream, rather than differences in retrieval speed.

Keywords: language processing; working memory; interference; two-alternative forced-choice task; drift diffusion modeling

Introduction

Successful language comprehension requires the ability to encode complex linguistic representations in memory and accurately access specific pieces of information in those representations to guide further elaboration of the discourse. For example, to relate the verb *play* in (1) with its subject for number agreement and thematic binding, memory retrieval mechanisms must access the encoding of the plural target subject *kids* and ignore featurally-similar items in non-target positions, such as the embedded plural noun *teachers*.

(1) **The kids**$_{pl}$ [that **the teachers**$_{pl}$ watched closely] ***played*** on the slide.

However, many studies have shown that featurally-similar items in non-target positions can interfere with retrieval of the target, impacting judgments of acceptability and reading times (for a review, see Parker, Shvartsman, & Van Dyke, 2017). Such effects are commonly called "similarity-based interference" (Gordon, Hendrick, & Johnson, 2001; Lewis & Vasishth, 2005; Lewis, Vasishth, & Van Dyke, 2006; Van Dyke, 2007; Van Dyke & Johns, 2012; Van Dyke & McElree, 2006, 2011). The goal of the current study is to help identify the source of such effects in language comprehension.

Often, interference from non-target items during retrieval for linguistic dependency formation slows reading times and lowers acceptability. This type of interference is called "inhibitory" interference (see Jäger, Engelmann, & Vasishth, 2017, for a review) and occurs in multiple match configurations where the target and a distractor overlap in some features that are relevant for retrieval, as in (1).

It has also been shown that interference can sometimes *speed up* processing and boost acceptability, resulting in an effect known as "facilitatory interference" or more commonly, "attraction" (Jäger et al., 2017). Attraction arises when the target and distractor are distinct in feature content, but neither is a perfect match to the retrieval cues. Such effects are commonly observed in the processing of subject-verb number agreement. For instance, Wagers and colleagues (2009) examined the comprehension of subject-verb agreement in sentences like (2) using self-paced reading and speeded acceptability judgments. The sentences in (2c-d) are ungrammatical because the plural verb *were* does not agree in number with the head of its subject noun phrase (NP) *key*.

(2) a. The key to the cabinets certainly was rusty …
b. The key to the cabinet certainly was rusty …
c. *The key to the cabinets certainly were rusty …
d. *The key to the cabinet certainly were rusty …

Wagers and colleagues found that in grammatical sentences like (2b), the number marking on the plural attractor *cabinet(s)* did not impact acceptability or RTs after the verb. However, in ungrammatical sentences like (2c), the plural distractor *cabinets* (the "attractor"), which matched the number of the verb *were*, boosted acceptability and facilitated RTs after the verb, relative to the ungrammatical condition with the singular noun *cabinet* (2d). Wagers and colleagues argued that the effects of facilitation and boosted

acceptability of sentences like (2c) were due to erroneous retrieval of the plural attractor. According to their account, retrieval functions as an error-driven repair mechanism that is triggered by the detection of an agreement violation. In (2), the subject NP predicts the number of the verb. When the verb form violates this prediction, as in (2c-d), the parser engages a cue-based retrieval at the verb to recover a number matching noun to license agreement. The attractor *cabinets* in (2c) will sometimes be incorrectly retrieved because it matches the verb in number, easing processing in a way that facilitates reading and boosts overall acceptability. In the grammatical conditions (2a-b), the verb fulfills the number prediction made by the subject NP, and therefore retrieval is not engaged, reducing the likelihood of attraction.

Alternative accounts exist, but many researchers concur that agreement attraction arises due to incorrect memory retrieval (e.g., Dillon, Mishler, Sloggett, & Phillips, 2013; Lago, Shalom, Sigman, Lau, & Phillips, 2015; Phillips, Wagers, & Lau, 2011; Schlueter, Williams, & Lau, 2018; Tanner, Nicol, & Brehm, 2014; Tucker & Almeida, 2017; Tucker, Idrissi, & Almeida, 2015). However, the reason for why incorrect retrieval facilitates RTs is debated and the relationship between RTs and retrieval accuracy remains underspecified.

For example, the prominent activation-based model of memory retrieval (ACT-R) developed by Lewis and Vasishth (Lewis & Vasishth, 2005) claims that the differences in RTs due to facilitatory interference (e.g., 2c vs. 2d) reflect differences in the *speed* of retrieval (i.e., the amount of time it takes to retrieve a memory item). In their model, the strength of an item's activation at the moment of retrieval determines the item's retrieval accuracy and its retrieval speed, such that items with higher activation are more likely to be retrieved and will be retrieved more quickly than items with a lower activation. In sentences that show attraction, like (2c), the plural attractor will have a higher activation than the singular attractor in (2d) because it provides a better match to the cues of the verb, and therefore will have a faster retrieval latency, resulting in faster RTs and boosted acceptability.

The activation-based model has been shown to provide a good fit to a wide range of behavioral data (Parker et al., 2017), but it is inconsistent with empirical evidence showing that retrieval speed is constant (i.e., time invariant) due to the use of a direct-access procedure (Martin & McElree, 2008, 2009, 2011; McElree, 2000; McElree & Dosher, 1989; McElree, Foraker, & Dyer, 2003; Van Dyke & McElree, 2011). According to direct-access accounts, the cues at retrieval make direct contact with the items in memory based on their content, rather than their location, which allows items to be retrieved at a constant speed, regardless of their position or dependency length. Items are differentially activated based on their (partial) match to the cues and the item that is most strongly activated is retrieved for dependency formation. On this view, the differences in RTs in (2c) vs. (2d) reflect differences in the quality (activation strength or availability) of the candidate memory representations, rather than differences in retrieval speed. For instance, the attractors in (2c) and (2d) will be retrieved in equal time, but the plural attractor in (2c) will be integrated into the processing stream more quickly because it provides a better match to the cues, resulting in faster RTs and boosted acceptability.

At present, it is difficult to distinguish between these accounts because the typical measures used to investigate attraction (e.g., reading times and judgments) do not discriminate between effects that arise from differences in retrieval speed and differences in representation quality. Furthermore, the argument for direct-access is based entirely on studies of *inhibitory* interference where distractors slow RTs (see Parker et al., 2017, for a review) and it remains unclear whether facilitatory interference effects like attraction show the same retrieval dynamics as inhibitory interference. These issues are addressed in the present study.

The Present Study

The goal of the present study is to tease apart existing predictions about retrieval speed and representation quality to better understand the source of facilitatory interference effects in language processing. Previously, research on retrieval in sentence processing has relied on the speed-accuracy trade-off (SAT) procedure (Dosher, 1979; Reed, 1973; Wickelgren, 1977) to examine the effects of retrieval speed orthogonally from effects of representation quality. In an SAT task, participants read sentences presented via rapid serial visual presentation (RSVP) and make binary judgments about sentence acceptability at cued intervals, ranging from before the tail of the critical dependency to 3-6 seconds after the dependent constituent is presented. Participants' average performance at these cue times is interpolated into an exponential curve that summarizes the speed-accuracy tradeoff function revealing the time course of retrieval. Importantly, by sampling a range of intervals, independent estimates of retrieval speed and accuracy become available. This method provides a profile of memory retrieval processes that is characterized by three parameters: (i) the **asymptote**, which reflects retrieval accuracy, (ii) the **intercept**, which reflects the time to retrieve an item from memory, and (iii) **rate**, which reflects the speed at which accuracy grows from the intercept to the asymptote. Differences in either the intercept or rate are presented as evidence for differences in retrieval speed, and differences in asymptote are taken to reflect differences in representation quality.

The SAT methodology has been pivotal in arguing that retrieval for sentence processing employs a time-invariant direct-access procedure (e.g., Martin & McElree, 2008, 2009, 2011; McElree, 2000; McElree et al., 2003). For instance, Van Dyke and McElree (2011) found that interference impacts asymptotic accuracy, but not processing speed (SAT intercept and rate parameters). But as noted, existing studies that have used SAT to investigate interference effects have been limited to tests of inhibitory interference. Furthermore, the SAT methodology is time-consuming and resource-intensive (see Chen & Husband, 2018, for discussion).

The current study employed a more efficient alternative methodology, **Drift Diffusion Modeling (DDM)**, which has

also been used to jointly analyze the effects of accuracy and processing speed and model the timing of retrieval (Chen & Husband, 2018; McElree & Dosher, 1989; Ratcliff, 1978; Ratcliff, Smith, Brown, & McKoon, 2016). Importantly, recent research on memory retrieval in sentence processing has shown that DDM yields results that are comparable to the more costly SAT methodology (Chen & Husband, 2018). Based on these results, we extended the DDM methodology to test existing predictions about retrieval speed and representation quality regarding facilitatory interference effects (i.e., activation-based vs. direct-access models of retrieval).

DDM uses data from two-alternative forced choice (2AFC) tasks to generate a conditional cumulative distribution function (CDF) that relates a time *T* to the probability that a correct response is faster than or equal to *T*. Crucially, it relies on four parameters that have been argued to reflect distinct underlying memory retrieval processes in sentence processing (Chen & Husband, 2018):

(i) **τ non-decision time**: encoding and motor response time, including the time to extract the relevant information from memory to make a decision
(ii) **α boundary separation**: the amount of evidence needed to make a decision
(iii) **δ drift rate:** rate of evidence accumulation
(iv) **β response bias**: the bias to respond to a particular alternative

In the current study, we tested a standard agreement attraction paradigm like that in (2) as a hallmark of facilitatory interference in a high-powered (N=200) 2AFC experiment and modeled the data using drift diffusion modeling to distinguish between effects arising from differences in retrieval speed vs. differences in representation quality. Recent research has used DDM to investigate how response biases impact the amount of attraction in sentences like (2c), as measured with the β response bias parameter (Hammerly, Staub, & Dillon, unpublished ms.). However, this work did not test the current predictions about retrieval speed, nor did it explicitly address the question of retrieval time. The present study applies the same methodology, but focuses on the issue of processing dynamics to better understand why interference eases processing in sentences like (2c).

Under both the activation-based and direct-access accounts, facilitatory interference should negatively impact asymptotic accuracy (DDM δ drift rate), such that the sentences that give rise to attraction (2c) should have an overall lower accuracy relative to the other conditions (2a, b, d). Where the accounts differ, however, is in their predictions for processing dynamics. If facilitatory interference arises due to faster memory access, as claimed by activation-based accounts, then we should see a faster intercept (τ non-decision time) for sentences that show attraction (2c). By contrast, if retrieval occurs via direct access, then the intercept parameters should be comparable across conditions.

Method

Participants

Participants were 200 college-age native speakers of English. The large sample size was chosen to ensure high statistical power (i.e., reduce Type II error) and accurate estimation of the DDM parameters. All participants provided informed consent and received credit in an introductory psychology or linguistics course. All participants were naïve to the purpose of the experiment. The experiment lasted approximately 20 mins.

Materials

Experimental materials consisted of 64 sets of 4 items like those shown in Table 1. The high number of item sets was chosen to ensure a stable estimation of the DDM parameters. Experimental conditions consisted of a 2 × 2 factorial design that crossed grammaticality (grammatical/ungrammatical) and attractor number (singular/plural). In all conditions, the subject head noun was modified by a prepositional phrase that contained the attractor. The critical verb was always a full lexical verb in sentence-final position. An adverb created a buffer between the subject and the critical verb to control for processing effects associated with plural nouns (see Wagers et al, 2009). Grammaticality was manipulated by varying the verb number such that it either matched or mismatched the number of the subject head noun. Attractor number was manipulated by varying the number of the attractor such that it either matched or mismatched the verb number.

The 64 target items were distributed across 4 lists in a Latin square design and combined with 66 fillers. Half of the fillers were ungrammatical, yielding an overall grammatical-to-ungrammatical ratio of 1:1. Approximately half of the grammatical fillers involved sentence-final plural verbs in structures similar to the target items and approximately half of the ungrammatical fillers involved sentence-final singular verbs to unconfound grammaticality with verb number in the target items. The remaining fillers involved relative clause structures from an unrelated experiment.

Table 1: Sample set of experimental materials. PL = plural. SG = Singular

Condition	Sentence
Grammatical PL attractor	The tutor for the students often rambles.
Grammatical SG attractor	The tutor for the student often rambles.
Ungrammatical PL attractor	The tutor for the students often ramble.
Ungrammatical SG attractor	The tutor for the student often ramble.

Procedure

Sentences were presented using Ibex (Drummond) one word at a time in the center of the screen in RSVP mode with a stimulus onset asynchrony (SOA) of 300 ms per word and an interstimulus interval (ISI) of 100 ms. Participants were instructed to read each sentence carefully and judge whether each sentence was an acceptable sentence of English. A response screen appeared for 3 s at the end of each sentence during which participants made a 'yes/no' response by button press. If participants waited longer than 3 s to respond, they were given feedback that their response was too slow. The order of presentation was randomized for each participant.

Data Analysis

All data were included in the analyses. A logistic mixed-effects model was fit to the judgment accuracy data and a linear model was fit to the raw response latencies using the *lmerTest* package (Kuznetsova, Brockhoff, & Christensen, 2014) in the *R* software environment (R Development Core Team, 2018), with fixed factors for the experimental manipulations (i.e., grammaticality and attractor number) and their interaction. All models were fit with the maximal random effects structure supported by the data (Barr, Levy, Scheepers, & Tily, 2013). An effect was considered significant if $|t/z| > 2$.

For the DDM analysis, the *RWeiner* package (Wabersich & Vandekerckhove, 2014) was used to fit a Weiner drift diffusion model to each condition for each participant. Parameter values that did not converge were excluded, following Chen and Husband (2018). A linear model was fit to the by-participant parameter fits following the same procedure used in the analysis of the response latencies. All data and code are available via Open Science Framework: https://osf.io/bu2kh/.

Results

Judgments and Response Latencies

Figure 1 shows the percentage of 'yes' responses and latencies (in ms) for the four experimental conditions. Main effects of grammaticality and attractor were observed in the judgments and latencies ($z > |3|$ in all cases). Grammatical sentences were more likely to be accepted and had faster latencies than ungrammatical sentences, and sentences with a plural attractor were more likely to be accepted and had longer latencies than sentences with a singular attractor. Crucially, judgments also showed a significant interaction of grammaticality with attractor number (z = -12.48). Planned pairwise comparisons revealed that this interaction was carried by the ungrammatical conditions: participants were more likely to accept an ungrammatical sentence when a plural attractor was present (z = 12.11). No such effect was observed in the grammatical conditions (z = -1.13). This profile reflects the behavioral signature of agreement attraction (Phillips et al., 2011) and provides an appropriate basis to examine the relationship between retrieval accuracy and retrieval speed using the DDM methodology.

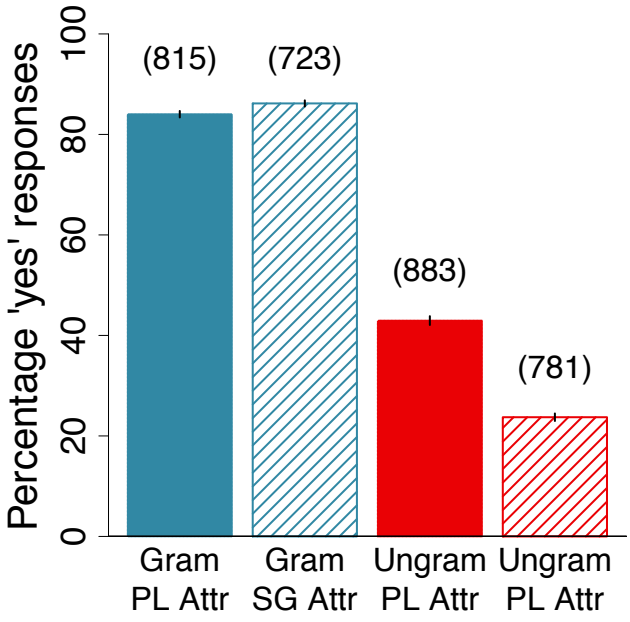

Figure 1: Mean percentage of 'yes' responses and response latencies in (ms) in parentheses by condition. Error bars indicate standard error of the mean. PL = plural, SG = singular.

Drift Diffusion Model (DDM)

Average DDM parameters by condition are shown in Table 2, and the *t*-values for model estimates of effects on DDM parameters are shown in Table 3. Figure 2 shows the cumulative density of accurate responses as a function of response time by condition. DDM revealed an effect of attraction on δ drift rate (asymptotic accuracy), qualified by an interaction between grammaticality and attractor number, such that participants were less accurate in ungrammatical sentences with a plural attractor than in those with a singular attractor. This effect is predicted by both accounts.

With respect to processing dynamics, which is where the accounts diverge, DDM revealed no significant effect of attraction on the processing dynamics reflected in τ non-decision time (intercept). These results suggest that agreement attraction impacts retrieval accuracy but not retrieval speed, consistent with a direct-access model of memory retrieval.

Results also showed a main effect of grammaticality on τ non-decision time (intercept), as grammatical sentences showed faster response latencies than ungrammatical sentences. This effect is unrelated to interference and likely reflects facilitation due to predictive processing in the grammatical conditions (Wagers et al., 2009).

Table 2: DDM parameters by condition.

	τ	α	δ	β
Grammatical PL attractor	0.26	2.03	0.90	0.60
Grammatical SG attractor	0.23	2.18	1.12	0.62
Ungrammatical PL attractor	0.30	1.99	-0.24	0.47
Ungrammatical SG attractor	0.29	2.39	-1.05	0.41

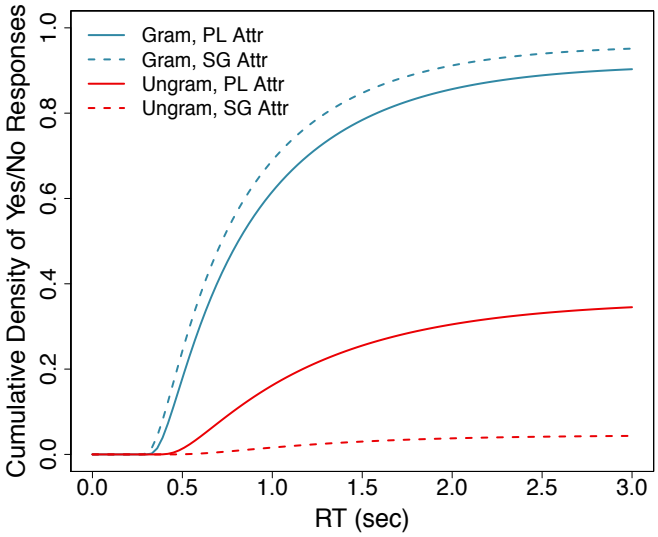

Figure 2: DDM estimations of the cumulative density of "yes" (1) and "no" (0) responsesas a function of response time by condition. PL = plural, SG = singular.

Discussion

The goal of the present study was to distinguish between existing predictions about retrieval speed and retrieval accuracy to better understand the source of interference effects in language processing. On the one hand, activation-based models of retrieval (e.g., Lewis & Vasishth, 2005) claim that differences in processing difficulty due to interference in standard RT measures and judgments reflect differences in the speed of retrieval. On the other hand, direct-access accounts claim that differences in judgments or RTs due to interference arise from differences in the quality of the candidate memory representations, rather than differences in retrieval speed, based on behavioral data showing that retrieval time is constant. To adjudicate between these accounts, we tested for facilitatory interference paradigm in a high-powered 2AFC experiment and modeled the results using DDM to disassociate the effects retrieval speed and representational quality.

Results of the 2AFC task replicated the classic attraction profile, such that ungrammatical sentences with a plural attractor that matched the number of the verb showed boosted acceptability relative to ungrammatical sentences with a singular attractor. Results of the DDM analysis revealed that in the ungrammatical conditions, the presence of a number-matching plural attractor lowered overall asymptotic accuracy, but did not affect retrieval speed.

The lack of an effect on non-decision time is consistent with the predictions of a direct-access procedure. These results suggest that the differences in judgments and RTs observed in agreement attraction studies reflect differences in the ease of integrating the retrieved item back into the current processing stream, rather than differences in retrieval speed.

More specifically, we argue that the quality of the memory representation (described in terms of activation strength) impacts the post-access stage of "binding", rather than the speed of access. In the memory literature, binding refers to the mechanisms by which information in memory is integrated together (Cohen & Eichenbaum, 1993; Hagoort, 2003; van der Velde & de Kamps, 2006), and it has been suggested that the effort required for integration is governed, in part, by the item's representation quality (Budiu & Anderson, 2004). On this view, retrieval of an item that satisfies at least some of the search criteria, such as the number matching attractor in sentences like (2c), will make post-retrieval integration faster compared to integration of an item that does not satisfy the search requirements, such as in (2d), giving rise to facilitatory interference.

More broadly, the current results are consistent with the recent claim that differences in the quality or availability of the information in memory leads to differences in accuracy and that those differences underlie the differences in reaction time studies (Martin & McElree, 2018). The current study extends this conclusion to facilitatory interference, motivating a unified analysis of inhibitory and facilitatory interference as the signature of direct-access retrieval.

Abstract

Natural language is replete with figurative expressions like *my lawyer is a shark*, and listeners are expected to intuitively understand the intended, rather than the literal, meaning of such expressions. But what cognitive resources are involved in attaining meaning for such sentences? Most research into metaphor comprehension has employed *offline* reading tasks that provide no insight into the time-course of metaphor processing. In order to investigate the moment-by-moment on-line processes involved in metaphor comprehension, the present study used a naturalistic cross-modal lexical decision paradigm (Swinney, 1979) with novel brief masked target presentations during and after the vehicle word (*shark*). Results obtained from a preliminary sample demonstrated priming of related target words across conditions, but no significant differences between conditions. These results may best be interpreted as supporting an exhaustive-access account of metaphor interpretation, which suggests that literal and metaphorical interpretations are simultaneously accessed during the early stages of metaphor/simile interpretation.

Keywords: metaphors; similes; language comprehension; psycholinguistics; cross-modal lexical decision task; pragmatics

Introduction

How are metaphors interpreted in real time? This question is central to cognitive science because metaphors involve blatantly false statements that are nonetheless easily understood as conveying an ulterior, non-expressed meaning. For instance, upon hearing *my lawyer is a shark,* the listener does not call out the absurdity of the speaker's statement, rather assigning to it an interpretation that supposedly captures the speaker's intended meaning.

Various theories have been proposed to account for how listeners attain meaning for nominal metaphors in the form *X is Y*. Pragmatic theories take metaphors to convey initially a *literal* meaning which works as an invitation for the reader/listener to an interpretation based on the speaker's intended meaning (Davidson, 1978; Grice, 1975; Searle, 1979). While these authors differ in their approach to how metaphor is ultimately understood, they all suggest that the intended meaning can only be understood after an initial rejection of the literal, propositional meaning. In psycholinguistic circles this has been known as the *pragmatic model*, on the assumption that comprehension involves a three-stage process, beginning with the literal interpretation, followed by a rejection of the literal, and a search for the metaphorical meaning.

By contrast, the *direct-access* model suggests that metaphors are immediately comprehensible by the linguistic system and do not involve additional cognitive resources (e.g. Glucksberg & Keysar, 1990; Gibbs, 1994; Wolff & Gentner, 2000). Direct access is obtained either via a mechanism where metaphors are taken as comparisons between categories (e.g. Glucksberg & Keysar, 1990; Glucksberg, 2003), or via mapping of *constituent features* (say, features of *lawyers* and *sharks*), which are stored in the linguistic system as lexical properties of individual words (Wolff & Gentner, 2000). [1]

Although metaphors are pervasive in natural language and cognitive scientists have long debated the nature of their interpretation, to date few empirical studies have investigated the moment-by-moment process of metaphor comprehension using *online* experimental methods such as cross-modal priming with lexical decision (CMLD; e.g., Blasko & Connine, 1993); self-paced reading (e.g., Janus & Bever, 1985); ERP (Pynte, Besson, Robichon & Poli, 1996), and eye-tracking (Ashby, Roncero, de Almeida, & Agauas, 2018). However, support for the *direct-access* view is based primarily on studies involving *offline* tasks, i.e., tasks that require conscious judgment, and are thus not informative regarding what happens as sentences containing metaphors unfold in real time.

For instance, Glucksberg, Gildea, and Bookin (1982) asked participants to read literal and metaphorical sentences and to judge whether they were literally true or literally false. Based on a finding that it took longer for participants to judge statements as false if they had a common metaphorical interpretation (e.g. *jobs are jails*), the authors concluded that a metaphorical meaning is immediately available along with a literal meaning and thus interfered with subjects' classification of metaphorical sentences as

[1] The theories briefly mentioned here certainly do not exhaust the spectrum of metaphor theories. However, we restricted our review to theories concerned with the process of incremental interpretation, while leaving aside theories about the thinking processes that are triggered by or underlie metaphor production and comprehension (e.g., Lakoff & Johnson, 1978).

literally false (Glucksberg et al., 1982). The results obtained by *offline* studies such as Glucksberg and colleagues' (1982) could be equally compatible with the hypothesis that pragmatic processes interfere with literality judgments after the sentence has been fully processed, but before participants register a response.

Studies investigating on-line metaphor processing by measuring event-related potentials (ERP) have demonstrated that figurative targets elicited larger N400 amplitudes than literal targets (e.g. Pynte et al., 1996; Lai, Curran, & Menn, 2009), which suggests that figurative expressions are more difficult to process. This could be due to the detection of an incongruence between literal and intended speaker meaning. Crucially, these studies have not investigated what is accessed at the point at which a figurative expression is first processed.

The purpose of the present study was to investigate the nature of the representations computed during the real-time processing of metaphors and similes containing the same constituents, using an *online* cross-modal priming task. Specifically, we aimed to compare these two types of expressions in real time to elucidate differences in processing that might occur due to their fundamentally metaphorical and literal nature, respectively, and by doing so to shed light on the cognitive mechanisms involved in reaching an understanding of the meaning of such constructions. Our study is unique in that we aimed to study the very earliest moments of metaphor processing—the moment of lexical access—rather than later interpretation processes, and aimed to develop a new, more time-sensitive measure than in previous studies (e.g. Blasko & Connine, 1993).

We sought to compare the moment-by-moment comprehension of nominal metaphors in the form *X is Y* and similes in the form *X is like Y* using a cross-modal lexical decision task (CMLD; Swinney, 1979), and thus limited our study to nominal metaphors which could be compared to similes directly. Though they are traditionally thought to be an alternate form of the simile – a view dating back to Aristotle (trans. 1926) – the key difference between these two forms of expression is the word *like* in a simile, which renders it literally comprehensible. There is evidence that metaphors and similes are produced and understood differently (Ashby et al., 2018; Roncero, de Almeida, Martin, & de Caro, 2016; Roncero, Kennedy & Smyth, 2006) and yield different properties in offline studies (Roncero & de Almeida, 2015). Thus, we chose to use simile sentences as a literal control condition for nominal metaphor sentences due to their nearly identical constituent structure.

In the CMLD task, participants listen to aurally presented sentences for comprehension and are simultaneously presented with a visual target to perform a lexical decision task (i.e., pressing "yes" if the target is a word, "no" otherwise) in which response times (RTs) are collected. The main assumption behind the technique is that RTs to targets reflect the relation between a visual target and a prime word in the sentence (here, the vehicle *Y*). Specifically, recognition of the target word should be facilitated by hearing a related prime word, and thus yield a faster reaction time compared to a target that is semantically unrelated.

This method has two main advantages over other online techniques such as ERPs and offline tasks such as sentence judgments. First, listening to spoken metaphors during an *online* lexical decision task allows for an analysis of metaphor interpretation that is both highly time-sensitive and naturalistic. Using a simple lexical decision task rather than an *offline* judgment task means that participants do not base their responses on a conscious assessment of sentence meaning – indeed, they are not aware that this task is meant to test their comprehension of metaphors at all. Instead, priming for each target should reflect the interpretation of a sentence that is available at the moment visual targets are presented. Second, using similes as literal controls allows for all constituent words besides *like* (including target and vehicle) to remain identical, thus allowing for direct comparisons between literal and figurative interpretations of each topic-vehicle pair.

To our knowledge, the only other metaphor processing study to employ CMLD was that of Blasko and Connine (1993), which employed a substantially different method. In their study participants listened to metaphors and responded to targets presented at the offset of the vehicle. These targets were either (a) metaphor-related, (b) literal-related, or (c) control (unrelated to either the metaphor or the literal interpretation). In the present study, in addition to comparing metaphor to simile, we traced the time-course of interpretation by employing two target presentation points, thus probing for the potential access to literal or metaphorical interpretations over time. In addition, our first probe point was before the offset of the vehicle, during its *recognition point,* to test for the earliest possible position in which a literal or metaphorical interpretation could be obtained. Moreover, unlike Blasko and Connine (1993), our targets were forward- and backward-masked with a series of crosshatches, and presented at a fast rate (80ms) in an attempt to circumvent subjects' potential detection of a relation between prime and target.

Method

Participants

Participants were 37 native English speakers between the ages of 19 and 59 (M = 26.32, SD = 8.07; 26F) with normal or corrected-to-normal vision and hearing who met the following inclusion criteria: (1) They learned English before the age of 5 (M = 1.19, SD = 1.47) and identified it as their native and dominant language; (2) they rated themselves as fluent in speaking, listening, and reading English; (3) they reported no history of hearing or reading disability. Participants who were recruited via Concordia University's online participant pool were compensated with course credit while all other participants were compensated with $10 for one hour of participation. Participants for two pretests are described along with the pretests below.

Materials Experimental materials consisted of 32 sentences containing metaphors/similes in the form *X is (like) Y* and 160 filler sentences. Metaphor/simile sentences were selected from Roncero and de Almeida (2015), which consists of a set of metaphor/simile sentences with accompanying norms. The sentences were chosen on the basis of their high aptness ratings (rated above 6 on a scale of 1 to 10, with 10 being the most apt), but had a broad range of familiarity ratings. The Roncero and de Almeida (2015) norming study asked participants to generate associates/explanatory words for both the simile and metaphor versions of each sentence and for the topic and vehicle words in isolation. For use as our figuratively related targets, we selected explanatory words generated for each metaphor by the highest possible number of participants, which did not appear as associates for the vehicle word in isolation. For our literally related targets, we selected words which were generated as associates of the vehicle word by the highest possible number of participants and which did not appear as explanatory words for the metaphor on the whole.

Exclusion of Automatic Associates To ensure that any potential priming effects were not derived from an 'automatic' association between the vehicle and target words (i.e., due to being frequently paired in speech, like *salt* and *pepper*), we conducted a norming experiment where each vehicle word was read aloud to 12 native speakers of English, who were asked to say out loud the first word that came to mind. Their responses were collected and any word which was named more than twice was excluded from selection as a target for that vehicle word.

The unrelated control words selected to calculate priming effects were chosen according to the following criteria: For each related target word, written frequency was calculated from the Corpus of Contemporary American English (COCA; Davies, 2008), a database of American English texts collected from 1990-2017 including fiction, non-fiction and academic texts. Matched (unrelated) control words were selected to have the same number of letters, same number of syllables, same morphological structure and similar frequency in the COCA database.

Sentence Recording and Target Selection Metaphors/similes were embedded in longer sentences with explanatory contexts which we generated, with the word *because* following each vehicle word to control for interference from explanatory contexts; these sentences also began with generic *proposition-attitude* statements (e.g., *It is hardly a secret that lawyers are sharks, because with few exceptions, lawyers are bloodthirsty and ruthless*). Filler sentences did not repeat the topic or vehicle words of any experimental sentences. Of these, 32 followed a similar sentence structure as experimental sentences, while 128 filler sentences did not syntactically resemble experimental sentences. Visual targets for filler sentences were 64 real English words and 96 'nonsense' strings of letters that did not resemble English words, of varied lengths to reflect the varied lengths of experimental targets. All sentences were read by a female native English speaker and recorded for aural presentation, with natural prosody and reading speed. Special attention was given to matching the prosody and timing of metaphor and simile pairs, to make them nearly identical except for the word *like*.

Recognition Times We employed a gating paradigm to determine the recognition point of each vehicle word, following the procedure developed by Zwitserlood (1989). Recordings of each vehicle word were cut into slices increasing by 50ms each. These were played consecutively to 10 native speakers of English over noise cancelling headphones. Participants were asked to write down what word they thought they were hearing after each slice was presented. Their responses were collected and recognition times for each word were defined as the moment when 80 percent of participants correctly identified the word (with or without pluralization). During the lexical decision task, the early time point was defined as 40ms prior to recognition time, to account for screen refresh rate and the fact that the word could have become recognizable anytime within the 50ms slice participants heard during the gating task. Late time points were defined as 500ms following recognition time to avoid interference from words later in the sentence.

Experimental Design

A total of 16 counterbalanced lists were created following a 2 x 2 x 2 x 2 design. Each topic/vehicle pair was presented in either a metaphor- or simile-containing sentence, along with a figuratively related target, literal target or matched control target, at an early (*recognition*) or late time point. Each block contained two experimental sentences in each condition along with all 160 filler sentences, 20 of which were followed by comprehension questions to ensure participants were attending to aural stimuli. Each participant completed two blocks containing one list each – i.e., each participant heard both the simile and metaphor version of each sentence once in total. The sentences were randomized in order within each block of trials and participants were randomly assigned to each set of lists.

Procedure

Participants were tested on an iMac computer using Psyscope X B57 (Cohen, MacWhinney, Flatt, & Provost, 1993) using a button box. After voluntary consent was obtained, each participant was seated in front of the screen in a dark room, equipped with noise-cancelling headphones, and instructed to attend to both the aurally presented sentences and visual stimuli on the screen. Participants were instructed that their primary task was to identify whether the letters they saw on the screen constituted an English word and to press a button to indicate YES or NO as quickly and accurately as possible, while their secondary task was to answer comprehension questions about the sentences they heard over the headphones.

Each trial consisted of a prompt asking participants to press a button when they were ready for the next trial, followed by an aural presentation of each sentence. Target words appeared in white 20-point Arial font text in capital letters on a black screen for 80ms each, preceded and followed by masks which appeared for 100ms. This brief masked priming procedure was meant to reflect faster and more automatic processes of recognition rather than slower processes of judgment. Masked priming (see Forster, 1999) reflects early processes of lexical recognition which should be uncontaminated by other semantic factors. Each participant was given five randomized practice trials, during which the experimenter answered questions and corrected mistakes.

Data Analysis

Analysis of reaction times (RTs) was restricted to correct trials (i.e., those where participants correctly identified the target as an English word) while incorrect trials were omitted (13% of all data points). As is standard in lexical decision paradigms (Friedmann, Taranto, Shapiro & Swinney, 2008), all reaction times above 2 seconds were discarded prior to data analysis (2% of all data points). Based on a priori decisions, we discarded blocks of trials where participants answered fewer than 70% of comprehension questions correctly.

Results

We performed a linear mixed-effects model regression analysis with subjects and items (vehicles) entered as random effects with random intercepts. Raw RTs were regressed on priming (control/experimental targets), sentence literality (metaphor/simile conditions), target type (figurative/literal) and time-point (early/late), as well as all first order interaction terms. For ease of interpretation, priming effects (RT to control – RT to target) are presented in Figure 1. The full RT model was compared to a null model including only random effects (subject and item), using the Likelihood Ratio Test to determine significance. Our model provided a better fit to the data than the null model ($\chi^2(10) = 25.70$, $p = 0.004$). We derived p-values for all main effects and interactions using the Likelihood Ratio Test to compare the full model to a model excluding the relevant term (see Table 1) and found only one significant main effect of priming.

As predicted, participants took significantly longer to respond to unrelated targets than to related targets ($\chi^2(4) = 22.38$, $p < 0.001$) – overall, RTs to related targets were 40ms faster (*SEM*=23.88). While no other main terms or interaction terms reached significance, the respective means of each condition seemed to show trends which may be worth investigating with a larger sample. Specifically, in the metaphor condition, early priming values were lower for the figurative condition than for the literal condition, but priming for the figurative condition was higher at the later time point. In the simile condition, the reverse was true, with higher priming for literal targets at the late time point. Unexpectedly, the largest priming effect was observed for figuratively related targets at the early time point of the simile condition.

Table 1: Mixed-effects linear model of response times.

Predictor	Estimate	SE	t	95% CI	Null Comparison
Constant	718.19	23.88	30.08	[671.39, 765.00]	
Priming	-39.51	16.10	-2.45	[-71.06, -7.95]	$\chi^2(4)=22.38$, $p<.001$
Time-point	-1.84	16.05	-0.11	[-33.29, 29.61]	$\chi^2(4)=1.67$, $p=.80$
Target type	-16.44	16.15	-1.02	[-48.10, 15.22]	$\chi^2(4)=1.27$, $p=.87$
Sentence literality	-18.04	16.02	-1.13	[-49.44, 13.37]	$\chi^2(4)=2.31$, $p=.68$
Priming x Time-point	1.43	15.81	0.09	[-29.55, 32.40]	$\chi^2(1)=0.0083$, $p=.93$
Priming x Target type	8.09	15.87	0.51	[-23.02, 39.19]	$\chi^2(1)=0.26$, $p=.61$
Priming x Sentence literality	-4.50	15.83	-0.28	[-35.52, 26.52]	$\chi^2(1)=0.08$, $p=.78$

.

Discussion

We used a novel, masked rapid-presentation CMLD task to gain insight into the moment-by-moment processing of metaphors and similes of the form *X is/is like Y*. The results obtained showed significant priming in all conditions and at all time points; and, contrary to our predictions (and those of the *pragmatic* model) no statistically significant differences in priming between conditions were obtained.

These results can be partially accounted for by different models of metaphor interpretation, in particular models that assume some form of exhaustive access. This is so because, contrary to what both *pragmatic* and direct-access models would predict, literally related target words were still primed as much at the later time point (b) as at point (a), suggesting that even after a sentence has been fully processed (and, presumably, understood to have a non-literal intended meaning), literal representations of the vehicle word linger.

We take these results to suggest that metaphor/simile interpretation trigger an *exhaustive* access, an effect also found in some lexical ambiguity resolution studies (e.g., Swinney, 1979). Exhaustive access, in the context of metaphor processing, entails the access to both the literal meaning and a meaning commonly associated to the metaphorical use of the same word. According to Carston (2010), two simultaneous processes contribute to the understanding of metaphorical language—a fast, *online* formation of *ad hoc* concepts linked to the metaphorical vehicle (for example, while the lexical item *shark* may conceptually represent the large predatory fish, it may also represent a concept like *aggressive* or *mean*, especially for highly apt/conventional metaphors such as many of those used in our experiment), and a more nuanced, *offline* process of interpreting the meaning of a metaphorical passage that relies on its literal meaning and the "images" the literal meaning evokes. Thus, according to Carston's (2010) model, the early priming of figuratively related targets presented at recognition point (a) could be a result of *ad hoc* concept formation relating the vehicle word to figurative concepts, while the persistence of priming for literally related targets at point (b) could be explained by the persistent, simultaneous activation of literal (or imagistic) representations. However, it is not clear whether these *ad hoc* concepts—which are obtained from contextually-driven *inferences*—are in fact accessed within the 80 ms window of target processing. In Carston's relevance-theoretical approach, these *ad hoc* concepts would have to be constrained by context. But this would imply a sentence type x target type interaction, which we did not obtain. Alternatively, these *ad hoc* concepts are already associated with the vehicles, such that a rapid *shark→MEAN* access could be obtained similarly to the literally related *shark→BLOOD*.

Our results are also partially compatible with Giora's (2003) graded salience hypothesis and in particular its ancillary hypothesis, *retention*. These hypotheses can be summarized as follows. Effects such as frequency or familiarity lead to a graded representation for meanings or senses of a word. These factors determine a form of exhaustive, but ordered access to meanings in the course of interpretation. For metaphors, this means that the most salient meaning—metaphorical or not—will always be accessed first, or activated more strongly. This theory is, in

large part, context-insensitive; that is, it takes the order of access to be determined by lexical-semantic encoding factors, not determined by context. We only say that our results are partially compatible with this theory because we have not tested specifically for the salience of particular senses.

A third compatible view takes relations between lexical concepts to be established in terms of meaning postulates (see, e.g., de Almeida, 1999; Partee, 1995; and Fodor, 1998). An application of this view to the interpretation of the present results would take vehicle meanings to quickly trigger their related postulates, whether they are related to literal or to figurative meanings. Thus, for example, a meaning postulate would constitute a relation between the meaning of the prime (*shark*) and the meanings of the targets, via postulates with the form such as $(\forall x[P(x)] \rightarrow [Q(x)])_n$. This view requires both $\forall x[SHARK(x)] \rightarrow [MEAN(x)]$ and $\forall x[SHARK(x)] \rightarrow [BLOOD(x)]$ to be postulates related to the meaning of *shark*, with both being equally primed, independent of context, and as a function of lexical-conceptual relations established not *by necessity* (i.e., *analytic*) but as a function of use (i.e., *synthetic*).[2]

Our results cannot currently set these theories apart, nor was this experiment conceived to contrast them directly. Moreover, despite our exhaustive-access effects, tendencies observed in the group means for each condition suggest that there may be differences in priming between conditions. In the metaphor condition, mean priming for figurative targets was higher at time point (b) than at time point (a), and priming for literal targets was higher at time point (a) than (b), although none of these differences reached a threshold of significance, which may suggest that figurative associations of the vehicle word are accessed more easily after *pragmatic* processes have been implemented. Additionally, priming for figurative targets at time point (b) was higher than for literal targets, which may suggest that literal associations with the target word are inhibited once the metaphor has been fully processed and understood.

Conversely, in the simile condition, group means indicated that priming was higher for literal targets at time point (b) than at time point (a); priming for literal targets at time point (b) was also higher than for figurative targets at the same point (b). These results suggest that similes are interpreted as literally true sentences and tend to activate literal meanings once fully processed, as the *pragmatic* model suggests. One unexpected tendency observed in the group means was that figurative targets were primed more at recognition point (a) than literal targets, and primed more at point (a) in the simile condition than the metaphor condition. A possible explanation for this result is that the word *like* in similes could lead participants to anticipate an upcoming vehicle word that is not typically literally related to the topic of the sentence.

The gating paradigm used to determine recognition points tested the moment at which each word is recognized in isolation, but context could bias listeners to correctly identify the word earlier when presented within a sentence. In the context of highly familiar similes such as *time is like money*, the word *like* could in fact trigger an assumption in the listener that the word *money* will follow, due to the frequency with which the simile is used in common language use—and cause the recognition point of the vehicle word to occur earlier than anticipated. In order to test this possibility, additional experiments are being conducted relating the strength of the early figurative priming effect to the familiarity rating of each simile.

A major methodological difference between our study and other psycholinguistic experiments employing cross-modal lexical priming (e.g., Swinney, 1979; Friedmann et al., 2008) was our use of briefly presented masked visual targets. Typically, cross-modal lexical decision tasks employ an unmasked visual target presentation lasting at least 500ms (e.g. Friedmann et al., 2008), which allows for much higher response accuracy. Forster (1999) explained that the use of very rapid masked primes should circumvent conscious thought processes about prime and target words and, instead, reflect unconscious processes of word association. Our use of masked visual targets presented for 80ms combined with presentation times at the recognition point of aurally presented vehicle words followed the rationale that in order to observe unconscious *on-line* access to semantically related concepts during metaphor processing, participants should not be allowed time to consciously consider either visual target or aurally presented vehicle. This created a speed-accuracy trade-off that resulted in a loss of data; however, the data obtained should be reflective of unconscious (*online*) facilitation processes. Experiments with greater statistical power might resolve whether tendencies observed in support of the *pragmatic* model reflect real differences in priming between conditions. Alternatively, we have also considered three views that seem compatible with an exhaustive access of both metaphorical and literal representations. What our present results seem to indicate is that there is no direct access to the contextually-determined, conventional metaphorical interpretation (e.g., Gibbs, 1994) without access to the literal meaning.

In conclusion, we found priming to targets related to both figurative and literal interpretations of metaphor and simile vehicles. The effect was found at both the recognition point (i.e., before the offset of the *vehicle*), and 500ms later. What is surprising is that we obtained priming effects at a fast target presentation time (80ms) under masking conditions, suggesting exhaustive access to literal and nonliteral-related targets before conscious judgments of metaphoricity could be made.

[2] For ease of exposition, we are simplifying the presentation of these meanings postulates, which might involve other predicate-argument relations.

Family Resemblance in Unsupervised Categorization: A Dissociation Between Production and Evaluation

Abstract

A plurality of the categories we hold exhibit family resemblance (FR; i.e., many characteristic but few defining features), suggesting FR may occupy a central role in human category formation. However, research in unsupervised learning has shown that when people are asked to sort an array of novel items into categories, they ubiquitously use a unidimensional (UNI) rule – despite the availability of a FR solution. This work suggests that, perhaps, FR similarity is *not* a core tendency in category formation. Here, we question whether the UNI bias is a result of the sorting paradigm. Specifically, we speculate the paradigm conflates two components vital for category formation: production and evaluation. Across three experiments we show that when evaluation is separated from generation – by using a novel forced-choice task that pits different category organizational schemes against one another – people exhibit a FR over UNI preference. The implications of these results are discussed.

Keywords: unsupervised categorization; similarity; family resemblance; unidimensional bias; category construction

Introduction

Understanding the cognitive basis on which we create novel categories in the absence of feedback is foundational to understanding human category learning more broadly. One way to address this question is simply by studying the categories we already hold. Theoretical and behavioral work has shown that the natural categories are described by a family resemblance (FR), or overall similarity, structure wherein members of a category share many characteristic features but share few or no defining features (Rosch & Mervis, 1975, Wittgenstein, 1953). Given the prevalence of FR among natural categories, an intuitive hypothesis is that overall similarity is the preferred or default basis on which we form novel categories.

Under this hypothesis, Medin, Wattenmaker, and Hampson (1987) sought to investigate unsupervised category formation more directly by using a sorting paradigm in which the participant was given an array of novel, multi-dimensional stimuli and asked to sort them into two equal-size categories. Critically, the examples could be sorted based on FR or, alternatively, based on a unidimensional (UNI) rule (e.g., 'red things in one category, blue things in another'). Contrary to their expectations, Medin et al. (1987) demonstrated across several experiments that people overwhelmingly preferred to construct categories described by a UNI rule; they *very seldom* created categories adherent to FR, despite UNI solutions having less within-category, and more between-category, similarities than those based on FR (Medin et al., 1987). Much work has subsequently replicated the strong UNI bias under the full-array sorting task (e.g., Ahn & Medin, 1992; Lassaline & Murphy, 1999; Regehr & Brooks, 1995; Wattenmaker, 1992).

The inconsistency between the UNI bias in the full-array sorting task and the tendency for natural categories to be described by FR has puzzled the field, and much research has been devoted to understanding why such an inconsistency exists. Coarsely, this work has two central themes: feature and task effects. Research on feature effects has shown that, generally speaking, changing the quality or the number of features is ineffective at reversing the UNI bias – and in some cases can exacerbate it (Regehr & Brooks, 1995). This of course comes with one notable exception: prior knowledge. People produce more FR sorting when the features of the FR categories map onto known concepts (e.g., the features of extro- vs. introversion), or novel concepts taught to participants, that explain and relate the features to one another (e.g., Ahn, 1999; Medin et al., 1987). This work is important for understanding category formation; however, we consider it to address a fundamentally different question. Instead of asking, "what is the organizational basis used when forming a completely novel/artificial category," it asks, "given a latent or manifest conceptual/causal basis in the features, do people construct categories by it?"

Research on task effects has shown two critical findings. First, Lassaline and Murphy (1996) showed that an inference task (e.g., 'if it has feature A on dimension 1, what feature is it likely to have on dimension 2') prior to the sorting task increased FR responding. This experiment shows that encoding feature co-prediction is vital for generating FR. However, it leaves open the question of whether people do this kind of feature encoding spontaneously during category formation.

Second, Regehr and Brooks (1995) used a novel Match-to-Standards (MTS) task in which participants sorted each item, one at a time, by matching them to one example item from each FR category; each sorted example covered up the previous example that was sorted into that category and the standards remained visible throughout the task. The MTS task led to much greater FR responding, relative to the full-array sorting task. This is suggestive that FR structure in

natural categories might be an emergent property of many item-item matches, though this connection has never been empirically drawn. Several subsequent studies have followed up on this approach to studying unsupervised categorization, examining factors such as feature separability, time pressure, and working memory load (Milton, Longmore, & Wills, 2008; Milton & Wills, 2004; Wills, Milton, Longmore, Hester, & Robinson, 2013).

However, we have two concerns with the MTS task, as the data currently stand. One, it is based on local item-to-item matching in which only the most recent item sorted into each category is visible (along with the standards); thus, while people produced more FR responding, it is unclear if that responding is attributable to the participant's appreciation of similarity structure generated across examples in each category or if instead FR responding was simply a product of making local matches (without appreciating category-level structure). Two, the task does not measure unsupervised category formation. Given the supervision, in the form of standards from each category, the task is instead a measure of semi-supervised category formation (Patterson & Kurtz, 2018; Vong, Navarro, & Perfors, 2016).

The goal of the current work was to investigate task effects in unsupervised category formation from a novel perspective that aims to address some of the limitations of previous research on task effects. We ask whether UNI similarity is indeed a deep organizational preference in category formation or if, instead, it is a direct product of the standard full-array sorting paradigm (e.g., Medin et al., 1987). We identify three aspects of the sorting task that independently or in conjunction could encourage UNI solutions. First, the task presents a whole array of multi-dimensional stimuli to the participant simultaneously. Intuitively, complexity in both the number of items and number of features might encourage problem simplification in the form of sample or dimensionality reduction. As sample reduction is not an option (participants must include all items in the solution), dimensionality reduction may be utilized.

Second, the goal of the sorting task is to produce two categories; this goal is decidedly intentional and discriminative – i.e., goal is to predict/separate class. Research has shown that intentional and discriminative learning leads to greater rule focus relative to either incidental learning or learning where class-prediction is softened (Levering & Kurtz, 2015; Love, 2002). Third, and critically, the standard sorting task conflates two intuitively essential components for category formation: the *generation* of a candidate category structure and the *evaluation* of that structure relative to possible alternatives. Given the goal of the task is to generate *one* candidate structure, the evaluation of this structure is likely to be inadequate due to insufficient alternative structures with which to compare it to. Furthermore, we expect candidate structures in naturalistic settings are generated not cold (as in the standard paradigm), and not *necessarily* with prior top-down knowledge, but through feature statistics that accrue with incidental experience (Lassaline & Murphy, 1996; Love, 2002). As such, we expect the structure hypotheses generated by participants in the sorting paradigm to be immature.

In the experiments that follow, we introduce a novel Structure Choice Task (SCT) in which two candidate structures are presented side-by-side and the participant chooses which they prefer. The task thus obviates the need to generate structure hypotheses (which we believe are undermined in the standard sorting paradigm) and isolates structure evaluation. If FR is a preferred organizational principle in category formation (and if the UNI bias is a product of the standard sorting paradigm), we should expect people to choose the FR structure more frequently than the UNI one.

We point out that the SCT resolves limitations from previous task effects research in two ways. First, the task does not rely on any pre-task encoding manipulations; participants encode the items/structures however they wish and make a judgment. As such, the preferences produced are spontaneous. Second, the task does not restrict the number of stimuli that are under consideration, as in the MTS task. Because the SCT presents whole categories, organized in two different ways, it should reflect the participant's category-level similarity preference (rather than local matching).

In Experiment 1A, we pit FR against UNI in the SCT and provide first-ever evidence of a spontaneous FR preference in a category-level task that uses knowledge-poor features. In Experiment 1B, we replicate E1A and extend it by comparing SCT results to full-array sorts completed either before or after the SCT; despite replicating the FR preference in the SCT, effectively nobody produced FR sorts – suggesting the standard sorting paradigm encourages UNI solutions. In Experiment 2, we address potential critiques to FR supremacy in the SCT.

Experiment 1A

In a within-subjects design, FR and UNI organizations of the same items were pitted against one another in the SCT. Without having to generate hypotheses, we predicted participants would prefer FR organizations.

Method

Participants 108 undergraduate students at Binghamton University participated.

Materials and Design The stimuli were based on a five-dimensional variant of the abstract FR category structure from Medin et al. (1987); each binary dimension is represented as a pair features (see Figure 1). Each category consisted of a prototype – containing all five characteristic features of the category – and five 'one-off' items that differed from the prototype by a feature that was consistent with the opposite prototype. Five 12-item stimulus sets, from distinct domains (see Figure 1 for prototypes), were

created from this abstract structure.

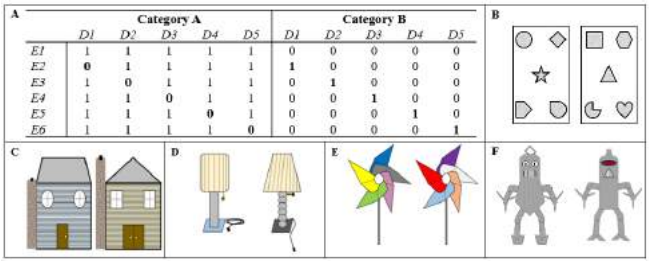

Figure 1: (A) The abstract FR structure [prototypes: row 1]; (B-F) Prototypes from all five stimulus sets: and prototypes of each category structure for all five stimulus sets, respectively: Card, House, Lamp, Pinwheel, Robot.

On each trial of the SCT, two completed sorts from the same stimulus set were presented side-by-side on the computer screen, one a FR solution and the other a UNI solution (see Figure 2 for an example trial). The UNI solution was generated on each trial of the experiment by swapping one-offs of a randomly selected row in the abstract structure, between category. Stimulus sets were presented in a randomized order. The order of items in each category of each completed sort, as well as the side on which FR was shown (left vs. right), were also randomized.

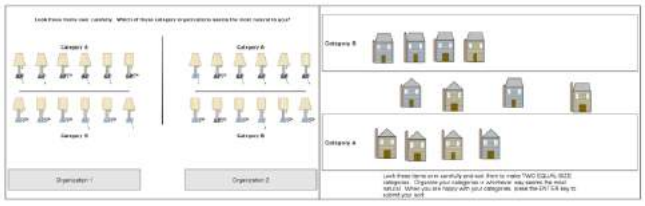

Figure 2. The left panel contains an example trial of the SCT containing a FR (right) and UNI organization (left; base color). The right panel contains an in-progress example of the sort task.

Procedure The SCT was programmed and administered via computer. Immediately prior to the task, participants were given instructions: "In this study you will be presented with a single set of items that is organized in two different ways. An example trial is pictured below. On each trial, carefully look at both organizations and select whichever one seems the most natural to you." The example trial shown with the instructions was identical to Figure 2, except the lamps were replaced with naturalistic ducks and bats – one organization had ducks and bats separated as categories A and B, while the other had them intermixed between categories. After the instructions, participants sequentially performed the SCT on each of the five domains. Participants selected their preference by clicking a button located below the organizations with the mouse. After responding, participants proceeded to the next trial/stimulus set.

Results & Discussion

We obtained a difference score for each participant that reflected their net preference (total FR selections minus total UNI selections). As there were five trials, difference scores could range from -5 (all UNI selections) to 5 (all FR selections). The analysis showed that FR organizations were selected reliably more frequently than UNI ones (the ordinal, non-normal data were subjected to a Wilcoxon signed-rank test: $Mdn = 1$, $Z = 3.787$, $p < .001$; see Figure 3). Supplemental analyses[1] provide a histogram of difference scores (pp. 1) and an analysis of preference by stimulus domain (pp. 2-3).

These results show clearly that when people's structural preferences are assayed – in the absence of being asked to produce candidate structures – they prefer FR. This provides inaugural evidence that FR may be a deep organizational basis that is sought in naïve, unsupervised category formation. Compared to the UNI bias typically seen in the full-array sorting paradigm, these findings represent a massive divergence – suggesting the affinity for UNI organizations in the sorting task is related to shortcomings in the generation of candidate structures. However, these stimuli have never been subjected to a direct comparison between the SCT and the full-array sorting task. It is possible that the stimuli we used are somehow generally more prone to be categorized by FR. This potential critique is addressed in Experiment 1B.

Experiment 1B

In this experiment, we sought to replicate the FR advantage and relate the outcomes of the SCT and the full-array sorting task using the same stimulus sets. To this end, each participant completed both the SCT and the full-array sorting task for all the stimulus sets in a task-blocked format (e.g., SCT for all sets, then sorting task for all sets). The order of the tasks was balanced across participants. We predicted participants would display a profound UNI bias in the sorting task, but that people would readily choose FR in the SCT.

Method

Participants 140 undergraduate students at Binghamton University participated. Participants were randomly assigned to the SCT first (SCT-SORT; $N = 71$) or the sort first (SORT-SCT; $N = 69$) condition.

Materials and Design The materials were identical to Experiment 1A. The same stimuli were used in both the SCT and sort task.

Procedure Both tasks were administered through a computer program. The SCT procedure was identical to that of E1A. In the SORT task, participants were instructed that there were many ways to create two equal-size categories, but their goal was to sort them in a way they thought most natural; an example sort, using the same demo images used

[1] The supplemental analyses can be viewed at this link: https://osf.io/jr2wu/?view_only=de559c73f1ef4b4da3781f4ef680f74f

for the SCT demo, was provided with the instructions. After instructions, participants then sorted each stimulus set in random order. For each stimulus set, the stimuli initialized to a row in the middle of the screen in a random order. Above and below that row were the two category bins. Participants used the mouse to drag and drop items into either category bin, and were able to reclassify the items freely. When finished, participants hit the enter key to submit. Sorts were coded as FR, UNI, or OTHER. OTHER sorts reflect any type of category produced by participants that is not FR or UNI; these sorts lack any interpretable structure. In the SORT-SCT group, participants sorted each of the randomly ordered stimulus sets before then completing the SCT for each set. The SCT-SORT group was the same, but the order of the two tasks was swapped.

Results & Discussion

The primary goal of the experiment was to replicate the FR advantage in the SCT; we use the same SCT analysis as in E1A. The SCT difference scores did not differ as a function of condition (SORT-SCT: *Mdn* = 1; SCT-SORT: *Mdn* = 1; Z = -0.41, p = .682). As such, SCT data from the two conditions were combined. Our analysis using the magnitude of the difference scores showed that participants selected the FR structure reliably more frequently than the UNI one (Wilcoxon signed-rank: *Mdn* = 1, Z = 2.98, p = .003; see Figure 3). Thus, we replicated the effect found in E1A and illustrate that when the task is constrained to the evaluation of candidate structures, FR is preferred over UNI solutions (see supplemental analyses pp. 2-3 for an analysis of preference by stimulus domain).

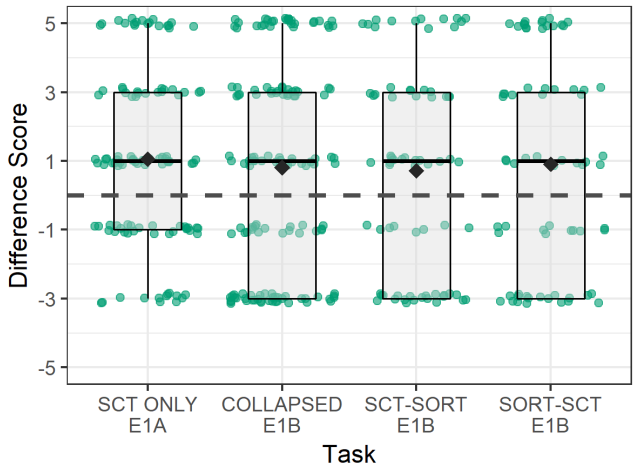

Figure 3. SCT preferences in Experiments 1A (left) and 1B (right three). COLLAPSED reflects an aggregation of both SCT-SORT and SORT-SCT conditions. Green dots reflect participant difference scores. Diamonds show means. Dashed line shows a difference score of 0 (FR = UNI).

The second goal of Experiment 1B was to compare the SCT to the standard full-array sorting paradigm, using the same stimuli as in the SCT. A potential concern from E1A is that the preponderance of FR responding in the SCT is a result of the stimuli, rather than a result of separating evaluation from production. As with the SCT data, we collapsed sort task data across conditions; the conditions did not reliably differ in the number of UNI solutions provided (SORT-SCT: 99%, SCT-SORT: 97%; $\chi^2(1, N = 593) = 0.002$, p = .967), and there were too few alternative solutions generated (FR/OTHER) to compare across order conditions. For the collapsed data, we replicated the prevalent UNI bias; participants produced significantly more UNI sorts (98%) than FR (0.2%) and OTHER sorts (1.8%) [UNI vs. FR: $\chi^2(1, N = 594) = 590.1$, $p < .001$; UNI vs. OTHER: $\chi^2(1, N = 604) = 560.8$, $p < .001$]. Moreover, more OTHER sorts were produced than FR sorts, reflecting the rarity of FR solutions produced in the sorting paradigm [$\chi^2(1, N = 12) = 8.333$, $p = .004$].

Overall, these findings show a successful replication of the FR preference under the SCT. By contrast – and consistent with previous research using the array sorting task – the sorting task led to an overwhelming number of UNI sorts. This highlights two points. First, there were only 12 non-UNI sorts produced; this means the very same people who produced consistent UNI sorts found FR to be more compelling than UNI in the SCT, under the same stimuli. This strongly suggests that the UNI bias in the sorting task arises not because participants evaluate UNI as a superior organizational principle (which the SCT data shows), but instead because some element(s) of the sorting task encourages it. Second, regarding the concern that our stimuli might generally be more prone to FR preference, the strong UNI bias in the full-array sorting task indicates that is not the case.

Experiment 2

The purpose of this experiment is to address an alternative account of the FR advantage observed and replicated in E1. Specifically, we were concerned that participants might have failed to notice the UNI rule and, in the (perceived) absence of a UNI rule, chose FR as a best of bad options (perhaps without appreciating the FR similarity).

In this experiment, we use a three-condition (within-subjects) version of the SCT. The first condition is the same FR vs. UNI choice task as in the previous experiments. However, we introduce two new conditions: UNI vs. OTHER and FR vs. OTHER. Note that the UNI vs. OTHER condition should make UNI a compelling option – provided people do notice the UNI rule in the SCT; a UNI over OTHER preference would thus suggest participants in the previous experiments did notice the UNI rule, but preferred FR. A potential concern about this design is that, by elevating UNI to an 'optimal' choice on those trials, it might invite a demand characteristic (e.g., 'UNI is better option here, maybe they want me to find/select the UNI option elsewhere') or make UNI organizations more appealing than they might otherwise be. The FR vs. OTHER condition was included to minimize these effects, as it serves to balance the number of times FR and UNI were 'optimal' vs.

OTHER groupings. In addition, it allows us to examine if FR is preferred over OTHER organizations and affords us a global measure of preference by making each response type equally probable due to chance (total FR vs. UNI, across all trial types).

Method

Participants 363 undergraduate students from Binghamton University participated.

Materials and Design The materials were the same as in Experiment 1. The design was like E1A, but expanded to include UNI vs. OTHER and FR vs. OTHER trial types, all within-subjects. OTHER organizations were created by taking a FR organization and swapping three randomly-chosen, non-prototype items from one category with three items occupying the same rows in the opposite category, according to the abstract structure shown in Figure 1; these arrangements had no discernible structure. In sum, there were three trial types: 1) FR–UNI, 2) FR–OTHER, and 3) UNI–OTHER. The particular OTHER and UNI groupings that were created for each subject were held constant across trial types within a domain (e.g., if the UNI rule was on the base color for the Lamp set [see Figure 2] in the FR-UNI trial, base color would also be used to form the UNI rule in the UNI-OTHER trial for Lamps). This was done to ensure a consistent comparison across trial types in a stimulus set.

Procedure The procedure was like Experiment 1A. Participants were presented with each stimulus set sequentially, in a random order. For each stimulus set, the participant was presented with each trial type sequentially, in a random order. In each trial type, the participant selected which of the two organizations they preferred. Unlike in the previous experiments, the participants were elicited for an explanation of their choice for each trial type in the first and last stimulus sets.

Results & Discussion

Separate difference scores were calculated for each trial type: UNI minus OTHER, FR minus OTHER, and FR minus UNI. Wilcoxon signed-rank tests were conducted on the magnitudes of the difference scores. Supplemental analyses include a histogram of difference scores (pp. 4) an analysis of preference by stimulus domain (pp. 5-6) and an analysis of FR-UNI trials based on the previous trial (pp. 7).

Our primary concern in this experiment was to determine whether people do in fact detect UNI rules in the SCT. The critical trial type for assessing this was UNI-OTHER; a UNI preference would suggest participants do detect the UNI rule. The analysis of the UNI-OTHER condition yielded a reliable UNI over OTHER preference (Wilcoxon signed-rank: $Mdn = 3$, $Z = 12.487$, $p < .001$). Importantly, the UNI preference provides strong evidence that people do in fact notice UNI rule embedded in UNI organizations and suggests that the FR over UNI preferences observed in E1A and E1B are not derived from participants simply failing to notice the rule.

The same pattern was observed in the FR-OTHER condition; participants selected significantly more FR organizations than OTHER organizations (Wilcoxon signed-rank: $Mdn = 3$, $Z = 13.195$, $p < .001$). As a complement to the UNI-OTHER analysis, this finding shows that people are sensitive to FR as a coherent organizational basis and find it compelling relative to less coherent options.

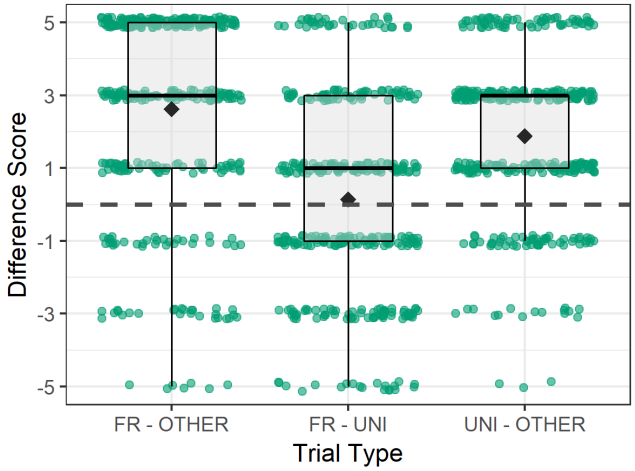

Figure 4. SCT preferences by trial type in Experiment 2. Green dots show each participant's difference score. Diamonds show means. Dashed line shows a difference score of 0. Positive scores in the FR-OTHER and FR-UNI trials reflect a FR preference; positive scores reflect a UNI preference in the UNI-OTHER trials.

Looking to the FR-UNI condition – a replication plus extension (given the novel trial types) – we failed to find the FR preference observed in E1A and E1B. The difference score magnitude did not differ from zero (Wilcoxon signed-rank: $Mdn = 1$, $Z = 0.851$, $p = .395$; see Figure 4). The failure to replicate is curious. One possibility is that the FR preference observed across E1A and E1B is a Type 1 error. However, both of those experiments were well-powered and the effect was replicated. Another possibility is that by introducing: (1) the new trial types; and/or, (2) the verbal explanations for preferences on the first (and last) stimulus set altered participants' behavior in the task. The use of OTHER organizations as a comparator effectively set up both UNI and FR organizations as 'correct' answers to the task. Then, on FR-UNI trials, the participant must decide which 'correct' answer is 'more correct'. Given UNI rules lend themselves more easily to verbal description (e.g., Zeithamova & Maddox, 2006), and given we asked participants for verbal descriptions, participants may have surmised that UNI was the 'more correct' choice and chose it more frequently than in the previous experiments. Upcoming studies will seek to disentangle these possibilities.

Lastly, we consider the global preference measure (all FR minus all UNI, across all trial types within subject). Consistent with the FR preference observed in the previous

two experiments, we found that people chose FR reliably more frequently than UNI organizations (Wilcoxon signed-rank: $Mdn = 1$, $Z = 2.543$, $p = .011$). This suggests that, despite not showing a preference for FR over UNI organizations on FR-UNI trials, participants did demonstrate an overall preference for FR when collapsing across all trial types.

In sum, we provided evidence that the FR over UNI preference observed across E1A and E1B is not attributable to people failing to notice the rule. Moreover, we provided additional evidence that people are sensitive to FR. Although the FR over UNI advantage did not replicate (potentially due to manipulations introduced in the current experiment), the FR over OTHER advantage indicates that people view FR as a meaningful organizing principle for categories.

General Discussion

The widespread UNI bias in unsupervised category formation – and its inconsistency with the FR structure of natural categories – has remained a question mark in the field for decades. In the experiments above, we approach the question from the perspective that the standard sorting paradigm encourages UNI responding by virtue of being an intentional, production-focused task that does not afford the requisite incidental exposure for learners to generate candidate structures as they might otherwise in naturalistic settings. To circumvent these issues, we introduced the SCT – a task that requires only the evaluation of provided candidate structures rather than both generation and evaluation.

Across two high-powered experiments, we observed a FR over UNI preference in the SCT – contesting the prevalent UNI bias under the sorting paradigm. This preference emerged even despite the use of knowledge-poor features (Medin et al., 1987), a full-array format (Regehr & Brooks, 1995), and despite the omission of a pre-task encoding phase (Lassaline & Murphy, 1996). Experiment 1B showed that the FR preference observed in the SCT is not due to the stimuli being generally FR-prone, as evidenced by the sorting task, and showed that people sort according to UNI rules, regardless of their SCT preference. In an extended form of the SCT, we showed in Experiment 2 that the FR preferences observed in the preceding experiments did not arise from a failure to identify the UNI rule in UNI organizations and provided further evidence that people view FR as a meaningful way of organizing categories.

These results are compelling for a number of reasons. First, they suggest that, at one extreme, people prefer FR over UNI structures in category formation (E1A & E1B). At the other extreme, they suggest that people do not have a preference between UNI and FR structures (E2). Regardless of which is true, the data show that people are sensitive to and appreciative of both types of category-level similarity, and this represents a massive departure from the strict UNI bias observed in – to our awareness – every unsupervised category learning study with domain-naïve participants and no additional encoding tasks (though see Pothos & Close, 2008; Pothos et al., 2011 which address multidimensional vs. UNI sorting – though not the specific tension between FR and UNI). As such, these findings present a potential alignment with the basis of similarity that apparently underlies natural categories (Rosch & Mervis, 1975).

Second, these results highlight the importance of task in the behaviors that are produced, afforded, and encouraged. Although we found evidence that people appreciate FR, in E1B we showed that people – many of which displayed a FR preference in the SCT – uniformly produced UNI sort solutions. Thus, by isolating a sub-component of the overall formation task, we found radically different outcomes. This suggests the discrepancy between natural and sort-task categories is tied to the generation of candidate structures and reinforces a need for researchers to examine phenomena with an array of task formats.

We note a few limitations of the present work that motivate future studies. First, though we found and replicated the FR over UNI advantage, this advantage failed to replicate in E2. In future work, we aim to disentangle if and how the additional manipulations are attributable. Second, while our data show that people prefer FR when given candidate structures, our study does not speak to how people might initially generate FR as a candidate structure in the first place. We speculate this might occur through incidental experience (without class prediction) that leads to knowledge of feature statistics, as is hinted at by previous work (Lassaline & Murphy, 1996; Love, 2002). In future work, we intend to assess if a novel, repeated, item-matching task (like MTS, but without supervision) leads to such knowledge that transfers to the sorting task. Finally, the SCT involves an absolute, forced judgment between candidate structures. In future work, we plan to: (1) assess the degree to which people prefer one structure over another using a rating scale to determine if FR is viewed as a compelling way to structure categories as opposed to the better of two poor options; and, (2) afford the option of 'no judgment' to gain greater fidelity in our results.

Abstract

Rock, Paper, Scissors (RPS) is a competitive game. There are three actions: rock, paper, and scissors. The game's rules are simple: scissors beats paper, rock beats scissors and paper beats rock (all signs stalemate against themselves). Over multiple games with the same opponent, optimal play according to a Nash Equilibrium requires subjects to play with genuine randomness. To examine randomness judgments in the context of competition, we tested subjects with identical sequences in two conditions: one produced from a dice roll, one from someone playing rock, paper, scissors. We compared these findings to models of subjective randomness from Falk and Konold (1997) and from Griffiths and Tenenbaum (2001), which explain assessments of randomness as a function of algorithmic complexity and statistical inference, respectively. In both conditions the models fail to adequately describe subjective randomness judgements of ternary outcomes. We also observe that context influences perceptions of randomness such that some isomorphic sequences produced from intentional play are perceived as less random than dice rolls. We discuss this finding in terms of the relation between patterns and opponent modeling.

Keywords: Randomness, pattern recognition, opponent modeling

Introduction

Humans often detect patterns in everyday life—so much so that they often attribute spurious patterns (generated by a random mechanism) to intentional actions. For example, in the *gambler's fallacy* (Kahneman & Tverksy, 1972), people believe that "a Red is due" after observing several Black rolls from a roulette wheel, despite the rolls being independent from one another. Conversely, according to the *hot hand effect*, if a player has scored several free throws in a row in basketball practice, people believe that player is more likely to score again, despite this not being true empirically (Gilovich, Vallone, & Tversky, 1985). Why are the patterns that people detect sensitive to their context?

Psychologists have approached these phenomena in terms of *subjective randomness*, or the perceived randomness of observations. Previous literature has shown that in some circumstances, people tend to judge sequences as random even when the underlying pattern is systematic. In a classic example, people tend to believe that a sequence of coin flips will have more alternations (e.g., heads followed by tails) and fewer streaks (e.g., several heads in a row) than is likely to occur in a sequence produced by flipping an unbiased coin repeatedly (Falk & Konold, 1997). To date, much of the literature on subjective randomness has focused on binary sequences or grids generated from a truly random mechanism, such as a coin flip, an animate mechanism (Ayton & Fischer, 2004), or a human or other intentional agent (Burns & Corpus, 2004; Caruso, Waytz, & Eply, 2010).

In this article, we compare the subjective randomness of sequences generated from a die roll to comparable sequences generated by a player who is in direct competition with another player in a non-cooperative game: Rock, Paper, Scissors (RPS; also called RoShamBo). We had two hypotheses: (1) sequences generated from a random mechanism (a die roll) would be judged as more random than equivalent sequences generated from a human playing RPS, and (2) "complex" sequences generated from a human playing RPS would be perceived even less random due to opponent modeling in a competitive context.

The rules of RPS are straightforward. Two players simultaneously present one of three hand signs, "rock", "paper", or "scissors". The scoring of the game is also simple: scissors beats paper, rock beats scissors, and paper beats rock (all signs stalemate against themselves). From a game-theoretic perspective, the Nash equilibrium (Nash, 1950) is generating signs uniformly at random. Thus, if people played according to the Nash equilibrium, they would be required to produce truly random sequences. This strategy would prevent any player from gaining advantage over another after playing repeated games over time. However, this is unlikely as people are poor at producing random sequences (Baddeley, 1966, Towse, 1998).

Although RPS may appear to be a simple game, it is actually much more complex than one might first think. For instance, while one might expect that the winners of RPS are determined by luck or chance, there are genuine RPS masters. RPS tournaments have been held throughout the world where experienced RPS players will consistently outplace novices (Hegen, 2004). One might at first think that this is simply due to extraneous factors. For example, perhaps one player produces their sign slightly before the other and the other player uses that information to change their play (note that this is illegal in tournament play). However, it is reported that a player in 2001 was allowed to bring a random number generator to inform his sequence generation. He failed to even make the qualifying rounds in the regional tournament (Hegan, 2004).

Further, there have also been machine RPS competitions (Billings, 1999), where researchers submitted automated RPS agents or "bots" to play against each other. Even when only bots compete against each other (no human players), certain

strategies are far more advantageous than others (Billings, 2000). In fact, a bot playing the Nash equilibrium using a random number generator tends to score poorly in these competitions. The results of human and machine tournaments naturally lead to the question of how opponent modeling of intentionally produced sequences might affect subjective judgments of randomness.

In a recent study of multiple repeated games of RPS between human players, Wang (2014) round that a Nash Equilibrium was never obtained by any subset of the population of participants. Rather, successful players often employ a 'win-stay, lose switch' strategy which is beneficial in identifying patterns in another's strategy, exploiting them and also retaining a fail-safe strategy which prevents repeated loses. This is notable as win-stay lose-switch has also been proposed as an explanation of human category learning (Restle, 1962), and recently has been shown to approximate Bayesian inference in some cases (Bonawitz Denison, Gopnik, & Griffiths, 2014).

Below we outline two cognitive models of subjective randomness and introduce an experiment to test their robustness in explaining ternary sequences in competitive and non-competitive environments. We close by discussing the implications and limitations of the experiment in furthering our understanding of subjective randomness.

Models of Subjective Randomness

People's judgments of randomness notoriously deviate from the prescriptions of formal probability theory in systematic ways. In experimental settings, subjects are less likely to agree that a set of coin flips that come up HHHHHHHHHH are random when compared to a set of flips that came up HTTTHTHHT. Yet, both sets of results are exactly as likely as the other given a fair coin. Even after learning probability theory, it is hard for people to escape the intuition that the latter *feels* more random than the former. How do we explain this intuition?

One popular way to model human deviations from a straightforward probabilistic account is to assume randomness judgments are a function of how difficult it is to encode a sequence or its "complexity". In these models, psychologists try to identify an encoding process or measure of sequence complexity by specifying a theoretically motivated model that is correlated with subjective ratings. Below, we discuss two prominent models from the literature.

Falk and Konold (1997). Building on an intuition from Kahenman and Tversky (1972), Falk and Konold (1997) proposed that people 'chunk' a sequence into smaller subsequences which are easier to encode and remember. The perceived randomness of the sequence is inversely related to the ease with which humans can divide sequences into fewer, more manageable subsequences. To quantify this process, Falk and Konold (1997) developed their model, the Difficulty Predictor (DP), to define the complexity of a sequence to be a function of the number of runs (subsequences with the same outcome) and alternations (subsequences which switch between two outcomes repeatedly). For example, the sequence "XXOXOX" can be described as "X twice, OX twice." Each sequence can be encoded in terms of runs and alternations. The DP of a sequence is the sum of the number of runs and two times the number of alternations. For example, the above sequence would assign one point for a sequence length of one for the first subsequence ("X") and a score of two for a sequence length of two in the second subsequence ("OX"). The DP for this sequence is three.

Only the smallest repeating unit is needed to calculate the score for a subsequence. As such "OXOX" and "OXOXOXOX" are both given a score of two points. Any given sequence can be apportioned many different ways: for example, the sequence "XOXOO" can be described a "XO twice, O once" (DP of 3) or "XOX once, O twice" (DP of 4). DP is the minimal score over possible encodings of a sequence.

This formalization of subjective randomness instantiates the concept of Kolmogorov complexity (Kolmogorov, 1965), which states that the complexity of an object is the length of the shortest program that can be used to generate that object. Previous work in psychology suggests that humans are adept at finding patterns in data and encoding them in a way consistent with Kolmogorov complexity (Chater, 1996, 1999). In fact, Griffiths et al. (2018) showed that DP is a special case of the complexity producing the sequence on a finite state machine with four motifs: all Hs, all Ts, alternating HTs, and alternating THs. The machine is biased to stay in its current motif.

Griffiths and Tenenbaum (2001) Griffiths and Tenenbaum (2001) propose an alternative model of subjective randomness by realizing that randomness judgments are not made in a vacuum: The randomness of a sequence is its relative likelihood of having been generated from a random rather than a *regular* process. Thus,

$$\text{random}(x) = \frac{P(\text{random}|x)}{P(\text{regular}|x)} = \frac{P(x|\text{random})}{P(x|\text{regular})}\frac{P(\text{random})}{P(\text{regular})}$$

Their Bayesian model then differs from the standard normative account, which only considers the likelihood of the sequence assuming a random generating process, or random(x) = P(x|random). They implement a Bayesian model that captures the likelihood of a sequence being generated by a random process compared to a regular (non-random) process. Here, we generalize their model from binary sequences to the ternary sequences that we use in our experiment.

The probability of a ternary sequence x of length N being generated by a random process is:

$$P(x|\text{random}) = (1/3)^N$$

In contrast to a random sequence, we define a regular sequence as one that is generated by a systematic process in which each token in a sequence is generated by a multinomial

process with parameter vector $\vec{\theta}$. $\vec{\theta}$ gives the probability of each type, and so θ_1 would be the probability of the first type. Because the multinomial parameters are unknown for "regular processes", an ideal observer should consider all possible parameter combinations:

$$P(x|\text{regular},\vec{\alpha}) = \int P(x|\vec{\theta})P(\vec{\theta}|\vec{\alpha})d\vec{\theta}$$

where $\vec{\alpha}$ represents the parameters for the prior distribution. We use the Dirichlet distribution due to its conjugacy with the Multinomial distribution. Integrating over all possible values for $\vec{\theta}$, we find:

$$P(x|\text{regular},\vec{\alpha}) = \frac{\Gamma(A)}{\Gamma(\text{N}+\text{A})}\prod_{k=1}^{K}\frac{\Gamma(n_k+\alpha_k)}{\Gamma(\alpha_k)}$$

where $\Gamma(x)$ is the Gamma function evaluated at x, n_k denotes the number of tokens of type k in a sequence and $A = \sum \alpha_k$. Assuming equal prior odds, $P(x|\text{random}) = P(x|\text{regular})$, the complexity of a sequence can then be defined as the log-likelihood that it was generated by a random process, as opposed to a regular process:

$$\text{LR} = \log\frac{P(x|\text{random})}{P(x|\text{regular},\vec{\alpha})}$$

Sequences with a LR greater than zero are more likely to have been generated by a random process, whereas sequences with a LR less than zero are more likely to have been generated by a regular process than a random process. Prior odds can be included in the model to shift the boundary between regular and random to a value other than zero. See Williams and Griffiths (2013) for additional empirical support of this model in capturing human randomness judgments for binary sequences.

Experiment

In previous work and both models, randomness judgments are not made in the context of two intentional human agents directly competing where the result of their competition is based on their joint decisions. Motivated by these considerations, we ask: how does a sequence being generated within a competitive context affect its perceived randomness?

In the present study we examine how well these models explain ternary sequences, rather than binary ones. We also manipulate conditions of how the sequence is assumed to be generated: either by a person playing RPS (competitive) or by the roll of a die (neutral).

Materials and Methods

We collected data from 148 subjects on Amazon Mechanical Turk. We excluded 42 subjects (28%) who had a mean response time of less than 800ms in either condition. This minimum average response time was based on an estimate of how long a subject would need to view the sequence, encode any perceived patterns and make a motor response. The data presented here reflect the remaining 106 subjects (mean age 37.3, 53 male, 52 female, 1 unknown). Each subject saw 100 sequences (sequentially) in each of the two conditions: die (neutral context) and RPS (competitive context).

In the die condition, subjects were told that a friend was playing a board game with a six-sided die that had two blue faces, two yellow faces, and two red faces. On each trial, the subject observed a sequence of seven rolls from that die.

In the RPS condition, subjects were told that they were watching two friends play a game of rock, paper, scissors. On each trial, the subject observed a sequence of seven hand gestures from the game. (See Figure 1.)

Figure 1. (A) An example sequence from the die condition. (B) An example sequence from the RPS condition that is conceptually identical to the die sequence.

There are 2,187 possible ternary sequences of length seven. We assumed that the perceived randomness of individual classes was irrelevant. e.g. that a die sequence BLUE YELLOW YELLOW is perceived as equally random as YELLOW BLUE BLUE. This reduces the pool of sequences to 729. For each subject, sequences were randomly selected without replacement from the 729 possible sequences. Images were assigned randomly to the three types so that all 2,187 sequences were observed.

The two conditions were blocked so that subjects saw 100 trials from one condition, followed by 100 trials from the other condition. The starting condition (RPS or die) was counterbalanced between subjects. The order of trials within a condition was random, but identical for both conditions for each subject (e.g., if a subject saw sequence A from Figure 1 as trial 1, they might see the isomorphic sequence B from Figure 1 as trial 101).

Subjects rated each sequence on a Likert scale from 1 ("Not random at all") to 10 ("Very random"), with midpoint label of "Somewhat random." Following the experiment, subjects completed a brief demographic survey that also included questions about their level of education, experience playing rock paper scissors, and whether they had taken a statistics or probability course.

Results

We began with two hypotheses: (1) sequences generated from a random mechanism (a die roll) would be judged as more random than equivalent sequences generated from a human playing RPS, and (2) high alternation sequences generated by an intentional agent in the context of a game

would be perceived even less random due to opponent modeling in a competitive context.

To test the effect of sequence production on a subject's randomness judgments, we first compared the scores of reported randomness between conditions. We found a significant effect, with sequences produced from a die being considered more random than sequences produced by games of rock, paper, scissors, $M_{die} = 5.78$, $M_{RPS} = 5.47$, $t(105) = 2.93$, $p = .004$. This confirms our first hypothesis that participants perceive outcomes produced by people to be more random than those produced by a die.

Though individual subjects varied greatly in their mean scores of subjective randomness, there is a clear trend towards evaluating sequences from the RPS condition as more random than the sequences produced from the dice condition. See Figure 2.

We expanded this analysis further by examining whether randomness judgments are partially explained by the difficulty of encoding a sequence to memory (as they were in Falk and Konold, 1997). Using response time as a proxy for encoding difficulty, we found that there was a significant effect for reaction time between conditions, $M_{die} = 2372$ms, $M_{RPS} = 3091$ms, $t(105) = 4.45$, $p < .001$. This means subjects took longer to respond to randomness judgements in the RPS condition compared to the dice condition.

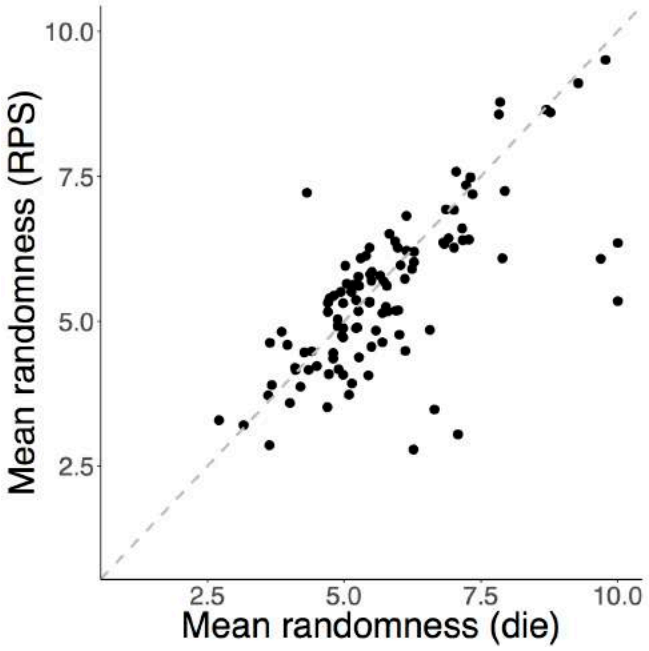

Figure 2. Each point denotes an individual subject's mean randomness judgment for the die condition (x-axis) and RPS condition (y-axis). The identity line is shown for comparison.

We calculated the complexity of each sequence according to three measures: Falk and Konold (1997)'s difficulty predictor (DP), Griffiths and Tenenbaum (2001)'s Likelihood Ratio (LR), and the probability of alternation. Overall, all three measures were highly correlated with subjective randomness judgments (see Figure 3). We found a difference in subjective randomness judgments by condition that was moderated by the complexity of the sequence. Sequences of low complexity (as judged by either DP, LR, or probability of alternation) were judged to be equally non-random regardless of whether the sequence was in the die or RPS condition. However sequences of high complexity were judged to be more random in the die condition compared to the RPS condition. We discuss this further later in the article.

Discussion

Classic studies on subjective randomness have had subjects judge binary (e.g., heads and tails, black and white tiles), or digit sequences. The pattern of performance described by Falk and Konold (1997) is that subjects will overestimate the number of alternations that would need to be present in a truly random sequence. In a sequence of tosses from a fair coin, we expect that a genuinely random sequence has a probability of alternation of 0.5. While subjects studying coin flips might overestimate the number of alterations in a given sequence, a fully alternating sequence would not be seen as random but following a predictable alternating pattern.

This contrasts sharply with the current findings, where a truly random sequence would have a probability of 0.67. Subjects continue to overestimate the number of alterations within a random sequence, but they do so without showing a decline towards less randomness at higher alteration values. This is because using the probability of alternation is not as useful as a measure in the case of ternary sequences. For example, the sequence RPRPRP has the same probability of alternation as the sequence RPSPSR, though the latter appears more random. In a binary sequence, an "alternation" implies what the next item in the sequence will be, but this is not true for ternary sequences. This highlights a limitation of using probability of alternation as a proxy for subjective randomness judgments.

We found that on average, a sequence of die rolls was judged to be more random than an equivalent sequence of rock paper scissors throws. This effect seems to be driven by higher judgments of randomness for high-complexity sequences in the die condition compared to the RPS condition. Currently, no model adequately describes why this difference between conditions might occur, or why the differences between conditions should be primarily observed in high complexity sequences.

There are several potential explanations for these trends. One possibility is that that randomness judgments are primarily influenced by the mechanism that generates that sequence, rather than the sequence itself.

The fact that RPS throws are the product of intentional action, while die outcomes are generated by chance is a promising hypothesis. Caruso, Waytz, and Epley (2010) explored this type of intentional action as a possible explanation for differences between the hot hand effect and the gambler's fallacy. They found that participants who were told to focus on the intentions of a coin tosser were more likely to expect a coin toss streak to continue compared to

participants who were told to focus on the motor actions of the tosser. However participants were never asked explicitly to judge the randomness of sequences and it was not a directly competitive context. Similarly, Ayton and Fischer (2004) tested whether differences in gambler's fallacy and hot hand might be accounted for by animacy in the generation process. Neither of these mechanisms alone explain the results observed in our study where only high complexity sequences appear to show differences in randomness ratings.

A related explanation is that subjects may be reluctant to use the upper end of the randomness scale in the RPS condition because they are explicitly told that the sequences were generated by a human, and their belief that humans cannot (or do not) produce truly random sequences. This interpretation is anticipated by Burns and Corpus (2004) who found that subjects expect streaks to continue if they are generated by a non-random process ie: a human player. Therefore subjects might perceive sequences with high rates of alternation as less likely.

There is some counterevidence to this hypothesis in our results: z-scoring each participants' ratings does not eliminate the lower randomness ratings specific to more complex sequences..

A second hypothesis is that in the context of playing a game of RPS, subjects expect to see more complex sequences. A competent rock, paper, scissors player should try to make each throw as unpredictable as possible in order to beat his or her opponent. Therefore, we should expect a player to generate complex sequences intentionally. Subjects may have judged highly complex sequence as less random in the RPS condition because they believe a player planned that sequence in order to fool their opponent. Somewhat paradoxically, this means that sequences that are descriptively more random are seen as less random, due to the fact that they are unsurprising in the context of the game. This distinction between descriptive complexity and observed complexity has been used to explain, for instance, why descriptively simple lottery results (such as 1-2-3-4-5) are seen as more surprising (Dessalles, 2017).

Thirdly, RPS presents a sequence in a two-player game. This may lead subjects to underestimate randomness by urging them to look more closely for possible subtle patterns in the sequences generated by opponent modeling. In the die condition, each roll is assumed to be independent of the previous roll. But in the RPS condition, each throw may be conditionally dependent not only on the player's previous throw, but also the opponent's previous throw. This naturally leads to a larger hypothesis space from which subjects may be inferring potential patterns. This expansion of the hypothesis space could disproportionately affect more complex sequences and therefore explain the observed differences between low and high complexity sequences.

Hypotheses 2 and 3 operate under the assumption that expectations based on both context and generation method contribute to perceptions of randomness. While previous studies have shown that generation method plays a role, they do not explicitly contrast between a sequence produced in a directly competitive vs. non-competitive contexts. An aim of future research will be to understand how generation process, context and the complexity of a sequence may interact in order to explain the current results.

One limitation of the current study is that subjects may have a biased prior belief that die rolls are more random than RPS sequences, independently of the likelihood of a given sequence. Future studies may explicitly equate these priors. For instance, subjects could be shown two sequences of die rolls and informed that one sequence was generated by a fair die (random) and the other by a weighted die. Identifying the "cheater" in this case depends only on the likelihood, as the experiment can be designed so that the prior probability of each die is equal (0.5).

Another limitation is that our stimuli consist only of sequences of length 7, and each unit in the sequence can only be one of three possible types. It is not clear whether our results extend to longer sequences, and to multinomial sequences beyond three types. We also do not account for perceptual similarity in our stimuli: the die images in our experiment are similar to each other (except for color), and

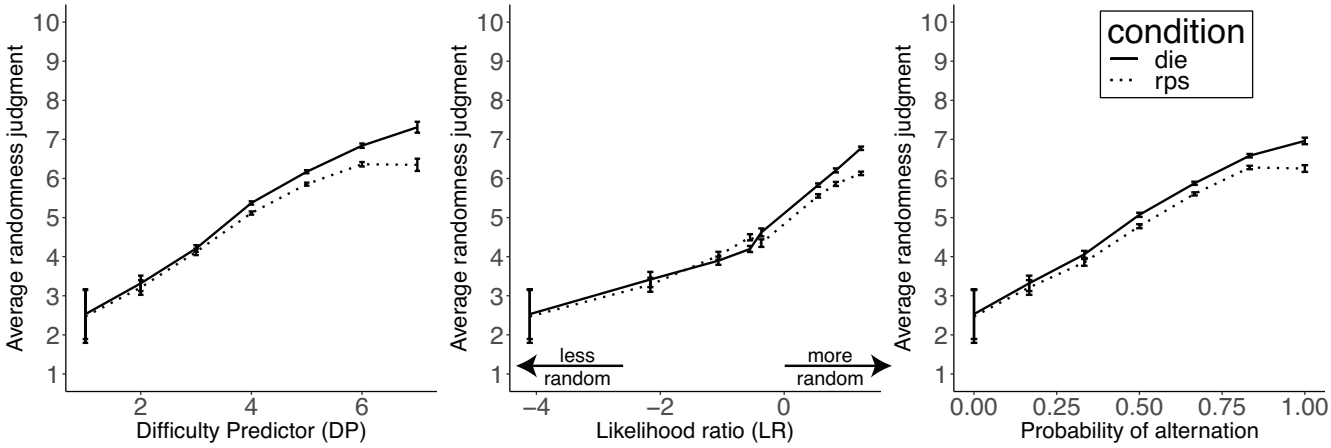

Figure 3. Average subjective randomness ratings were correlated with Falk and Konold (1997)'s Difficulty Predictor (left), Griffiths and Tenenbaum (2001)'s Likelihood Ratio (center) and the probability of alternation (right).

participants may be sensitive to perceptual similarity when assessing sequences.

Humans are notoriously poor at inferring randomness from sequences. This cognitive error seems to be exacerbated in competitive contexts. However, this might just as easily be reframed in a different light: People are more attuned to possible patterns of behavior when they are inspecting it within a competitive context. This may lead them to be less likely to write off certain patterns as 'mere luck' when they might carry valuable adaptive information for future planning and strategizing.

Modelling mental imagery in the ACT-R cognitive architecture

David Peebles (d.peebles@hud.ac.uk)
Department of Psychology, University of Huddersfield
Queensgate, Huddersfield, HD1 3DH, UK

Abstract

I present a novel approach to modelling spatial mental imagery within the ACT-R cognitive architecture. The proposed method augments ACT-R's representation of visual objects to enable the processing of spatial extent and incorporates a set of linear and affine transformation functions to allow the manipulation of internal spatial representations. The assumptions of the modified architecture are then tested by using it to develop models of two classic mental imagery phenomena: the mental scanning study of Kosslyn, Ball, and Reiser (1978) and mental rotation (Shepard & Metzler, 1971). Both models provide very close fits to human response time data.

Keywords: Mental imagery; Mental rotation; Image scanning; ACT-R; Cognitive architectures.

Introduction

Mental imagery plays a crucial role in many aspects of cognition, from problem solving, creativity and scientific discovery to psychological disorders such as post-traumatic stress disorder, social phobia and depression (Kosslyn, Thompson, & Ganis, 2006; Pearson, Deeprose, Wallace-Hadrill, Burnett Heyes, & Holmes, 2013). Mental imagery has also been the subject of one of the longest running and fiercest debates in cognitive science (Kosslyn & Pomerantz, 1977; Pylyshyn, 1973; Anderson, 1978; Tye, 2000) and the nature of the mental representations and processes underlying mental imagery is still a subject of contention.

Two related issues concern the degree to which mental representations bear some structural correspondence to what they represent and whether mental imagery is supported by abstract, amodal propositional representations or depictive representations grounded in perception. In contrast to abstract propositional representations, imagistic visual representations depict rather than describe what they represent and retain the spatial relationships of their referents by having elements with geometric properties organised topographically (Reisberg, 2013).

This debate has been—and continues to be—driven and informed by the various attempts to provide formal computational accounts of mental imagery phenomena (e.g., Glasgow & Papadias, 1992; Kunda, McGreggor, & Goel, 2013; Tabachneck-Schijf, Leonardo, & Simon, 1997; Just & Carpenter, 1985) and the issue of whether imagery requires some form of array based representation or can be accomplished by more abstract, amodal representations and processes.

An early and influential cognitive model that combined pixel array based representations and more abstract representations is the CaMeRa model of expert problem solving with multiple representations (Tabachneck-Schijf et al., 1997). A more recent example is a model of problem solving on the Raven's Progressive Matrices test by Kunda et al. (2013) using 2D arrays of grayscale pixels and associated transformation operations. Using only these representations and processes, the model is able solve between 55% and 63% of Standard Progressive Matrices problems.

Figure 1: Stimulus used by Kosslyn et al. (1978).

Mental imagery in cognitive architectures

In recent years there have been a number of attempts to develop computational accounts of mental imagery from within the assumptions and constraints of *cognitive architectures* (e.g., Rosenbloom, 2012; Wintermute, 2012). Cognitive architectures are theories of the core memory and control structures, learning mechanisms, and perception-action processes required for general intelligence and how they are integrated into a "system of systems" to enable human cognition and autonomous, human-level artificial cognitive agents.

The cognitive architecture with one of the most well developed and comprehensive set of representations for spatial reasoning and visual imagery is Soar (Laird, 2012) and its *Spatial/Visual System* (SVS) (Lathrop, Wintermute, & Laird, 2011; Wintermute, 2012). The SVS system contains two layers of representation: a *visual depictive* layer (a bitmap array representation of space and the topological structure of objects), and a *quantitative spatial* layer (an amodal symbolic/numerical representation of objects and their spatial coordinates, location, rotation and scaling)[1].

SVS also contains operations to transform the continuous information in the quantitative spatial layer into symbolic information that can be used by Soar for reasoning. These pro-

[1] In the current (9.6.0) version of Soar, the visual depictive level has been omitted from SVS.

cesses allow Soar agents to perform mental imagery operations that can manipulate the representations and then extract spatial relationships from the modified states.

Several proposals have been put forward to endow the ACT-R cognitive architecture (Anderson, 2007) with spatial abilities. For example Gunzelmann and Lyon (2007) outlined an extensive proposal for modelling a range of spatial behaviour (including imagery) by augmenting the architecture with a spatial module and several additional buffers and processes for transforming spatial information. These proposals have, as yet, not been implemented however and so it remains to be seen whether the suggested changes would be able to account for human spatial competence.

An alternative approach to providing ACT-R with spatial capacities is the ACT-R/E project to embody ACT-R in robots (Trafton et al., 2013). ACT-R/E incorporates the *Specialized Egocentrically Coordinated Spaces* (SECS) framework (Trafton & Harrison, 2011; Harrison & Schunn, 2002) which adds modules for three aspects of spatial processing: 2D-retinotopic space, configural space for navigation and localisation, and manipulative space for the region that can be grasped by the robot.

Both of these approaches are broad in the sense that they propose extensive changes to the architecture (i.e., new modules and buffers) and seek to endow ACT-R with a wide range of spatial capabilities related to different spaces (Montello, 1993). Neither approach has modelled spatial imagery however. The aim of the study reported here is to fill this gap by developing ACT-R models of human spatial imagery behaviour. The approach adopted here is more limited and focussed than those discussed above in that it does not propose new modules or buffers but seeks to determine whether the phenomena can be accounted for with only minor adjustments to the existing structures and assumptions of ACT-R.

In the following sections I describe the relevant structures and assumptions of ACT-R and the adaptations required to allow the architecture to model spatial imagery. I then test the approach by using it to develop two models of well known mental imagery phenomena: mental scanning and mental rotation. Finally I discuss the implications, strengths and weakness of the approach and consider further applications.

An ACT-R approach to mental imagery

A full description of ACT-R is beyond the scope of this paper and so this description will be limited to the two components most relevant to this work: the *vision* module which allows ACT-R to perceive objects in external task environments and the *imaginal* module, located at the intraparietal sulcus (Borst & Anderson, 2013; Borst, Nijboer, Taatgen, van Rijn, & Anderson, 2015) and which functions as ACT-R's limited capacity working memory store in which information is represented and manipulated during problem solving.

ACT-R's perceptual and motor systems were designed to support interaction with computer interfaces to simulate human participants in psychology experiments and therefore typically works within a screen-based 2D coordinate space. ACT-R's visual module doesn't interact with the computer interface directly but via a *visual icon*, an intermediate symbolic representation of the objects in the visual environment.

When ACT-R's visual attention is directed towards an object in the visual icon, information about the object enters two buffers: a *visual* buffer containing information about the object's features (type, shape, colour etc.), and a *visual-location* buffer representing the object's coordinate location. These two distinct buffers correspond to the dorsal *what* and ventral *where* pathways in human visual processing respectively (Ungerleider & Mishkin, 1982; Milner & Goodale, 1993).

Once information has entered the buffers, it is available for further processing, for example as a cue to retrieve further information from ACT-R's declarative memory module or to create a new problem state representation in the imaginal module. Compared to other modules, the imaginal module has a greater degree of flexibility in that, in addition having standard buffer for creating and holding information, it also has an *imaginal-action* buffer to allow the module to be extended with novel capabilities by enabling arbitrary actions to be performed on information in the imaginal buffer. This feature will be crucial for modelling mental imagery.

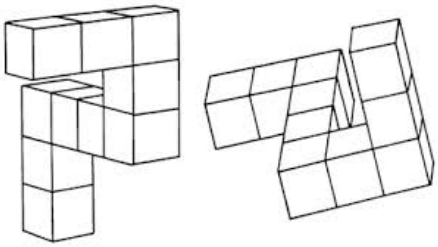

Figure 2: Stimuli used by Shepard and Metzler (1971).

Modifications required to model imagery

Many spatial imagery phenomena involve mental representations of the shape, location, orientation and spatial extent of the imagined objects and a set of processes that are able to transform and compare objects according to these characteristics. While the representational and processing assumptions of ACT-R outlined above impose strict but valuable constraints on methods for modelling mental imagery, in this regard, the discrete symbolic representations of ACT-R's visual module (e.g., shape = 'square') with only one x-y coordinate location for each object are currently inadequate.

In light of this, the approach I adopt augments ACT-R with the addition of a new feature slot in the visual object chunk and a number of functions for spatial processing. The first modification provides ACT-R with additional information regarding the outline shape of environmental objects (in the form of a list of x-y coordinate points). The second provides ACT-R with the ability to perform various imagery operations (e.g., translation, scanning, scaling, zooming, reflection, rotation and composition functions such as intersection, union

and subtraction) using a set of linear and affine transformation functions which act upon the new x-y outline coordinates in the imaginal module via the imaginal-action buffer.

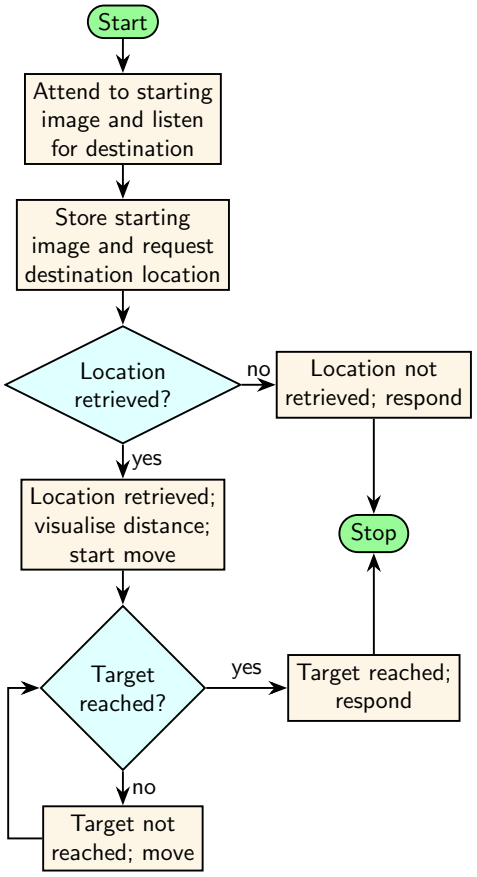

Figure 3: Control structure of the ACT-R model for a trial of the mental scanning experiment. Each rectangle corresponds to one production rule in the model.

Testing the approach

In the remaining sections, the assumptions set out above are tested by using the augmented ACT-R to develop models of two well known mental imagery phenomena: mental scanning and mental rotation[2]. The strategy adopted is one employed by Just and Carpenter (1985) in their model of mental rotation and is similar for both tasks in that the process consists of a series of discrete steps in which the mental image is repeatedly manipulated and then compared to the target image to determine whether they are sufficiently close to stop.

Mental scanning

The first test of the approach is the classic study of mental scanning by Kosslyn et al. (1978) in which people were required to memorise the locations of landmarks on a fictitious map and then imagine travelling between them (see Figure 1).

[2]Both ACT-R models are available to download from GitHub: https://github.com/djpeebles/act-r-imagery-models

On each trial of their experiment participants were asked first to focus on one of the landmarks and then were presented (aurally) with a *destination* word, which may or may not be a landmark. If the given word did name a landmark, participants were required to scan to it and press a button upon reaching it, but if the word was not a landmark, participants simply pressed a second button.

Scanning was performed by imagining a small black speck moving along the shortest straight line from initial to destination landmarks as quickly as possible while still remaining visible. Participants were timed while carrying out the task and analysis of the response times (RTs) revealed a linear relationship between the distance travelled and the time taken to reach the destination.

Modelling the mental scanning task An ACT-R model of the mental scanning task was created consisting of six production rules. The control structure of the model is shown in Figure 3. According to this model, when people hear a destination landmark, they retrieve its location from memory, visualise the distance to be travelled, and then execute a process which incrementally shifts a point from the initial location to the destination by a constant amount. After each movement step, the distance between current and target locations is reviewed to determine whether it is sufficiently short for the process to stop.

The key step involving the new representation and process is represented by a production rule ("Target not reached; move" in Figure 3) which evaluates the distance between the current and target locations and if it is greater than a stopping threshold, uses a translation function to move the current point closer by a fixed amount.

The model assumes that the process of imagining the actual inter-point distance, d_a, is subject to a degree of perceptual error which is a function of d_a, so that visualising greater distances is more errorful. This error, k, is represented by a random value sampled from a logistic distribution with mean 0 and variance $\ln(d_a)$ so that the imagined distance, d_i, is

$$d_i = d_a + bk \tag{1}$$

where b is a scaling parameter.

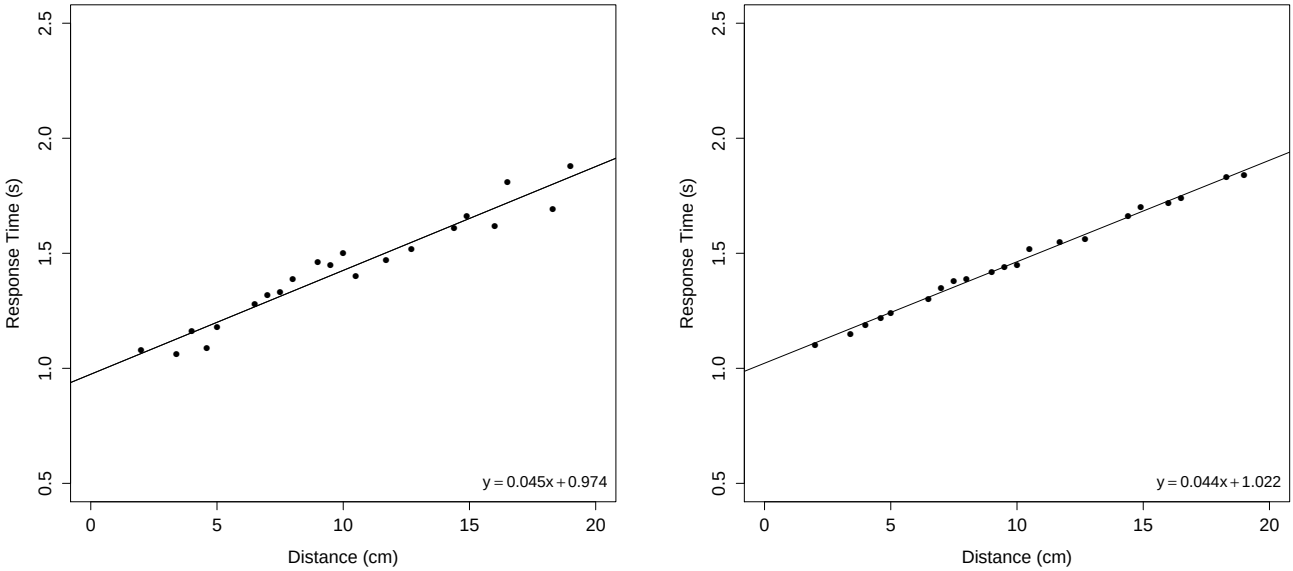
The key determinant of the time taken to traverse the imagined distance is the size of the movement, m, taken at each step and it is assumed that this is related to d_i so that the step size increases with the imagined distance according to

$$m = c \ln(d_i) \tag{2}$$

where c is a scaling parameter.

Finally, it is assumed that the decision to stop is related to the distance to the destination and that this may differ between individuals due to their degree of accuracy or diligence. This distance is represented in the model by a *proximity threshold* parameter, p.

In addition to the three task specific parameters, two ACT-R parameters were also allowed to vary: the *imaginal delay*



(a) Data from Kosslyn et al. (1978).

(b) Data from the ACT-R model

Figure 4: Mean scan time for different distances.

time, t which determines the time cost associated with transforming information in ACT-R's imaginal buffer, and the *latency factor* parameter, F, which modulates the retrieval time for declarative chunks.

To test the model, it was run 50 times (to simulate 50 participants) for all of the 21 distances in the original Kosslyn et al. (1978) study and the mean scan time for each distance computed. Figure 4b shows that the model (with parameters $b = 3$, $c = 18$, $p = 10$, $t = 0.1$ and $F = .75$) provided a close fit to the human data ($R^2 = .97$, RMSD $= 0.07$).

Mental rotation

The second application of the approach is to a mental rotation task, first devised by Shepard and Metzler (1971). In its original form, participants are presented with pairs of similar images, one of which has been rotated around its centre, and then required to decide whether the images are identical or not (see Figure 2). As with the mental scanning task, RT in the mental rotation task increases monotonically with distance—in this case the degree of angular rotation between the images—at approximately 1 second per 60°.

Mental rotation has been studied extensively in a wide variety of different forms and a number of different strategies have been identified (e.g., Khooshabeh, Hegarty, & Shipley, 2013). For this study I model a *holistic* rotation strategy by which mental images (in this case random 2D shapes (Cooper, 1975)) are rotated as single, whole units. This contrasts with a *piecemeal* strategy which subdivides the image and rotates the component pieces separately.

Modelling the mental rotation task An ACT-R model of the mental rotation task was created consisting of five production rules. The control structure of the model is shown in Figure 5. The mental rotation model employs a very similar strategy to the image scanning model in that it performs the task by transforming a current set of coordinate points (in this case by rotation rather than translation) incrementally towards the target, at each step evaluating the remaining distance (i.e., angular displacement) to determine whether or not to stop. As with the scanning model, the key step involving the new representation and process is carried out by a production rule ("Stimuli not aligned; rotate" in Figure 5) which gauges the distance between the current and target images and if it is greater than a stopping threshold, uses a counter-clockwise rotation function to move the current image closer by a fixed amount.

To test the model, it was compared to data from a standard rotation task conducted in Experiment 1 of a recent study conducted by Larsen (2014). The data are taken from a condition in which the target image and a rotated version of the image were presented side by side on a computer screen (the most common form of the task). Ten degrees of rotation were used, from 0 to 180 degrees in increments of 20.

According to the model, when performing the mental rotation task using a holistic strategy, people encode the rotated image, store it in working memory, and then encode the target image. Then, while maintaining visual attention on the target image, people execute a process which incrementally rotates the image counter-clockwise towards the target image by a constant amount (subject to a degree of perceptual er-

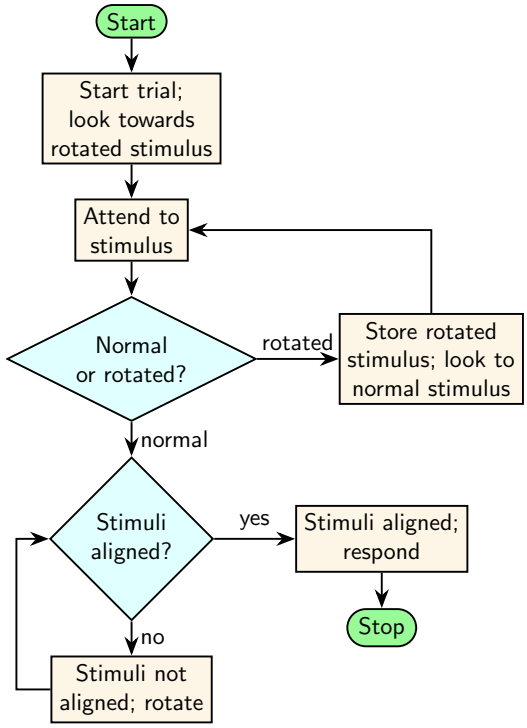


Figure 5: Control structure of the ACT-R model for a trial of the mental rotation experiment. Each rectangle corresponds to one production rule in the model.

ror, represented by a random value sampled from a logistic distribution with mean 0 and variance k).

After each rotation step, the angular disparity between current and target coordinate points is reviewed to determine whether they are sufficiently close for the process to stop. This test is a measure of image similarity in that if the points do not coincide then the rotation process will not stop.

The rotation model shares a number of the same free parameters as the scanning model. As with the scanning model, the rotation model assumes that RT is determined by the size of the rotation increment, m, taken at each step and the proximity threshold, p regulating the stop decision. In the rotation model, the ACT-R *imaginal delay time* parameter, t, was also set to the value of .1s in line with the scanning model.

To test the model, it was run 50 times (to simulate 50 participants) for all of the 10 rotation angles in the original Larsen (2014) study and the mean RT for each distance computed. Figure 6b shows that the model (with parameters $k = 2$, $m = 18$, $p = 10$ and $t = 0.1$) provided a close fit to the human data ($R^2 = .983$, RMSD $= 0.185$).

Discussion

The work described above demonstrates that with only relatively minor modifications and a small number of reasonable assumptions, ACT-R can be applied to develop models of mental imagery phenomena that match human RT data very closely. Crucially, the modifications are restricted to enabling the representation and transformation of shape information but the new representation and processes integrate with the existing control structures of ACT-R so that the behaviour of the model is primarily a result of the strategy encoded in the production rules (which is essentially the same for both tasks) and the information processing assumptions built into the ACT-R's imaginal module.

The architectural parameters used to fit the models are few in number and within acceptable limits. The *imaginal delay time* parameter was set to the same value of .1s for both models but this is shorter than the typical value of this parameter (.2s). The justification for this reduced time is that compared to other tasks that have been used to set this parameter (e.g., algebraic manipulation) the process being carried out in each model (incremental translation or rotation of a representation already in the buffer) is relatively simple and brief.

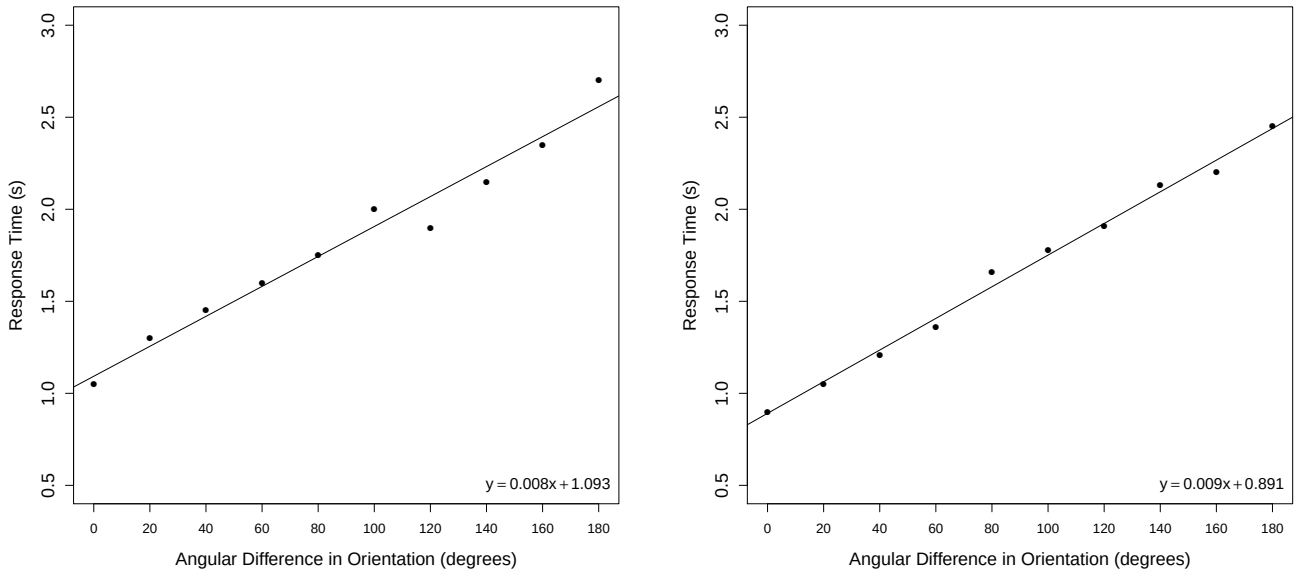
The representation of object spatial extent is not at the level of pixel arrays nor at the level of discrete symbols, but at an intermediate numerical level that abstracts from the pixel level. Similarly, The transformation processes incorporated into the architecture are quantitative in nature and are assumed to belong to the wider set of subsymbolic functions that act upon quantitative information in ACT-R at a level closer to the visual system than the qualitative reasoning processes over symbolic representations.

In this regard, the current work represents a modest step towards answering the question concerning the nature of the representations required to support mental imagery discussed in the introduction. Like many other cognitive architectures, ACT-R is rooted in the classical tradition of cognitive science and the physical symbol system hypothesis (Newell & Simon, 1976) and relies predominantly on amodal symbolic representations and their associated quantitative metadata (Laird, Lebiere, & Rosenbloom, 2017).

As cognitive architectures evolve to capture ever more complex and varied behaviour however, the demand to represent more diverse information formats and computational processes will continue to grow. As this occurs, it will be crucial to investigate the computational capabilities and functional adequacy of alternative representations and processes by modelling tasks that require multiple internal and external representations to provide behavioural evidence for which representations are being used.

There is currently a range of proposals for such representations and processes, several of which were discussed in the introduction. Some advocate some form of bitmap representation to depict the topological structure of objects, while others argue for more abstract representations (or a combination of both). The demands of applying cognitive architectures to more complex, embodied, real world and real time tasks will provide a strong impetus to addressing these questions.

The two behavioural studies modelled here are classics in the literature that have been investigated extensively, and as such they provide a useful initial test of the assumptions. They are relatively simple in nature however (as revealed by



(a) Data from Larsen (2014).

(b) Data from the ACT-R model

Figure 6: Mean response time for different degrees of rotation.

the fact that they can both be modelled by a small number of production rules). A more stringent test of the assumptions is necessary therefore and this will come either from modelling different strategies in the mental rotation task or from different, more challenging tasks, for example the Raven's Progressive Matrices (c.f. Kunda et al., 2013), the *pedestal blocks world* or the *nonholonomic car motion planning* task (Wintermute, 2012) as these require more complex strategies involving a wider range of spatial transformations and will provide richer behavioural data. This is the plan for the next stage of this project.

Abstract

We see the world as continuous with smooth movements of objects and people, even though visual inputs can consist of stationary frames. The perceptual construction of smooth movements depends not only on low-level spatiotemporal features but also high-level knowledge. Here, we examined the role of causality in guiding perceptual interpolation of motion in the observation of human actions. We recorded videos of natural human-object interactions. Frame rate was manipulated to yield short and long stimulus-onset-asynchrony (SOA) displays for a short clip in which a catcher prepared to receive a ball. The facing direction of the catcher was either maintained intact to generate a meaningful interaction consistent with causality, or was transformed by a mirror reflection to create a non-causal situation lacking a meaningful interaction. Across three experiments, participants were asked to judge whether the catcher's action showed smooth movements or sudden changes. Participants were more likely to judge the catcher's actions to be continuous in the causal condition than in the non-causal condition, even with long SOA displays. This causal interpolation effect was robust to manipulations of body orientation (i.e. upright versus inverted). These findings indicate that causality in human actions guides interpolation of body movements, thereby completing the history of an observed action despite gaps in the sensory information. Hence, causal knowledge not only makes us see the future, but also fills in information about recent history.

Keywords: causality; causal action; motion interpolation; human action; human interaction

Introduction

In our daily life, we are constantly incorporating new visual information to form a continuous impression of the dynamic world. However, the perceptual construction of smooth movements is not a trivial task, since visual inputs are actually discrete frames or disjointed clips separated by constant eye movements. Flipbooks, for example, exploit our susceptibility to apparent motion (Wertheimer, 1912), where our visual system induces the perception of dynamic scenes from the presentation of static images in rapid succession. Apparent motion offers an illustrative case of the human visual system's tendency to interpolate the paths of perceptual objects over time, and to produce the perception of smooth motion across discrete samples of visual stimuli at different time points. It is well-known that the appearance of smooth motion is determined not only by low-level visual features, such as inter-frame spatial displacement and temporal sampling rate (Braddick, 1974; Burr, Ross & Morrone, 1986), but also by high-level visual knowledge about shapes, objects and events involved in the stimuli (Sigman & Rock, 1974; Braddick, 1980; Shiffrar & Freyd, 1990; 1993; Chen & Scholl, 2016).

In the present paper, we examine whether causal knowledge inherent in human actions influences the extent to which the visual system interpolates body motion. The sense of cause-effect relation can emerge from the irresistible perception of events involving causation, demonstrated by the well-known launching effect between two colliding objects (Michotte, 1946). However, such automatic perception arises not just for physical causation, but also for intentional causation in the social environment. Even as young as 9-month-old, infants perceive objects as "intentional agents" whose states can cause behavioral activities (Crisbra et. al., 1999). Both physical and social causal perceptions are susceptible to the change of spatiotemporal features in dynamic scenes. For example, the perceived causation in the launching event depends on relative speeds of objects in the scene, spatial gaps between those objects, temporal gaps between objects' motions, objects' path lengths (Scholl & Tremoulet, 2000). On the other hand, causal perception can also influence perceptual judgments and memory about spatiotemporal properties in dynamic events.

Previous research has shown that humans rely on their prior knowledge about the causal relation between limb movements and body motions in perceiving human actions (Peng, Thurman, & Lu, 2017), as actions are perceived more natural if visual stimuli are in accordance with causal expectation for human body movements. Causal knowledge has also been shown to elicit false memories of body movements. Strickland and Keil (2011) found that implicit causal connections between agents and objects led to false memories of action frames that were never presented. For example, adults watched videos in which an actor kicked a ball, but the videos omitted the moment in which the actor actually contacted the ball. In a later recall task, participants falsely reported seeing the physical contact when the subsequent footage implied a causal relation between the actor's movements and the motion of the ball. Similarly, Bechlivanidis and Lagnado (2013, 2016) demonstrated that causal knowledge can induce false memories about the temporal order of events. Having a belief that event type A causes event type B made participants more likely to misremember sequences of observed events that violated those causal beliefs (i.e., when an event of type B

temporally preceded an event of type A) than sequences that coincided with their causal belief.

These findings present compelling cases in which causal knowledge plays an influential role in consolidating memories about actions and events. In addition, work on causal binding has shown that causal knowledge biases the perception of time and space (Humphreys & Buehner, 2009, 2010; Buehner, 2012). For example, Buehner and Humphreys (2009) demonstrated that when one event is represented as causing another, the perceived time lapse between the two events appears shorter than when the two events are not causally related. This finding indicates that two causally related events are more likely to trigger the perception of spatiotemporal contiguity.

In the present paper, we test the hypothesis that the perceptual system uses prior knowledge about causal relations in actions to fill in missing information between static frames, yielding the subjective experience of smooth motion in human actions. We recorded videos of human-object interactions in a natural environment (a thrower directing a ball to a catcher). For short clips in which the catcher prepared to receive the ball, the frame rate was manipulated to introduce short and long inter-frame durations, defined as stimulus-onset-asynchrony (SOA). The duration of short SOAs was 33.3 ms/frame; that of long SOAs was 100 ms/frame. For causal actions, the facing direction of the catcher was maintained to generate a meaningful interaction consistent with a causal interpretation. For non-causal actions, the facing direction of the catcher was inverted to disrupt any meaningful interaction and generate an action sequence inconsistent with a causal interpretation. Participants were asked to judge whether the catcher's action showed smooth body movements or sudden changes. If causal knowledge in actions creates a top-down influence on interpolation of discrete pieces of motion information, observers will be more likely to perceive smooth actions when observing causal than non-causal actions. In addition, the predicted effect is expected to be stronger for long-SOA displays in which the visual inputs are sparse, with fewer image frames.

Experiment 1

Experiment 1 was designed to assess how a causal action between an agent and a physical object influences interpolation in the perception of smooth human actions. Causal actions were generated with an agent interacting with a moving object. Non-causal actions were generated with the same agent facing away from the moving object. We hypothesized that in the causal action condition, discretized human actions would be more likely to be perceived as smooth motion sequences.

Method

Participants

Fifty undergraduate students at UCLA (mean age = 21.1; 40 female) participated in the experiment for course credit. All experimental procedures were approved by the UCLA Office for Protection of Human Subjects. All participants had normal or corrected-to-normal vision.

Stimuli

Action videos were filmed in a gym using a camera with a temporal resolution of 30 frames/s. Two pairs of actors (one male pair and one female pair) were filmed. Each pair performed three throwing-catching actions (bounce pass, overhead pass, and chest pass), with each actor being the thrower once and catcher once. Seven video clips were selected as experimental stimuli. Sample video stimuli can be viewed at https://yujiapeng.com/causal-illusion-real.

In Experiment 1, only the catcher and the ball appeared in the video; the thrower was not shown. For each video, a short critical period was selected during which the catcher's arms showed the largest rising momentum during preparation to catch the ball. Each video lasted for 567 ms. There were 10 frames before the critical period, and 1 frame after the critical period. The critical period began when the catcher's arms started to rise, and it ended right before the actor's hands touched the ball. The duration of the critical period was 200 ms. In the long-SOA condition, only the first and the last frame of the catcher's body movements were presented, all the middle frames were omitted. The presentation duration of the first and the last frames were lengthened to cover half of the critical period at 100 ms per frame. In the short-SOA condition, all six frames showing body movements of the catcher were displayed, with the frame duration at 33.3 ms/frame. Note that the duration of the critical period was the same (200 ms) for both long-SOA and short-SOA displays. The movements of the ball were also the same and were kept intact in both long-SOA and short-SOA displays (Figure 1).

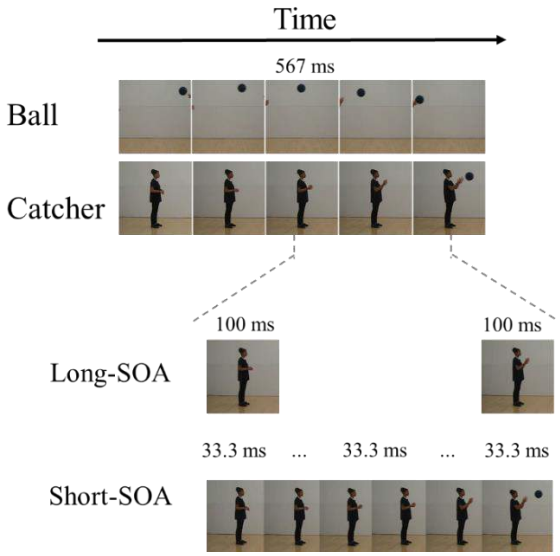

Figure 1. Illustrations of the critical clip in the long-SOA display with two frames (100 ms/frame) with a sudden posture change, and in the short-SOA display with six frames (33 ms/frame).

As shown in Figure 2, the causal condition showed the catcher facing toward the ball as the ball movement causes the catcher to move his or her body in preparation. To generate non-causal actions, image frames were processed using Matlab and Adobe Photoshop to horizontally reverse the facing direction of the catcher. The catcher was flipped horizontally to face away from the ball in the entire video, while keeping the background and the ball movement intact.

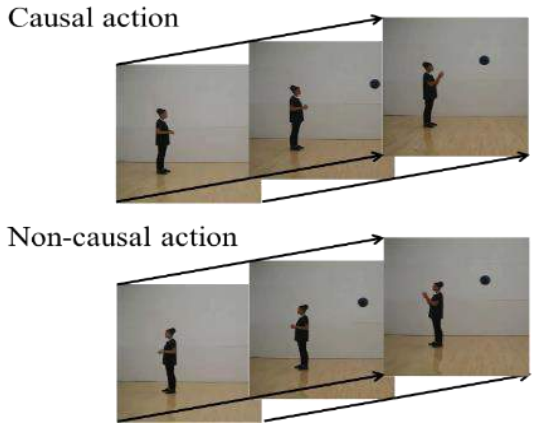

Figure 2. Sample frames of a causal action with the catcher facing towards the ball, and a non-causal action with the catcher facing away from the ball.

Procedure

Participants were seated 35 cm in front of a monitor with a 1024×768 resolution and 60 Hz refresh rate. All the stimuli were generated by MATLAB Psychtoolbox (Brainard, 1997). Participants were instructed, "You will view an actor playing sports (such as passing a basketball) with someone else who is occluded by a whiteboard. The task is to judge whether the catcher actor shows a smooth action or a non-smooth sudden posture change. For a smooth action, the actor smoothly moves from one posture to another. For a non-smooth action, the actor suddenly moves from one posture to another."

On each trial, a white fixation cross was presented at the center of the screen. Participants were asked to focus on the fixation cross throughout the experiment and to use their peripheral vision to see the video without making saccades. The center of the video was presented 13.7 degrees to the left or to the right of the fixation point with a height of 18 degrees. Showing the video in peripheral vision reduced the possibility that observers would track movements of the catcher without paying attention to other parts of the display. Half of the trials presented the video on the left of the fixation and the other half on the right. The catcher actor was always presented on the side relatively farther away from the fixation point. For example, if the video was presented on the right side, the ball flew from left to right and the catcher was located on the right side of the ball. After the video display, participants were asked to press one of two buttons to judge whether the video demonstrated actions with smooth body movements or sudden posture changes.

Participants were first presented with two blocks of practice trials to familiarize them with the task. In the practice blocks, participants saw "correct" on the screen plus a beep after each correct response, and saw "incorrect" without a beep after each incorrect response. Each practice block consisted of eight trials. A separate video was used as the stimulus for the practice block; this video was not presented in the test. In the first block of practice, videos were slowed down to show the entire video with the frame rate of 66.6 ms/frame and to display the critical period for 666 ms. This manipulation was intended to allow participants to become familiar with the experimental setting and to understand the difference between smooth motion and sudden posture changes in body movements. In the second block of practice trials, videos were presented at a frame rate of 33.3 ms/frames, and the duration of the critical period was 200 ms, as in the test session.

The test session followed the practice blocks. Test trials were identical to those in the second practice block with two exceptions: participants received no feedback on test trials, and test trials employed six new videos that were not used in practice blocks. A total of five test blocks were administered, each with 24 trials (causal/non-causal x long-/short SOA x 6 actions). In each block, the presentation order of videos was randomly shuffled. Proportions of responses in judging actions as smooth motion were recorded for each condition.

Results

We first examined the data in Block 1, as performance on subsequent blocks was likely to be affected by increased familiarity with the six videos used in the experiment. We conducted a 2 (SOA: short- vs. long-SOA) by 2 (causality: causal action vs. non-causal action) repeated-measures ANOVA on the proportion of responses judging the catcher's action as smooth motion. As shown in Figure 3a, results revealed a significant main effect of causal action, $F(1,49) = 4.742$, $p = .034$. Specifically, the proportion of "smooth" responses was significantly higher in the causal action condition in the long-SOA condition, in which the catcher faced towards the flying ball than in the non-causal action condition in which the catcher faced away from the ball ($t(49) = 2.243$, $p = .029$). This contrast was not significant in the short-SOA condition ($t(49) = 1.193$, $p = .239$), probably due to much less room of interpolation given the nature of smoothness of short-SOA videos. Note that the smooth motion signal was much weaker in the long-SOA display, since the stimulus included only two static postures with the largest spatial displacements. However, the causal relation between the ball and the body movements of the catcher enhanced interpolation between the two distinct postures, resulting in more misperception of sudden posture changes as smooth body movements. These results indicate that the effect of causality on motion interpolation emerged at the very beginning of the experiment. Not surprisingly, the main effect of the SOA was significant, $F(1,49) = 124.803$, $p < .001$, as short-SOA displays provided stronger motion signals with short inter-frame spatial displacements than did long-SOA

displays. The two-way interaction effect between causality and SOA was not significant, $F(1,49) = .662$, $p = .42$.

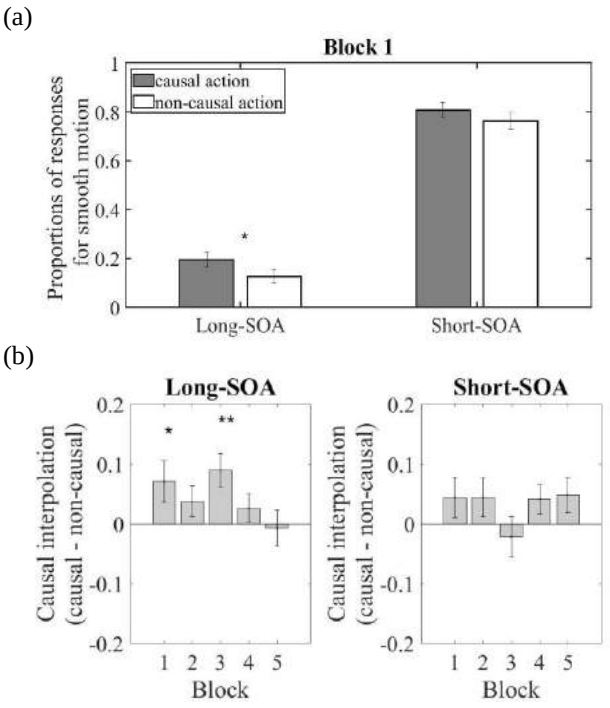

Figure 3. Results of Experiment 1. (a) Proportions of responses in block 1 judging the catcher's action as smooth motion. Asterisks indicate statistically significant differences between conditions (* $p < .05$, ** $p < .01$). (b) The difference between proportions of responses to causal and non-causal actions across 5 blocks in long- or short-SOA displays.

Results of the causal interpolation effect across 5 blocks were presented in Figure 3b. To investigate whether the impact of causal actions on motion interpolation was maintained across blocks despite increased familiarity with the six videos, we conducted a three-way repeated measures ANOVA with blocks as the third factor. We found a significant main effect of causal actions ($F(1,49) = 12.419$, $p = .001$), reflecting a larger proportion of "smooth" responses in the causal condition than non-causal condition. This result suggests that the facilitatory influence of causality on the perception of smooth movements was maintained, even with increased familiarity with the videos. However, this main effect was qualified by a significant three-way interaction ($F(4,196) = 2.815$, $p = .027$), reflecting a complex relation between familiarity and the influence of causal knowledge on the perceptual task. The block variable had a strong impact on responses in the long-SOA displays ($F(4,196) = 4.572$, $p = .001$), but a relatively weaker impact on short-SOA displays, for which the simple main effect of block was not reliable ($F(4,196) = 1.722$, $p = .15$). This pattern was likely the result of close-to-ceiling performance in perceiving smooth motion in the short-SOA displays.

Experiment 2

In Experiment 1, we found evidence that causal interactions between a catcher and the ball facilitated the perception of smooth movements. In Experiment 2, we investigated whether the effect could be generalized from human-object interactions to human-human interactivity. We predict that when the two agents show a causal relation connecting their movements (i.e. one agent throwing and one agent catching), observers will also be more likely to perceive smooth body movements.

Method

Participants

Forty-eight new UCLA students (mean age = 20.48; 33 female) participated in the experiment for course credit. All participants had normal or corrected-to-normal vision.

Stimuli and Procedure

The experiment employed the same basic videos as in Experiment 1, showing two actors pass balls. The stimuli included the body movements of the thrower and the catcher (Figure 4). A white occluder was presented at the center of the video to cover the movements of the ball. Depending on the actual duration of action sequences, the stimuli ranged from 633 ms to 1233 ms. There were 10 frames before the critical period, and 1 frame after the critical period. The duration of the critical period was 200 ms. In the instructions, participants were asked to respond to the movements of the catcher while paying attention to the entire video. The causal manipulation in Experiment 2 was the same as Experiment 1: the facing direction of the catcher was horizontally reversed to generate the non-causal condition. The procedure for Experiment 2 was the same as that for Experiment 1.

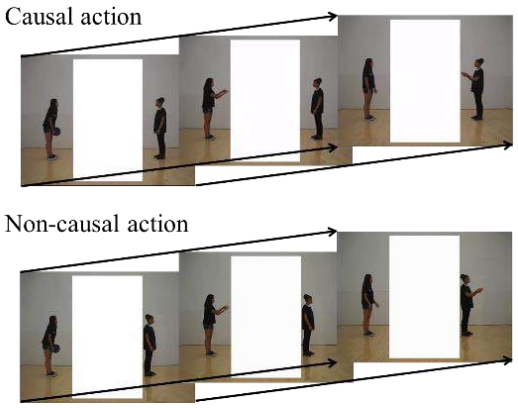

Figure 4. Sample frames of a causal action with the catcher facing towards the thrower, and a non-causal action with the catcher facing away from the thrower.

Results

As shown in Figure 5a, the proportion of smooth responses in Block 1 again revealed a significant main effect of causality ($F(1,47) = 9.874$, $p = .003$). Despite a longer temporal delay between the two actors' actions, the causal relation between the two actors' body movements impacted the visual

experience of the catcher, as perceiving the catcher's movements elicited perception of more smooth and coherent motion. The proportion of smooth responses was significantly greater in the causal action condition compared to the non-causal action condition for the long-SOA condition ($t(47) = 2.887$, $p = .006$), but not for the short-SOA condition ($t(47) = 1.681$, $p = .099$). No interaction effect was found, $F(1,47) = 0.407$, $p = .527$. These results extended the pattern of causal effects observed in Experiment 1.

Results of the causal interpolation effect across 5 blocks were presented in Figure 5b. A three-way repeated measures ANOVA with blocks as the third factor showed a significant main effect of causal actions ($F(1,47) = 6.508$, $p = .014$), with a greater proportion of "smooth" responses in the causal condition than the non-causal condition. There was also a significant main effect of block ($F(4,188) = 5.904$, $p < .001$). Neither the two-way interactions nor the three-way interaction was reliable. In summary, the converging results from the two experiments indicate that the influence of causal action on motion interpolation persisted even with increased familiarity with the videos.

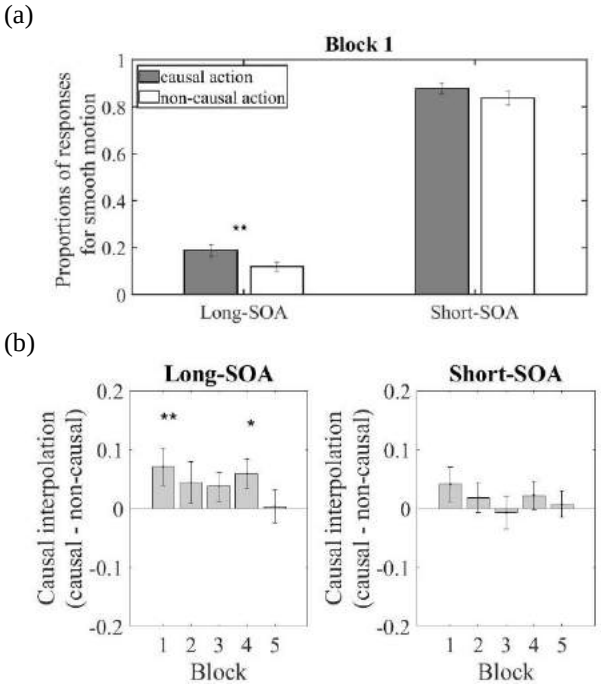

Figure 5. Results of Experiment 2. (a) Proportions of responses in block 1 judging the catcher's action as smooth motion (* $p < .05$, ** $p < .01$). (b) The difference between proportions of responses to causal and non-causal actions across 5 blocks in long- or short-SOA displays.

Experiment 3

Experiment 3 aimed to investigate whether the influence of causal actions on motion interpolation depends on other visual cues. Body orientation is a well-known cue for action recognition (Pavlova & Sokolov, 2000), as observers show worse recognition performance when actions are presented upside-down. If the interpolation effect revealed in the previous two experiments was induced by high-level causal knowledge, then inverting the video would *not* yield a significant difference between upright versus upside-down actions, since both cases preserve the temporal contingency and the causal relation between humans and objects.

Methods

Participants

Fifty-two new UCLA undergraduate students (mean age = 20.0; 43 female) participated in the experiment for course credit. All participants had a normal or corrected-to-normal vision.

Stimuli and Procedure

Experiment 3 used the same stimuli as the causal condition in Experiment 1. On half of the trials, the stimuli used inverted videos, and the other half used intact videos (Figure 6). The task and procedure of Experiment 3 were otherwise the same as in Experiment 1.

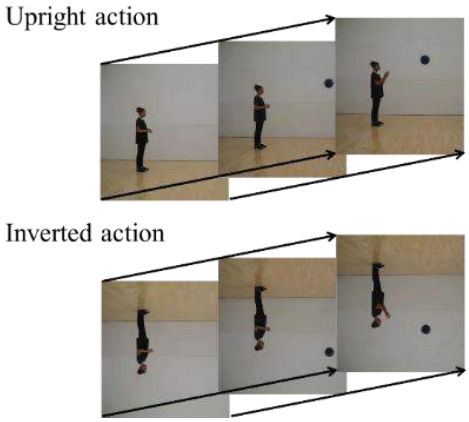

Figure 6. An illustration showing sample frames of an upright and an inverted action in Experiment 3.

Results

We first conducted a 2 (SOA: short- vs. long-SOA) by 2 (orientation: upright vs. inverted) repeated-measures ANOVA on the proportion of responses in Block 1 judging the catcher's action to be smooth motion. As shown in Figure 7a, the main effect of orientation was not significant ($F(1,51) = 2.509$, $p = .119$). The interaction between body orientation and SOA was also not significant ($F(1,51) = 1.525$, $p = .222$). The results from Block 1 suggest that as long as the causal relation is maintained in observed activities, body orientation does not affect the misperception of seeing smooth movements, even when the motion signals were weak (in the long-SOA displays).

Results of the causal interpolation effect across 5 blocks were presented in Figure 7b. To investigate whether the impact of body orientation on motion interpolation changed across blocks with increased familiarity with the six videos, we further conducted a three-way repeated measures ANOVA with blocks as the third factor. This analysis revealed a significant main effect of orientation ($F(1,51) = 5.554$, $p =$

.022). This main effect was largely driven by a significant difference between the upright and inverted conditions in later blocks. For example, in the final block (Block 5), a greater proportion of "smooth" responses was made in the upright conditions than the inverted conditions for the long-SOA condition ($t(51) = 2.139$, $p = .037$). This pattern suggests that the impact of body orientation on visual analysis of actions increased with familiarity of the stimuli.

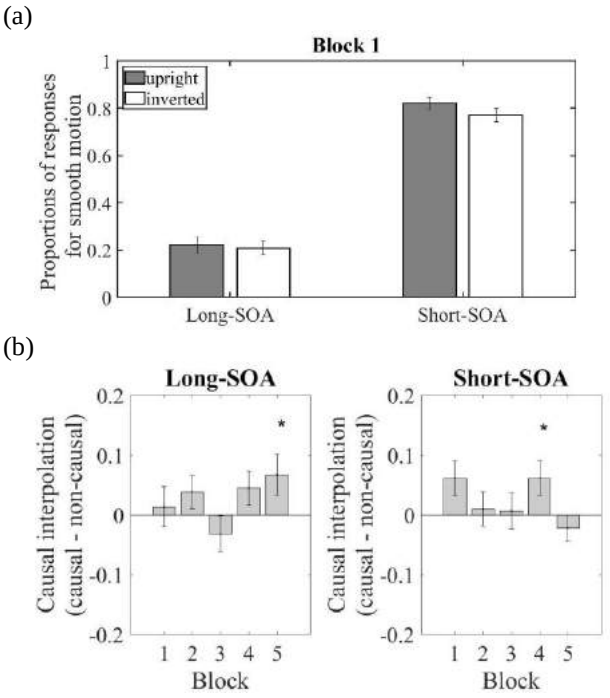

Figure 7: Results of Experiment 3. (a) Proportions of videos in block 1 judged as smooth actions (* $p < .05$, ** $p < .01$). (b) The difference between proportions of responses to causal and non-causal actions across 5 blocks in long- or short-SOA displays.

General Discussion

Apparent motion perception makes it possible to record movements of objects and humans by sampling the motion and displaying the samples as stationary pictures in sequence (e.g., videos, cinema). This study showed that a causal interaction between an agent and a physical object increased the likelihood that people would perceive smooth actions even when the stimuli showed a sudden change in long-SOA displays. This result suggests that causality acts as a temporal "glue" to fill in observers' visual experience by interpolating discrete image frames to produce the perception of smooth, continuous motion. These results extended previous evidence that perception in physical causation helps to fill in important visual information left out from a sequence of events to social causal perception. The representation of an object's implicit causal history has been shown to induce a transformational apparent motion (Tse, Cavanagh, & Nakayama, 1998) of simple objects (Chen & Scholl, 2016), akin to the "causal filling in" effect reported by Strickland and Keil (2011). A "causal filling in" mechanism could have benefitted from evolutionary selection pressure by aiding the continuous perception of animal motions despite occlusion by trees or other obstacles.

Causal knowledge about human body movements may not only help to connect discrete events in the perceptual process, but also may facilitate the process of making inferences and predictions about actions. A causal framework may help the visual system to infer the past. For example, human observers get a vivid feeling of seeing the immediate past of objects or human postures presented in static frames (Kourtzi, 2004). This phenomenon suggests that causal knowledge aids the visual system in inferring and reconstructing the causal history of objects and human actions. On the other hand, as earlier research on motion perception has suggested that the visual system anticipates the positions of simple objects based on their apparent motion trajectory (Freyd & Finke, 1984), more recent research has suggested that similar anticipatory visual processing is also affected by comparatively complex causal knowledge of human actions. For example, Su and Lu (2017) used skeletal biological motion displays and found a flash-lag effect, such that when a briefly-flashed dot was presented physically in perfect alignment with a continuously-moving limb, the flashed dot was perceived to lag behind the position of the moving joint. This finding suggests that the representation of human actions is anticipatory, due to a potential top-down action prediction mechanism. It has also been found that infants as young as five months are able to gaze toward the future direction implied by the static posture of a runner (Shirai & Imura, 2014, 2016), suggesting the early emergence in infancy of an ability to predict dynamic human actions from still pictures.

The present results demonstrated rapid effects of learning across blocks. Experiment 1 showed a significant three-way interaction between block, causality and SOA, suggesting an interaction between the top-down influence of causality and bottom-up perceptual processing of motion stimuli. The top-down influence of causality may be stronger in situations in which uncertainty about the visual input is high, such as when dynamic stimuli are presented in peripheral vision or embedded in noise. The effect may be weakened after repetitive exposures to the stimuli, as perceptual learning may enhance performance for visual tasks. These results are consistent with previous findings that causal perception can change upon repeated exposure of the same stimuli (Rolfs, Dambacher & Cavanagh, 2013).

In conclusion, the current study provides evidence of the important role played by causal knowledge in the perception of smooth motion. Causal relations involving human actions, and their interactions with objects and other agents, have a strong influence on motion perception for body movements. The causal relations involved in actions facilitate visual interpolation of discrete dynamic events to provide a continuous perception of human-involved activities. The top-down influence of knowledge about human actions interacts with bottom-up perceptual processes to enhance the robustness and efficiency in action perception (Lu, Tjan & Liu, 2006; Thurman & Lu, 2014) and intention inference (Shu et. al.,

2018). Causal knowledge not only makes us see the future, but also fills in information about recent history.

Abstract

Previous research evaluating the influence of category knowledge on memory found that children, like adults, rely on category information to facilitate recall (Duffy, Huttenlocher, & Crawford, 2006). A model that combines category and target information (Integrative) provides a superior fit to preschoolers recall data compared to a category only (Prototype) and target only (Target) model (Macias, Persaud, Hemmer, & Bonawitz, in revision). Utilizing data and computational approaches from Macias et al., (in revision), we explore whether individual and age-related differences persist in the model fits. Results revealed that a greater proportion of preschoolers recall was best fit by the Prototype model and trials where children displayed individuating behaviors, such as spontaneously labeling, were also best fit by the Prototype model. Furthermore, the best fitting model varied by age. This work demonstrates a rich complexity and variation in recall between developmental groups that can be illuminated by computationally evaluating individual differences.

Keywords: Episodic Memory; Children; Computational Models; Category Knowledge; Color

Introduction

Reconstructing events from memory is an important facet of cognition, given that it informs how we perceive, interact with, and reason about the world around us. As with all computational processes, human memory is limited in its capacity and resolution, raising questions of how the mind handles the reconstruction of events from memory. That is, how do we strategically encode information that supports later use, while minimizing effort, error, and large demands on storage? This question is doubly interesting for young children whose memory systems are still developing. Relative to adults, children have comparatively limited cognitive resources (Davinson, Amso, Anderson, & Diamond, 2006; Diamond, 2006; Keresztes, Ngo, Lindenberger, & Newcombe, 2018), and their ability to maintain information in memory becomes compromised when faced with increased cognitive load (e.g., increased inhibition demands). Thus, an important question of development is what cognitive strategies might young learners employ to reduce uncertainty (i.e., noise or error) when retrieving information from memory?

To tackle strategic reconstruction of episodic events, research in adult cognition suggests that adults use prior knowledge and expectations to facilitate retrieval of information from memory. Adults develop prior knowledge and expectations that are well-calibrated to the statistical regularities of the environment (e.g., Griffiths & Tenenbaum, 2006), and use this knowledge to optimally perform on a broad range of cognitive tasks including: categorization (Huttenlocher, Hedges, & Vevea, 2000), reasoning (Oaksford & Chater, 1994), and generalization (Tenenbaum & Griffiths, 2001). In memory, well-calibrated knowledge and expectations for a stimulus category can improve average recall (Huttenlocher, Hedges, & Duncan, 1991; Huttenlocher et al., 2000). For example, Huttenlocher et al. (2000) found that people quickly develop expectations for the underlying categorical distribution of stimulus features, and use this knowledge to fill in noisy and incomplete memories. They demonstrated that responses regressed toward the mean of the overall category, thereby improving average recall.

This relationship between prior knowledge and episodic memory can be captured within a simple Bayesian framework which assumes that prior knowledge and expectations for the environment are optimally combined with noisy episodic content to produce recall of episodic experiences (Hemmer & Steyvers, 2009; Huttenlocher et al., 2000; Persaud & Hemmer, 2014; Steyvers & Dennis, 2006). Bayes rule provides a principled account of how to combine noisy memory representations with prior expectations to calculate the posterior probability for recall.

$$p(\theta|y) \propto p(y|\theta)p(\theta)$$

The posterior probability $p(\theta|y)$ describes how likely a recalled feature θ is, given prior expectations for the recalled feature $p(\theta)$ and noisy memory traces y. In this way, the Bayesian framework makes specific predictions about patterns that are explicitly borne out of the data, namely a regression to the category mean effect. It predicts that recall of stimulus features (e.g., different shades of red) is either over or under-estimated toward the mean of the category.

Recent evidence suggests that children, like adults, adopt a similar process of integrating prior category knowledge with episodic traces to reconstruct events in memory. For example, Duffy et al. (2006) used assumptions of the Category Adjustment model (CAM) (Huttenlocher et al., 1991, 2000) to

evaluate the contribution of category knowledge to memory for object sizes in children. CAM assumes that if category knowledge is integrated in memory, recall would exhibit regression to the mean effects. The model also assumes that the more noisy the episodic information, like memories in children, the stronger recall will regress to the mean. Duffy et al. (2006) found that like adults, children's recall regressed toward the mean of the underlying category distribution. This suggests that on an individual trial, a child might not have remembered the exact studied size, so they might use their learned category knowledge of the most frequently studied object sizes to help reconstruct the true size. They concluded that children use category knowledge to estimate stimulus features from memory.

Similarly, Macias and colleagues (in revision) used a simple episodic memory task, where children were shown shapes paired with different colors and were asked to recall the color-shape pairings. They found that children's recall regressed toward the mean of the seven color categories that were studied, indicating an influence of category knowledge on memory. To further assess episodic memory, they then evaluated the fits of three computational models of memory to explain the data: a Noisy Target model that assumes recall solely mirrors episodic information (i.e., the target color values plus random noise), a Noisy Prototype model that assumes that recall solely mirrors category information (plus noise), and an Integrative model that assumes that recall is an integration of episodic and category information. Quantitative model fits to the aggregate data favored the Integrative model.

These studies of memory in children, taken together, highlight an important role that category knowledge plays in episodic memory at early development (i.e., preschool age) and provide a watershed moment to explore the reconstructive nature of episodic memory at earlier stages. More specifically, this work facilitates the opportunity to perform a critical in-depth analysis of children's recall data to tease apart underlying individual and group-related differences in the reconstructive process. Exploring individual and age related differences is motivated by the Duffy et al. (2006) finding that not only do children rely on category knowledge, but also that memory in younger children exhibited steeper regression to the mean patterns, relative to older children. Recall based solely on category information could also result in steeper regression to the mean, and in turn, might be better fit by the Macias et al., Noisy Prototype ('category only') model. In other words, it could be the case that at the individual subject level, children might differ in the best fitting model, such that those with steeper regression might be better fit by the Noisy Prototype model, while less steep regression might be better captured by an Integrative model.

Furthermore, recall performance in children might not only differ at the individual subject level, but also at the individual trial level, especially if contextual strategies, such as spontaneously labeling study features, are employed to facilitate recall performance. For example, while running their study, Macias et al., observed that participants spontaneously labeled the colors, as they studied them and/or as they recalled them. For example, one older learner (age = 4.64years), stated, "Purple, purple, purple. I got this.", while studying a purple hue value. Counterintuitively, while labeling may boost the learner's ability to remember that an item was observed from a particular category, it may also lead to noisier storage of specific stimuli that deviate from category means, because the label provides a cheaper (albeit potentially less accurate) compression option than storing the details of the original. In this way, this individuating behavior of labeling might impact the reconstruction of events in memory at either the individual subject or trial level. Recent research suggests that labeling can influence recall of continuous color values, such that labeling results in information being lost gradually as opposed to suddenly (see, Donkin, Nosofsky, Gold, & Shiffrin, 2014 for discussion on the role of labeling, sudden death, and gradual decay in memory). To this end, there might be a difference in the best fitting models for children who spontaneously label colors or for specific trials where colors are labeled.

Therefore, the goal of this paper is to assess individual and age related differences in the reconstruction of events from memory in early development. More specifically, we sought to evaluate whether younger and older children employ different strategies to recall episodic events and whether the behavior of spontaneously labeling was better fit by a particular model. We hypothesized that young and older children would differ in their reconstructive processes, such that a different proportion of children from each group would be better fit by the three models. We expected that older children would be better explained by an Integrative model (i.e., combining noisy episodic traces with category knowledge), mirroring the behavior of adults, and younger children would be better explained by a Noisy Prototype model, given the degree of inexactness in their memory traces.

We also hypothesized that the individuating behavior of spontaneous labeling would impact memory reconstruction such that trials where labels were spontaneously provided would be better captured by the Noisy Prototype model. To test our hypotheses, we fit the Noisy Target, Noisy Prototype, and Integrative models to the experimental data from Macias et al., (in revision) at the individual subject level.

We then evaluated the log likelihood scores of the model fits to determine which account most often explained memory performance in younger and older children. In other words, we looked to see which model explained behavior for the greater proportion of children. After, we explored best fitting parameter values that would capture the amount of noise in the recall data for young and older children. A difference in the amount of noise in the data is one potential explanation for age related differences in the best fitting model. Finally we assessed whether labeling behavior affected the proportion of children fit by each of the models.

Three Models of Memory

Noisy Target Model The Noisy Target model assumes that information is stored in episodic memory as noisy traces of studied values (e.g., specific color values). In this way, reconstructed events are just inexact representations of true studied values (and not altered by category knowledge). If children are using the Noisy Target model, we should expect the noise (or error) in recall to be normally distributed around the true studied feature values, with no apparent bias toward a particular recall value. To evaluate this model relative to the data, we calculated the probability of responses given a Gaussian distribution centered on the target value, with noise in memory (we assume the same memory noise value learned from Macias et al.).

Noisy Prototype Model The Noisy Prototype model assumes that information is stored in episodic memory as categorical representations of studied features (e.g., the mean of the category to which the studied value belongs). In other words, under this model, the initial encoding of the representation is simply a pointer to the participant's prototype in that category. Other information about the studied value is not stored. Memory is simply a recall of the prototype – which we define as a sample drawn from this category, assuming a particular distribution, mean, and variance associated with it. To evaluate this model relative to the data, we calculated the probability of responses given a Gaussian distribution centered on the category prototype (i.e., mean) value given by participant ratings in Macias et al., (in revision), with noise on the category also calculated from noise given in a separate study [1].

Integrative Model The Integrative model amalgamates the assumptions of both the Noisy Target and Noisy Prototype models and assumes that recall is an integration of noisy episodic content and prior category knowledge. Under this model, prior category knowledge is used to fill in the gaps when episodic traces are noisy or incomplete. When the category representation is strong, and the memory trace is noisy, recall will resemble the category representation. The probability of responses under the Integrative model are relatively straightforward to calculate, because both the prior and likelihood distributions are Gaussian (which are self-conjugate). Furthermore, there are not specific weights assigned to the contributions of each model – this falls out naturally based on the degree of variance of each target and prototype models. We evaluate this model relative to the data, by calculating the probability of responses given the Gaussian that results from integrating these two Gaussian. Specifically, for the Integrative model, which integrates the Noisy Target and Prototype distributions, the standard solution for the mean and variance is given by,

$$\mu = \frac{1}{\frac{1}{\sigma_t^2} + \frac{n}{\sigma_p^2}}\left(\frac{t}{\sigma_t^2} + \frac{\mu_p}{\sigma_p^2}\right), \sigma = \frac{1}{\frac{1}{\sigma_t^2} + \frac{n}{\sigma_p^2}} \quad (1)$$

where σ_t refers to the memory noise on the target distribution, σ_p refers to the noise on the prototype distribution, t refers to the studied target value, μ_p refers to the mean of the prototype distribution to which the target value belong, and n=1.

Table 1: Frequency of Children Best Fit to Each Model

Model	Count(%)
Integrative	11 (33.33%)
Noisy Target	7 (21.21%)
Noisy Prototype	15 (45.45%)

In what follows, we first briefly explain the experimental methods employed by Macias et al., (in revision), to assess the role of category knowledge in episodic memory in children. We then discuss the results of the model fitting at the individual subject level in general, and age related differences, more specifically.

Experimental Methods and Results

Macias et al., (in revision) conducted two developmental experiments where they examined the relationship between prior color category knowledge and episodic memory in preschoolers (mean age: 54 mos.; range: 43 mos.-73 mos.). In the prior knowledge assessment, participants were presented with 9 color category labels (red, orange, yellow, green, blue, light blue, dark blue, purple, and pink) one at a time on a computer screen, along with a color wheel. The color wheel varied in hue only while luminance and saturation were held constant at 50 and 100 units respectively. Children were asked to point to a location on a color wheel to indicate the color that best represented the label.

In the episodic memory task, 33 participants studied 15 shapes uniquely paired with 15[2] colors, one at a time on a computer screen. At test, participants were presented with a studied shape (filled in white with a black border), along with the color wheel used in the prior knowledge assessment. The task for the participants was to choose along the color wheel to indicate the color they recalled being paired with the presented shape. For complete experimental methodology, refer to the source publication (Macias, et al., in revision).

The results of the memory task revealed a regression to the category mean effect in a majority of the studied color categories such that studied hue values that were greater than the mean of the category were underestimated and studied hue values less than the mean of the category were overestimated. This regression to the mean effect is taken as evidence of an

[1] We also assessed a model in which we sample over variance, but best fit variance matched participant responses on Macias et al.'s prior knowledge task.

[2] One of the study trials was treated as a filler in order to counterbalance presentation order and was therefore removed from the data set prior to running any analyses.

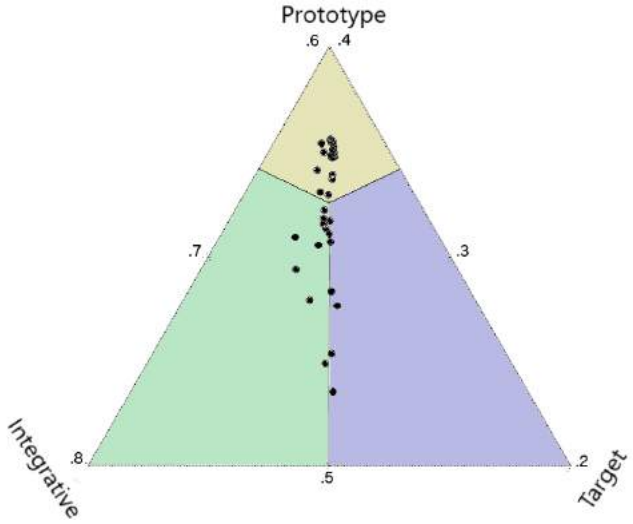

Figure 1: Ternary plot of the proportion of Log probabilities of the Integrative, Noisy Target, and Noisy Prototype models fit to each participant's data. Data points fall within the region of the model where it is best fit. Note that the figure has been zoomed in to the approximate center of the Ternary plot for better visualization of the data.

influence of category knowledge in episodic memory. Macias et al., (in revision) implemented three models and determined that the Integrative model provided the superior fit to the child data on aggregate. Here we fit the three models to individual subject data to assess for age related differences in the best fitting model.

Model Results

We sought to evaluate age and performance related differences between individual subjects and the fits of each model. Here we report the results of the model fits to children overall and then we evaluate the role of age.

Data Preparation for Evaluating Individual Differences

The data were prepared to perform four specific analyses: to evaluate individual differences in the best fitting model across the entire sample of children, to assess age related differences in the proportion of participants best described by each model, to assess additional group differences in the model fitting (e.g., the role of spontaneous labeling), and to evaluate age differences in best fitting model parameter values. We first fit the three models to each subjects' data. As with Macias et al., (in revision), the best fitting model was determined by the model with the largest log-likelihood value. To evaluate group differences, we performed a median split to classify children as younger and older learners (Table 2) and then compared the proportion of younger and older children described by each model. Of the 33 participants in the study, 16 were classified as young and 17 were classified as older. The median age of the total sample was 53 mos. (*sd*=6 mos.).

Table 2: Frequency of Model Fits by Age

Model	Count(%)	
	Young	Older
Integrative	6 (37.50%)	5 (29.41%)
Noisy Target	6 (37.50%)	1 (5.88%)
Noisy Prototype	4 (25.00%)	11 (64.71%)

The median ages for younger and older children were 49 mos. (*sd*=2 mos.) and 56 mos. (*sd*=5 mos.), respectively.

We also sought to evaluate group differences due to spontaneous labeling that was borne out of the experimental task. Of the 16 children classified as younger, 7 produced as least one label and of the 17 older children, 12 produced at least one label. This further suggests that labeling was a consistent strategy employed by children in this task. To evaluate best fitting models based on labeling, we first classified children into two groups: labelers and non-labelers. Labelers referred to learners who provided labels (at either study, test, or both) on more than 50% of trials (*n*=10/33) and non-labelers were all other children tested (*n*=23/33). We chose to use this classification because spontaneously labeling on more than 50% of trials suggests a consistent strategy of the individual to assist in recall.

To evaluate age related differences in the best fitting noise value, we implemented the Integrative model and for each participant, we searched over the space of possible noise values for the value that maximized the likelihood for each participant's data.

Model Fitting Results

Although the Integrative model is the best fitting model at the aggregate data level, it appears that at the individual level a greater proportion of children are better fit by the Noisy Prototype model (*n*=15/33), followed by the Integrative model (*n*=11/33), and then the Noisy Target model (*n*=7/33) (see Table 1). However, as can be seen in Figure 1, although a larger proportion of data points (each representing an individual child) fall towards the prototype apex, these points cluster towards the center (with near equal weight for the Target and Integrative models), suggesting that children who are classified as Prototype fits are nearly equally well fit by the other models. In contrast, for participants that are not best fit by the Prototype model, results skew significantly farther away from the center, suggesting that children who are better fit by other models are much more poorly fit by the Prototype. In light of this result, we next evaluated whether age plays a role in the proportion of children best fit by the models.

Age and Best Fitting Model To evaluate whether the proportion of children best fit by each of the three models was dependent upon age, we used the Freeman-Halton extension of the Fisher's Exact test to compute the (two-tailed) probability of obtaining a distribution of values in a 2(young vs older)x3(Integrative vs Noisy Target vs Noisy Prototype)

contingency table, given the number of observations in each cell. The results revealed that the observed proportion of best fitting models was dependent on age (p=.031). In other words, there was a significant difference in the distribution of best fitting models between the age groups. Young children were evenly split in the number fit by the Integrative (n=6) and Noisy Target (n=6) models, followed closely by the Noisy Prototype model (n=4). Interestingly, however, older children had a different composition. An much larger proportion of older children were better fit by the Noisy Prototype model (n=11), followed by the Integrative model (n=5), and almost not at all described by the Noisy Target model (n=1) (see Table 2).

Age and Best Fitting Noise Parameter Macias et al., (in revision), demonstrated that for aggregated child data, the best fitting model was the Integrative model. To evaluate the fit of the Integrative model to young learners' data, they searched for the best fitting noise parameter value. Comparing this parameter to the best fit for adults revealed a significantly larger noise parameter for the children, suggesting that as children develop the fidelity of their memory gets sharper. Here we searched for the best fitting noise value at the individual subject level to test for age related differences within the preschool population. The goal was to assess whether a difference in the amount of noise between age groups could explain why young and older children were better fit by different models. In conflict with our prediction, there was a weak non-significant *negative* correlation between age and best fitting noise value (r-= -0.17, p=.35). This suggests that a difference in the best fitting model between age group was not a result of a difference in the amount of noise in the data[3]. We return to this point later.

Additional Group Differences and Best Fitting Model Similar to the evaluation of age, we then employed a Fisher's Exact test to evaluate whether the proportion of children best fit by the three models differed between *labelers* and *non-labelers*. To reiterate, we classified labelers as children who spontaneously provided a color label on more than 50% of trials. Figure 2 shows the composition of labelers and non-labelers fit by each model. A Fisher's Exact test yielded, p=.50 , suggesting no difference in the proportion of *labelers* and *non-labelers* best fit by the three models.

Although the difference between the proportion fits was not significant, there appeared to be a trend in which most *labelers* were described by the Noisy Prototype model (60%), while *non-labelers* were more diffused across the three models. Thus, to further evaluate the role of labeling, we separated participants' label trials from the non-labeled trials, creating two new datasets. We fit the three models to the

[3] An alternative explanation is that the sample sizes for young and older children split between each model was insufficient to detect a significant difference. However, the trending direction of the data ran counter to our developmental prediction, suggesting that even if greater power revealed differences, they would be in the unpredicted direction

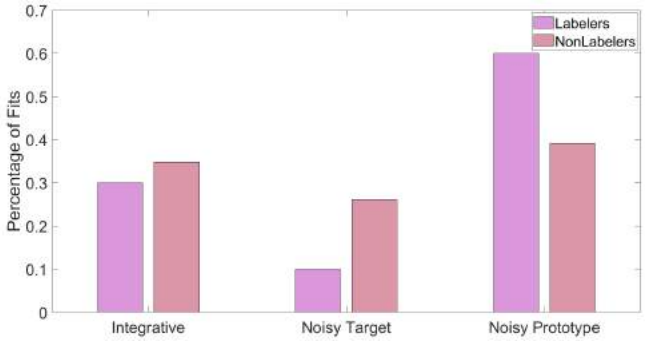

Figure 2: Proportion of Labelers and Non-labelers best fit by each model. Labelers were more likely to be best fit by the Noisy Prototype.

Table 3: Frequency of Model Fits based on Labeled and Non-Labeled Trials

Model	Count(%)	
	Label	Non-label
Integrative	3 (0.10%)	9 (27.27%)
Noisy Target	4 (0.12%)	7 (21.21%)
Noisy Prototype	26 (78.78%)	17 (51.51%)

aggregated label data and the aggregated non-label data. Unsurprisingly, the Integrative model provided the superior fit to both datasets, presumably because the model pays a lower cost for responses that, over the aggregate span between the observed target and category mean. Thus, to better understand the effects of labeling at the trial level, we then fit the three models at the individual subject level, again separating labelled trials from non-labelled trials. For the labelled trials, we found that 3 participants were best fit by the Integrative model, 4 by the Noisy Target model, but the majority of trials (26) were best fit by the Noisy Prototype model. In contrast, for the non-label trials, the distribution was less skewed, with 9 participants were best fit by the Integrative model, 7 by the Noisy Target model, and 17 by the Noisy Prototype model. A Fisher's Exact test revealed a marginally significant difference (p=.054) in the distribution of best fitting models between the labelled trials and non-labelled trials, such that most participants' label trials were best described by the Prototype model, while the non-label trials were slightly more dispersed.

Based on the finding of a difference in model fits between labeled and non-labeled trials, we re-examined the role of labeling on age. We had originally classified whole individuals as either labelers or non-labelers, and found no significant difference by age. Instead, we calculated the proportion of labeled trials provided by younger and older children, to test whether as a group, older children were more likely to provide labels during testing. A Fisher's Exact Probability Test revealed a significant difference in the proportions of la-

beled and non-labeled trials contributed by each age group (p=.002). A larger proportion of labeled trials were generated by older (66%) compared to younger children (34%).

Discussion

Our goal was to evaluate whether age-related differences persist in the strategies young learners use to reconstruct events from memory. Recent work has found that young learners, like adults, adopt the strategy of integrating prior category expectations with noisy episodic traces to reconstruct events from memory (Macias, et al., in revision). This was evidenced by a model that assumes an integration of target and category information (i.e., Integrative model) providing a superior fit to the preschool data. Here we evaluate individual differences in the best fitting strategies. We first fit three models at the individual subject level and found that the larger proportion of children were better fit by the Noisy Prototype model compared to the other models.

In addition, there were marked differences in the proportion of young and older children best fit by each model. While young children were almost evenly split in fit across the three models, surprisingly, older children were most frequently fit by the Prototype model. This result might have been bolstered by the number of trials where older children spontaneously labeled. Recall that a significantly large proportion of labeled trials belonged to older children. In this way, spontaneously labeling during study and test might have induced older children to encode and/or retrieve the prototype of the category they verbally labeled. Thus, older children may have been more likely to adopt a general strategy (labeling) that instead led to less accurate recall of the specific observation. Future work might further explore the role of spontaneous labeling on children's recall performance. For example, it is unclear whether children were still using a labeling strategy on trials where they did not spontaneously label aloud. It is possible that they were silently labeling during the task. It is unlikely that this is the case, given that we found a significant difference in performance between labeled and non-labelled trials in terms of the model fitting. However, this is an empirical for future investigation. For instance, follow up studies could use verbal interference tasks to manipulate children's ability to provide verbal labels during encoding and retrieval to evaluate whether labeling alone encourages the use of the category prototype.

What might explain the finding that the Noisy Prototype model slightly outperformed the Integrative model in terms of best fit at the individual level? First, early memory development is marked by an up-prioritization of category information over nuanced episodic information (Keresztes et al., 2018). Such behavior would equate to encoding a red color value as a prototypical shade of red (e.g., the color of a red apple) as opposed to encoding the specific shade of red studied. Thus, during study, a majority of children may have encoded target information as a pointer to the category from which the target belongs, such as a category representative (i.e., the category mean) as opposed to encoding the exact color value studied.

Alternatively, it could be the case that the use of category knowledge happens at retrieval. After the initial testing phase, the original studied information could have degraded over time and instead of reproducing the degraded information, children reproduced a value closer to the category representative to reduce error or uncertainty. Whether the influence of category knowledge occurs at encoding, retrieval, or both is a question for future research.

A third potential explanation for why a slightly great portion of children were best fit by the Noisy Prototype model might be due to the particular information studied. It should be noted that the study values for each category were selected such that they fell one standard deviation above and below the mean of the category (mean and standard deviations learned from the prior knowledge task). Given that children only studied colors that fell in close proximity of the prototypes, this might have propelled learners to rely on their category expectations, that is, adopting the Prototype strategy. Thus, the finding of a large portion of older children who are better fit by the Noisy Prototype model might be a consequence of the study values falling relatively close to the prototype. Future work might explore whether the model fitting results vary when children are presented with colors that substantially deviate from the prototype (i.e., more than 1 sd).

There were a number of limitations in this study that warrant caution in the interpretation of the results. First, the initial goal of Macias et al., (in revision), was to compare children's episodic memory performance to adults. For this purpose, a sample of 33 child participants was sufficient. However, to evaluate individual and age-related differences, a significantly larger sample of participants is needed to achieve strong statistical power for analysis. Second, the goal of this paper was to assess age related differences. Although a median split of children revealed some clear trends in a difference in model fitting by age, a more diverse age sample of children could provide further insight into differences in memory strategy by age. For instance, we anticipated that older children might rely less on the prototype to facilitate recall (although this might interact with the contrary strategy to label as children get older), but it is possible that the sample of children used here did not contain a wide enough age-range to observe this pattern. To this end, a natural future direction would be to collect more data for the purposes of evaluating age differences.

Despite these limitations, this paper demonstrates clear trends in age related differences in model fitting. Furthermore, we hope to have demonstrated that an approach that applies model fits at the individual level can provide insight into how different cognitive strategies (such as labeling) may color recall.

Abstract

When reasoning about evidence, we must carefully consider the impact of different structures. For instance, if in the process of evaluating multiple reports, we find they rely on the same, *shared* evidence, then the support proffered by those reports is dependent on that evidence. Critically, normative accounts suggest that such a dependency results in redundant information across reports (reducing evidential support), relative to reports based on distinct items of evidence. In the present work we disentangle the structural and observation-based indicators of this form of dependency. In so doing, we present novel findings that lay reasoners are not only insensitive to shared evidence structures when updating their beliefs, but also that reasoners do not necessarily prefer more diverse sources of evidence. Finally, we replicate prior effects in reasoning under uncertainty, including conservative sequential updating, and difficulty in integrating contradictory reports.

Keywords: evidential reasoning; probabilistic reasoning; dependence; Bayesian Networks; belief updating

Introduction

Over the course of an investigation, you are faced with the weighing up of contradicting reports. Two of your investigators confirm the hypothesis, whilst two disconfirm it. How do you discern which pair may carry more (evidential) weight? One important aspect is what evidence those investigators are relying upon. For instance, if your two confirming investigators are relying on the *same* piece of evidence to inform their reports, whilst the two disconfirming investigators are relying on separate, independent pieces of evidence, then, *ceterus paribus*, the standard intuition is to side with the disconfimers.

This example highlights the traditional understanding of one form of dependency in evidential reasoning. Specifically, the notion of "shared" evidence (Schum & Martin, 1982; Schum, 1994), which is considered to be inferior to reports based on distinct (separate) evidence, i.e. dependence as a form of redundancy (Hogarth, 1989; Schum & Martin, 1982; Soll, 1999).

How such information *should* be integrated is important to a number of areas, from everyday reasoning to investigative domains such as medicine (Eddy, 1982), law (Faigman & Baglioni Jr, 1988; Fenton & Neil, 2012, Fenton, Neil & Lagnado, 2013, Harris & Hahn, 2009; Lagnado, 2011; Pennington & Hastie, 1986; Schum, 1994), risk analysis (Fenton & Neil, 2012), and to the intelligence community (Heuer, 1999). Consequently, failures to account for such dependencies between evidence items – although easing computation (Pearl, 1988; Schum, 1994) – can lead to deleterious overweighting of the support provided by such evidence (e.g., naïve Bayes in medicine – where evidence is assumed to always be independent; Koller & Friedman, 2009; Kononenko, 1993).

The notion of shared-evidence as a form of dependence fits with the correlation-based conceptualisation of dependencies as a form of redundancy in prediction errors (e.g. Soll, 1999). More precisely, when two sources are using the same evidence to inform their reports, vs the same two sources using two different items of evidence, the former case results in an "overlap" of information provided (Schum, 1994). It thus becomes more likely that reports in the former case rely on the *same* information, and the pair of reports therefore carry some redundant information. As a consequence, such correlated reports provide a lesser degree of support for the hypothesis being informed upon.

In the present work, we seek to provide an empirical baseline for lay reasoners judgments regarding this form of dependence. We not only investigate whether belief-updating is in line with the shared-evidence-as-inferior hypothesis proposed in formal work, but whether lay reasoners seek more diverse evidence in their search preferences.

Formalising reasoning about shared evidence

To illustrate what is meant by shared evidence, Fig. 1 below presents a directed acyclic graph (DAG) of an example case. Here there is a hypothesis under investigation (H), three pieces of evidence that inform that hypothesis (E1-3), and four sources (or witnesses) who in turn *report* on said evidence (R1-4). Crucially, the evidence itself remains unobserved, so we are instead trying to infer diagnostically about H (via E1-3) from the reports provided by R1-4, and notably how to judge R1 and R2 (who rely on the same evidence, E1), versus R3 and R4 (who rely on separate evidence, E2 and E3 respectively).

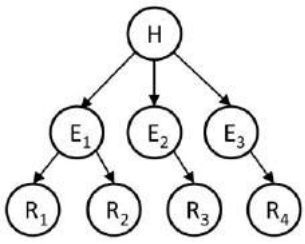

Figure 1. Graphical representation of a hypothesis (H), evidence items that inform upon it (E1-E3), and sources informing their reports upon said evidence (R1-R4).

To understand how reasoners *should* update their beliefs given these observed reports, we use a Bayesian Network (BN) formalism, wherein a DAG is supplemented by conditional probabilities and the use of Bayes theorem, so as to make optimal (i.e. inaccuracy minimization) inferences (Pearl, 1988; 2009). This computational framework for reasoning under uncertainty has been used effectively to model (and shed light on human inferences by comparison) direct dependencies between sources (Pilditch, Hahn & Lagnado, 2018), and dependencies as shared-backgrounds among sources (Madsen, Hahn & Pilditch, 2018), and integration across sources of differing reliabilities (Phillips, Hahn, & Pilditch, 2018).

If we assume, in the above example, that all evidence items are equally diagnostic[1], and all sources are equally reliable[2], then the sole difference-maker between sources is the structural difference entailed by the shared evidence (E1). To best illustrate the impact of shared evidence, we first consider the point at which we have only observed a confirmatory report from R1. Via conditionalization, E1 is now already more likely to be confirmatory than E2 and E3. Given this, if we are to decide whether we want to see a report from R2 (who also relies on E1), or a report from R3, a confirming report from the latter provides *more potential information* regarding H, given that P(E1) – which is already more probable, given the report from R1 – increases less given R2 than P(E2) does, given R3.

Present research We seek to empirically test the degree to which lay reasoners are sensitive to the impact of shared evidence structures on belief updating. More precisely, we use the above formalism to provide an empirical baseline for lay reasoning regarding such dependencies, and notably whether participant probability estimates fit with normative predictions of dependence inferiority. Additionally, we explore two research questions that the formalism allows us to investigate, via the separation of *structural* dependencies from dependencies inferred from (correlated) observations:

First, how do reasoners deal with contradiction across a shared evidence item (as opposed to contradiction across different evidence items)? Recent research that exploits the capacity to tease apart the structural form of a dependency from the dependency inferred from (correlated) observation – as possible in the present work – exposes lay reasoner difficulties in accurately updating (both qualitatively and quantitatively) when an observed contradiction occurs *across* a structural dependency (i.e. information is directly shared from one source to another equally reliable source, yet those sources then disagree; Pilditch, Hahn, & Lagnado, 2018). We predict the same difficulty here.

Second, the present work allows for the investigation into evidence diversity preferences. The computational framework underpinning this work allows for the calculation of the predicted informative value of evidence items, for which we calculate the Kullback-Liebler Divergence (KL-D; a measure of entropy reduction; Kullback & Liebler, 1951)[3].

$$KL(E_j) = \sum P(h_i|e_j) * \log\left(\frac{P(h_i|e_j)}{P(h_i)}\right)$$

where E_j is a set of items of evidence $\{E_1, E_{2...}E_j\}$, e_i the set of possible states of the evidence, $\{e_1, e_2, e_i\}$, and h_i is a set of hypotheses, $\{h_1, h_{2...}h_i\}$. In the present case, we compute the information provided by R2 in reference to the hypothesis (H; given we have already observed R1) when a) R2 also relies on E1, vs b) R2 relies on E2, taking a difference measure between these two values.

As such, in asking lay reasoners for their preference for a forthcoming report to be based on shared evidence (i.e. based on an item of evidence already informed by one report) or new evidence, we may observe whether lay reasoning (if in line with normative expectations) predicates an evidence selection preference for more diverse items.

In sum, the present work uses a BN formalism to disentangle the structural vs observation-based forms of shared evidence dependencies. In so doing we are able to not only establish an empirical baseline of when the two forms agree (and thus whether reasoners fit with standard normative expectations), but also examine how reasoners deal with cases of disagreement (where observations appear uncorrelated, but a structural dependence remains), and use structural relations to determine (diversity-based) evidence preferences.

Method

Participants 200 US participants were recruited and participated online through Amazon Mechanical Turk. Three participants were removed for incomplete data, and 1 for not being a native English speaker. Of the 196 remaining participants, 84 identified as female, and the median age was 34 (*SD* = 9.8). All participants gave informed consent, and were paid for their time (*Mdn* = 8.74 minutes, *SD* = 6.63).

Procedure & Design Participants were presented with a scenario in which *a patient, "RN", may have a disease "MTL"* ("H" in Fig. 1). The participant is placed in the role of a diagnostician, attempting to confirm the above diagnosis. They are informed that the patient has had a number of *cell samples* taken (these can be considered $E_{1\text{-}3}$ in Fig. 1), both independently, and of equal diagnosticity. More precisely, that each *cell sample* may contain a *biomarker*, which has a 90% chance of being due to MTL

[1] I.e. P(E1|H) = P(E2|H) = P(E3|H), and P(E1|¬H) = P(E2|¬H) = P(E3|¬H).

[2] I.e. P(R1|E1) = P(R2|E1) = P(R3|E2) = P(R4|E3), and P(R1|¬E1) = P(R2|¬E1) = P(R3|¬E2) = P(R4|¬E3).

[3] Other information measures exist, such as impact (see Nelson, 2005), information gain (Lindley, 1956), and Bayesian diagnosticity (Good, 1950), though empirical work suggests such measures are highly correlated (Nelson, 2005), and are thus considered interchangeable for the present work.

(hit rate), but also a 10% probability of being a false positive.

Participants are then informed that they are unable to examine the *cell samples* themselves, but must rely on *lab technicians* (R1-4 in Fig. 1), who will independently examine the *cell samples* and provide a *report of whether biomarkers are present or absent*. Crucially, all the lab technicians are indicated as equally reliable, in that they have an 80% chance of detecting and reporting a biomarker (irrespective of whether it is due to MTL), when a biomarker is present (hit rate), and a 20% chance of a false positive.

Lastly, participants were informed that prior to receiving any reports from their lab technicians, given the facts of the case so far, they should assume a prior probability of patient RN having MTL of 50% ("Finally, *prior to getting the reports*, you can assume an initial probability of 50% that patient RN has MTL, based on the facts of the diagnostic process so far… Before you start finding out reports, please answer the following question … What is the probability that **patient RN has MTL**?"). This prior probability was then immediately elicited from participants, for use in individual model fitting (see results section below).

Elicitation Stages Participants then received reports from each of 4 lab technicians in turn (resulting in a total of 4 elicitation stages). Following each new report, participants were asked to provide a new probability estimate of patient RN having MTL – given *everything they now know* (i.e. background + gradually accumulating reports). These probability estimates were the main dependent variable.

Each report statement took the form "*Based on their assessment of* ***cell sample [1/2/3]****, lab tech [1/2/3/4] reports that the* ***biomarker is [present/absent]***."

Crucially, there were two independent, between-subject variables employed, making a 2x2 design. The first of these was the *evidence used by the second lab technician* ("R2Evidence"). Whilst the first lab technician always used cell sample 1, the third cell sample 2, and the fourth cell sample 3, the second lab technician used cell sample 1 in one condition (R2E1), and cell sample 2 in the other (R2E2). This allowed for a) the between-subject comparison of 2 reporters using independent (R2E2) vs shared evidence (R2E1), and b) allowed for the disentanglement of *structure* (i.e. dependency relations) from *order of observations* (i.e. is over/under updating due to the second report relying on shared evidence, or simply because it is the *second* report).

The second between subject factor was the order of positive (biomarker present) and negative (biomarker absent) reports ("RepOrder"). More precisely, either the first lab technicians 1 and 2 gave positive reports (and 3 & 4 gave negative reports; "PosFirst"), or the reverse ("NegFirst"). This general structuring, when taken in conjunction with the R2Evidence factor, allowed for the assessment of the influence of shared evidence when reporters agree about the same evidence (R2E1) or disagree (R2E2 – as lab technicians 2 & 3 will always disagree, yet will share cell sample 2). Additionally, this allows for the further disentanglement of observation *type* from shared evidence (structural) influences. For instance, in R2E1 conditions, the reports from shared evidence (lab technicians 1 & 2) will half the time be positive, and the reports from independent evidence (lab technicians 3 & 4) will half the time be negative, and vice versa. Thus, one may discern the influence of (dis)confirming observations vs structural differences.

Dependent variables Along with the probability estimates elicited at each elicitation stage (0-100% slider, no default)[4], one further qualitative question was asked after the first lab technician provided a report (i.e. elicitation stage 1):

"Given the choice, would you rather *Lab Tech 2* **also independently investigated cell sample 1 for a biomarker, or investigated a different cell sample (cell sample 2)**?" ["Same cell sample (cell sample 1)" / "Different cell sample (cell sample 2)" / "There is no difference."] Forced choice, randomized order of presentation.

The purpose of this question was to assess participant preferences for diversity (independence in this case) in their observations.

Taken together, the probability estimates and evidence preference judgment allow for the assessment of the impact of shared evidence, both in terms of predicted support, and consequent reasoning (and belief-updating), whilst taking into account the influence of observation types and orders.

To concretize the research questions into hypotheses, we predict:

H1. Shared Evidence Structure - Shared evidence will result in estimates of reduced impact of affected reports, in comparison to reports from distinct items of evidence, *ceterus paribus*. Tested via the between subject comparison of the impact of *lab technician 2* at the second elicitation stage when *lab technician 2* does/does not share *cell sample 1* with *lab technician 1* (i.e. R2E1 vs R2E2 conditions).

H2. Contradictions and Dependence – Reasoners will find the integration of two contradicting reporters using the *same* evidence (i.e. *within* a shared evidence item) more difficult than when contradictions are based on separate evidence items. Tested via the comparison to normative expectation at third elicitation stage (when *lab technician 1, lab technician 2,* and *lab technician 3* have reported) in R2E2 condition in comparison to R2E1 condition, where contradiction cuts across (rather than within) evidence items. Such a prediction is informed by previous work that has found lay reasoners struggle with inferences from contradicting reports across a dependency (Pilditch, Hahn, & Lagnado, 2018).

H3. Diversity Preference - Participants (correctly) prefer more diverse evidence (prefer *lab technician 2* to use evidence *cell sample 2*.

i. An additional question of interest is whether diversity preferences will be lower when *lab*

[4] Open text reasoning responses were also collected at the end of each elicitation stage, but for the sake of brevity are not reported here.

technician 1 provides negative evidence (NegFirst condition), than when *lab technician 1* provides positive evidence (PosFirst)?

Fig. 2 below shows the different structural and report order comparisons for the 2x2 design (each cell is a between subject condition), with T1 to T4 within each cell as the within-subject order of evidence. Thus, H1 is investigated by comparing T2 in the top row (when R2 is reliant on the same evidence as R1) with T2 on the bottom row (when R2 is using different evidence). We can then assess H2 by comparing T2 to T3 in the top row (contradiction based on separate items) to the bottom row (contradiction based on shared evidence. H3 is assessed having seen the report at T1 (and is asked prospectively about T2), and H3i. is based on the comparison of responses to the H3 question in left versus right columns of Fig. 2.

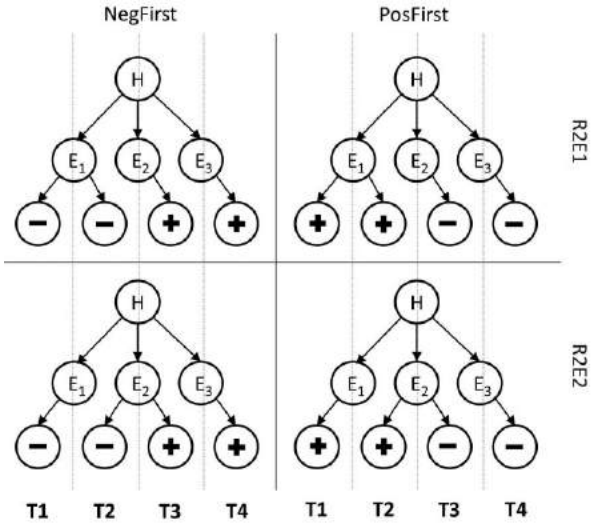

Figure 2. Underlying networks, split by R2Evidence (rows) and RepOrder (columns) conditions. T1 to T4 reflect sequence of reports (within-subjects).

Results

Bayesian statistics were employed throughout[5] using the JASP statistical software (JASP Team, 2018). Using the gRain package in R (Højsgaard, 2012), the elicited priors from each participant were used to individually fit BNs for each participant. Remaining parameters were as specified in the background information presented to participants. The posterior probabilities at each elicitation stage generated from each BIBN model (representing each participant) were used in subsequent comparison analyses.

Probability Estimates

The hypothesis-directed analyses used to unpack a) the influence of when shared evidence is introduced (*H1*), and b) the influence of contradiction within/outside a dependency (*H2*), first employed an RM-ANOVA on participant estimates alone (including between subject factors), so as to determine participant behavior, followed by a further analysis that compared these estimates to BIBN predictions, to determine the "correctness" of this behaviour.

H1. Firstly, to assess *H1*, an RM-ANOVA on participant estimates from T1 to T2, found participants were insensitive to R2Evidence condition overall, $BF_{Inclusion}$ = 0.102, or in interaction with elicitation stage, $BF_{Inclusion}$ = 0.105. This was despite participants updating in light of new evidence *in general*, $BF_{Inclusion}$ > 10000, and whether that evidence was positive or negative, $BF_{Inclusion}$ > 10000. This was further evidenced by the interaction of elicitation stage and RepOrder (participants decreased estimates as negative reports came in, and increased as positive reports came in), $BF_{Inclusion}$ > 10000. Consequently, the model of participant estimates without R2Evidence yielded the strongest fit, BF_M = 63.2, and was decisive overall, BF_{10} > 10000.

Consequently, by subsequent inclusion of the BIBN predictions for each participant (the Observed vs Predicted factor), this insensitivity to shared evidence (i.e. the influence of R2Evidence, was shown to be insufficient relative to (fitted) normative expectation. This was evidenced by a main effect of Observed vs Predicted, $BF_{Inclusion}$ = 5479.38, and critically, strong evidence for the interaction of R2Evidience and Observed vs Predicted (BIBN predictions changed with R2Evidence, whilst participant estimates do not), $BF_{Inclusion}$ = 11.72.

In sum, these analyses revealed participants were insensitive to impact of shared evidence structures, as compared to their fitted Bayesian predictions (*H1*).

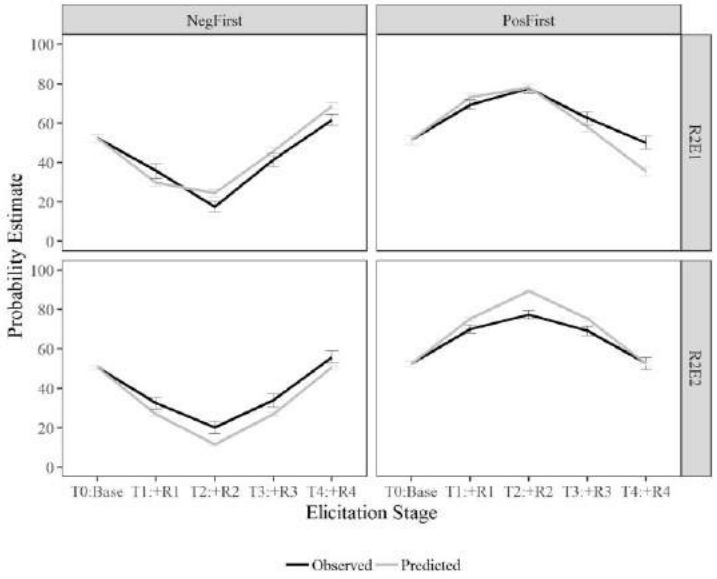

Figure 3. Probability estimates across elicitation stages, split by condition. Error bars reflect standard error.

H2. Secondly, to assess *H2*, the same analytical protocol was used on elicitation stages T2 to T3. This corroborated H1 findings, in that the insensitivity to the influence of

[5] For all analyses, an uninformed prior was used. Wherever possible, sample sizes for a given analysis (*N*), and Bayesian Credibility Intervals (95% CI) are indicated.

R2Evidence (this time via the presence of shared evidence in concert with contradicting reports either outside, R2E1, or within, R2E2, the same shared evidence) persisted both overall, $BF_{Inclusion} = 0.315$, and in interaction with elicitation stage, $BF_{Inclusion} = 0.321$. However, once again participants were sensitive to the introduction of new evidence in general, $BF_{Inclusion} > 10000$, its valence, $BF_{Inclusion} > 10000$, and the interaction of these factors (newly introduced positive reports lead to increased estimates, whilst newly introduced negative reports lead to decreased estimates), $BF_{Inclusion} > 10000$. As with the *H1* analysis, the model of participant estimates without R2Evidence yielded the strongest fit, $BF_M = 20.425$, and was decisive overall, $BF_{10} > 10000$.

To again determine whether this insensitivity was erroneous, BIBN predictions for each participant were included as another within subject factor (Observed vs Predicted). Again, participant estimates were shown to not only be generally insufficient in comparison to BIBN predictions, $BF_{Inclusion} > 10000$, but that this insensitivity extended to shared evidence (R2Evidence x Observed vs Predicted; BIBN estimates change with condition, participant estimates do not), $BF_{Inclusion} > 10000$.

In conclusion, the above analyses corroborate the insensitivity findings of *H1*, extending them to the issue of contradiction (of reports) being based on the same or different evidence items (*H2*).

Taken together, *H1* and *H2* findings suggest participants were insensitive to the impact of shared evidence, both when reporters are corroborating with, and contradicting each other.

Evidence Preference

The BIBN models for each participant, having taken into account the elicited prior for the hypothesis, generated the expected information gained in KL-D, having observed the positive/negative report from the first lab technician, for two models; one in which the second lab technician used the same evidence as the first (E1), and one where the second lab technician used different evidence (E2). The difference in expected information gain between these two models was used to generate a normative preference (based on maximum expected information) for the second lab technician using E1, E2, or them being equivalent ("NoPref").

To assess the observed evidence preferences, a Bayesian binomial test was conducted on observed preferences (dark grey bars of Fig. 4), comparing them to chance responding (0.33). Preferences for the second lab technician to use the *same* evidence as the first lab technician (E1) were found to be at chance level (0.36, 95% CI: [0.293, 0.426]; $N = 196$), $BF_{10} = 0.118$, whilst diversity preferences (second lab technician to use E2) were found to occur decisively above chance (0.51, 95% CI: [0.441, 0.579]; $N = 196$), $BF_{10} > 10000$, lending some support to the diversity preference predicted (*H3*). The frequency of participants opting for "no preference" was decisively below that expected by chance, (0.13, 95% CI: [0.092, 0.187]; $N = 196$), $BF_{10} > 10000$. A Bayesian contingency table revealed these frequencies to not be influenced by whether the first lab technician had made a positive (right-hand facet of Fig. 4) or negative (left-hand facet of Fig. 4) report ($N = 196$), $BF_{10} = 0.045$, speaking against hypothesis *H3i*.

Crucially, participant preferences for the second lab technician to use the *same* evidence as the first lab technician are substantially higher than that predicted by BIBN models (i.e. 0; see light grey bars of Fig. 4). This is corroborated by the decisive deviation in frequencies between observed and predicted preferences ($N = 392$), $BF_{10} > 10000$. Put another way, and contrary to predictions of *H3*, approximately 1/3rd of participants retain an explicit preference for the information-poorer reports that "confirm" (i.e. are based on evidence that has already formed the basis of an observed report), rather than a diversity preference or lack of preference.

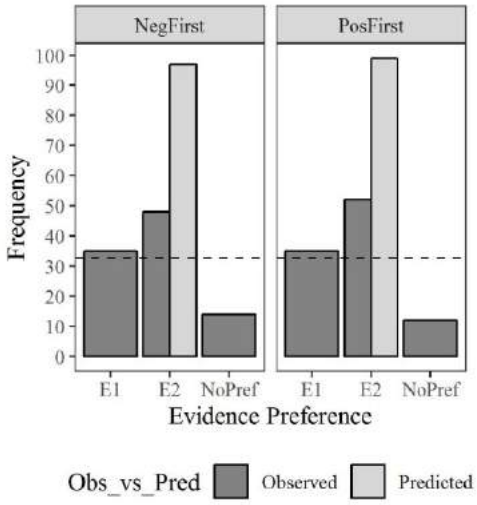

Figure 4. Evidence Preferences, split by condition. Dashed line represents chance level (33%).

Conclusions

When reasoning under uncertainty, an important consideration is the impact of dependencies among evidence items. More precisely, seemingly separate reports, which in fact stem from the same source (or evidence basis), carry redundant information, relative to truly separate reports (based on distinct information). To mistake the former for the latter can lead to overweighting support for a given hypothesis, to deleterious consequences (Dror et al., 2006; Koller & Friedman, 2009).

Here, we show that lay reasoners seem rather insensitive to the impact of this form of dependency and consider the two cases equivalent when estimating degrees of support for a hypothesis. At the same time, our findings corroborate prior research in terms of both a) the consistent under-weighting of introduced evidence (see e.g. Faigman &

Baglioni, 1988; Nance & Morris, 2005), and b) more substantial deviations when having to deal with contradictory reports (Pilditch et al., 2018).

Finally, we present a second novel finding in lay reasoners preferences for further reports based on shared (i.e. previously informed upon) evidence (a "confirmatory" preference) or separate (unseen) evidence (a "diversity" preference). Though the majority of participants conform to a diversity preference in line with maximising expected information, approximately 1/3rd of lay reasoners have a confirmatory preference. While failures to appreciate diversity have been reported before (e.g., Soll, 1999), there are clear preferences for diversity in other inferential contexts (e.g., Rips, 1979; Osherson et al., 1990), even in children (Heit & Hahn, 2001). Hence further work will be required to pinpoint exactly for when, where and why diversity is appreciated and when it is not. It is worth note in this context that where the reliability of the reporting sources is not exactly known (unlike the lab technicians in the present study), diverse evidence is arguably not always normatively superior (see Bovens & Hartmann, 2003). Whether lay reasoners have any understanding of the different circumstances where a diversity advantage does and does not obtain remains to be seen.

Asymmetric belief sensitivity and justification explain the Wells Effect

Abstract

Wells (1992) found that jurors are more likely to find a defendant guilty when the evidence against them is 'specific' (that is, when the evidence provides a causal mechanism for how an event occurred) as opposed to being based on base-rate information, or what Wells calls 'general' evidence. Enoch, Spectre, and Fisher (2012) propose that this epistemic difference can be explained by the "sensitivity" of beliefs formed on the basis of these two types of evidence where sensitivity is understood as a counterfactual condition on knowledge judgments. They argue that beliefs are sensitive when formed on the basis of specific evidence, but not when they are formed on the basis of general evidence. In two preregistered experiments, we tested this hypothesis. We replicated an earlier finding that specific, as opposed to general evidence, is more likely to lead to knowledge judgments. Consistent with the hypothesis of Enoch and colleagues, we also found that sensitivity partially mediates the relationship between evidence type and knowledge attributions.

Keywords: Wells effect; counterfactual reasoning; knowledge sensitivity; open science

Introduction

Imagine that you are a juror deliberating on a civil suit against the Blue bus company which is being accused of running over a dog during one of its routes. The only evidence that is presented to you is that a commercial bus killed a dog and that 80% of the commercial buses in the area are run by the Blue bus company. Is the Blue bus company guilty of killing the dog? According to Wells (1992), most people do not think you should convict on this evidence. Now suppose instead that the only evidence presented to you is that a witness reports seeing a Blue bus run over the dog and that this witness is 80% reliable. In this case, is the evidence sufficient for finding the Blue bus company guilty of killing the dog? According to Wells (1992), people are more likely to find a defendant guilty when the second kind of evidence, termed specific evidence, is given than when the first kind of evidence is given (termed "general" evidence). Strikingly, people exhibit this pattern of judgments even though they also perceive the probability of guilt as being the same in both cases. The tendency to trust specific more than general evidence is also reflected in the law. As Enoch and Fisher (2015) report, "Courts and legal scholars often view [general evidence] with suspicion, treating it as inadmissible even when it is probabilistically equivalent to individualized [specific] evidence." The explanation of the Wells effect is therefore not only important to understanding how people reason about evidence but is also pertinent to the law.

What explains the Wells effect? One possibility is that in the first case, the evidence is purely general in the sense that it is not causally connected to the actual killing of the dog: the fact that 80% of the buses are operated by the Blue bus company is, in a sense, independent of the actual killing of the dog. In contrast, the evidence in the second case is specific to the case; there is a causal connection between a witness reporting the Blue Bus company killed the dog and the dog being killed. Consistent with this possible explanation, empirical accounts on the Wells Effect often focus on *counterfactual thinking*—the ability to consider what could have happened but did not happen. For example, Niedermeier, Horowitz, & Kerr (1999) and Sykes and Johnson (1999) account for the reluctance to find the defendant guilty in general cases by appealing to the ease in which the possibility that the defendant is innocent comes to mind. Along these lines, Enoch et al. (2012) proposed that general evidence is considered weaker than specific evidence because beliefs formed on the basis of the former, but not the latter, are sensitive (a term which we explain below). The main goal of this paper is to test this hypothesis.

Many philosophers think that the notion of sensitive belief can explain a wide range of judgments similar to the Wells Effect (Black & Murphy, 2007; DeRose, 1999; Dretske, 1981; Ichikawa, 2011; Nozick, 1981; Roush, 2005). Philosophers typically define a 'sensitive belief' as follows:

> An agent's belief that *P* is 'sensitive' just in case If *P* were false, then the agent would no longer believe *P*.

For example, your belief that you are reading a paper right now is sensitive. This is because if you weren't reading a paper, you would be making coffee, let us suppose, and so would no longer believe you were reading a paper. Sensitive beliefs are counterfactually robust in the sense that they "track" the facts in possible circumstances. This is why

some philosophers have held that if an agent knows *P*, then her belief that *P* has to be sensitive. Let's call this thesis itself 'sensitivity'. Sensitivity is a type of counterfactual condition on knowledge.

Take another example: Consider a person who believes that his beloved pet is healthy, not through good evidence, but because of wishful thinking. We can suppose further that his pet is in fact healthy. Our intuitive reaction is that this agent does not really know his pet is healthy. But why doesn't the agent know this? According to the sensitivity account, the reason is that this agent's belief is not sensitive. For example, although his pet is actually healthy, if the pet were sick, the wishful-thinking agent would continue to think that the pet was healthy. Because his belief is not properly tracking the facts in the world, he doesn't really know his pet is healthy. In contrast, suppose the agent believes his pet is healthy, not through wishful thinking, but because he got a good report from a reliable vet. In this case, his belief is more likely to be sensitive (and hence truth tracking) because if his pet were sick, he would believe that his pet was sick. This is because if his pet were sick, the reliable vet would have told him so.

These two examples demonstrate how the sensitivity hypothesis is supposed to account for our epistemic intuitions. For our purposes, what is important is that sensitivity gives us a counterfactual condition on the perceived strength of one's evidence. We know that counterfactual reasoning also plays a role in a number of other cognitive phenomena. It has been implicated in planning and prediction (Barbey & Sloman, 2007; Epstude & Roese, 2008; Markman, McMullen, & Elizaga, 2008; Roese, 1999; Smallman & Roese, 2009; Tobia, Guo, Schwarze, Boehmer, Gläsher, Finckh, & Sommer, 2014), generating emotions (Alicke, Buckingham, Zell, & Davis, 2008; Brassen, Gamer, Peters, Gluth, & Buchel, 2012; Coricelli & Rustichini, 2010; Davis, Lehman, Wortman, Silver, & Thompson, 1995; Miller, Markman, Wagner, & Hunt, 2013; Pieters & Zeelenberg, 2005; Roese & Olson, 1997, 2007), learning (Byrne, 1997; Epstude & Roese, 2008; Smallman & McCulloch, 2012), as well as in moral and causal reasoning (Halpern & Hitchcock, 2015; Malle, Guglielmo, & Monroe, 2014). Although counterfactual reasoning has been found to play a large role in thinking across many psychological domains, we are not aware of any experimental work *directly* examining how counterfactual judgments, such as those involved in the definition of sensitivity, relate to attributions of knowledge. This is notable because, as discussed, counterfactual reasoning is prominently featured in theories of knowledge attributions in the philosophical literature.

In the present studies, we investigated whether people's judgments about knowledge can be explained by the sensitivity hypothesis. Specifically, we sought to test this sensitivity account as an explanation for the Wells effect, and related effects central to ongoing debates in epistemology (Friedman & Turri, 2014). The original Wells effect concerned judgments about whether a defendant should be found guilty. Following Wells and our discussion so far, our approach is to investigate not determinations of guilt, but attributions of knowledge. We predicted that people differentiate general and specific evidence because of their differential sensitivity—beliefs formed on general evidence are less sensitive than beliefs formed on specific evidence.

General Methods

Analytic Approach To test our hypotheses, we performed Bayesian mixed-effects modeling using the R package `brms` (Bürkner, 2018). We set regularizing priors for all population-level effects in our models, which we detail below. These priors are recommended because they provide conservative effect size estimates and reduce the likelihood of overfitting (Gelman, Lee, & Guo, 2015; McElreath, 2016). Following the recommendations of Liddell & Kruschke (2018), Likert data were modeled with a cumulative probability distribution. The cumulative distribution is recommended for Likert scale data because it assumes that ordered responses represent a continuous latent construct (in this case, the tendency to attribute knowledge to an agent).

Preregistration We preregistered the data collection plan, analyses, and predictions for both experiments. Experimental scripts, analyses, and supplementary online materials are available on the Open Science Framework at https://osf.io/pw7s8/.

Experiment 1

Participants We powered our study to detect a Cohen's d of .2 for a two-condition within-subjects design with 80% power. To this end, 201 participants were recruited through Amazon's Mechanical Turk (43% women, M_{age} = 36 years old). Participants were paid $0.50 for participating in the study. Participants were excluded for missing questions checking their attention (e.g., "Select perhaps knows from the options below"). Our exclusion criteria were determined a priori and were in accordance with our study preregistration. After excluding participants who missed questions checking their attention, 170 participants remained in our sample.

Procedure In Experiment 1, we examined whether the Wells effect can be explained by the sensitivity hypothesis. To test this, we randomly presented participants with six scenarios in a within-subjects design (three topics $\times$ two conditions = six vignettes) adapted from Friedman and Turri (2014). In these scenarios, a protagonist is described as researching a question in which they rely on either general, base-rate information or specific, mechanistic information to draw their conclusion. For example, participants considered the following scenarios:

> *General*: Bob wonders if his spider plant contains the chemical aracnium. He consults a very reliable book on

spider plants. The book says that [98 or 99% randomly presented] of spider plants contain aracnium. So Bob concludes that his spider plant contains aracnium. And he is right: it contains aracnium.

Specific: Joseph wonders if his stinkwood flower will grow yellow stalks. He conducts a very reliable DNA test on the flower. The test shows that it is [98 or 99% randomly presented] likely that the stinkwood flower will grow yellow stalks. So Joseph concludes that his stinkwood flower will grow yellow stalks. And he is right: the flower grows yellow stalks

After reading each scenario, participants were asked on a four-point Likert scale whether, for example, "Bob knows his spider plant contains aracnium" (1 = Definitely does not [know], 4 = Definitely does [know]). After answering this question, participants then answered a question aimed at assessing the sensitivity of the protagonist's belief:

"If Bob's spider plant hadn't contained the chemical aracnium, what would Bob have thought after checking with the book on spider plants?"

Participants then judged whether "Bob would [would not] have thought that his plant contains the chemical aracnium." If participants agreed that Bob would have thought his plant contains aranium regardless, this would mean participants thought that Bob's belief was not sensitive. If they thought that Bob would not have thought that, then this would indicate participants thought that Bob's belief was sensitive.

Predictions We predicted that knowledge judgments would vary based on the condition participants read. Namely, we predicted that participants would be more likely to attribute knowledge to protagonists that formed their belief on the basis of specific rather than general information. In addition, we predicted that participants would think that a protagonist's belief in the General condition is not sensitive (relative to the Specific condition) and this would in turn lead to reduced knowledge attributions.

Results and Discussion

To test our first hypothesis, we performed ordinal mixed-effects modeling. This model regressed knowledge judgments on condition (Reference = General condition) and included two group-level effects: (1) A group-level effect on vignette that allowed for heterogeneity in vignette intercept, (2) a group-level effect on Subject, which allowed for heterogeneity in both the slope and intercept of the condition effect on knowledge judgments. The model is specified below in `brms` syntax:

```
Model 1 <- Knowledge Response ~
Condition + (1|Item) + (1 +
Condition|Subject)
```

Bayesian analyses formulate model parameters as probability distributions wherein the posterior distribution

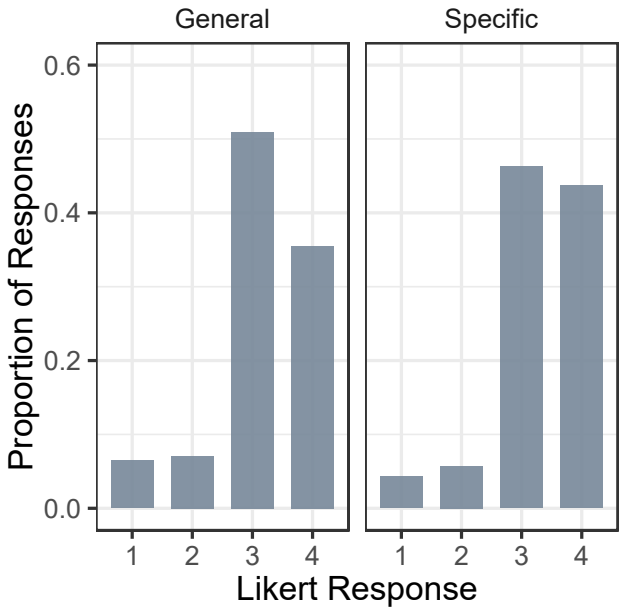

Figure 1: A histogram of the proportion of responses at a given Likert scale point (e.g., 1 = Definitely does not know; 4 = Definitely knows) in the General and Specific conditions in Experiment 1. The figure indicates that participants were less likely to attribute knowledge in the General condition than the Specific condition.

for a parameter θ is computed via the prior and the likelihood of θ. To model the joint probability distribution of participants' knowledge responses, we specified the following priors over the possible effects each parameter could have on the response variable:

Experiment 1 - Model 1 Priors:

$\beta_{Intercept[1]} \sim \mathcal{N}(-1.73, 1)$
$\beta_{Intercept[2]} \sim \mathcal{N}(-.61, 1)$
$\beta_{Intercept[3]} \sim \mathcal{N}(.84, 1)$
$\beta_{Condition} \sim \mathcal{N}(0, .5)$
$\Omega_k \sim LKJ(1)$ where Ω_k is a correlation matrix of group-level parameters
Group-level parameters were distributed as $\mathcal{N}(1, 1)$

We predicted that participants would be more likely to attribute knowledge in the Specific condition than the General condition. This is what we observed, b = 0.72, 95% CI [0.38, 1.05]. Figure 1 indicates that in the General condition, the third Likert scale point [Perhaps knows] was the most probable response. In contrast, in the Specific condition both 3 [Perhaps knows] and 4 [Definitely knows] were probable responses, indicating that participants were more likely to attribute knowledge to a protagonist when the means by which the protagonist formed their belief was specific rather than general, as had been previously found (Friedman & Turri, 2014).

What explains people's tendency to differentially ascribe

knowledge when the probabilities in both situations are perceived as being similar? Our hypothesis is that this effect may be at least partially explained by sensitivity. That is, we predicted that people would think that an agent's beliefs in the Specific condition would be more sensitive than in the General condition. To test this prediction, we first performed logistic mixed-effects modeling. This model regressed participants' judgments of belief sensitivity (i.e., 1 = Protagonist would still believe, 0 = Protagonist would not still believe) on condition.

```
Model 2 <- Counterfactual Response ~ 0 +
intercept + Condition + (1|Item) +
(1 + Condition|Subject)
```

Experiment 1 - Model 2 Priors:

$\beta_0 \sim \mathcal{N}(.75, .25)$
$\beta_{Condition} \sim \mathcal{N}(0, .5)$
$\Omega_k \sim LKJ(1)$
Group-level parameters were distributed as $\mathcal{N}(1, 1)$

Here too, we observed the predicted effect of condition on participants assessments of belief sensitivity, $b = -0.60$, 95% CI [−0.94, −0.25] (see Figure 2).

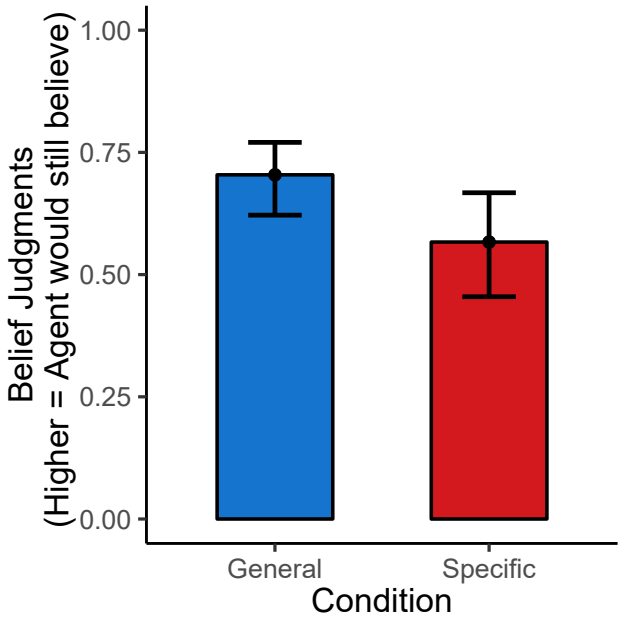

Figure 2: A marginal effects plot of belief sensitivity in the General and Specific conditions in Experiment 1. Error bars represent 95% Credible Intervals (see Cummings, 2005 for interpreting within-subjects 95% CIs).

Our hypothesis was that people tend to differentially attribute knowledge in General and Specific conditions because of the sensitivity of the protagonists' beliefs in these two situations. We observed this effect. We followed up on this observation by performing mixed-effects mediation modeling to test whether sensitivity mediated the relationship between condition and knowledge attributions, as suggested by the partial correlations.

```
Knowledge Model =
bf(Knowledge ~ Condition +
Counterfactual +
(1 + Condition|Subject))

Counterfactual Model =
bf(Counterfactual ~ Condition +
(1 + Condition|Subject))

Mediation Model =
brm(Knowledge Model +
Counterfactual Model)
```

Mediation Model Priors:

All $\beta \sim \mathcal{N}(0, .5)$
$\Omega_k \sim LKJ(1)$
Intercept and group-level parameters were distributed as $t(3,0,10)$

Consistent with our hypothesis, we observed the predicted mediation, *ab* path = .37, 95% CI [.08, .81].

Experiment 2

Experiment 1 provides preliminary evidence for the hypothesis that sensitivity can account for people being less likely to attribute knowledge in general versus specific cases. However, one possibility is that people think the agents in these two situations are not equally justified in drawing their conclusions and, further, that belief sensitivity is correlated with attributions of justification. Although it is often assumed that people are equally justified in believing that *P* in both general and specific cases, this assumption has not been empirically tested. Consequently, we sought to rule out this alternative explanation of the results of Experiment 1 because justification is likely one of the most strongly predictive factors of knowledge attributions. To address this possibility, Experiment 2 directly replicated Experiment 1 but also included a measure of justification.

Participants We powered our study to detect a Cohen's d of .15 for a two-condition within-subjects design with 80% power. We anticipated the effect of counterfactual responses on knowledge attributions would be smaller after accounting for differences in justification between general and specific cases. A total of 344 participants were recruited through Amazon's Mechanical Turk (46% women, M_{age} = 36 years old). Participants were paid $0.50 for participating in the study. After excluding participants who missed questions checking their attention, 288 participants remained in our sample. Our sample size and exclusion criteria were determined a priori and were in accordance with our study preregistration.

Procedure and Predictions The procedure of Experiment 2 was identical to that of Experiment 1. However, in Experiment 2, participants answered additional questions

testing whether they thought the protagonist's beliefs were justified. For example, after reading each vignette participants also judged whether Bob was justified in concluding that his plant contains aracnium. Complete materials can be found in Table S4 in the SOM.

As in Experiment 1, we predicted that knowledge and sensitivity judgments would differ in the General and Specific conditions, and that sensitivity would mediate the relationship between condition and knowledge attributions. However, Experiment 2 also allowed us to test whether participants thought that (1) the protagonists in the Specific condition were more justified in drawing their conclusions and (2) rule out the possibility that justification alone rather than belief sensitivity accounts for the differential attribution of knowledge attributions in the General and Specific conditions.

Results and Discussion

As in Experiment 1, we first examined how condition (General vs Specific) affected knowledge and sensitivity judgments. We performed the same analytic procedure as in Experiment 1. These analyses again revealed that both knowledge and sensitivity were predicted by whether the case participants were reading was general or specific, Knowledge: b = 1.10, 95% CI [0.81, 1.41) and Counterfactual: b = –.52, 95% CI [–0.86, –.18) (see Figures 3 and 4), along with the mediation of knowledge judgments by sensitivity *ab* path = .27, 95% CI [.05, .60). We then tested whether participants differentially attributed justification to the protagonists in the General and Specific conditions. We found that, indeed, participants judged that the protagonist in the Specific condition was more justified in drawing their conclusion than in the General condition, b = .86, 95% CI [0.51, 1.20]. Does justification, rather than sensitivity, account for the difference in knowledge attributions in general and specific cases? To examine this possibility, we performed ordinal mixed-effects modeling regressing knowledge attributions on justification and counterfactual judgments. Justification responses were treated as monotonic effects, following the recommendations of Bürkner and Charpentier (2018):

```
Model 3 <- Knowledge Response ~
Counterfactual + mo(Justification) +
(1|Item) + (1|Subject)
```

Experiment 2 - Model 3 Priors

$\beta_{Intercept[1]} \sim \mathcal{N}(-2,1)$
$\beta_{Intercept[2]} \sim \mathcal{N}(-1.5,1)$
$\beta_{Intercept[3]} \sim \mathcal{N}(4,1)$
$\beta_{Counterfactual} \sim \mathcal{N}(0,.5)$
$\beta_{Justification} \sim \mathcal{N}(2,4)$
Group-level parameters were distributed as $\mathcal{N}(1,1)$

This analysis revealed that sensitivity accounted for unique variance in knowledge attributions over and above attributions of justification, b = –0.51, 95% CI [–0.83, –0.19]. Thus, Experiment 2 provides evidence for two further conclusions: First, knowledge attributions likely

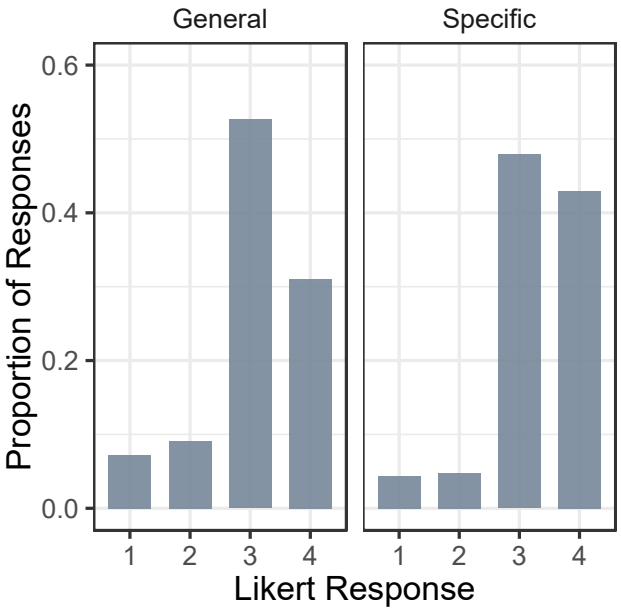

Figure 3: A histogram of the proportion of responses at a given Likert scale point (e.g., 1 = Definitely does not know; 4 = Definitely knows) in the General and Specific conditions in Experiment 2. The figure indicates that participants were less likely to attribute knowledge in the General condition.

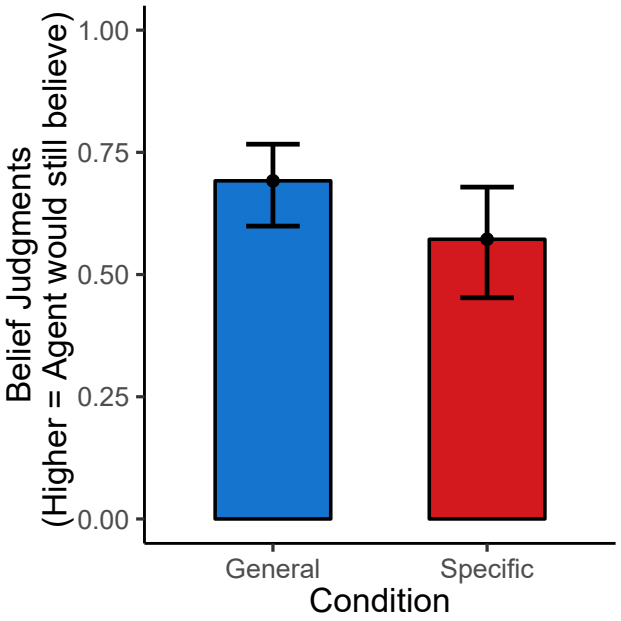

Figure 4: A marginal effects plot of belief sensitivity in the General and Specific conditions in Experiment 2. Error bars represent 95% Credible Intervals.

differ in general and specific cases because of a difference in the perceived justification of agents in these situations. Second, and consistent with our prediction, people judge that beliefs formed on the basis of general evidence are insensitive (relatively) compared to beliefs formed on the basis of specific evidence, an effect that holds over and above the effect of justification.

Discussion

In psychology and the law, researchers have observed that jurors are less likely to trust general as opposed to specific evidence (Wells, 1992). However, this effect appears to extend beyond the courtroom: We found that knowledge attributions were similarly affected by manipulating whether evidence was general or specific, replicating earlier work that third-person knowledge attributions increase when the evidence available to the protagonist is specific as opposed to general. It is notable that this effect was found in cases that have little to do with the law or with witnesses, thus suggesting that the Wells effect is an instance of a more general phenomenon that goes beyond cases of witnesses or eyewitness memory specifically.

What explains people's tendency to distinguish general and specific evidence, given that the probabilities are fixed? We explored the hypothesis that general and specific evidence differ along more lines than their probabilities: namely, we examined whether sensitivity (a counterfactual condition) can account for the tendency to attribute knowledge in specific compared to general cases. Experiment 1 provided evidence that what explains the difference in knowledge judgments (across general and specific cases) is the perceived sensitivity of the belief at issue. In Experiment 2, we considered the alternative hypothesis that justification rather than sensitivity accounts for the difference in people's knowledge attributions in general and specific cases. We found that assessments of sensitivity account for variance in knowledge attributions over and above justification, although justification also differed by condition.

These experiments constitute the first empirical investigation demonstrating a link between knowledge attributions and sensitivity among non-philosophers. Further, this is the first piece of experimental evidence which suggests that a well-known effect in legal decision making—the Wells effect—can be understood in terms of epistemic theories that highlight the link between knowledge attributions and counterfactuals. Still, questions remain about the ability of the sensitivity hypothesis to account for other core epistemic phenomena. Indeed, a number of philosophers, for example, Williamson (2000), Blome-Tillmann (2015), and Hawthorne (2003), have pointed out that the sensitivity hypothesis cannot fully explain a range of intuitions regarding knowledge attributions. Consequently, subsequent experimental work should investigate these proposals to establish the scope and limits of the sensitivity hypothesis.

Egocentric Tendencies in Theory of Mind Reasoning: An Empirical and Computational Analysis

Jan Pöppel (jpoeppel@techfak.uni-bielefeld.de) and **Stefan Kopp (skopp@techfak.uni-bielefeld.de)**

Abstract

Humans develop an ability for Theory of Mind (ToM) by the age of six, which enables them to infer another agent's mental state and to differentiate it from one's own. Much evidence suggests that humans can do this in a presumably optimal way and, correspondingly, a Bayesian Theory of Mind (BToM) framework has been shown to match human inferences and attributions. Mostly, this has been investigated with specific, explicit mentalizing tasks. However, other research has shown that humans often deviate from optimal reasoning in various ways. We investigate whether typical BToM models really capture human ToM reasoning in tasks that solicit more intuitive reasoning. We present results of an empirical study where humans deviate from Bayesian optimal reasoning in a ToM task but instead exhibit egocentric tendencies. We also discuss how computational models can better account for such sub-optimal processing.

Keywords: Theory of Mind; Bayesian Modeling; Egocentric Tendencies; Bounded rationality

Introduction

An important ability of humans is to infer and reason about ones own as well as other's mental states such as intentions, (potentially false) beliefs, or emotions (Wellman & Liu, 2004). While the exact development of this so-called Theory of Mind (ToM) (Premack & Woodruff, 1978) is still not clear, there is a consensus that we acquire full ToM abilities around the age of six (Wellman & Liu, 2004). This allows us to make sense of our social environment, to learn more from the actions around us (Jara-Ettinger, Baker, & Tenenbaum, 2012) and to better understand or even manipulate others in cooperative or competitive interactions (Heyes & Frith, 2014).

Because of its importance for social interaction, there is a great interest in endowing artificial systems with similar capabilities. Recently, the most prominent approach has been the Bayesian Theory of Mind (BToM) framework (Baker, Saxe, & Tenenbaum, 2009). Building upon the rational agent assumption (Dennett, 1989) and inverse planning, the BToM framework constructs probabilistic generative models that relate hidden mental states to observable actions. These models can then be inverted to infer mental states from behavior, while accounting for inherent uncertainty. This framework has been shown to make inferences that correlate well with those made by humans in a wide range of different tasks, such as the inference of desires and beliefs (Baker, Jara-Ettinger, Saxe, & Tenenbaum, 2017) or preferences (Jern, Lucas, & Kemp, 2017). It is also in line with the Bayesian Brain hypothesis positing that humans incorporate information similar to optimal observers (Knill & Pouget, 2004).

At the same time, humans do not always behave like optimal observers or reasoners. Instead, they exhibit a range of fallacies leading to systematic errors in different types of inference (Haselton, Nettle, & Murray, 2015). This has also been argued to hold for social interaction. For example, Keysar (2007) showed that adults fail to adjust correctly for different perspectives in communication tasks. This trait is often referred to as *egocentric tendency* and refers to the tendency to impute one's own mental perspective on others (Nickerson, 1999). Keysar, Lin, and Barr (2003) present an experiment in which even adults fail a false-belief test, showing that an egocentric tendency is not always effectively suppressed. In other words, we do not appear to always use our ToM capabilities to the fullest extent (cf. (De Weerd, Verbrugge, & Verheij, 2013)). This is often attributed to limited mental resources, such as working memory and processing time. Vul, Goodman, Griffiths, and Tenenbaum (2014) argue that many biases are actually optimal when seen as the result of the number of samples for inference being limited.

It is unclear how those limitations affect ToM reasoning in humans. While the BToM framework has been shown to correlate well with humans' explicit ToM reasoning, it has not been evaluated with regard to humans' intuitive or implicit inferences, i.e. when sophisticated ToM reasoning is not explicitly evoked. Recently, Nakahashi and Yamada (2018) showed that a full inverse planning approach based on the BToM framework overestimates the rationality of humans and that modified inference achieves better correlations with human judgments. We are interested in whether, in an intuitive setting, humans employ different kinds of ToM models as a function of, e.g., computational costs, available resources, or current task demands. We have argued elsewhere that employing different kinds of ToM models for "satisficing mentalizing" can be beneficial for artificial systems, where full Bayesian models often suffer from intractabilities (Pöppel & Kopp, 2018). Here, we study whether humans may also employ different simpler, non-optimal models depending on the given circumstances and, specifically, whether they may fail to realize or account for differences between one's own and another one's mental states. We thus focus on the extent to which humans employ mentalizing in a settings that is more implicit than those used in previous BToM research.

In the remainder of this paper, we present empirical evidence suggesting that humans exhibit different degrees of egocentric tendencies in a simple ToM reasoning task, thus deviating from rational optimal observers usually assumed in previous BToM models. The next section first describes the scenario we are looking at. Then, we present an empirical study we have carried out in this scenario to investigate in-

tuitive human ToM reasoning. After this, we present different computational ToM models, partially based on the BToM framework, and report their correlations with our data.

Scenario

The scenario we chose for our empirical study is the inference of an agent's desire in a navigation task within a 2D maze. The maze has four exits, each of which leading to a distinct destination (denoted Red, Yellow, Blue or Orange). The agent has to find the exit that leads to one specific destination, which we consider to be the agent's desire. In previous work we already gathered behavioral data in the form of trajectories of human participants solving this navigation task in different mazes with differing amounts of information available (Pöppel & Kopp, 2018). Here, we consider the task of an additional observer, who watches the agent move around in the maze and has to infer the agent's desire – a perceptual and cognitive task humans solve frequently in everyday life. According to the ToM scale by Wellman and Liu (2004), this kind of inference is also among the first ones to be mastered by children.

In order to create a need for differentiating between the mental perspectives of the agent and the observer, we employ two conditions: in the first condition, participants acting as agents had full knowledge of the maze, the locations of all exits, and the destinations behind them. That is, they could take an optimal path in order to reach their desired destination. In the second condition, the acting participants knew about the locations of the exits in the maze, but had to discover the corresponding destinations themselves by establishing a line of sight with the exit. Thus participants had to search for the specific exit (one out of four) that leads to their desired destination, resulting in an exploration behavior. This scenario is similar to earlier work on BToM, e.g. (Baker et al., 2017), in that it involves navigating a simple grid-world to achieve a desired outcome with potential uncertainty about the true location of that outcome.

Figure 1 shows an example of the different stimuli that the acting participants received in the two conditions. In the bottom example belonging to the second condition, the exits are marked but covered. Note that in this situation the agent has moved to a position, where it could see the exit thus revealing its corresponding destination (Blue). In the present study, we use recordings of the online navigation behavior in these two conditions and let human participants play the role of the observer. In particular, their task is to identify the desired destination of the observed agent at different points on the recorded trajectory.

Empirical Study: ToM Reasoning in Humans

Humans employ their ToM capabilities rarely to their fullest extent. However, it is still unclear what factors, apart from cognitive load, may influence the extent to which a person employs her ToM capabilities. Previous research has shown that explicit asking for likelihood ratings of all alternatives yields responses predicted by the BToM framework. However, we conjecture that this experimental design inherently evokes explicit reasoning about mental states in the participants, including the full consideration and comparison of all alternatives. This evocation may be part of the reason for the discrepancy between very good fittings in BToM research and findings of suboptimal behavior in other research. In contrast to previous research, we therefore deliberately chose not to ask for likelihood ratings for all possible desires, but instead ask for *soft forced-choice* responses in order to test for a more intuitive and natural ToM reasoning. We call it *soft* because we gave participants the additional option "I do not know".

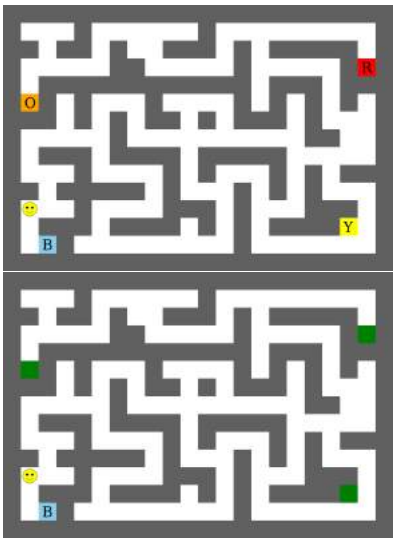

Figure 1: View of the navigating agents. Top: full knowledge about exits and destinations; Bottom: exits only reveal their destination once a line of sight is established.

We also included a second group of participants who were additionally prompted to self-assess their belief about the observed agent's knowledge. We included this group to test the effect of putting an agent's belief into focus of (more explicit) ToM reasoning, thus testing if different task demands influence the employed ToM models.

Participants We recruited two distinct groups of participants (first group 120; second group 65) each via an online platform called "figure-eight" (formerly crowdflower). All participants had a "contributor level three", which is advertised as "Highest Quality: Smallest group of most experienced, highest accuracy contributors". After completion of the study, participants were reimbursed with $0.20 via the figure-eight system.

Stimuli For each of the two conditions mentioned above, we chose two typical trajectory recordings in two different mazes. The four trajectories are shown in figure 2. Participants could see the maze and, importantly, all destinations behind the different exits. That is, they always had full knowl-

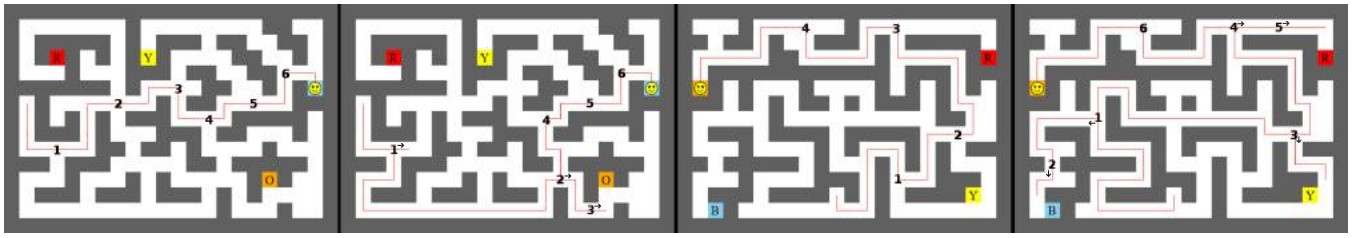

Figure 2: The recordings 1 through 4 used as stimuli, one from each condition (destinations known/unknown to the agent) in two different mazes. Numbers indicate the location of query points at which participants had to give their responses. Small arrows indicate the agent's next action after the query point when ambiguous.

edge about the destinations, while the agents they observed might or might not have had the same knowledge. Participants would see the agent navigating the maze according to the recordings, leaving behind a red trail as in figure 2, so that participants always knew where the agent moved. We chose to replay these recordings with fixed time intervals between two steps in order to remove potential noise within the trajectories (while also eliminating information about speed or possible hesitations of the agents).

Procedure All participants received the same initial instruction that they were going to watch the recordings of four different human players navigating a maze. They were informed that the maze had four exits, each leading to a different destination, and that each player had her own specific destination she had to reach as quickly as possible. We further explained that the four players were part of two different conditions. In one condition, they had full knowledge about the destinations behind the exits, while in the other they had to first discover which exit led to which destination. In order to make this clear, we provided participants with the images in figure 1 alongside the instructions. The instructions read: "*Now you will watch the agents follow their trajectories while you will be able to see which exit corresponds to which destination. At certain points in time you will be asked to tell the agent's desired destination (R,B,Y,O). You may also say that you do not know*." The query points are those shown in figure 2. We deliberately asked for the agent's *desired destination* instead of an exit to focus on the agent's desire instead of the exit locations close to the agent. The second group of participants were further instructed about the additional question regarding the agent's knowledge, which read "*Additionally, you will be asked to specify if you think the agent knows which exit leads to which destination*.".

Upon confirming these instructions, participants got to see the first maze as in figure 2 (without the query point numbers) with the agent at the beginning of its trajectory. After hitting a *Start* button the agent started to move leaving behind the red trail. The playback stopped at each QP and participants were asked to choose one out of the four possible goal destinations, or to signal that they cannot tell otherwise, which we will refer to as *Uncertain* (U) from here on. In order to avoid misinterpretations (such as having asked for current target location only), we instructed participants with: "*Please specify which destination you think the agent wants to reach after leaving the maze*." The second group of participants received an additional question before identifying the agent's destination: "*Do you think the agent you are watching currently knows which exit leads to which destination?*" Participants could respond with either "Yes" or "No". Once the agent reached its destination, participants could proceed to the next recording. In total, each of the 185 participant had to make 22 judgements (taking less than 400s on average for the first group and less than 485s for the second group).

For the first group, we counter-balanced the order in which participants saw the different recordings/mazes. We used a Fisher's exact test on the response frequencies in order to test whether or not the order in which the stimuli was presented had any effect on participants' responses. The test revealed no significant effects of the stimuli ordering for all but one responses (recording 1, QP 6). We thus concluded that the order of presentation of recorded trajectories/mazes did not influence participant's responses. We thus collapse the results of participants in the first group for the analyses in the remainder of this paper. Furthermore, we decided to use only one ordering for the second group in order to simplify the design.

For analyses, we excluded all participant's responses for a particular recording if participants always picked the same destination and if this destination was not the correct one within one recording. We further excluded responses if participants chose to predict a destination after the agent already turned away from it in recordings 2 and 4. We assume that these participants did not really pay attention to the actual trajectories as these are obvious errors. After excluding such participants, we had 110 participants in group 1 and 57 participants in group 2 remaining.

Results Figures 3 and 4 show normalized response frequencies for several interesting query points in the two groups. Note, however, that the reported tendencies also hold for the other recordings and query points.

For the first group of participants who only had to identify the likely destination of the agent, we find a strong bias

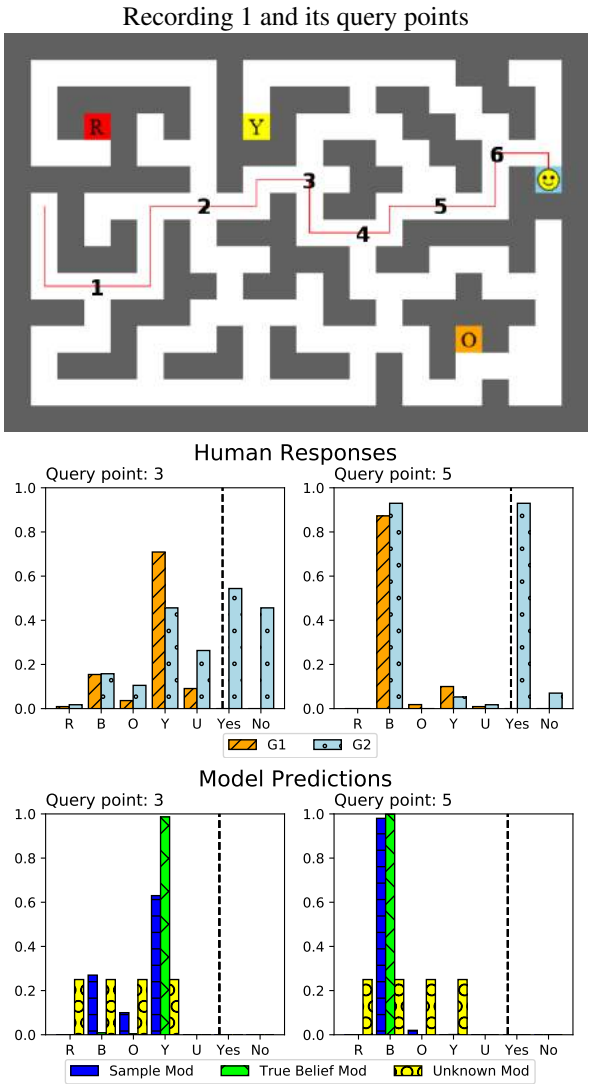

Figure 3: Relative response frequencies by the participants in both groups for Recording 1, query points 3 and 5 and the corresponding predictions made by the models using the likelihood modification

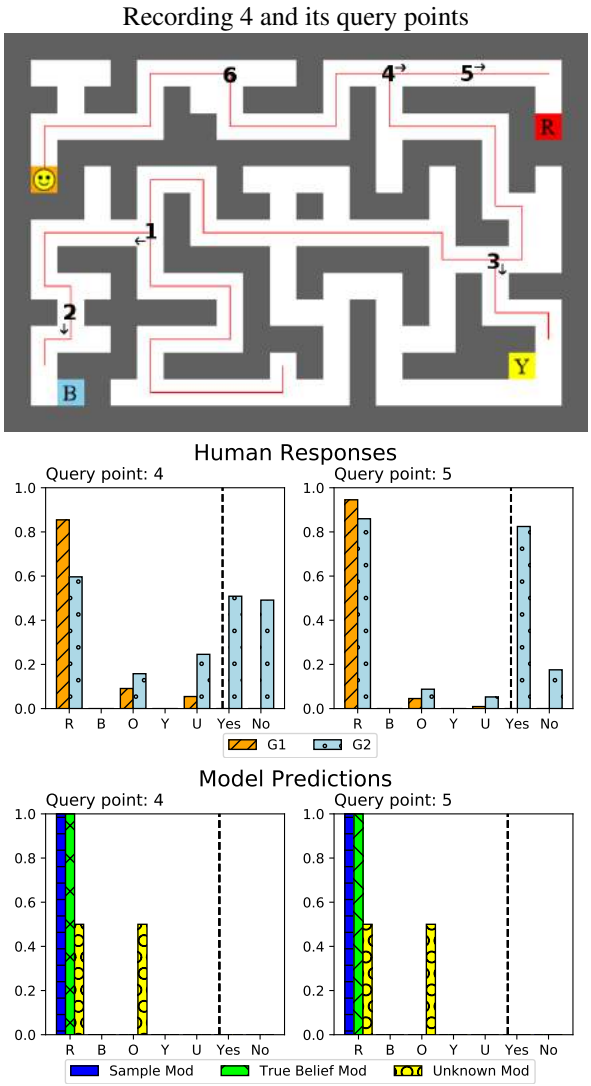

Figure 4: Relative response frequencies by the participants in both groups for Recording 4, query points 4 and 5 and the corresponding predictions made by the models using the likelihood modification.

towards assuming that the agent is seeking the destination behind the closest exit. This also holds true for points at which an agent's behavior was optimally directed to multiple exits (cf. Yellow responses for QP 3 in figures 3). We also find that participants ignore that the agent may have a knowledge state different from their own. For example, in the Red responses at QPs 4 and 5 in figure 4, they had already seen the agent turning away from two exits. Thus they should assume that the agent does not know which exit leads to which destination, even if they see the agent moving towards Red. They thus show an egocentric tendency in their reasoning.

When looking at the second group, i.e. participants that were first asked about the knowledge state of the agent before trying to identify the agent's desire, we find significantly different desire response distributions for 12 of the 22 QPs ($p \ll 0.05$ according to Fisher's exact test). These differences manifest themselves primarily in a difference of the percentage of Uncertain responses, which is significantly higher for the second group (14.9% vs 4.7%, $t = 3.86$ $p < 0.001$), also visible at QP 3 in figure 3 and QP 4 in figure 4. We further find interesting results regarding the preceding question about their belief of the agent's knowledge state: "No" responses (i.e. they believe the agent does not know) increase after an agent turned away from an exit it saw, as expected (e.g. in recording 4 "No" responses are only around 20% at QP 2, but increase to around 45% at QP 3). However, the percentage for "No" never exceeds 55% and quickly decreases again as the agent moves towards any particular exit, as seen for QP 5 in figure 4.

Computational Modeling

These results indicate that our participants in groups 1 and 2 performed their ToM reasoning differently, but neither group appears to make use of their ToM capabilities to their fullest extend. In fact, participants may even employ different strategies at different parts of the recordings. In this section we explore different models for the desire ToM task and present how they correlate with our empirical data.

BToM models The first two models we are considering, which are taken from previous work (Pöppel & Kopp, 2018), follow the general BToM framework and were designed to correspond to the mental states induced by the two conditions described above.

The *True Belief* model assumes that the agent has full knowledge regarding which exit leads to which destination:

$$P(a_{t+1}|\boldsymbol{a}_t) = \sum_{d \in D} P(a_{t+1}|d, b_d^*) P(d|\boldsymbol{a}_t) \tag{1}$$

The *Unknown* model assumes that the agent does not initially know which exit leads to which destination, which is why it needs to consider all possible combinations:

$$P(a_{t+1}|\boldsymbol{a}_t) = \sum_{\substack{d \in D \\ b_d \in B_d}} P(a_{t+1}|d, b_d) P(b_d|\boldsymbol{a}_t) P(d|\boldsymbol{a}_t) \tag{2}$$

With D being the set of desirable destinations and B_d the set of beliefs about which exit leads to which destination. b_d^* is the true belief, i.e. it maps exits to destinations correctly. $\boldsymbol{a}_t = a_1, .., a_t$ is the sequence of past actions, observed up to this point t.

The likelihood $P(a_{t+1}|d, b_d)$ is modeled following the commonly used Boltzmann noisy rationality:

$$P(a_{t+1}|d, b_d) = \frac{exp(\beta U(a_{t+1}, b_d, d))}{\sum_{a_i \in A} exp(\beta U(a_i, b_d, d))} \tag{3}$$

with β specifying the degree of rationality. Low values of β will allow more sub-optimal actions, while a larger β will result in the probability mass to be concentrated on the action with the highest utility $U(a_{t+1}, b_d, d)$ which in this simple scenario can be equated to the remaining distance to the exit leading to d according to belief b_d after executing the action a_{t+1}. The belief b_d is updated when the agent actually sees one of the exits by dismissing any beliefs which do not conform to the evidence.

Simple sampling model As a third model we introduce a model correlating to shallow processing with egocentric tendencies by implementing a very naive sampling approach: At the start of the recording, the model samples one destination from the prior $P(D)$. After observing each action, its likelihood $P(a|d, b_d^*)$ is computed using eq. 3. We keep this sample with the probability of the likelihood. Conversely, we draw a new sample with probability $1 - P(a|d, b_d^*)$ again from the prior $P(D)$, while ensuring not to pick a previously discarded destination. This way, the worse a sample can predict the observed actions the more likely it is to be replaced. Once all destinations have been discarded, we are considering all of them again, as we must have discarded the correct one along the way. The prior $P(G)$ is computed every time we need to draw a sample and depends on the remaining distance between the agent's current position p and the destination:

$$P(d) \propto exp(-\beta dist(p, d)) \tag{4}$$

For our results presented below, we fit β in the range of 0.1 to 3 at 0.1 intervals via a grid search to maximize correlations for each model separately.

Modifications As we are interested in what kind of models are required to model different ToM reasoning strategies employed by humans, we further tested the following modification to the likelihood function (eq. 3) in order to be able to better reflect the biases found in our data. While these modifications may improve the correlations in this case, we note that they may actually decrease correlation with human judgments that employ more thorough ToM reasoning.

To better reflect the bias for the closest exit found in the data, we changed the rationality constant β to a dynamic variable, which decreases with the distance to the exit, effectively dampening the likelihoods for exits that are further away and boosting optimal actions towards closer exits.

$$\beta \propto \alpha exp(-\gamma dist_m(p, d)) \tag{5}$$

where $dist_m$ is the current Manhattan distance between the agent's position p and the considered destination d. In this case α and γ are meta parameters that were fit to maximize correlation with a grid search between 2 and 4 at 0.1 intervals for α and between 0.025 and 0.75 at 0.05 intervals for γ for the results.

Model evaluation We compare our models with our participants' responses both on each recording separately, as well as over all responses. As has been done in previous BToM research (e.g. (Baker et al., 2017)) we considered the correlations between participants' average responses and the models' predicted distributions at each of the different query points. For this we stack the relative response frequencies for the four possible destinations for all QPs within a single recording, resulting in a vector of $4 \times 6 = 24$ elements (16 for recording 3 as there were only 4 QPs). Likewise we stack the destination distributions predicted by our models before computing the Pearson's r correlation. For the sampling model, we generated 100 independent responses and used the resulting normalized frequencies as the model's distribution. We then further stack the vectors for all recordings for the overall comparison, yielding a vector with 88 elements. We are deliberately evaluating in favor of our models in order to consider a best case scenario: All meta-parameters (β, α and γ)

have been fit to maximize the resulting correlation across all recordings. Furthermore, we spread all Uncertain responses across the other alternatives proportional to the model's distribution.

In order to test how well the models match the participants individually, we further had the models create actual predictions and compared these to the responses of each participant. We sampled 100 discrete responses from our models' predictions and computed how often these responses match the participants' responses at each of the different query points. We then averaged these number of matches over all query points for each recording and over all participants to get the average matching performance of our models. Again, in order to evaluate in favor of the different models, we count Uncertain responses as matches.

Tables 1 and 2 summarize the resulting correlations as well as the average number of matching responses (values in brackets) between our models and their modifications with the human responses of the first and second group respectively. Missing correlation values (–) are due zero variance in predictions of the Unknown model in those recordings. Note that Recording 3 contained only 4, instead of 6 query points.

Exemplary model outputs can also be found in figures 3 and 4, which shows the response distributions of the different (modified) models for the same QPs as the human responses.

The first thing to note is that the Unknown model, being the most rational with the least amount of biased assumptions, performs significantly worse than all others. This holds true for both the average correlation, as well as the number of matches. In Recordings 1 and 3 where we cannot compute the correlation due to zero variance, the Unknown model fails to make any predictions, always yielding a uniform distribution, which turns the Unknown model into a random model when comparing response matches. The slightly higher than chance performance of the Unknown model can mostly be attributed to the U responses. Furthermore, we find that the Sampling model correlates best with our human data, with a significant difference to the True Belief model. These results are also reflected by the average number of response matches. All models without the modification, except for the Unknown model correlated significantly more with participants in group 2 than in group 1. With regard to the modifications introduced by eq. 5: The True Belief model can improve its correlation significantly for both groups, while the Sampling model only improves significantly for the first group. Finally, it is noteworthy that the best meta-parameters for the Sampling model differ quite strongly between the two groups. (All significance claims achieved $p < 0.05$ on a t-test using the correlation coefficients after employing a Fisher transformation.)

Discussion and Conclusion

The results reported here suggest that humans can deviate quite strongly from optimal ToM reasoning. The rare use of the U(ncertain) response overall indicates that participants do not always consider the likelihood of all valid alternatives, but rather focus on single alternatives. In particular, they often fail to give U responses even after it became apparent that the agent is not aware of the location of the desired destination. In contrast, optimal reasoning would dictate the use of U responses whenever more than one destination is the most probable, or whenever multiple alternatives have a non-zero probability. Instead, participants show egocentric tendencies by ascribing their own map knowledge to the agent, and moreover a strong bias towards the closest exit as destination. This is also reflected in the decrease of "No" responses in the second group as soon as the agent moves towards any exit: even participants that briefly suppressed this tendency after having observed the agent moving away form a seen exit, tend to discard this evidence again at the next QPs. The results of the second group indicate that posing a question about the mental state of the agent before requesting the desire inference, increases the number of considered ToM alternatives slightly. Still, even participants of the second group that correctly realised that the agent's knowledge state differed from their own, often did not account for it properly when reasoning about the desire of uncertain agents. These findings support the hypothesis that humans may perform ToM reasoning differently. The task to give likelihood ratings for all alternatives (as e.g. in (Baker et al., 2017; Jern et al., 2017)) might evoke more controlled and complex ToM reasoning, suppressing cognitive biases and resulting in good correlations with optimal Bayesian models.

One might object that the observed bias towards the closest exit may stem from interpreting the instructions as "*where do you think the agent is currently going?*". However, the actual instruction was deliberately chosen to prevent this interpretation by stating "*Please specify which destination you think the agent wants to reach after leaving the maze*." While we cannot be certain about the actual interpretation by participants in the online study, we do believe that the biases are more likely to originate from inherent tendencies to use simpler, less demanding mentalizing strategies.

Looking at the correlations with different computational models, we find only comparatively weak correlations of the Unknown model with the empirical data, indicating that participants' responses are quite different from optimal Bayesian reasoning. Instead, the exhibited egocentric tendencies and biases are matched better by the True Belief and Sampling models. The better correlations of the Sampling model compared to the True Belief model can be attributed to the fact that the True Belief model compares all alternative destinations equally, while the Sampling model sticks with the first best guess, which conforms to a closeness bias, as long as it is not invalidated. When introducing likelihood modifications that shift the focus to the closer exits, the True Belief model starts to behave similarly. The lower difference between the correlations with the True Belief models and the Sampling models in Group 2, as compared to in Group 1, also indicates that priming participants with an explicit ToM-related question reduced these biases.

Table 1: Average correlations and number of response matches (in brackets) of models with ratings of Group 1.

Model	Recording 1	Recording 2	Recording 3	Recording 4	Overall
True Belief ($\beta = 0.3$)	0.85 (4.73)	0.95 (2.43)	0.68 (3.84)	0.85 (5.24)	0.85 (4.06)

Overall, the actual ToM reasoning of humans appears to be more differentiated than assumed in the BToM literature. Mental reasoning is computationally expensive, especially when considering mental states of others. Unless explicitly triggered, humans appear not to perform a full-blown ToM reasoning but to resort to simpler heuristics instead. Artificial social systems can make use of these findings by adapting to different ToM models employed by their users and assisting when they might overlook important information.

Tracking the wandering mind: Memory, mouse movements and decision making styles

Mariana Rachel Dias da Silva (m.r.diasdasilva@tilburguniversity.edu)

Marie Postma (marie.postma@tilburguniversity.edu)

Warandelaan 2, 5037AB Tilburg, The Netherlands

Abstract

Mind wandering involves internally focused attention and is often conceptualized as the opposite of external attention that is oriented towards the task at hand. Individuals vary according to the amount they mind wander as well as with regards to the pattern of oscillations between mind wandering thoughts and externally directed, focused thought. Assuming that mind wandering is influenced by episodic contents, we explore the proposition that mind wandering frequency is related to the manner in which individuals deal with the contents of episodic memory, as reflected by a maximizing decision making style. Based on previous studies measuring cognitive processes, we assume that mouse trajectories towards a particular response on the screen are continuously updated by time-dependent and temporally-dynamic cognitive processes. As a behavioral methodology, mouse tracking provides potential cues to help predict mind wandering. In our experiment, a total of 274 students completed a decision making questionnaire, episodic and associative memory tests (during which mouse movements were recorded) and a working memory task, during which mind wandering thoughts were assessed. We found certain mouse movement characteristics to be significantly predictive of mind wandering. Also, a maximizing decision making style appeared to be related to a particular type of mind wandering, namely, task-related interference.

mind wandering; episodic memory; mouse-tracking; decision making; maximizing

Introduction

Conscious experience is fluid and dynamic. Mind wandering (MW) involves a flow of thoughts, often from one topic to another, back and forth between the outside external world and internal thoughts and feelings. Where do these thoughts come from? Why do our thoughts wander elsewhere when we are trying to focus on a task? Can we detect whenever a person is mind wandering from their behavior? Over the last two decades, researchers have been investigating these questions empirically in hopes of understanding how we navigate our stream of consciousness and the world around us. In this paper, we aim to shed additional light upon these questions by focusing on behavioral cues to MW and the link between MW and different decision making styles.

Factors influencing MW

During MW, thoughts frequently focus on events that occur in distinct periods in time, either in the past or future, which suggests self-generated mental content to be largely a product of the episodic memory system (Smallwood & Schooler, 2015). Neural accounts of MW demonstrate increased activation in the medial temporal lobe subsystem (Andrews-Hanna, Reidler, Huang, & Buckner, 2010; Ellamil, Dobson, Beeman, & Christoff, 2012), which is associated with episodic retrieval (Klinger, 2013; Mittner, Hawkins, Boekel, & Forstmann, 2016). In addition to being a part of veridical episodic events, details from past experiences can also be recombined in order to construe episodic mental simulations and other mental states that become part of the stream of thought. During MW there is also increased activation in the dorsal medial subsystem, which is associated with social processes, scenarios, meaning and comprehension. The *default variability hypothesis* (Mills, Herrera-Bennett, Faber, & Christoff, 2018) proposes that thoughts ceaselessly move from one topic to the next, with heightened variability over time. The ceaseless flow serves to distinguish different memories while the variability of content serves to provide a time buffer between memories, improving episodic memory efficiency. In addition, heightened variability enables the extraction of commonalities and differences between memories and the eventual development of categorization and category boundaries. Commonalities allow for the creation of meaning while dissimilarities prevent the overlearning of categories. Thus, the default content variability in MW increases the opportunities for interleaved episodic to semantic transformations.

Regular oscillations between engagement with the external environment and engagement in internal thoughts are normative to the human brain functioning (Mills et al., 2018). However, patterns of oscillations are subject to a wide range of individual differences, which vary according to the context (Seli et al., 2018). In particular, low demand contexts (Smallwood & Andrews-Hanna, 2013), less task interest (Unsworth & Mcmillan, 2012) and greater fatigue (Walker & Trick, 2018) are related to more MW, to name a few possible factors. In addition to these factors, we are interested in how a person's episodic memory performance is related to this pattern of oscillations. Previous research has investigated mind wandering during episodic memory tests (Riby, Smallwood, & Gunn, 2008), finding that regardless of the amount of MW reported in a retrospective questionnaire, participants performed equally well on an episodic memory test. However, Event-Related Potentials (ERP) analyses indicated that low MW groups differed from high MW groups in their retrieval strategy. Those who did not mind wander a lot used a pure

recollection strategy[1] for remembering words which they had previously seen before and words which were new. However, those who mind wandered frequently were unable to easily recollect stimuli; to compensate, they used additional monitoring and strategic processes[2] in order to aid episodic remembering.

Decision making styles as indicators of MW

Are there decision making styles that are related to mind wandering? Mind wandering content is dependent on what enters into episodic memory. At the same time, there is variability in the manner in which individuals select and sift through the contents of episodic memory. For example, some individuals tend to become more stuck on particular memories, while others have a greater tendency to quickly navigate from topic to topic. Similarly, there is variability in the manner in which individuals sift through information as they make decisions. When making decisions, individuals must select relevant information to attend to and create meaning out of in order to make a choice (Beach, 1993). Previous research has distinguished between two decision making styles, one which involves a tendency to find the best possible alternative, or *maximizing*, and one which involves a tendency to find the option that is good enough, or *satisficing*. *Maximizers* have more difficulty in making decisions and tend to be less satisfied with their choices, meanwhile *satisficers* tend to have an easier time making decisions and tend to be more satisfied with their choices (Schwartz et al., 2002). Yet, what is it about the nature of *maximizing* and *satisficing* that might be related to mind wandering? We postulate that the rigid quality of a *maximizing* decision making style may be related to greater rumination (Paivandy, Bullock, Reardon, & Kelly, 2008), and in turn manifest as type of MW which involves a tendency to worry about performance on the task at hand (Dias da Silva, Rusz, & Postma-Nilsenová, 2018), namely, task-related interference. We therefore would expect a tendency to *maximize* to be related to more interfering thoughts about performance on a task which inhibit actual performance of the task itself.

Computer mouse movements as indicators of MW

From an embodied cognition perspective, which assumes cognition is evidenced in our bodily behaviors (Barsalou, 2008), as our minds are decoupled from the sensory environment during MW, our minds seem to also disengage from controlling behavioral motor outputs. Consequently, motor performance becomes more automatic or degraded (Franklin, Smallwood, & Schooler, 2011). Initial evidence for this was found in a study by Kam et al. (2012), in which participants were instructed to track a moving ball on a screen with a joystick. Intermittently during the task, participants were asked whether or not they were MW. In trials during which participants were MW, they deviated further from the correct path than in times during which they were focused. Additionally, Arapakis, Lalmas, and Valkanas (2014) found that various mouse movement measures were able to predict engagement− which is often contrasted with MW − in an unsupervisied manner. It is thus plausible that MW in online tasks can be inferred by hand reach movements which are continuously updated by ongoing mental processes (Spivey & Dale, 2006) and become more degraded and automatic during MW (Kam et al., 2012), as attention decouples from the task at hand.

Current Study

The primary goal of the present study is to investigate if episodic memory, decision making style, mouse movements and task interest can predict MW. Previous research consistently indicates a strong negative relationship between MW and task interest. However, little has been done in terms of the relationship between performance on episodic memory tests, mouse movements and MW. To our knowledge, no research so far explored the relationship between mind wandering and decision making styles. Therefore, the guiding questions in this research are: 1) What is the relationship between episodic memory performance, motor output, and mind wandering? 2) How are task interest and decision making styles related to MW? As our aim is to explore the relationship between various measures, we do not propose directional hypotheses.

Methods

Participants and Procedure

In total, 274 participants between 17 and 41 years of age $M = 22.09$), 180 female, performed this experiment and received course credit for their participation. Three participants were excluded due to a procedural error. The study was approved by the university's Institutional Review Board. Before beginning the experiment, participants signed a consent form. Participants then answered questions about their demographics and choice making orientation. Next, they performed episodic and associative memory tests, a working memory test during which mind wandering was measured, and finally, they filled out a questionnaire about their interest in the task (see Figure 1). Note some of the data has been reported in Dias da Silva and Postma-Nilsenová (2019)[3] and, thus, the current data and that data are not from independent samples. Specifically, the MW responses from the current participants are shared with Dias da Silva and Postma-Nilsenová (2019). The purpose of that study was to examine relations between mouse movements and MW probes during an operation span task. In this study, we rather explore relationships between various additional measures from episodic memory tests and decision making styles with the overall MW frequency reported during the OSPAN task.

Materials

Decision Making Decision-making orientation (Schwartz et al., 2002) is an individual difference variable that differ-

[1] as indicated by a larger magnitude of the left-parietal ERP component.

[2] as indicated by larger central negativity effects.

[3] submitted for publication.

entiates people according to how they make decisions. At one extreme, *maximizing* involves a tendency to find the best possible alternative, while at the other extreme, satisficing involves a tendency to find the option that is good enough. Decision-making orientation was assessed by the Maximization Scale (Cronbach $\alpha = .64$), consisting of 13 items assessed on a 7-point Likert scale (1 = completely disagree to 7 = completely agree). Higher scores on the scale reflect a general tendency to *maximize*, while lower scores on the scale reflect a general tendency to *satisfice*.

Episodic Memory: 15-Word List Learning (WLLT) and Recognition Tests (WRT) THE WLLT consisted of free recall of 15 semantically unrelated words (concrete, imaginable nouns), in three trials. Words were selected from SUBTLEX-NL, a database of Dutch word frequencies based on 44 million words from film and television subtitles (Keuleers, Brysbaert, & New, 2010). All words were bisyllabic, had 6 letters, and had a medium frequency ($Range = 2.25 - 3.45$, $M = 2.56$, $Mdn = 2.46$) and a prevalence of above 98%. Each word was presented on the screen for 2 seconds, in a random sequence. Between each set of words, participants performed a 20-second Brown-Peterson distraction task[4], which required them to count backwards from a 3-digit number presented on the screen. During the recall phase, participants were asked to write down the words they could recall. The score was the total number of words reproduced over three trials (0-45). Immediately after the WLLT, participants were shown 30 words (15 distractor words were presented in addition to the ones previously seen) in a random order on a computer screen and were instructed to explicitly recognize whether or not they had seen the word by clicking on yes or no with the computer mouse on the screen. This part was WRT. The score was the sum of true positive and true negative answers (0-30).

Associative Memory: Paired-Associate Learning (PALT) and Recognition Tests (PART) The PALT consisted of cued recall of 12 semantically related word pairs, and 12 semantically unrelated word pairs, constructed in the same format of the 15-word list learning test, with three trials, and a Brown-Peterson distraction task. Words were selected from SUBTLEX-NL (Keuleers et al., 2010). Word length varied from 3 to 8. All words had a prevalence of above 98% and had a medium frequency ($Range : 1.56 - 4.56$, $M = 3.04$, $Mdn = 3.03$). Semantic associations were made according to De Deyne and Storms (2008)'s word association norms, and semantic distance was additionally checked with Snaut (Mandera, Keuleers, & Brysbaert, 2017). Each pair was presented on the screen for 2 seconds. Between each set of 24 pairs, participants performed a 20-second Brown-Peterson distraction task. During the recall phase, participants were asked to write down the target word in response to each cue word which was randomly presented on the screen. The score was the sum of pairs reproduced over three trials (0-72). The PALT was followed immediately by a recognition test (PART), which involved forced choice of the target words of the PALT in response to the presented cue words. In each trial, three distractor words were simultaneously presented on the screen together with the target and cue[5]. Each cue was always presented with 2 semantically related words, and 2 semantically unrelated words. The score was the sum of correct answers (0-24).

Mind Wandering Intermittent thought probes assessing participant's state of mind were presented during a working memory task (Operation Span task, (Conway, Cowan, Bunting, Therriault, & Minkoff, 2002; Mrazek et al., 2012)). MW was calculated as the percentage of thought probes during which participants responded that they were either having task-unrelated thought (TUT) or task-related interference (TRI) (Stawarczyk, Majerus, & D'Argembeau, 2013). Focused attention (FA) was calculated as the percentage of thought probes during which participants were focused on the task.

Task-interest As a last part of the experiment, task interest (TI) was assessed using a 5-point Likert scale with 4 questions (Cronbach $\alpha = .82$): (a) Did you enjoy performing this task? (b) Did you take interest in this task?; (c) Are you interested in performing tasks like this?; and (d) Did you feel pleasant while performing the task? The response categories vary from 1 (not at all) to 5 (very much) (Van Yperen, 2003).

Instrumentation All questionnaires were presented online via Qualtrics. The episodic and associative memory tasks were programmed on OpenSesame 3.1.6 (Mathôt, Schreij, & Theeuwes, 2012). The experiment was run on full screen mode, with a resolution of 1024 by 768 pixels on a Windows 7 operating system. The desktop computer was placed on the table so that participants had enough room to move the mouse without running out of space. Mouse settings were left at their default values (medium acceleration and medium speed). A Dell USB3 Button Scrollwheel Optical Mouse was used to record cursor coordinates during the memory tests. Mouse movements were recorded both in the Recognition parts of the Word List and Paired-Associates tests. In the WRT (Fig. 1a), once participants click on the start button (341 by 85 pixels), two words (a target and a distractor) were displayed to them on the extreme top right and left corners of the screen (192 by 128 pixels). Once participants determined which of the words they had learned in the previous portion of the task, they made a selection with the computer mouse. During the PART (Fig. 1b), once the participants clicked the start button (341 by 85 pixels), they viewed a cue at the center of

[4]The Brown-Peterson distraction task was administered in order to prevent the confounding of episodic memory with short-term memory (as a result of recency effects which occur during learning tests) (Spaan, 2016).

[5]There were always 2 semantically related and two non-semantically related words presented on the screen (i.e.: If the target was semantically related to the cue, one distractor would also be semantically related to the cue and the other two would not).

the screen, along with 1 target and 3 distractors (192 by 128 pixels) distributed along the 4 extreme corners of the screen. Once they determined which word was associated with the cue, they made a selection with the computer mouse.

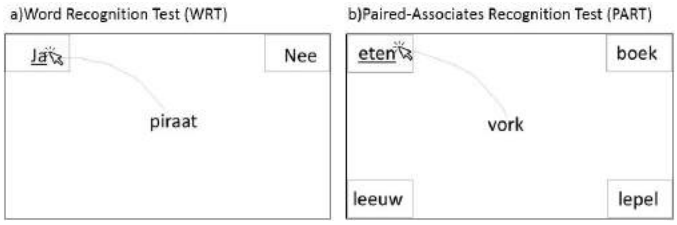

Figure 1: Illustration of the a)WRT and b)PART tests.

Data processing Participants' individual raw data files were merged and read into R version 3.4.1(R Core Team, n.d.). Mouse tracking data were imported and processed using the library mousetrap (Kieslich & Henninger, 2017). Trajectories were recorded from the moment the start button was clicked on, to the moment a target or distractor was selected in both the WRT and the PART tests. All trajectories aligned to a common starting position and were remapped onto one side. Various features such as total distance and maximum velocity[6] were calculated based on the mouse trajectories and aggregated per participant (see Supplementary Information).

Results

Data were analyzed for 271 participants. Descriptives for the WLLT, WRT, PALT, PART memory measures, decision making and task interest questionnaires can be found in Table 1. Ceiling effects were observed in the Word Learning Recognition Test (WRT) and in the Paired Associates Recognition Test (PART), as a majority participants had either perfect or near perfect scores on these tests. Therefore, they were not used further for statistical testing. As mouse movement coordinates were recorded during the tests, they were used for statistical testing instead.

Memory, computer mouse movements, and MW

Correlations In order to examine how both memory recall measures and mouse movements during the recognition tests[7] predict MW during a subsequent task, we first examined which variables were correlated with TUT, TRI, and FA. TUT frequency was found to be significantly correlated with mouse measures in the WRT, namely; maximum x-position ($r(269) = 0.17$, $p = .01$) and total distance travelled ($r(269) = 0.13$, $p = .04$). TRI frequency was positively correlated with various measures in the PART, namely; reaction time ($r(269) = 0.21$, $p < .000$), idle time ($r(269) = 0.18$, $p < .000$), time to maximum deviation towards the alternative response ($r(269) = 0.16$, $p = .01$), time to maximum deviation below the ideal path towards the selected response ($r(269) = 0.13$, $p = .03$), time to maximum deviation from the ideal path overall ($r(269) = 0.15$, $p = .01$), time to maximum acceleration ($r(269) = 0.19$, $p < .000$), time to maximum velocity ($r(269) = 0.18$, $p < .000$), and time to minimum acceleration ($r(269) = 0.19$, $p < .000$). In addition, TRI was negatively correlated with performance on non-semantic items in the paired recall test ($r(269) = -0.13$, $p = .03$). Lastly, FA was inversely correlated with the same measures that were positively correlated with TRI.

Table 1: Descriptives of Task Interest (TI), Maximizing, Word List Learning Test (WLT), Word Recognition Test (WRT), Paired Associates Learning Test (PALT), Paied Associates Recognition Test (PART), frequency of Task-unrelated Thoughts (TUT%), Task-Related Interference (TRI%), and Focused Attention (FA%).

Measure	Mean	SD	95% CI
TI (1-5)	3.31	0.84	3.21 - 3.41
Age	22.07	3.26	21.68 - 22.46
Maximizing (1-7)	4.38	0.70	4.30 - 4.46
WLLT	0.60	0.14	0.59 - 0.62
WRT	0.99	0.03	0.98 - 0.99
PALT	0.75	0.15	0.73 - 0.76
PALT s.	0.86	0.13	0.84 - 0.87
PALT n.s.	0.63	0.20	0.61 - 0.66
PART	0.97	0.09	0.96 - 0.98
PART s.	0.98	0.05	0.98 - 0.99
PART n.s	0.95	0.14	0.93 - 0.97
TUT(%)	8.51	13.46	6.91 - 10.11
TRI(%)	22.58	21.48	20.03 - 25.14
FA(%)	68.91	26.27	65.78 - 72.03

Note: s. = semantic; n.s. = nonsemantic

Dimensionality reduction Pearson's correlations between the mouse-tracking features indicate that some features may be measuring nearly identical underlying constructs (e.g.: *time to reach maximum velocity (WRT)* and *time to reach minimum acceleration (WRT)*, $r = 0.98$). Therefore, PCA (with oblimin rotation) was used to reduce the dimensionality of the data separately for the WRT and PART features, removing any multicollinearity. We used Kaiser's Criterion in order to determine the number of principal components in the WRT and in the PART separately. Five components were used that cumulatively accounted for 29% 57% 70% 77% and 85% of the variance in the mouse-tracking data in the WRT test, respectively. For the PART, 4 components were used that cumulatively accounted for 33% 61% 76% and 86% of the variance in the mouse-tracking data.

Regressions Subsequently, we performed two separate regressions, one with TRI percentage as the dependent variable and one with FA percentage as the dependent variable. As

[6] 28 mouse features for the WRT and 28 for the PART.

[7] Mouse movements were recorded during the WRT and PART.

input for the regressions, we included the PCA components which significantly correlated with MW frequency. Note that no PCA components were significantly correlated with TUT. The second component (temporal) from the PART was significantly correlated with TRI and FA frequency ($r = 0.18$ for TRI and $r = -0.17$ for FA).

Results of the regression indicate that percentage of TRI was significantly predicted by the temporal principal component ($R = .17$, adjusted-$R^2 = 0.03$, $F(1,269) = 8.56$, $p = .004$). Regression coefficients are shown in Table 2.

Table 2: Temporal Principal Component as a predictor of Task-related Interference.

	B	*SE(B)*	*t*	*p*
(Intercept)	22.68	1.29	17.57	$< .000$
PART TC2 (temporal)	3.78	1.29	2.93	.004

Adjusted $R^2 = 0.03$, $p = .004$

Similarly, percentage of FA was also significantly predicted by the temporal principal component ($R = .17$, adjusted-$R^2 = 0.03$, $F(1,269) = 8.23$, $p = .004$). Regression coefficients are shown in Table 3.

Table 3: Temporal Principal Component as a predictor of Focused Attention.

	B	*SE(B)*	*t*	*p*
(Intercept)	68.81	1.58	43.55	$< .000$
PART TC2 (temporal)	-4.54	1.58	-2.87	.004

Adjusted $R^2 = 0.03$, $p = .004$

Task Interest, Decision Making Style, and MW

In order to investigate the relationship between task interest, decision making style, and MW, we observed correlations between the variables. In line with previous findings (Unsworth & Mcmillan, 2012), task interest was positively correlated with FA ($r = 0.18$) and negatively correlated with TUT ($r = -0.24$). Interestingly, and novel to this research, we found that maximizing was positively related to TRI ($r = 0.12$) and negatively correlated to FA ($r = -0.12$). 2).

Discussion

In accordance with previous literature (Unsworth & Mcmillan, 2012), we found that MW is negatively correlated with task interest. Interestingly, we found a *maximizing* decision-making style to be be positively related to TRI and negatively related to FA. Novel to our research, we discovered that TRI percentage is related to more *maximizing*, while FA percentage is related to more *satisficing*. That is, the need to select the best possible option is reflected in the amount of TRI in a

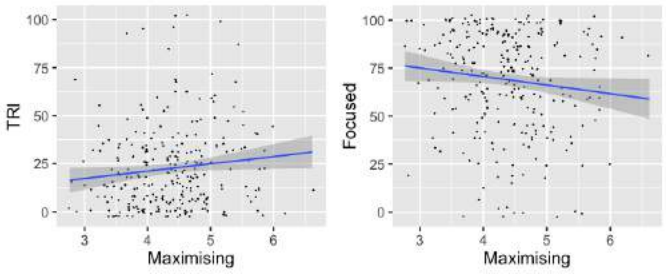

Figure 2: Relationship between TRI and Maximizing ($r = 0.12$) and FA and Maximizing ($r = -0.12$)

task, while satisfaction with selecting the good enough alternative is more related to FA during a task. This relationship has important implications, as it may be that a *maximizing* trait could potentially influence, through rumination, a tendency for having task-related interference, leading to poorer performance in tasks. Although this relationship was not directly tested in this study, future research could investigate the relationship between *maximizing*, rumination, and task-related interference further.

Moreover, we found a negative correlation between performance on non-semantic items in the Paired Recall task and TRI; however, we found no effect of any of the other memory tests on the proportion of TUT or TRI. This may be explained by two reasons. First, it may be that the tests were too easy, as reflected by the particularly high scores on the recognition tests. Second, it is likely that the scores on the episodic and associative memory tests do not accurately represent the aspects of episodic memory that are related to MW, i.e., aspects that are most likely contextually dependent and vary from individual to individual. Finally, if we observe the distribution of MW scores, over half of the participants never reported having TUT during the working memory task. This indicates that the OSPAN task was too engaging and demanding, leaving little room for TUT.

According to the *default variability hypothesis* (Mills et al., 2018), mind wandering serves the purpose of (episodic) memory consolidation. The results found by Riby et al. (2008) demonstrate that performance on episodic memory tests is unaffected by the proportion of mind wandering. However, low mind wanderers used a pure recollection strategy while high mind wanderers used additional monitoring strategies. Thus, it may be that mind wandering about the items in the episodic memory task helped consolidate memories of high mind wanderers during the task. However, something that neither Riby et al. (2008) nor our study did was assess the content of MW thoughts during the task. In order for us to verify the *default variability hypothesis* in the short term, as measured by episodic memory tests, it is also necessary that we consider the contents of mind wandering thoughts. For instance, MW about the items in the episodic memory task versus MW about something completely unrelated would likely have differential effects on memory con-

solidation.

Despite the ceiling effects we found in the recognition tests, we did find that mouse movements recorded during both episodic and associative forced choice recognition tests are related (albeit weakly) to MW in a subsequent working memory task. Therefore, it may be that a greater proportion of MW during a task is related to a general tendency to mind wander and, thereby, be detectable in specific overall motor behaviors beyond the task during which a person is mind wandering. In this study, mouse movements during episodic and associative memory tasks served to predict task-related interference (albeit weakly) and focused attention during a subsequent task. The most important feature in predicting task-related interference and focused attention was a temporal principal component, which contains information about the evolution of trajectories over time. This is consistent with the highly significant correlations that emerged between TRI and the various time-related mouse measures (*RT, idle time, time to reach maximum deviation, time to reach maximum velocity, etc.*) Such features characterize the degree of commitment towards a response during mind wandering, such that negative correlations (with FA) represent quicker and more automatic decisions, while positive correlations (with TRI) represent a delay in the commitment towards a response.

Returning to Riby et al. (2008)'s findings, high mind wanderers differed from low mind wanderers in their use of additional monitoring and strategic processing to compensate for mind wandering. Linking their findings to ours, it may be that monitoring and strategic processing are indicated differently by general mouse movement features according to the type of MW thought. Our findings indicate that some mouse movement features correlated with TUT in one task, and other mouse movements correlated with and predicted TRI and FA in another task. This may be explained by the differences in the two tasks (WRT & PART). The WRT only had 2 alternatives, while the PART had 4 alternatives. Moreover, the tests recruited different parts of memory differentially - the WRT only involved recognition of previously seen words during the WLLT, while the PART required the recruitment of associative memory[8] for remembering associations between words.

Finally, in order to better understand how MW may be related to decision making as well as performance on episodic memory tasks and overall motor behaviors, it would be relevant to assess trait differences in MW in addition to state differences. Moreover, it would be interesting to see if the relationship between trait MW and motor movements generalize to different types of computer mouse-based tasks.

Conclusion

The relationship between episodic memory and MW is a complex one, and it is likely that the episodic and associative memory tests which we used were unable to capture this relationship fully. This may be either due to the tests demands being too low and hence not able to capture individual differences in terms of accuracy, or because the tests did not capture the aspects of episodic memory that vary according to the context and to the individual. Interestingly though, we have found evidence for a relationship between specific computer mouse movements and MW, which warrant further investigation. In particular, future research should see if our findings generalize to unseen data. Lastly, we have found a novel relationship between MW and *maximizing*, in that *maximizing* was related to an increased frequency of TRI and less FA. Our aim in this study was to explore an encompassing model of mind wandering starting from its inputs, determined by what enters into episodic memory and ending with behavioral outputs, which are visible in mouse movement patterns. We believe we have taken a small step for a better understanding of how our minds wander and navigate this world.

[8] In addition, the PART requires inhibition of previously learned semantic associations learned in different contexts.

Crowdsourcing effective educational interventions

J. Hunter Priniski (priniski@ucla.edu)

Phoenix, AZ, USA

Abstract

Creating effective educational interventions that correct people's misconceptions is difficult. This has led many researchers to conclude that people do not properly attend to new information in a way that they should. However, even if a scientifically-grounded intervention fails, it is still possible that other interventions would be effective. Yet, it is not practically feasible to systematically explore and test the entire hypothesis space of possible interventions. Here, we examined whether researchers could use online arguments to develop effective educational interventions, in effect, narrowing the intervention hypothesis space. Across two experiments ($N = 1,816$), we found that arguments crowdsourced from Reddit's Change My View were as effective or more effective at changing beliefs than interventions developed by academics and published in top-tier scientific journals. These results suggest that researchers can build on successful crowdsourced arguments to develop effective educational interventions likely to correct people's misconceptions in more naturalistic settings.

Keywords: belief change; crowdsourcing; crowd work

Introduction

It can be difficult to find common ground with people we disagree with. People's beliefs about polarizing issues are often deeply entrenched and evidence that counters these beliefs generally does not lead people to change their minds. This intransigence comes at a cost: Polarization is a growing problem in the United States (Pew Research Center, 2014) and widespread misinformation and misconceptions about, for example, climate change only exacerbate polarization, posing considerable challenges to society. What's more, even in situations when very few people hold a misinformed belief——such as believing that vaccines cause autism——the consequences can still have a widespread negative effect in society; this is evident from the recent resurgence of measles borne from parents refusing to vaccinate their children, citing fears that vaccines cause autism (Center for Disease Control, 2019).

To effectively educate the public, researchers have attempted to confront belief polarization and resistance to evidence by experimentally testing whether educational interventions can induce rational belief updating (e.g., Horne, Powell, Hummel, & Holyoak, 2015; Lai et al., 2014; Nyhan & Reifler, 2015; Nyhan, Reifler, Richey, & Freed, 2014; Turetsky & Sanderson, 2018). Ideally, people would always properly update their beliefs in accordance with the evidence. However, many interventions developed by scientists are ineffective (e.g., Nyhan et al., 2014), leading researchers to conclude that people cannot change their beliefs about issues such as climate change, vaccination, or immigration.

There are several psychological explanations that might explain why educational interventions are often ineffective. First, people interpret evidence to confirm their previously-held beliefs (Klayman, 1995; Nickerson, 1998), and our strongly-held beliefs——such as political and moral beliefs——are deeply rooted in our views of ourselves (e.g., Strohminger & Nichols, 2014; Carney, Jost, Gosling, & Potter, 2008), and thus are particularly resistant to change (Kahan, Peters, Wittlin, Slovic, & Ouellette, 2012). Second, even when people assimilate evidence, they do so imperfectly, requiring much more evidence than seems epistemically warranted (e.g., Priniski & Horne, 2018). Even massive education campaigns seem to yield only minor changes in public opinion and behavior (e.g., Fiore et al., 1990). Together, these results have led many researchers to either conclude that meaningful belief change is, in a practical sense, infeasible or that something other than education and evidence is needed to overcome strongly-held beliefs.

However, when an educational intervention fails to change people's misconceptions, this does not entail that other educational interventions (even similar interventions) would fail as well. It is an empirical question whether an untested intervention would turn out to be efficacious. Indeed, researchers have successfully developed effective educational interventions. For instance, Lewandowsky, Gignac, & Vaughan (2013) found that making people aware of the scientific consensus surrounding climate change using icon arrays positively affected people's beliefs. More recently, researchers have found that educational interventions can change vaccine intentions (Horne et al., 2015), correct mental health misperceptions (Turetsky & Sanderson, 2017), and address implicit racial biases, though these changes may be transient (Lai et al., 2014). However, beyond combing the academic literature, researchers have little to go on in predicting whether a given untested intervention will succeed or fail. Moreover, educational interventions are rarely tested outside of the lab, which allows for the possibility that effective educational interventions developed in the lab will fail to generalize beyond tightly controlled settings (Priniski & Horne, 2018). To complicate matters further, the hypothesis space of

possible interventions is very large (read, infinite). Consequently, it is not feasible for any given lab or even a group of labs to systematically explore the entire hypothesis space of educational interventions to determine whether a possible intervention could change people's beliefs about a given topic. A methodological advance is needed to avoid a protracted search through the intervention hypothesis space.

We propose a new method for developing educational interventions: Using successful persuasive arguments culled from online discussions (for example, from the Reddit forum Change My View). We propose that developing interventions based on existing arguments that have proven to be effective in naturalistic environments provides a compelling starting place for the development of effective educational interventions.

Change My View

Change My View is a popular Reddit forum where users post their views on issues ranging from gun control to opinions about movies. Redditors posting in this community understand that others will attempt to change their view by providing arguments opposing their beliefs (see Table S1 in Supplemental Materials, found at https://osf.io/v54ut/). As one would expect, some arguments are more persuasive than others and thus the variance in argument quality found on the forum provides a naturalistic resource for examining the features of effective arguments.

As a naturalistic data source, Change My View has provided several insights into how belief change occurs outside of the lab. For example, Priniski and Horne (2018) found that arguments containing more statistical language and links to news or scientific articles were more likely to change other users' strongly-held beliefs—evidence can change people's minds. Other researchers have examined the logical qualities of effective arguments on the forum (e.g., use of classical modes of persuasion: ethos, logos, pathos, Hidey, Musi, Hwang, Muresan, & McKeown, 2018). Research on Change My View has extended beyond social psychology. Computer scientists have developed computational models that extract features of argumentation, such as predicting the probability an argument is effective given linguistic features (Tan, Niculae, Danescu-Niculescu-Mizil, & Lee, 2016) or machine classifying "parts" of beliefs most amenable to change (Jo et. al, 2018).

While many researchers have examined the factors that predict belief change among Change My View users, it is unknown whether effective arguments taken from this forum would be equally effective in more controlled contexts or among a population not seeking arguments opposing their beliefs. In fact, there are several reasons why belief revision may look different on Change My View than it does in the lab. These reasons pose concern for the generalizability of effective arguments found on Change My View and need to be experimentally addressed before Change My View can be recommended as a crowdsourcing platform for effective educational interventions.

For one, people who discuss certain topics——and particularly users on Reddit's Change My View——may be more willing to change their minds and consider evidence for an opposing argument. This may not be true for the public at large, limiting the generalizability of these prior findings. Second, people engaged in a debate on a particular topic may be more motivated to deliberate on the topics they're discussing. This fact may make online communities such as Change My View an ideal population to study central rather than peripheral routes to persuasion (Petty & Cacioppo, 1986). However, it may also make online communities unrepresentative of the general population who may not be so ready to entertain evidence that is contrary to their beliefs.

Altogether, controlled laboratory research is necessary to understand if the persuasive tactics deployed online can generalize to other populations and, in turn, serve as a starting place for developing educational interventions.

Present Experiments

In the present experiments, we identified successful arguments on Change My View and performed a head-to-head comparison to interventions reported in academic psychology, public policy, political science, communications, and behavioral economics articles—adopting a methodological approach most analogous to a strategy relied on in clinical trials (e.g., Leuch, et al., 2013). Namely, we compared crowdsourced arguments to academic arguments that have been shown to be somewhat effective at changing people's beliefs (or at a minimum, exert the same task demands on participants). Performing this comparison allowed us to predict whether effective educational interventions can be culled from online communities and used as effective interventions in controlled laboratory settings.

It is worth highlighting how this experimental strategy diverges from comparing the performance of an intervention to an inactive control condition. As opposed to controlling for features of naturalistic interventions to uncover what makes them effective, the paradigm we are proposing first identifies the interventions that yield desirable consequences (e.g., a reduction in misconceptions surrounding structural racism), at which point we can subsequently uncover the mechanisms that realize these positive effects. As a consequence, academic and crowdsourced interventions will differ along many unknown dimensions (including length, the task performed, the information presented, and so on). However, we do have prior evidence (either from empirical studies or from data mined from discussion forums) that signal the efficacy of each of the interventions being compared. Ultimately, researchers aim to develop interventions that can effectively educate the public, making this dimension——efficacy——the most central on which to assess an educational intervention.

With this goal in mind, in Experiment 1 we compared the efficacy of crowdsourced and academic interventions at changing beliefs across four hotly-debated topics. Experiment 2 was an extension of Experiment 1, where we further examined whether crowdsourced arguments would be as effective as academic intervention across four new topics.

Experiment 1

Preregistration The projected sample size, predictions, and analysis scripts were preregistered through Open Science Framework. Experimental scripts, analyses, scales, and Supplemental Materials are available at https://osf.io/v54ut/.

Participants We recruited 916 participants through Amazon's Mechanical Turk to be 80% powered to detect a Cohen's *d* of .1 in a within-subjects design. Of the participants recruited, 816 passed attention checks and were included in the analysis of this study (333 men, 476 women, 4 non-binary, 4 preferred not to say; the median age of participants was 35 years old).

Interventions Participants received four separate interventions that focused on either (a) reducing racist beliefs, (b) increasing support for vaccines, (c) increasing support for gun control, and (d) reducing xenophobic attitudes directed at immigrants. Participants received two crowdsourced interventions and two academic interventions (intervention type: within-subjects) with one intervention for each topic. Therefore, we tested the efficacy of eight interventions in total. Crowdsourced interventions were copied-and-pasted comments that were awarded a "delta" in a Change My View discussion—a signification that the argument changed the view of at least one user on the forum. We selected discussion comments from Change My View as crowdsourced interventions if they met the following three criteria. First, the comment was related to a topic that psychologists have traditionally studied in the lab (e.g., climate change, gun control, xenophobia, etc.). Second, the comment had been awarded a delta. Third, the content of the comments could be developed into an intervention with little-to-no editing, content change, or manipulation. Many comments on Change My View satisfy these criteria and *could* have been empirically tested, but the aim of the present studies is to consider how several representative crowdsourced examples could be developed into effective educational interventions. (Detailed information about the interventions can be found at https://osf.io/v54ut/).

Pretest and Posttest Measures We examined how participants' beliefs about four controversial topics changed as a function of exposure to one of two educational interventions (crowdsourced or academic) for a given topic. Prior to completing the main portion of the study, participants answered four questions assessing their pretest beliefs about each topic. For instance, participants rated their agreement with the assertion, "Gun control in America is ineffective at reducing overall violence and crime", which was taken from a Change My View post (in this case, a post about gun control). After responding to these four assertions, participants proceeded to the intervention and post-test portion of the experiment.

We developed four separate scales to measure people's beliefs about racism, vaccines, gun control, and xenophobia directed at immigrants. Each scale was composed of five items (with two items reverse coded). Items in a topic's posttest scale were created by rewording or expanding on a pretest assertion. For example, an item in the posttest gun control scale stated, "Societies with strict gun control have similar crime rates as societies with little to no gun control." See the Supplemental Materials for more details on pretest and posttest measures.

Procedure The experiment proceeded as follows: First, participants rated their agreement with items measuring their pretest beliefs towards all four topics. Next, participants were randomly assigned either an academic or a crowdsourced intervention for a given topic. After completing this intervention (e.g., after reading information about gun control), participants responded to that topic's posttest scale. After completing the posttest scale for a given topic, participants advanced to a new topic and the procedure was reiterated until they finished reading and responding to questions about all four topics. The ordering and exposure to a given intervention type was counterbalanced and randomized.

Results and Discussion

Analytic Approach To test our hypotheses, we performed Bayesian mixed effects modeling using the R package `brms` (Burkner, 2018). We set regularizing priors for all population-level effects in our models, which we detail below. These priors are recommended because they provide conservative effect size estimates and reduce the likelihood of overfitting (Gelman, Lee, & Guo, 2015; McElreath, 2016). Following the recommendations of Liddell & Kruschke (2018), Likert data were modeled with a cumulative probability distribution. The cumulative distribution is recommended for Likert scale data because it assumes that ordered responses represent a continuous latent construct.

We tested our hypothesis by fitting an ordinal mixed-effects model predicting posttest beliefs based on the interaction between condition (Reference = Academic condition) and topic (Reference = Guns). This model controlled for participants' responses to the pretest statement, which we treated as a monotonic effect. This model included group-level effects of Subject and Topic and allowed for heterogeneity in the slopes of the effects of Condition and Topic on participants' responses. Our model is specified below in `brms` syntax (Bürkner, 2018):

```
Response ~ Condition*Topic + mo(PreTest)
+ (1 + Topic + Condition | Subject)
```

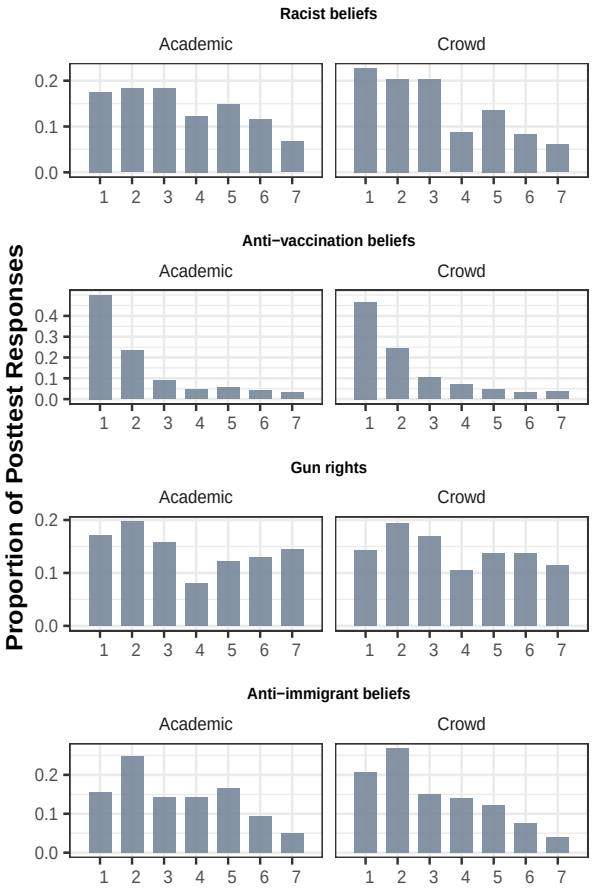

Figure 1: Posttest responses for each intervention tested in Experiment 1 (1 = Strongly disagree; 7 = Strongly agree). Relative effectiveness of a crowdsourced intervention can be seen by comparing the leftward shift of responses across interventions for a topic. Figures S5 through S8 in the Supplemental Materials show posttest responses grouped by pretest response for each intervention tested in tested in Experiment 1.

Bayesian analyses formulate model parameters as probability distributions wherein the posterior distribution for a parameter θ is computed via the prior and likelihood of θ. To model the joint probability distribution of participants' responses, we specified priors over the possible effects each parameter could have on our response variable:

$\beta_{Intercept[1]} \sim \mathcal{N}(2.19, 1)$
$\beta_{Intercept[2]} \sim \mathcal{N}(2.94, 1)$
$\beta_{Intercept[3]} \sim \mathcal{N}(3.17, 1)$
$\beta_{Intercept[4]} \sim \mathcal{N}(3.47, 1)$
$\beta_{Intercept[5]} \sim \mathcal{N}(3.89, 1)$
$\beta_{Intercept[6]} \sim \mathcal{N}(4.59, 1)$
$\beta_{Condition} \sim \mathcal{N}(0, .5)$
$\beta_{Pretest\ Beliefs} \sim \mathcal{N}(4, 2)$
$\beta_{Topics} \sim \mathcal{N}(0, 3)$
$\beta_{Topic \times Condition\ Interactions} \sim \mathcal{N}(0, .5)$
$\Omega_k \sim LKJ(1)$ where Ω_k is a correlation matrix of group-level parameter
Group-level parameters $\sim \mathcal{N}(1, 2)$

These analyses revealed that the crowdsourced interventions countering racist (b = −.58, 95% CI [−.80, −.37]) and anti-immigrant beliefs (b = −.40, 95% CI [−.60, −.18]) were credibly more effective than an academic intervention; interventions on vaccines and gun control were equally effective (see Figure 1). These results suggest that there are arguments being developed in online communities that are comparably effective to interventions behavioral scientists have developed. And considering crowdsourced arguments have the additional virtue of being shown to be effective in a naturalistic setting free from task demands, this may give additional motivation for beginning development of educational interventions on the basis of crowdsourced arguments.

However, given that the present design lacks a completely neutral control condition, it is important to be clear on what these results do not show. First, these results do not demonstrate the true magnitude of the effect of a given intervention. Second, there is a large amount of variance in intervention quality and effectiveness for any intervention type, and there is no reason to think that all crowdsourced arguments will always be as effective or more effective than academic interventions. Rather, one should interpret the results of Experiment 1 as suggesting that crowdsourced arguments can provide a starting place for developing educational interventions and doing so has the additional virtue of giving us a priori reason to think they will generalize to comparatively more naturalistic settings.

Experiment 2

Experiment 2 was a preregistered extension of Experiment 1. The registration for this project can be found at https://osf.io/v54ut/. This experiment followed an identical procedure but tested the efficacy of academic and crowdsourced interventions on four new topics: (a) reducing sexist beliefs, (b) reducing transphobic beliefs, (c) reducing denial in the negative effects of climate change, and (d) reducing favor for capital punishment.

Participants We recruited 900 participants through Amazon's Mechanical Turk to be 80% powered to detect a Cohen's d of .1 in a within-subjects design. Of the participants recruited, 745 passed attention checks and were included in the analysis of this study (325 men, 416 women, 3 non-binary, 1 preferred not to say; the median age of participants was 33 years old).

Results and Discussion

Like Experiment 1, we predicted that crowdsourced interventions would be as effective or more effective than academic interventions for the four new topics. We fit the same ordinal regression model with the same priors as

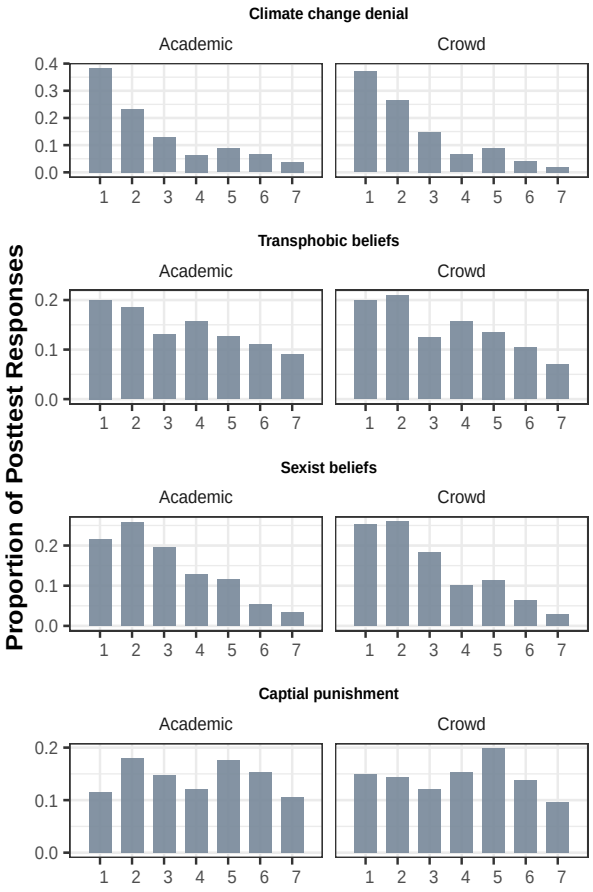

Figure 2: Posttest responses for each intervention tested in Experiment 2 (1 = Strongly disagree; 7 = Strongly agree). Relative effectiveness of a crowdsourced intervention can be seen by comparing the leftward shift of responses across interventions for a topic. Figures S9 through S12 in the Supplemental Materials show posttest responses grouped by pretest response for each intervention tested in tested in Experiment 2.

Experiment 1.

In Experiment 2, we found that crowdsourced interventions were equally effective as academic interventions across three topics; the academic intervention aimed at shifting people's beliefs about climate change was more effective than the crowdsourced intervention, b = .24, 95% CI [.00, .40].

Discussion

People's beliefs about topics like science and morality are stubbornly resistant to new information. Developing educational interventions to correct these beliefs is a difficult task that often results in fruitless outcomes. It is also often unknown whether an intervention that manages to successfully shift beliefs in the lab will be similarly effective in a more naturalistic setting. The present studies suggest that researchers can use crowdsourced arguments to better predict and develop effective educational interventions. Furthermore, crowdsourcing effective arguments can impact the study of belief revision directly by elucidating which types of information are most effective at changing strongly held beliefs: a topic of interest to many researchers studying higher-level cognitive processes. In two experiments, we tested whether arguments crowdsourced from the Reddit forum Change My View could be used to such an end. In Experiments 1 and 2, we compared arguments crowdsourced from Change My View to interventions taken from academic research in psychology, communications, political science, behavioral economics, and public policy. In Experiment 1, we found that across four topics, crowdsourced arguments were as effective or more effective at changing beliefs compared to previously published or tested educational interventions developed by academics. Experiment 2 followed the same procedure, finding that crowdsourced interventions were as effective at changing beliefs in three of four topics. In only one case did an academic intervention perform better at correcting scientific misconceptions than a crowdsourced intervention.

In light of these results, we propose that arguments mined from online communities can be used to develop educational interventions. How might this process work? Consider the results in Experiment 2: We observed that an academic intervention containing an icon array (Lewandowski, et al., 2013) was more persuasive than a similar crowdsourced intervention that did not contain data visualization. This finding is consistent with a large body of research demonstrating that data visualizations can effectively communicate complex information (e.g., Fernandes, Walls, Munson, Hullman, & Kay, 2018). In future research, we propose that researchers could begin to develop an educational intervention by first turning to crowdsourced interventions that appear effective and then extending them based on well-established theoretical considerations. For instance, we found that a crowdsourced intervention about the repercussions of structural racism was much more effective than an academic intervention aimed at shifting people's implicit racial biases (Lai et al., 2014). One possibility, then, is that we could further improve the efficacy of this crowdsourced intervention by augmenting it with compelling visualizations. In this way, researchers would be able to develop interventions that have the twin virtues of demonstrating prior success in naturalistic environments and having strong empirical support from controlled laboratory studies.

However, the present experiments have some clear limitations. By design, both experiments lacked a true control condition, leaving an important question unanswered: Exactly how effective are these interventions at changing beliefs? The present studies compared the *relative* effectiveness of crowdsourced interventions to academic interventions, and didn't demonstrate how effective they are

with respect to a neutral control condition. Future work should compare interventions to a true control condition in order to make explicit how effective a given intervention is at changing beliefs.

Change My View is also not the only place researchers could crowdsource effective arguments; a web application could also assist in mining, for example, Facebook and Twitter for effective arguments. The tool we are proposing could take queries (e.g., topics for an intervention) and return effective arguments filtered by the searched terms. Such a system could allow researchers to not only crowdsource educational interventions more effectively, but also gain an understanding of how arguments are communicated and received among members of online communities.

A cursory look on Reddit, Twitter, and Facebook demonstrates that people naturally engage in (sometimes) persuasive argumentation. Here, we proposed that psychologists can mine this information to efficiently create educational interventions that are more likely to persuade people than the methods researchers currently use—crowdsourced interventions have the advantage of being vetted, so to speak, in naturalistic contexts. Two experiments provide support for this proposal. We observed that crowdsourced arguments were more effective or often as effective as academic interventions aimed at correcting misconceptions about several societally important topics.

Outcomes Speak Louder than Actions? Testing a Challenge to the Two-Process Model of Moral Judgment

Abstract

Curiously, people assign less punishment to a person who attempts and fails to harm somebody if their intended victim happens to suffer the harm for coincidental reasons. This "blame blocking" effect provides an important evidence in support of the two-process model of moral judgment (Cushman, 2008). Yet, recent proposals suggest that it might be due to an unintended interpretation of the dependent measure in cases of coincidental harm (Prochownik, 2017; also Malle, Guglielmo, & Monroe, 2014). If so, this would deprive the two-process model of an important source of empirical support. We report and discuss results that speak against this alternative account.

Keywords: blame blocking; two-process model; punishment; outcomes; actions; pragmatics

Introduction

Imagine that two runners compete in a championship race. One of the runners is a frequent winner, and so another racer decides to kill him and exclude him from the competition. He mistakenly believes that his rival is fatally allergic to poppy seeds, and so he sprinkles some on his rival's food at the banquet. The champion is not allergic to poppy seeds at all, however, but instead to hazelnuts. What's more, completely by coincidence, the chef happens to have served a hazelnut salad, and the champion dies as a result of consuming it.

The "blame blocking" phenomenon, first reported in the set of studies by Cushman (2008), is that people will tend to reduce blame and punishment assigned to the attempted harmdoer because of the coincidental harm caused by the salad. In other words, if the salad has no hazelnuts and the intended victim survives, the attempted harmdoer is blamed and punished more. This effect is notably large. Specifically, in the study based on the above story Cushman (2008) found that about half as many subjects assigned *no punishment* to the runner where no harm occurred compared with the case in which the rival coincidentally died (p. 374). That is, the coincidental death of the rival made participants twice as likely to let the runner off the hook.

One explanation of this puzzling effect posits two processes of moral judgment that render moral judgments separately on the basis of (1) causal responsibility for harm, or (2) a culpable mental state, such as intent to harm (Cushman, 2008). According to the model, then, when there was no causal input in the story (i.e., no coincidental harm occurs), the "mental state process" dominates and punishment judgments are therefore based on the evaluation of the agent's mental states alone. Because the relevant mental state was severe intentional harm, this tends to result in non-zero levels of punishment. On the other hand, when causal inputs are present (i.e., a coincidental harm occurs) but the runner himself is non-causal, the process of moral judgment predicated on causal responsibility competitively dominates (or "blocks") the evaluation of his mental states. The causal responsibility process assigns no punishment to the runner (who, of course, has no causal responsibility for the harm). Stated more generally, a two-process model of moral judgment can accommodate the pattern of results because it posits competition between a causal process seeking full exculpation (no punishment) and a mental state process seeking full inculpation (punishment) in cases of failed attempts to harm with independently caused harm, while the relative influence of the causal process is minimized in cases of pure failed attempts.

The two-process model is compatible with theories of moral judgments that identify intentional and causal evaluations as primary contributors to blame and punishment (e.g., Alicke, 2000; Alicke & Rose, 2012; Carlsmith & Darley, 2008; Darley & Shultz, 1990; Fincham & Jaspers, 1979; Shultz, Schleifer, & Altman, 1981; Shultz, Wright, & Schleifer, 1986; Weiner, 1995; Guglielmo, Monroe, & Malle, 2009; Malle, Guglielmo, & Monroe, 2014; Piaget, 1932/1965). It departs from most of these theories, however, in the assumption that causal and mental state evaluations proceed separately and compete during moral judgments of blame and punishment, rather than being combined and integrated in a single process.

In addition to the blame blocking phenomenon, some independent evidence provides support for the two-process model. Young, Cushman, Hauser, and Saxe (2007) found neurological signature of conflict for adult judgments of accidental harms in which intentional and causal evaluations point in different directions. Several studies show that punishment judgments are especially strongly influenced by the causal process in ordinary cases of harm (Martin & Cushman, 2015, 2016), and developmental evidence suggests that this pattern is a vestige of an early-emerging "causal" process of moral judgment augmented by a later-emerging

"mental state" process (Cushman, Sheketoff, Wharton, & Carey, 2013).

Here, we consider another explanation of the blame blocking effect—one that depends on assumptions about how people interpret the pragmatics of the dependent measure used to trigger this effect. Specifically, the question "How much prison time does [agent] deserve?" used by Cushman (2008) might be interpreted by participants differently across conditions: as implicitly referring to punishment *for behavior* (how much should the runner be punished for trying to kill his rival with poppy seeds) in the "no harm" condition, but as implicitly referring to punishment *for a harmful outcome* (how much should the runner be punished for the victim's death by the hazelnuts) in the coincidental harm condition (see also Prochownik, 2017). If the agent in two scenarios were evaluated against these very different standards in each case it would explain the blame blocking effect without appeal to two processes of moral judgment. We call this alternative "pragmatics account" because it relies on an assumption that people take a broad context into account when deciding what for to punish others (cf. Prochownik, 2017).[1]

In this paper we examined this alternative hypothesis by conducting two experiments. In Experiment 1, we manipulated the question about punishment to ensure that it is interpreted with a wide scope, encompassing not only what the agent caused (or did not), but also what he intended. Next, in Experiment 2, we used the original dependent measure that was previously used to elicit the blame blocking effect, and then asked participants a series of questions designed to clarify how they understood it.

Collectively, the results of these experiments suggest that unintended interpretations of the dependent measure are not sufficient to explain the full blame blocking effect.

Experiment 1

The goal of Experiment 1 was to test whether a more precise phrasing of the dependent measure would eliminate the previously observed blame blocking effect. In the baseline condition ("unspecified") we left the question identical to previous experiments by Cushman (2008): "In your opinion, how much prison time does *X* deserve?" In the novel condition ("specified") we modified the question so that it more clearly pointed at the agent's total set of behaviors as the target of punishment, thus diminishing the chance that it would be interpreted in terms of outcome alone (following in this respect Prochownik, 2017): "Suppose that X were apprehended by the police and put on trial. Given the complete set of behaviors and facts, in your opinion how much prison time does he deserve?"

The language that we used in the "specified" condition was borrowed from earlier research. In particular, Prochownik (2017) found that people with legal education tended to manifest the blame blocking effect only when the punishment question was unspecified, but the effect disappeared when it was specified, suggesting a key role for pragmatics in this group of respondents. However, Prochownik & Unterhuber (2018) did not replicate this finding in their comparative study including both lay people and legal experts. In Experiment 1 we use the same version of the "specified punishment question" as these researchers, but we focus exclusively on lay people in a well-powered study, and also examine it more systematically (across sixteen scenario contexts instead of just two or three as in these previous studies).

Methods

We tested 20 participants in each of 64 cells of a 2 (harm vs. no harm) x 2 (specified vs. unspecified) x 16 (scenario context) design, for a total sample of 1280. Participants were recruited on MTurk in the US. After consenting to participate in a short study for small compensation ($0.30), they filled an online Qualtrics survey comprised of one scenario, a punishment probe, and demographic questions (age, gender, nationality, exposure to moral philosophy, religiosity, etc.). Participants marked their answers on a scale with 11 anchored options: "None", "1 week", "1 month", "3 months", "6 months", "1 year", "2 years", "4 years", "8 years", "16 years", "32 years".[2]

The total set of 16 scenarios varied along several dimensions. Most notably, half of them involved physical harm (burning, cutting, stabbing, etc.) while the remaining half involved property harm (arson, defacement, etc.). The full text of all study scenarios is available online as Supplementary Materials:
https://osf.io/9w4ke/.

Results

As summarized in Figure 1, we observed the basic blame blocking effect in both the "specified" and "unspecified" conditions. Indeed, if anything, the blame blocking effect was slightly larger in the new "specified" condition. In order to analyze the data more fully we conducted a linear mixed effect analysis. First, we constructed a null model without fixed effects for harm or punishment question type, but including a random effect for scenario. We then found that this model was significantly improved by modelling the harm factor, $\chi^2(3) = 61.49$, $p < .001$. Next, we found that this "harm only" model was not significantly improved by modelling the punishment question type factor $\chi^2(4) = 1.17$, $p = .8826$, or

[1] The importance of pragmatic considerations for participants´ (re)interpretations of research stimuli has been also raised by some recent studies (e.g., Guglielmo & Malle, 2010; Samland & Waldmann, 2016; Wiegmann, Samland, & Waldmann, 2016; Hagan & Rozyman, 2017).

[2] The "unspecified" punishment question was taken from Cushman (2008): Experiment 4. However, the scale differed from the 9-points scale used by Cushman in his study as for the majority of scenario contexts we did not use attempted murders but attempts of less severe crimes (including bodily injuries and damages to property) for which we needed a greater range of less severe sentences. As a result, we could also examine if the previous findings replicate when a different scale of punishment ratings is used.

by modelling both this factor and its interaction with harm χ^2 (9) = 4.1, p = .9047. In summary, then, the best-fitting model included only harm as a factor. In other words, we observe a significant effect for the harm vs. no harm factor, but no significant effect for the specified vs. unspecified factor, or for its interaction with harm.

We next assessed whether there are significant differences between scenarios in the magnitude of the blame blocking effect that they induce by testing whether random intercepts (i.e., an interaction between scenario context and the effect of the "harm" variable) contribute significantly to the model. They do, χ^2 (2) = 20.9, p < .001, indicating meaningful variability between vignettes. We next tested whether the model was improved by adding a fixed effect for "physical" versus "property" harms, but it was not χ^2 (9) = 7.94, p = .54. The precise nature of the relevant differences between scenarios therefore remains an important topic for further research.

Discussion

Experiment 1 shows that the blame blocking effect is not diminished by an alternative phrasing of the dependent measure designed to clarify that punishment could apply to any aspect of an attempted harmdoer's conduct—including, most importantly, the attempted harm.

These results speak against the alternative interpretation of that effect in terms of the pragmatic constraint on the way ordinary people assign punishment, and instead support the two-process model of moral judgment.

However, one limitation to this experiment is that by asking participants to consider the entire event when making their punishment judgments, we cannot completely exclude the possibility that some participants interpreted the question as referring to the outcome alone. If so, it is still possible that people who interpreted the question as referring to the outcome were driving the blame blocking effect. To address this problem we conducted an additional experiment which faithfully replicated the original "runners study" by Cushman (2008) but differed in one important element: participants in the "Harm" condition were presented with an additional question about how they understood the question about punishment (i.e., what they thought the punishment was meant to be for).

Experiment 2

In this experiment we replicated Cushman`s Experiment 4 (2008) but we presented participants in the "Harm" condition with an additional question about how they understood the punishment question after they have responded to it. Specifically, we asked explicitly whether they understood the question "how much punishment does *X* deserve?" to refer to "punishment *for the actual harm*" (e.g., death of a runner) in the coincidental harm condition. Such an interpretation, which is consistent with the pragmatics account, would explain away the purported "blame blocking effect."

We offered participants two alternatives to this interpretation of the question: First, that "punishment" referred only to the attempted harm (e.g., the sprinkling of poppy seeds on a salad with intent to cause an allergic reaction) and, second, that it referred to *both* the attempted

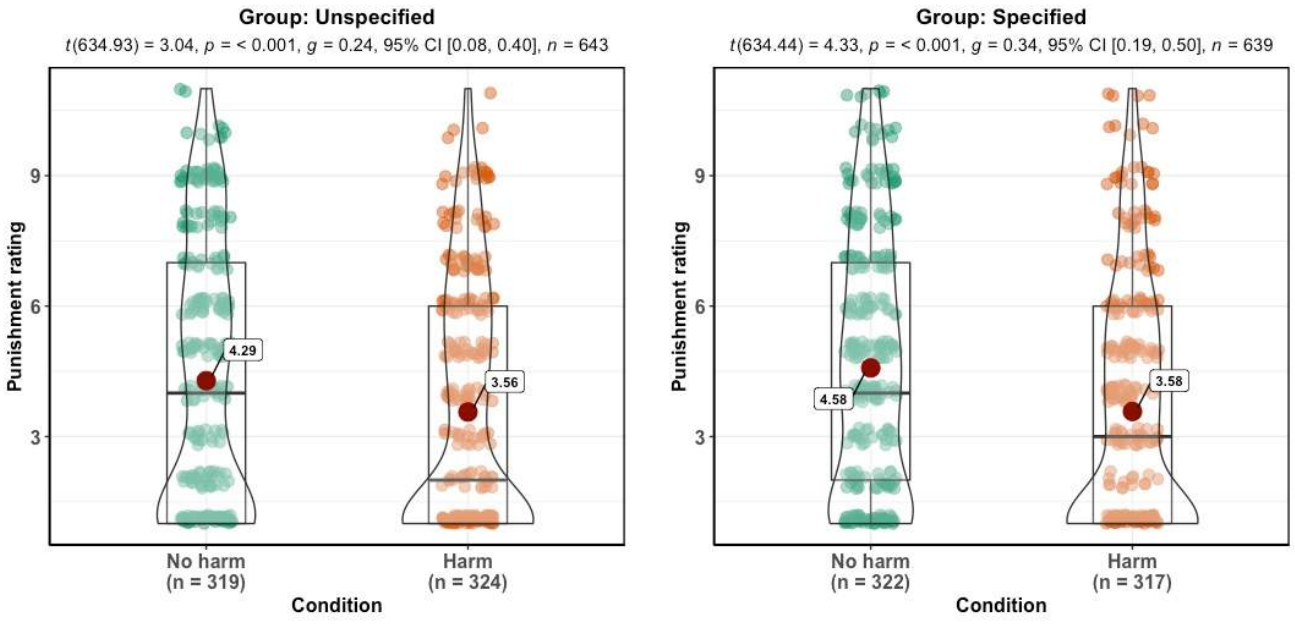

Figure 1: The blame blocking effect was replicated both in the "unspecified" condition, which directly matches the original demonstration (Cushman, 2008) and in the "specified" condition, which was designed to eliminate the alternative explanation of the effect in terms of pragmatics.

and actual harm. The blame blocking model is agnostic with respect to these alternatives—crucially, both of them entail sensitivity to the attempted harm, and thus the null prediction would be equal punishment across the no harm and coincidental harm conditions, both of which involve this attempted harm. The two-process model attempts to explain why participants who interpret the punishment question to *include* this key shared element—the attempted harm—would nevertheless be more likely to fully exonerate the attempted harmdoer in the coincidental harm case.

Study hypotheses, methods of analyses, sample size calculation and exclusion criteria were preregistered (the OSF preregistration document can be viewed at https://osf.io/pf574).

Methods

1007 complete responses were collected via TurkPrime in the US using Qualtrics anonymous link (we intended to recruit 500 participants per each of the study conditions). Participants were payed $0.50 for taking part in the survey.

Participants were asked to imagine that they are in a jury in a case of a defendant named Brown. In following, they were presented with a story of two runners named Brown and Smith competing in a championship race. One group of participants saw the variant of the story where Brown tries to kill Smith by sprinkling the poppy seeds on his food, but no harm results ("No Harm" condition). Another group of participants was presented with the story in which Smith dies because of the hazelnuts in the salad that he is served, completely independently of Brown´s actions ("Harm" condition). After reading the story all participants were asked: "How much prison time does Brown deserve?", and chose between the nine following options: "None", "6 months", "1 year", "2 years", "4 years", "8 years", "16 years", "32 years", "Life" (Cushman, 2008).

On the next page of the survey, participants in the "Harm" condition were presented with the following "Harm Understanding Question":

"On the last screen you were asked to decide how much prison time Brown deserved. Which of the following did you think was meant by that:

1. How much prison time for sprinkling poppy seeds on Smith's food?
2. How much prison time for the death of Smith?
3. How much prison time for both sprinkling poppy seeds on Smith´s food and the death of Smith?"[3]

Participants who chose the third option ("for both") were additionally asked two questions about punishment for the action alone and for the outcome alone to enable the researchers better understand their previous answers: "How much prison time does Brown deserve only for the death of Smith?" and "How much prison time does Brown deserve only for sprinkling poppy seeds on Smith´s food?". Answers to both questions were marked on the same 9-points scale as above.

Finally, all participants were asked two comprehension questions about the story they read: "Why did Brown sprinkle poppy seeds on Smith´s food?" (multi-choice question) and "Did Smith die as a result of Brown sprinkling poppy seeds on his salad?" (two-choice question).[4]

Participants were excluded from the analysis if they answered incorrectly to any of the two comprehension questions (i.e., if to the first question they provided any answer other than "Because he wanted to kill Smith" and/or if they answered "Yes" to the second question). This resulted in 840 responses included in the analysis (N_{Harm} = 420, N_{NoHarm} = 420).

Results

Percentages of different responses to the "Harm Understanding Question" (n = 420, 100%) were as follows**:** 56.4% (n = 237) respondents understood the punishment question as being for sprinkling poppy seeds on Smith´s food, 19.3% (n = 81) as being for the death of Smith, and 24.3% (n = 102) as being for both sprinkling poppy seeds on Smith´s food and the death of Smith.

Consistent with our preregistered plan, and following the key analysis by Cushman (2008), we recoded the responses to the main punishment question to a binary variable with the following values: "No punishment" (all "None" responses) and "Any punishment" (all the responses assigning some punishment from "6 months" to "Life"). Subsequently, to test the main hypothesis we performed two chi-square tests comparing the frequencies of "No punishment" vs. "Any punishment" responses across two study conditions "Harm" and "No Harm": (1) a chi-square test with the overall sample (analysis repeating Cushman, 2008, Experiment 4), and (2) a chi-square test excluding people in the "Harm" condition who in the "Harm Understanding Question" replied that they understood the punishment question as referring to the outcome alone (i.e., the death of Smith).

Overall, 35% people assigned "No punishment" in the "Harm" condition, while in the "No Harm" condition barely half as many (18%) of people did so.[5] The difference was statistically significant, χ^2 (1, N = 840) 31.740, p < .001. Critically, this result held even after excluding participants who indicated that they thought the punishment question referred to punishment for the outcome only: among the remaining participants, 28% assigned "No punishment" in the "Harm" condition comparing to 18% in the "No Harm" condition. The difference was statistically significant, χ^2 (1, n = 759) 11.763, p = .001 (Figure 2).

[3] This and two following questions were omitted in the "No Harm" condition as no death of Smith resulted in this story.

[4] In the first multi-choice comprehension question participants could choose from the following responses: "Because he thought the poppy seeds would make Smith sick for a couple of days", "Because he thought Smith liked poppy seeds"; "Because he wanted to kill Smith", "Because he wanted Smith to go to the bathroom". In the second question they could choose between two options: "Yes" or "No".

[5] Note that in Cushman (2008) the numbers were very similar, with 34.5% participants in the "Harm" and 19.5% in the "No Harm" case deciding not to punish Brown at all (p. 374).

In addition to the main analyses reported above, we also assessed whether the result is driven by remaining participants who understood the punishment question to refer to the attempted harm only, or by those who understood it to refer to both the attempted harm and the outcome. We found that the effect was maintained among those who understood the question to refer to both the attempted harm and the outcome: 43% people decided not to punish in this group comparing to 18% in the no harm group, χ^2 (1, n = 522) 29.801, p < .001. It was not significant, however, among those who understood the question to refer to the attempted harm only; among this group, 22% people assigned "No punishment" in the "Harm" condition, comparing to 18% in the "No Harm" condition, χ^2 (1, n = 657) 1.620, p = .203.[6]

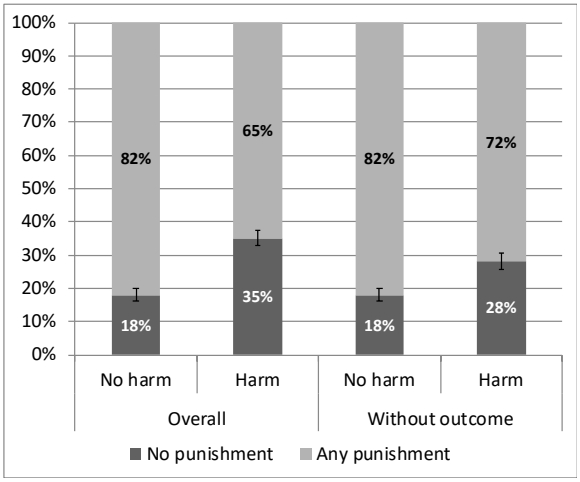

Figure 2: Percentage of punishment responses in different study conditions: overall sample and sample without people who referred to the outcome alone (error bars indicate standard error).

Discussion

Experiment 2 demonstrated that the blame blocking effect persists even after excluding participants who interpreted the punishment question as referring to the outcome alone. This suggests that the "pragmatics account" is insufficient to fully explain the effect.

Notably, however, the effect is driven by participants who say that they interpreted the punishment question to refer to "both" the attempted harm (sprinkling poppy seeds) and the coincidental harm (death by hazelnuts). It is weak, and perhaps entirely absent, among participants who say they interpreted the punishment question instead to refer exclusively to the attempted harm.

On the one hand, this data is consistent with a natural interpretation of the two-process model, according to which some attention to the harm (in the coincidental harm case) is necessary to produce the competitive interaction between the causal process and the mental state process. After all, according to the two-process model, it is precisely the attention paid to (the absence of) causal responsibility for the coincidental harm that competitively blocks assessment of the culpable mental state of the attempted harmdoer in the coincidental harm case.

On the other hand, this data is also consistent with an alternative explanation that we have not yet considered. A variant of this alternative is proposed by Malle, Guglielmo, and Monroe (2014)[7], who argue that blame in the coincidental harm case is the *average* of a high level of blame for the attempted harm and a low level of blame for the coincidental harm, whereas the blame in the no harm case is simply the high level for the attempted harm. In other words, when people interpret the punishment question as "both" about the attempted harm and the coincidental harm, they may therefore assign amount intermediate between these two values.[8]

We are in a good position to evaluate this alternative by analyzing an additional element of our data. Recall that, among people who said they interpreted punishment to refer to "both" the harm and the attempt, we then asked them to assign a specific amount of punishment to just the harm (presumably zero, as the harm was coincidental), and a specific amount of punishment to just the attempt. Thus, we can ask whether the *total* amount of punishment assigned was, on average, lower than the amount of punishment assigned to the *attempt alone*. This would be necessarily true on Malle and colleagues' hypothesis, since they assume that the total amount of punishment will be intermediate between the amount of punishment assigned to each of the two elements individually. Contrary to this prediction, however,

[6] We focused on the binarized results because these were the key analyses to report the blame blocking effect in the original study (Cushman, 2008). However, for the sake of transparency we also report the analyses with the full range of responses. Following the original study we ran Mann Whitney Ranked Sums tests for three groups of participants: (1) in the overall sample participants assigned more punishment in the "No Harm" case than in the "Harm" case (Mdn_H = 3, Mdn_{NH} = 4). The difference was statistically significant, Z(840) = 3.372, p = .001; (2) in the analysis without people who referred to the outcome alone, the difference was marginally statistically significant (Mdn_H = 4, Mdn_{NH} = 4), Z(759) = 1.897, p = .058, (3) in the analysis without people who referred to the outcome alone and both outcome and action, the difference was not statistically significant (Mdn_H = 4, Mdn_{NH} = 4), Z(657) = 0.565, p = .572. Note that for these supplementary analyses Cushman (2008) reported marginally significant results with p = .11 (cf. p. 374).

[7] Malle et al. (2014) apply this reasoning to judgments of blame, but they point out that there exists a similar pattern for judgments of criminal liability (p. 169). Since in the paper we focus on judgments of punishment, we consider their proposal in relation to this class of moral judgments.

[8] This proposal is similar to the account examined above as it assumes that people in different conditions may be judging the perpetrator for two different events. However, while the former would perceive the blame blocking effect as a result of people interpreting the dependent measure in terms of outcome alone, Malle and colleagues` account would explain it in terms of people judging the perpetrator for the conjunction of attempt and outcome.

the mean punishment for the "composite" event (M = 3.57, SD = 3) was not lower than the mean punishment for the attempt alone (M = 3.29, SD = 2.73).[9] Similarly, 43% (n = 44) of these participants assigned "no punishment" to the composite event, while 40% (n = 41) assigned no punishment to the attempt alone (consistent with the principle "no harm, no foul"). This suggests that people did not, for instance, feel that the attempt was punishable and yet assign no punishment for the *composite* event because one cannot be punished at all for something they did do *and something they did not*.

Collectively, these data further speak against pragmatic interpretations of the blame blocking effect. Even among people who say that they judged the coincidental harm case in part by assigning punishment to the attempted harm—and even when asked to make a punishment judgment strictly about that attempted harm—the blame blocking effect persists.

General Discussion

Recent proposals have advanced a potential alternative explanation of the blame blocking effect that does not invoke two independent processes of moral evaluation. According to the "pragmatics alternative" people could have interpreted the pragmatics of punishment question differently across versions of the story with and without harm that were used to trigger this effect in studies by Cushman (2008). In order to address this alternative we conducted two experiments. In Experiment 1 we used two different versions of the punishment question in order to test if the blame blocking would remain after we specify the question as more clearly referring to the total set of the agent´s behaviors as the target of punishment (developing previous research by Prochownik, 2017 and Prochownik & Unterhuber, 2018). The results indicated that the blame blocking effect occurs regardless of the phrasing of the dependent measure. However, a potential limitation of this study was that it did not completely exclude the possibility that some participants could have still interpreted the punishment question (even when specified) as referring to the outcome alone. To address this problem, we conducted another experiment. In Experiment 2 we replicated one of the original studies by Cushman (2008) with one modification: after assigning a specific amount of punishment to the defendant, participants in the "Harm" condition indicated what they thought the punishment was meant to be for (for the attempt, for the outcome or for both the attempt and the outcome). The blame blocking effect was present in the overall sample and also after excluding participants who indicated they thought the punishment was for the outcome alone. Taken together, these two experiments suggest that the blame blocking effect cannot be accounted for in terms of people´s presumed tendency to interpret the punishment question in terms of outcomes rather than actions.

In addition, Experiment 2 speaks against a slightly different proposal by Malle, Guglielmo, and Monroe (2014). According to these researchers, people´s judgements are for the agent´s attempt alone in the "No Harm" case, while they result from the average of the punishment for the attempt and the outcome in the "Harm" case. Yet, in contrast to this prediction, our results suggest that people judge the "composite" event of the attempt and outcome almost the same as they judge the attempt alone. Therefore, the blame blocking effect is not likely to occur due to averaging.

Experiment 1 also recommends some further developments of the two-process model itself. In its original formulation, the model remained open regarding what type of consequences trigger the causal process of moral evaluation, and can eventually lead to the blame blocking effect. Scenarios used by Cushman (2008) featured harms to humans and presented coincidental harms that were roughly the same as the harms intended and attempted by the perpetrators (e.g., the same victim dies, and by similar means to those originally intended). The presence of the blame blocking effect across different scenario contexts in our first experiment suggests that this effect is robust across different types of harms including both severe bodily injuries and gross harms to property, as well as coincidental harms that are somewhat different than originally intended. This suggests a modification to the two-process model such that the blame blocking effect can be triggered by a wide variety of harmful events. However, more research in this direction would help to delineate the scope of the blame blocking phenomenon and the specific conditions under which it occurs.

Finally, although, our experiments suggest that the blame blocking effect cannot be accounted for simply in terms of people interpreting the dependent measure as referring to the outcomes and not the actions (thus outcomes do not speak louder than actions!), future research must test additional possible alternative explanations of blame blocking. Two stand out. First, it might be that people diminish the punishment in the "Harm" case comparing to the "No Harm" case because they think the harmful outcome would have occurred regardless of the agent's attempt to harm (e.g., because Smith would have been killed by the chef anyway people may perceive Brown´s attempted homicide as redundant and release him from responsibility). Second, the "Harm" case is more complex and contains more information than the "No Harm" case that may distract participants (e.g., that Smith ends up being killed by the chef may be an extra element drawing people´s attention away from Brown´s attempted homicide). Finally, in addition to testing these alternatives, the two-process model would benefit from more thorough research on how exactly the two processes of moral analyses operate and interact in everyday moral decision making.

[9] Because the mean might not be well suited to the ordinal scale like the one we used, we also calculated medians and modes for the two punishment questions. The results did not differ, as the medians (2="6 months") and modes (1="No punishment") were the same for both the main punishment rating and the punishment for the attempt alone (n = 102).

Acknowledgments

This work was supported by the research project No. 2014/13/N/HS5/01137 funded by the National Science Centre, Poland.

We would like to thank Alex Wiegmann and four anonymous reviewers for very helpful comments on the previous version of the manuscript.

Abstract

Over the last 20 years, causal-model theory has produced much knowledge about causal-based categorization. However, persistent violations to the normative causal-model theory are prevalent. In particular, violations to the Markov condition have been repeatedly found. These violations have received different explanations. Here, we develop a model that starts from generally accepted cognitive phenomena (e.g., processing limitations, the relevance of inference in cognitive processing) and assumes that people are not fully causal nor fully associative when performing causal-based categorization, offering a new explanation for Markov violations.

Keywords: causal-based categorization; causal-model theory; causal inference; Markov condition

Introduction

Causal-model theory has taught us much about causal cognition (see Rehder, 2017; Sloman & Lagnado, 2015). However, problematic violations of the theory's predictions persist. The most important violation is that of the Markov condition. This condition states that when the state of a variable's immediate causes is known, then that variable is rendered conditionally independent of all its non-descendants (Pearl, 2000). Illustrative examples of violations are found in Rehder and Burnett (2005), and in Puebla and Chaigneau (2014). There, participants needing to infer the state of an unknown variable used information about other properties, even if those properties were conditionally independent from the unknown variable.

Some authors explain these violations by arguing that they are only apparent, because subjects do not necessarily use the same causal model specified by experimenters (Park & Sloman, 2013). Other authors argue that people may resort to associationist thinking and interpret directed causal links as bidirectional associations (Rehder, 2014). In contrast, here we hypothesize that violations occur because people may combine a partial understanding of causality with underlying similarity-based processing. In what follows, we present a process model of causal categorization, use it to make specific predictions about properties' conceptual weights, and fit it to empirical data.

Informed probabilities influence property-weights

Prior research consistently reports that when people need to infer a central property for categorization (i.e., because they lack information about the state of that property), properties that are causally related to the absent property increase their relevance for categorization proportionately to their informativeness about the missing property (Chaigneau, Barsalou, & Sloman, 2004; Puebla & Chaigneau, 2014; Rehder & Kim, 2009). In the current work we extend these findings to conditions in which the central property's state is explicitly known.

We hypothesize that even if a central property's state is made explicit, there may still remain some uncertainty regarding the property's true state. Thus, other causally related properties may acquire their weight depending on their contribution to decreasing that uncertainty. This idea is discussed in Rehder and Burnett (2005), and preliminary evidence for it can be found in Chaigneau et al. (2004, Exp. 7). In causal-model research, information about a property's inferential contribution is generally provided in the form of probabilities of effects given causes (i.e., p(effect|cause)). Consequently, we assume that when cues indicate that a given property is central, other causally linked conceptual properties acquire their weight as a function of how informative they are of the central property. In particular, in our Exp. 1 we used a causal chain model (A→B→C; with an additional D property which was not causally linked to other variables), and told participants that property C was central (i.e., it gave the category its name), with the expectation that its directly linked properties (i.e., B) would acquire their weight proportional to their p(effect|cause), and that its indirectly linked properties (i.e., A) would be weighted proportional to their probabilistic contribution to the central property's direct causes (i.e., B). Note here that we are assuming that people are intransitive when using causal models to categorize (Johnson & Ahn, 2015).

Making the last property in a causal chain the central property is representative of many categories that are defined by their functions. For artifacts (Carrara & Mingardo, 2013; Chaigneau et al., 2004) and for functionally conceptualized natural kinds (e.g., Barsalou, Sloman, & Chaigneau, 2005; Lombrozo & Rehder, 2012), the goals that they achieve in their normal settings are central for their classification (e.g., an artificial heart is believed to belong to the heart category depending on it being able to pump blood to a greater extent than on it using any particular physical mechanism to achieve that goal).

Cognitive limitations

In typical causal classification experiments participants need to integrate several pieces of information, e.g., information

about the direct causal links and their associated probabilities (p(effect|cause)), the indirect causal links (two-way relations that are mediated by other properties), and also the particulars of the materials provided. Researchers generally assume that people are able to integrate all this information. In fact, as discussed in (Rehder, 2003a), the causal-model theory assumes that people classify entities as category members to the extent that the entity's distribution of properties would be expected from the category's ideal causal model.

In contrast, in our model we hypothesize that people simplify their task by analyzing information in a piecemeal fashion (thus, we call it the Piecemeal Strategy Model or PSM). In particular, we assume that they only evaluate pairs of directly connected properties, and that unconnected properties are considered in isolation (e.g., in the causal chain model A→B→C, with D as an isolated property, subjects would separately evaluate A→B, B→C and D). Regarding the type of computation subjects perform, we assume that they consider each directly connected pair (and each isolated property) in the ideal model presented to them, as a separate prototype with which to compare the particular instances they need to judge. To implement these ideas, we used Nosofsky (1992) Multiplicative Prototype model (MPM). This implies computing a distance, as given by,

$$\delta_{XY} = \sum_{i=X}^{Y} \left(\frac{p_i}{p_X + p_Y} \right) |x_i - M_i| \quad (1)$$

where X and Y are two directly connected properties in the causal model, p_i is the inferential contribution of a property, x_i corresponds to the state of the ith property in the currently considered instance, and M_i corresponds to the ideal state of the ith property in the causal model (i.e., the prototype). Note that the denominator inside the parenthesis allows Eq. 1 to comply with the MPM requirement that the weights (p_i) in the distance computation all add to one. For isolated properties (D in our scenarios), the corresponding distance is defined to be,

$$\delta_D = p_D |x_D - M_D| \quad (2)$$

where p_D is a free parameter estimated from the data, reflecting the inferential weight of the isolated property ($0 \leq p_D \leq 1$), x_D is the state of the D property in the currently considered instance, and M_D corresponds to the ideal state of the D property in the causal model (i.e., the prototype).

Distances cannot be considered by themselves, because they are linear. Similarity, in general, behaves like a generalization gradient (Shepard, 1987). For this reason, distances in Eqs. 1 and 2 need to be transformed into similarities by,

$$S_{XY} = e^{-b(\delta_{XY})} \quad (3)$$

where s_{XY} is similarity, and b is a sensibility parameter that determines the rate at which similarity falls with distance. In our model fitting, we fixed b = 1 (i.e., b was not estimated from the data). To compute the similarity s_D for the isolated D property, δ_{XY} is substituted by δ_D in Eq. 3.

Finally, we assume that the similarities from all the partial models under consideration are averaged to obtain an estimate of the overall similarity of the instance being judged relative to the prototype (i.e., the received causal model) by,

$$S_o = \frac{1}{n} \sum_{i=1}^{n} s_i \quad (4)$$

where so is the overall similarity of the instance being judged, n is the total number of separate pieces of information being considered (A→B, B→C, D), and s_i is the similarity according to Eq. 3. Because the PSM implies considering some properties twice (property B in the causal chain model), for modeling purposes we introduced an adjustment to pi simply by dividing it by 2 to reflect that those properties were being taken into account twice.

In summary, we propose that pairs of features that are causally related (and any features that are causally unrelated) are treated as features in separate multiplicative similarity prototype models, with classification ratings being a function of the averaged similarity of those feature pairs to their corresponding prototypes. A closely related model was proposed and tested by (Rehder, 2003a), but he concluded that the model failed to account for the data. In the Discussion section we will consider possible explanations for why our results suggest a different conclusion.

Experiments

Participants were trained on a causal model representing a given category, until they were able to answer correctly a set of 9 conditional and counterfactual questions. They then received the set of all possible combinations of present and absent properties involved in the causal model and were asked to rate how representative each combination was of the trained category.

Ratings were analyzed using the regression method (Rehder & Hastie, 2001). In this method, participants provide category membership ratings for all possible combinations of m properties in two possible states (present or absent), producing a total of 2^m combinations. For each combination, subjects provided a categorization rating on a 1 to 7 scale. When present and absent properties are coded respectively as 1 and -1 (i.e., effect coding), these values can be entered into individualized regression equations to predict a participant's categorization ratings. Furthermore, 2-way and higher-order interaction terms can be computed by entering the product of the corresponding property coded values as predictors into the equations. The corresponding regression coefficients can then be used as individual data points reflecting, across participants, the contribution of each predictor variable to the ratings.

Subjects were randomly assigned to one of two between-subjects conditions (domain: living things, artifacts) and provided data for two within-subjects conditions (information:

complete, incomplete). In the complete information condition, subjects received descriptions containing information about all properties (A, B, C, and D). In the incomplete information condition, subjects received descriptions lacking information about property C. Because prior research suggests that, in the context of causal classification the incomplete information condition promotes using other properties to infer the state of the unknown property (e.g., Puebla & Chaigneau, 2014), this design allowed us to compare conceptual properties' regression weights across the within-subjects condition. An increase in regression weights in the incomplete information relative to the complete information condition, would show that participants used a given property to infer the state of the unknown property C.

Predictions

The PSM makes the following predictions. Due to the piecemeal strategy, we predicted higher regression coefficients for directly connected properties interaction terms than for not directly connected properties. Furthermore, Eq. 3 predicts the type of interaction that we will find. People will prefer instances where properties X and Y are both in the same state as in the received model (e.g., X = 1, Y = 1), and any deviation (e.g., X = 1, Y = -1) will produce a large decrease in similarity (due to the b parameter). Note that all this means small interaction coefficients (i.e., smaller than main effect coefficients). This contrasts with predictions from the causal-model theory, where people are predicted to produce large interaction terms that are as large as main effects.

The PSM predicts that independent properties in our causal models will not interact. This is the same result that the causal-model theory would lead us to expect (i.e., properties A and C in the causal chain are independent conditional on the state of B). However, the PSM predicts this pattern of interactions, not because people conform to conditional independence principles, but because of the piecemeal simplification strategy. Thus, we expect our data from the complete information condition to only mimic adherence to the causal Markov condition. This should become evident in participants' performance in the incomplete information condition. When comparing regression weights across the information factor, the lack of information about the central C property should produce an increase in the regression weights of the independent properties (A and D in the causal chain) due to those properties being associated to the unknown property C. This is a violation of the Markov condition because only direct causes are normatively relevant to predict the state of the unknown property C. Thus, we predict an apparent adherence to Markov in the complete information condition, and a failure to adhere in the incomplete information condition.

Regarding the main effects, the PSM predicts that properties' conceptual weights will follow their inferentially derived weights (p_i). For the chain model in Exp. 1, we predict that regression coefficients for C will be greater than the average of A and B; D will be smaller than the average of A, B and C; and A will not be different from B.

Experiment 1

Design and Participants Exp. 1 followed a mixed factorial 2 (domain: living things, artifacts) x 2 (information: complete, incomplete) design, with the last being a within-subjects factor. Property D served as an inbuilt control condition for each subject and provided a baseline regression coefficient to which properties in the causal model could be compared. Also, D's interaction with other properties (AD, BD and CD) also provided a baseline for interaction terms' regression coefficients. Subjects (N = 66) were Adolfo Ibáñez University undergraduates (N = 41, males = 16) who participated for course credit, and undergraduate volunteers from other local universities (N = 25, males = 7).

Materials and Procedures The materials were verbal and graphical descriptions of two categories characterized by a chain causal structure. In the living things condition, materials described the structure of a fictional biological cell. In the artifacts condition, materials described the structure of a fictional particle accelerator. Stimuli were presented on screen by means of a locally programed software.

In the learning phase, participants were trained in the causal chain graph. Subjects learned that causes produced their effects with a 0.75 probability. Regarding property D, participants were informed that it occurred in category members with a probability of 0.75. Thus, property D was predictive of the category, but not causally related to the other properties. By keeping property D's probability equal to the conditional probabilities for the other properties, we kept everything other than belonging or not to the causal model constant for property D as compared to properties A, B and C. Importantly, subjects learned that property C gave the category its name (i.e., C was the central property).

In the classification phase, subjects had the causal graph in full view. In the complete information condition, participants received descriptions containing information about all properties either present or absent (16 combinations). In the incomplete information condition, participants received descriptions which lacked information about the state of the central property C (8 combinations). In total, participants classified 24 descriptions, presented in random order. For each description, subjects had to respond whether it was or not a member of the focal category using a 6-point rating scale.

Results Effect coding variables representing 10 variables per subject (4 main factors and 6 interactions, see Fig. 1) were entered as predictors in individualized regression equations with rating as dependent variable. The resulting individualized regression coefficients were submitted to a mixed 2 (domain: living things, artifacts) $\times$ 10 (coefficients) mixed ANOVA. The mixed ANOVA showed there was no effect of the domain factor ($F(1, 64)$=1.37, MS_e=.04, p=.25, ηp^2=.02, power=.21) and it did not interact with the coefficients factor ($F(9, 576)$=1.02, MS_e=.16, p=.39, ηp^2=.02, power=.30). Consequently, we collapsed this factor.

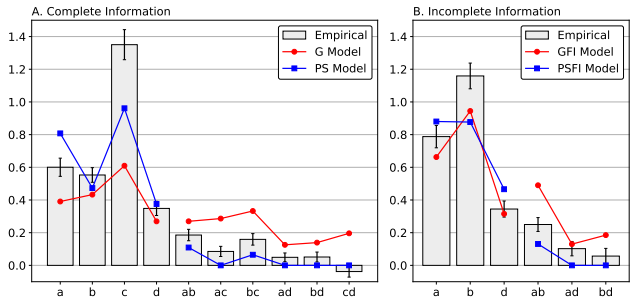

Figure 1: Regression weights for individual features and interactions of Exp. 1. Fits for the PSM (blue) and the GM (red) are superimposed on the data. Error bars are standard errors.

In accordance with our predictions for the main effects, orthogonal planned comparisons showed that the average coefficient for C was significantly greater than the average of coefficients for A and B ($F(1, 65)$=40.19, MS_e=.98, p<.001, ηp^2=.38, power>.99); the average coefficient for D was significantly lower than the average of coefficients for A, B and C ($F(1, 65)$=74.87, MS_e=.21, p<.001, ηp^2=.54, power>.99); and there was no difference between coefficients for A and B (F<1). This pattern of results for main effects suggests that subjects did indeed take information about p(effect|cause) as cue to properties inferential value, and that being in a causal structure increases inferential value beyond that of probabilistically related variables (property D).

Regarding the interaction coefficients, our predictions for the causal chain model were that the average of the AC interaction coefficients would be lower than the average of the AB and BC interaction coefficients (A and C are not directly connected in the causal graph); and that the average of the AB and BC interaction coefficients (directly connected properties) would be greater than the average of the AD, BD, and CD coefficients (i.e., our baseline conditions). As predicted, two non-orthogonal planned comparisons showed that the AC interaction was significantly smaller than the average of the AB and BC interactions ($F(1, 65)$=4.8, MS_e=.10, p=.03, ηp^2=.07, power=.58), and that the average of AB and BC interactions was significantly greater than the average of the AD, BD, and CD interactions ($F(1, 65)$=30.1, MS_e=1.81, p<.001, ηp^2=.32, power>.99).

Note that the low AC coefficient (which in fact was not significantly different from the interactions found for AD, BD and CD; $F(1, 65)$=3.8, MS_e=.07, p=.06, ηp^2=.06, power=.48), could be interpreted as participants complying with the Markov condition. However, analysis of the incomplete information condition reveals a different story. Under this condition, participants did not comply with Markov, using information about the state of property A (the screened-off property) and of property B (C's direct cause) to make inferences about the state of the missing C central property. Paired samples t tests revealed coefficients for properties A and B increased significantly when comparing the complete information condition with the incomplete information condition (respectively, complete information mean=0.60, incomplete information mean=0.79; $t(65)$=3.09, p=.003; complete information mean=0.55, incomplete information mean=1.16; $t(65)$=7.43, p<.001). In contrast, property D did not show evidence of being used to perform inferences about the state of property C (complete information mean=0.3485, incomplete information mean=0.3447; $t(65)$=.07, p=.94). Thus, data supported our hypothesis that subjects' performance in the complete information condition would mimic adherence to Markov.

Model fitting We fit the PSM to the classification ratings of Exp. 1. For comparison, we also fit the generative model (GM) of causal-based categorization (Rehder, 2003a; Rehder & Kim, 2009) (see Fig. 1). In the GM representation, a category k establishes a set of causal mechanisms. Each mechanism relates a feature j with its parent i operating with probability m_{ij} when i is present. Other background causes of j operate collectively with probability b_j. When j's parents operate independently, j's parents and the background causes produce j in members of category k conditional on the state of j's parents with probability,

$$p_k(f_i \mid Pa_k(f_j)) = 1 - (1 - b_j) \prod_{f_i \in Pa_k(f_i)} (1 - m_{ij})^{ind(f_i)} \quad (5)$$

where $ind(i)$ is an indicator variable that evaluates to 1 when i is present and 0 otherwise. The model assumes that root causes are independent of one another and the probability of each is represented with its own parameter c_j. The GM predicts that categorization judgments are a monotonic function of the joint distribution associated with the category's causal model,

$$p_k(f_{k,i}, \ldots, f_{k,N}) = \prod_{j=1 \ldots N} p_k(f_i \mid p_{a_k}(f_i)) \quad (6)$$

Participants ratings were predicted as follows:

$$rating^{PSM}(o_i) = s_k(o_i; p_A, p_B, p_C, p_D)/\beta$$
$$rating^{GM}(o_i) = 6 p_k(o_i; c_A, b_B, b_C, b_D, m_{AB}, m_{BC})^{\gamma}$$

where β and γ are free parameters. We fit both models by searching for the parameter values that minimized the squared difference between the predicted ratings and the empirical ones. In the complete information condition both models achieved a high correlation with the ratings: r_{PSM} = .85, r_{GM} = .90. We used the Akaikes information criterion (AIC[1]) to compare the degree of fit of both models controlling for the different number of parameters. The bigger AIC for the GM (15.2) in comparison to the PSM (12.1) indicates that, in fact, the PSM provides a slightly better characterization of the data

[1] AIC = $ln(SEE/n) + 2(p+1)$ where SSE is the sum of squared error for a participant, n is number of data points fit, and p is the model's number of parameters.

in this condition. The best-fitting parameters for the PSM were: $p_A = 0.325$, $p_B = 0.243$, $p_C = 0.775$, $p_D = 0.238$, $\beta = 0.094$ and for the GM: $c_A = 0.871$, $b_B = 0.802$, $b_C = 0.951$, $b_D = 0.765$, $m_{AB} = 0.558$, $m_{BC} = 0.327$, $\gamma = 0.565$. Note that while both models achieve a similar level of fit to the data, the GM achieves this by assigning values to the causal relation parameters lower than participants were taught during training (0.75).

In the incomplete information condition (see Fig. 2), we adjusted both the PSM and the GM to take into account the unknown state of C. We did this by inferring the probability of C being present given the state of its parent B using the GM equations: $p(E = 1 \mid C = 1) = 1 - (1 - m_{CE})(1 - b_E)$ and $p(E = 1 \mid C = 0) = b_E$. We treated this probability as the state of C and then proceeded as before for both models. In this condition the models achieved a high correlation with the ratings: $r_{PSM} = .89$, $r_{GM} = .92$. Again, we obtained a bigger AIC for the GM (15.0) in comparison to the PSM (12.7). The best-fitting parameters for the PSM were: $p_A = 0.347$, $p_B = 0.297$, $p_D = 0.264$, $b_C = 0.463$, $m_{BC} = 0.392$, $\beta = 0.083$ and for the GM: $c_A = 0.865$, $b_B = 0.884$, $b_C = 0.933$, $b_D = 0.687$, $m_{AB} = 0.552$, $m_{BC} = 0.617$, $\gamma = 0.505$. Note that the causal relation parameter for the relation between B and C was higher in this condition.

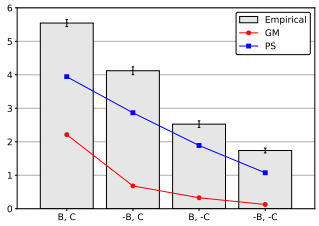

Figure 2: Average ratings for objects with different combinations of states (present or absent) for features B and C in Exp. 1, complete information condition. Fits for the PSM (blue) and the GM (red) are superimposed on the data. Error bars are standard errors.

Two things are noteworthy from these results. First, as shown in Fig. 1, the GM consistently overestimates the magnitude of the coherence effect (i.e., the 2-way interactions), while the PSM shows clearly better fits. Additionally, as shown in Fig. 2, the PSM is better able to predict the consequences of inconsistent information on participants ratings, as compared to the GM. This relates to similarity gradients implied by eq. (3).

Experiment 2

Because results like those of Exp. 1 are difficult to reconcile with causal-model theory, in particular the lack of a coherence effect, Rehder (2017) proposed that small property interactions in results like those of Exp. 1, occur because instructions and materials emphasized a single almost defining property (property C in Exp. 1). Had traditional category labels been used (i.e., a category name, such as "dog"), large interactions would emerge, as expected by causal-model theory. To test Rehder's (2017) hypothesis, in Exp. 2 we used the causal chain model, but subjects were not told that there was a central property that gave the category its name. Instead, an arbitrary category label was provided.

As there should be no inferential processes in this task, we predicted that all properties in the causal model would show about the same weight, and on average they would produce a greater regression weight than the isolated property D. Regarding the interactions, the PSM predicts that, because of the piecemeal strategy, directly connected properties (AB, BC) would exhibit a larger regression weight than the indirectly connected properties (AC), and that the AB and BC terms would show a higher regression weight than the interactions of not connected properties (AD, BD, CD).

Design and Participants Exp. 2's design was identical to that of Exp. 1. Subjects (N = 64) were Adolfo Ibáñez University undergraduates (males = 21) who participated for course credit.

Materials and Procedures Materials were identical to those used in Exp. 1. However, arbitrary names were used to label categories, and no property was described as central or described the category's function. Except for the arbitrary category name, procedures were identical to Exp. 1.

Results Results Individualized regression coefficients were submitted to a mixed 2 (domain: living things, artifacts) × 10 (coefficients) mixed ANOVA (see Fig. 3). The mixed ANOVA showed there was no effect of the domain factor ($F<1$) and it did not interact with the coefficients factor ($F<1$). Consequently, for all subsequent analyses we collapsed this factor.

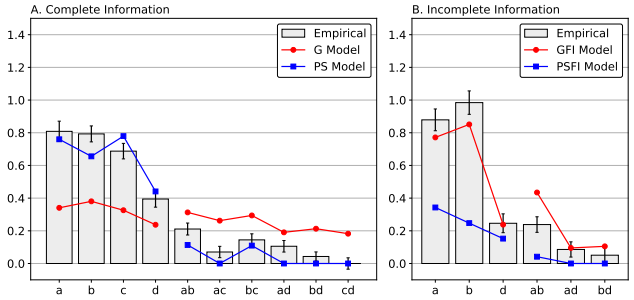

Figure 3: Regression weights for Exp. 2's individual features and interactions. Fits for the PSM (blue) and the GM (red) are superimposed on the data. Error bars are standard errors.

As predicted by the PSM, orthogonal planned comparisons showed that the average coefficient for D was significantly lower than the average of coefficients for A, B and C ($F(1, 63)=44.72$, $MS_e=.19$, $p<.001$, $\eta p^2=.42$, power$>.99$); but that there were no significant differences between C versus A and B ($F(1, 63)=3.46$, $MS_e=.24$, $p=.068$, $\eta p^2=.05$, power$=.45$), or A versus B ($F<1$). This pattern of results for main effects suggests that our subjects did indeed judge all properties to

be about equally central. This result contrasts with Exp. 1, where inference induced differential property weights. However, as in Exp. 1, property D was judged to be less central than properties belonging to the causal model. Again, this shows that participants are sensitive to causal information and are not disregarding it by using a pure associative strategy.

As predicted by the PSM, two non-orthogonal planned comparisons showed that the AC interaction was significantly smaller than the average of the AB and BC interactions ($F(1, 63)=7.02$, $MS_e=.42$, $p=.01$, $\eta p^2=.10$, power=.74), and that the average of AB and BC interactions was significantly greater than the average of the AD, BD, and CD interactions ($F(1, 63)=15.05$, $MS_e=2.52$, $p<.001$, $\eta p^2=.19$, power=.97).

As in Exp. 1, the low AC coefficient suggests that participants are complying with the causal Markov condition. At odds with Exp. 1, participants did not use property A (the screened-off property) to infer the state of property C (complete information mean=0.82, incomplete information mean=0.89; $t(63)=1.2$, $p=.24$), but used property B (Cs direct cause) (complete information mean=0.79, incomplete information mean=1.0; $t(63)=3.95$, $p<.001$). Furthermore, in the incomplete information condition, participants relied less on the isolated property D to make inferences (complete information mean=0.38, incomplete information mean=0.25; $t(63)=2.16$, $p=.04$). These results are broadly consistent with the hypothesis that using an arbitrary category label would promote causal classification.

Model fitting We fit the PSM and the GM to the classification ratings of Exp. 2 in the same ways as in Exp. 1 (Fig. 3). In the complete information condition both models achieved a high correlation with the ratings: $r_{PSM} = 0.83$, $r_{GM} = 0.84$. The bigger AIC for the GM (15.8) in comparison to the PSM (11.9) indicates that the PSM provides a slightly better characterization of the data in this condition. The best-fitting parameters for the PSM were: $p_A = 0.529$, $p_B = 0.455$, $p_C = 0.577$, $p_D = .293$, $\beta = 0.096$ and for the GM: $c_A = 0.921$, $b_B = 0.925$, $b_C = 0.887$, $b_D = 0.801$, $m_{AB} = 0.537$, $m_{BC} = 0.158$, $\gamma = 0.908$. As in Exp. 1, while fits for both models are similar, the GM achieves this by assigning values to the causal relation parameters lower than participants were taught.

For the incomplete information condition, we adjusted the PSM and the GM as in Exp. 1. The models achieved a high correlation with the ratings: $r_{PSM} = 0.88$, $r_{GM} = 0.90$. Again, we obtained a bigger AIC for the GM (14.6) in comparison to the PSM (13.0). The best-fitting parameters for the PSM were: $p_A = 0.316$, $p_B = 0.204$, $p_D = 0.236$, $b_C = 0.527$, $m_{BC} = 0.312$, $\beta = 0.230$ and for the GM: $c_A = 0.889$, $b_B = 0.847$, $b_C = 0.937$, $b_D = 0.640$, $m_{AB} = 0.439$, $m_{BC} = 0.592$, $\gamma = 0.431$. Note that, as in Exp. 1, the causal relation parameter for the relation between B and C was higher in this condition.

Just as for Exp. 1, in Exp. 2 the GM consistently overestimates the magnitude of the coherence effect (i.e., the 2-way interactions in Fig. 3, particularly in Panel A), while the PSM shows clearly better fits. Finally, as shown in Fig. 4, the PSM is better able to predict the consequences of inconsistent information on participants ratings, as compared to the GM.

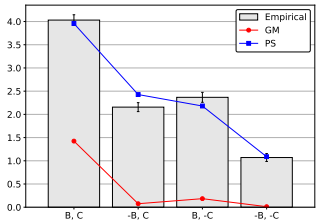

Figure 4: Average ratings for objects with different combinations of states (present or absent) for features B and C in Exp. 2. Fits for the PSM (blue) and the GM (red) are superimposed on the data. Error bars are standard errors.

General Discussion

In our experiments, the PSM was able to predict the pattern of results for main effects and interactions. Importantly, in both experiments the size of interaction coefficients remained low, and were not as high as those of main effects, as predicted by the GM. Furthermore, as would be expected if subjects were using associative mechanisms, the PSM was better able to predict ratings for objects with inconsistent information (Figs. 2 and 4). However, our results were not as clear regarding the mimicking Markov hypothesis. Exp. 1 produced data that is consistent with it, but Exp. 2 did not. In this latter experiment, participants appear to have complied with Markov both in the complete (i.e., low interaction coefficient for conditionally independent features) and in the incomplete information condition (i.e., appropriate screening-off of the conditionally independent distal cause). This pattern of results is consistent with the hypothesis that using an arbitrary category label enhances causal classification (Rehder, 2017). However, as in neither experiment did we obtain coherence effects, evidence for this hypothesis is mixed.

Prior research has found coherence effects in conditions similar to ours (e.g., in Rehder, 2003b, Fig. 4). The question then arises of how to account for these different results. In our experiments, we strove to use procedures as close as possible to those used by other researchers, so we tend to believe that differences do not lie in materials and procedures. Instead, we think it is possible that there are differences in how different populations handle causal information for categorization as well as for other tasks. Recently, using a causal inference task, (Rehder, 2018) found substantial variability in how individuals perform inferences (i.e., a single model was not able to account for the pattern of inferences of all participants, with a substantial minority behaving close to the predictions of an associative model). In a similar vein, we believe that no current model of causal cognition comfortably handles this variability and that future research should look to identify parameters that characterize tasks, individuals and populations in such a way that they are able to account for differences in causal categorization, and causal cognition in general.

Abstract

Humans can learn and reason about abstract concepts quickly, flexibly, and often from very little data. Here, we study how people learn novel concepts within a binary grid domain, and find that even this minimal task nonetheless necessitates the inference of highly structured parts as well as their compositional relationships. Furthermore, by changing the presentation condition of the learning examples, we reveal different approaches involved in learning such visual concepts: given the same images, human generalizations differ between rapid and static presentation conditions. We investigate this difference by developing several computational models that vary in their use of structured primitives and composition. We find that learning in the rapid presentation condition is best described as inference in simple models, while learning in the static presentation condition is best described as inference in a more structured space of graphics programs.

Keywords: Bayesian inference; concept learning; few-shot learning; program induction

Introduction

Human concept learning can involve remarkably fast and flexible abstraction. When we see a bridge or appreciate a sculpture, we not only perceive a set of objects, but also the underlying parts and their relationships. With such intuitive understanding of how the parts make the whole structure, human can productively compose learned primitives, generalize to new kinds of objects, and imagine new scenes.

We wish to study the compositional structure that underlies the richness of human visual concept learning by comparing computationally explicit models with human behavior. Prior work in cognitive psychology has built compositional models to describe human visual concept learning, typically by presupposing relevant, symbolically represented parts as inputs to the model, rather than operating directly on images (Shepard, Hovland, & Jenkins, 1961; Rehder & Hoffman, 2005; Goodman, Tenenbaum, Feldman, & Griffiths, 2008). These models are limited to a small stimulus space generated from the conjunction of the few predetermined features. In contrast, machine vision models successfully perform classification from arbitrary natural images (Krizhevsky, Sutskever, & Hinton, 2012), but recent work has found that these models lack the compositional structure necessary to recapitulate human visual concept learning in specific domains (Lake, Salakhutdinov, & Tenenbaum, 2015).

Here, we add to this literature by introducing a new minimal domain to incorporate both of these necessary ingredients: the inference of primitive parts directly from images, and the discovery of compositional structure that relates them. The domain we choose is 5×5 images with binary pixels. Despite the simplicity of this setup, Figure 1 shows that the visual concepts implied by these images can be complex and compositionally structured. In comparison to existing datasets that also occupy this space, our dataset focuses on occlusion and spatial juxtaposition that makes the basic parts particularly ambiguous, as well as concepts that lack prototypical images.

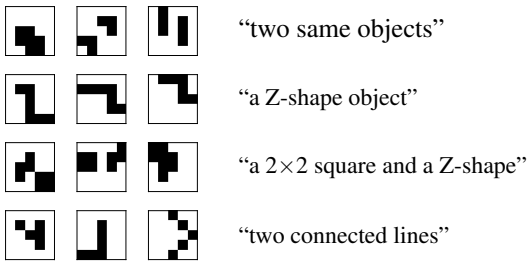

Figure 1: Abstract visual concepts represented by sets of images on a 5×5 binary grid.

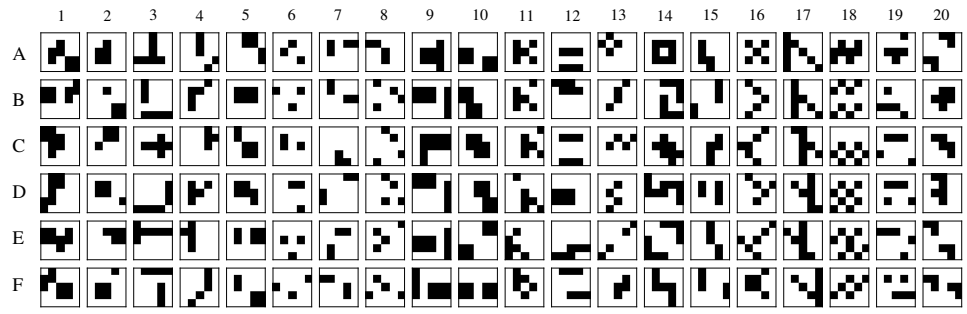
Based on these images we develop a few-shot learning task to be presented under either static or rapid viewing conditions. Participants are asked to perform a 9-way classification, for which we compare several computational models that vary in their degree of compositionality and type of structured primitives present. We include a hierarchical Bayesian program learning model, and several additional Bayesian models with alternative primitives. We evaluate these models by quantitatively comparing how the model predictions match human judgments in few-shot generalization. Across the several Bayesian models tested, we find that the ability to jointly infer parts and compose them is critical to explain human generalizations in even this minimal domain, so long as participants are given sufficient time to view the stimulus. However, for rapid viewing conditions, participants' judgements are better explained as inference in a much simpler model with less rich compositional structure.



(a) Set of 20 visual concepts (b) Behavioral task

Figure 2: Visual stimuli and task paradigm used in the behavioral experiments. 60 images (rows A-C) are used for learning concepts and 60 (rows D-F) for testing generalization.

Learning grid concepts

We manually design 20 sets of binary images in the 5×5 grid, covering object occlusion, repetitive structures, and other interesting visual patterns. Each column in Figure 2a is a set of images representing a certain concept. For each concept, three examples (A-C) are designated for learning and a further three (D-F) for testing generalization behaviors. We have 60 different test trials in total.

We use a classification task to compare how humans and models generalize from three examples. The basic task is to learn the underlying concept from the 3 provided examples, and then to select from 9 novel query images the one that most likely displays the same concept. To create each trial, we sample one query image from the same visual concept as the three observed examples, and 8 from distinct other concepts which are drawn uniformly at random (See Fig 2b, 2a col. 8).

To collect human judgements, 216 participants were recruited via Amazon Mechanical Turk to participate in a few-shot classification task, each completing 20 trials: Participants were instructed to observe interesting objects on the visual scenes in the grid world. Subjects were presented with three example images, and then asked to choose one of the new query images that most likely displays the same concept, as is illustrated in Figure 2b.

Each participant was assigned either to the 'rapid' or 'static' viewing condition. In the 'static' condition, subjects could see all three of the example images simultaneously, for as long as required to make a judgement. However, in the 'rapid' condition, subjects instead watched only a video containing the stimuli in quick succession, with an interval between stimulus onsets of 72ms. At the end of the video, a 5×5 grey noise patch was displayed for backward masking.

Bayesian models

Concept learning, from the computational perspective, is fundamentally linked to the generalization problem $P(e'|e_1, e_2, \ldots, e_k)$. Consider a set of k observed examples $e_1, e_2, \ldots, e_k$, and a new observation e'. A concept c naturally plays a role when we factorize the conditional probability $P(e'|e_1, e_2, \ldots, e_k)$ as $\sum_{c \in \mathcal{C}} P(e'|c)P(c|e_1, \ldots, e_k)$.

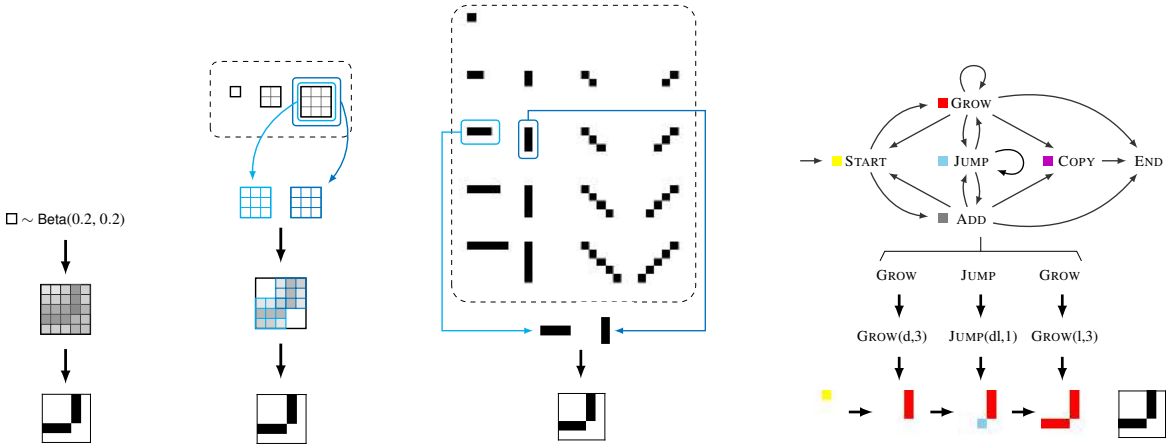
In the Bayesian framework of concept learning, we have the following according to Bayes rule and assuming conditional independence of observations given the concept c:

$$P(c|e_1, \ldots, e_k) = \frac{P(e_1, \ldots, e_k, c)}{\sum_{c \in \mathcal{C}} P(e_1, \ldots, e_k, c)} \propto \prod_{i=1}^{k} P(e_i|c)P(c) \tag{1}$$

The key component is about the structure of $P(e_1, \ldots, e_k, c)$, or more specifically $P(e|c)$ and $P(c)$. Here we construct four different models $P(e_1, \ldots, e_k, c)$ with various assumptions, levels of abstraction, and types of structured representation.

Independent Pixel Model This model assumes that the latent concept $c \in \mathcal{C}$ is a 25-element list of Bernoulli distribution parameters $[p_1, p_2, \ldots, p_{25}]$, each of which corresponds to one of the pixels in the grid and is sampled independently from a prior distribution $\text{Beta}(0.2, 0.2)$. An image instance e is generated from the concept c by sampling the binary state of each pixel in the grid according to its Bernoulli distribution parameter, as is shown in Figure 3a. This model lacks compositionality and complex structured representation, as the primitive available is just a single independent pixel.

Patch Model This model assumes that the latent concept $c \in \mathcal{C}$ is a list of patches drawn from a patch inventory of three different sizes (1×1, 2×2, 3×3), as is shown in Figure 3b. Specifically, c consists of the total number of patches as well as the size of each patches. To generate an image e from the concept c, the model first randomly localizes each patch on the grid and independently samples the Bernoulli distribution parameter for each pixel within the patches. Then an image instance is generated by sampling the binary state of each pixel within each localized patch according to the corresponding Bernoulli distribution parameter. The pixels out of the localized patches will always be turned off. This model has limited compositional structure, as it abstracts an image



(a) Pixel (b) Patch (c) Chunk (d) Program

Figure 3: Generative process of a concept and a image for different models.

as composition of several patches. However, the model lacks explicit structure within a patch, as the Bernoulli distribution parameters of the pixels within a certain patch are not shared at the concept level across multiple generated images.

Chunk Model This model assumes that the latent concept $c \in \mathcal{C}$ is a list of n chunks that are uniformly drawn from an inventory of line primitives (e.g. lines of various sizes and directions), as is shown in Figure 3c. An image e is generated by randomly placing on the grid the list of chunks from the concept c. The locations of the chunks are sampled during the image generation process and not shared at the concept level. While the built-in inventory of basic chunk primitives supports explicit structured representation, the model, however, lacks the mechanism to compose chunks into complex objects during the generative process.

Full Program Model Drawing inspiration from Lake et al. (2015), we design a model in which images are generated from a sequence of consecutive drawing actions. In the full program model, each concept $c \in \mathcal{C}$ takes the form of a probabilistic action program $\{a, \theta\}$, where a refers to the action type and θ refers to the parameters of each action. Once a concept c is generated, a binary image e is sampled from the concept by executing each action in the program step by step. Figure 3d illustrates how an example image is generated from the concept 'GROW(d,3) $\rightarrow$ JUMP(dl,1) $\rightarrow$ GROW(l,3)'.

To generate a concept, namely an action program in this model, the length of the program n is first sampled from an exponential distribution over all the possible program lengths ranging from 1 to 5 ($P(n) \propto \lambda^n$, where $\lambda = 0.9$), with preference to short programs. After that, a sequence of n actions, a, is sampled step by step from the plausible action primitives to construct the template of the program, under the constraints of the action transition grammar specified in Figure3d. For each action, the plausible transitions to other actions are uniformly distributed. The action primitives include GROW (adding pixels in a certain direction), JUMP (skipping over pixels in a certain direction), COPY (making copies of the current drawing trace and placing them randomly on the grid), ADD (generating a square patch of certain size and placing it randomly on the grid.), and START (placing currently generated trace on the grid and initializing a new trace).

After sampling the program template, the parameters θ_i of each action a_i in the program a (e.g. the direction and size of GROW) is uniformly sampled from the plausible values that a certain parameter type can take. There are eight basic values for the direction parameter, u (up), d (down), l (left), r (right), ul (upleft), ur (upright), dl (downleft), and dr (downright). The size parameter can take a number that is smaller or equal to the grid width size for GROW and JUMP actions, and a number less than 3 for COPY action. Both the direction and size parameter can also take a special parameter value '*any*', which refers to randomly sampling one of the basic directions or plausible size values during the image generation process.

Regarding the execution of an action program, the initial empty trace starts at the reference point $(0,0)$ on the temporary canvas. Following the action instructions, we draw pixels or move to other location on the canvas consecutively. The trace generated on the temporary canvas will be placed at a random place on the 5×5 grid once we encounter the end of the program or a START action. It is worth noticing here that the mechanism of composing action traces and starting new traces gives rise to the model's ability of utilizing more relational and object-like compositional structure. Therefore, Bayesian program learning model has more expressive compositionality and explicitly structured representation.

Few-Shot Classification and Generation

In order to evaluate each model against our collected human data, we must perform inference. However, this is computationally challenging to do exactly, and so we perform approx-

	H $_{\text{static}}$	H $_{\text{rapid}}$	M_1	M_2	M_3	M_4
Human $_{\text{static}}$	-	36	51	35	15	10
Human $_{\text{rapid}}$	36	-	36	25	11	10
Program [M_1]	51	36	-	35	15	9
Chunk [M_2]	35	25	35	-	14	6
Patch [M_3]	15	11	15	14	-	8
Pixel [M_4]	10	10	9	6	8	-

Table 1: Proportion of the same choices between model predictions and human judgements for 60 trials.

Model	Static presentation	Rapid presentation
Program	**0.39**	0.49
Chunk	0.43	0.47
Patch	0.52	**0.44**
Pixel	0.78	0.78
Uniform	0.56	0.46

Table 2: Hellinger distance averaged across 60 trials for each model compared to human data under each presentation condition (lower is better)

imate inference using a neural network trained for amortized few-shot classification in each model.

For each model, we train a separate network with a shared architecture, comprising a single convolutional layer and two fully connected layers with 200 hidden units. Each network was trained on model-generated data to produce a distribution of responses for 9-way classification of novel images. Specifically, we generate synthetic training data by sampling 9 concepts from each model's prior, drawing one image from each concept as the query examples, and a further 3 images from one concept as the observed examples. We optimise the network to classify the correct query example given the observed examples.

We then evaluate each of these trained networks on the same stimuli as presented to human subjects. Thus, regarding the behavioral task, each model's inference network is used to select the most likely query image from the 9 options.

For few-shot generation, we approximate the posterior $P(c|e_1,\ldots,e_k)$ using Markov Chain Monte Carlo (MCMC) implemented in WebPPL (Goodman & Stuhlmüller, 2014). Then we are able to produce novel instances from the inferred concepts.

Results

We are particularly interested in how human and the models proposed in this work make generalizations from few examples. We evaluate model predictions with respect to human judgments on 60 trials in the behavioral task, in each presentation condition.

Evaluation results of the models are listed in Table 1. We compute the proportion of choosing the same test images as the top choice for each pair between different models and human judgments. It is shown that the predictions of Bayesian program learning model largely matches the most popular (top 1) choice of human judgments in the static condition.

We compare the probability distribution of model's prediction to the distribution of human judgments over 9 test images for each trial in the experiment. We normalize human judgments to get a distribution of choice over the 9 test items, and similarly calculate $P(e'_i|e_1,e_2,e_3)$ over the 9 test items for each model. For each of 60 trials, we compute the Hellinger distance (Hellinger, 1909) between the distribution of model prediction and human judgement to quantify the distance between human and model responses. The average Hellinger distances are shown in Table 2, highlighting a difference between the two presentation conditions. For static presentations of the stimulus, the highly structured Bayesian program model is by far closest to human judgments in terms of the distribution of the choice in each trials. However, for rapid presentations of the stimulus, the program model suffers from overconfidence while the less structured 'chunk' model provides the best prediction of human judgements. Figure 4 visualizes the distribution of human judgments and models' predictions for several trials.

Regarding the question of what type of compositional structure supports human concept learning, the differences among the proportions of matched choices between human and four Bayesian models of different level of abstraction provide some interesting insights. As is discussed before, these Bayesian models can be summarized briefly with how much abstraction and what level of abstraction is built into the architecture: The pixel model does not have any compositional structures, while the patch model composes a scene by combining several patches. However, neither of these match human judgements well: the compositional ability of the patch model is largely limited due to the lack of explicitly structured primitives in its representation, as the patch only vaguely specify a pattern instead of clearly defining the structure of the pattern. With more structured primitives, the chunk model achieves significantly stronger results.

While the lack of structured representation makes it hard for the patch model to take the advantage of compositional structure in learning concepts, comparison between chunk and program models further suggest that hierarchical compositional structures are important in capturing human few-shot learning of simple visual concepts.

One final advantage of a Bayesian generative model is its generative process. Table 3 lists three of the inferred concepts by Bayesian program learning model, the approximate log posterior probabilities of these concepts, and the posterior samples for several sets of binary images used in the classification experiment. We can see that Bayesian program learning model successfully inferred the program and generated reasonable novel images of the same concept.

Discussion

Our work is an advanced investigation of similarity and generalization, along the line of research of classic Bayesian

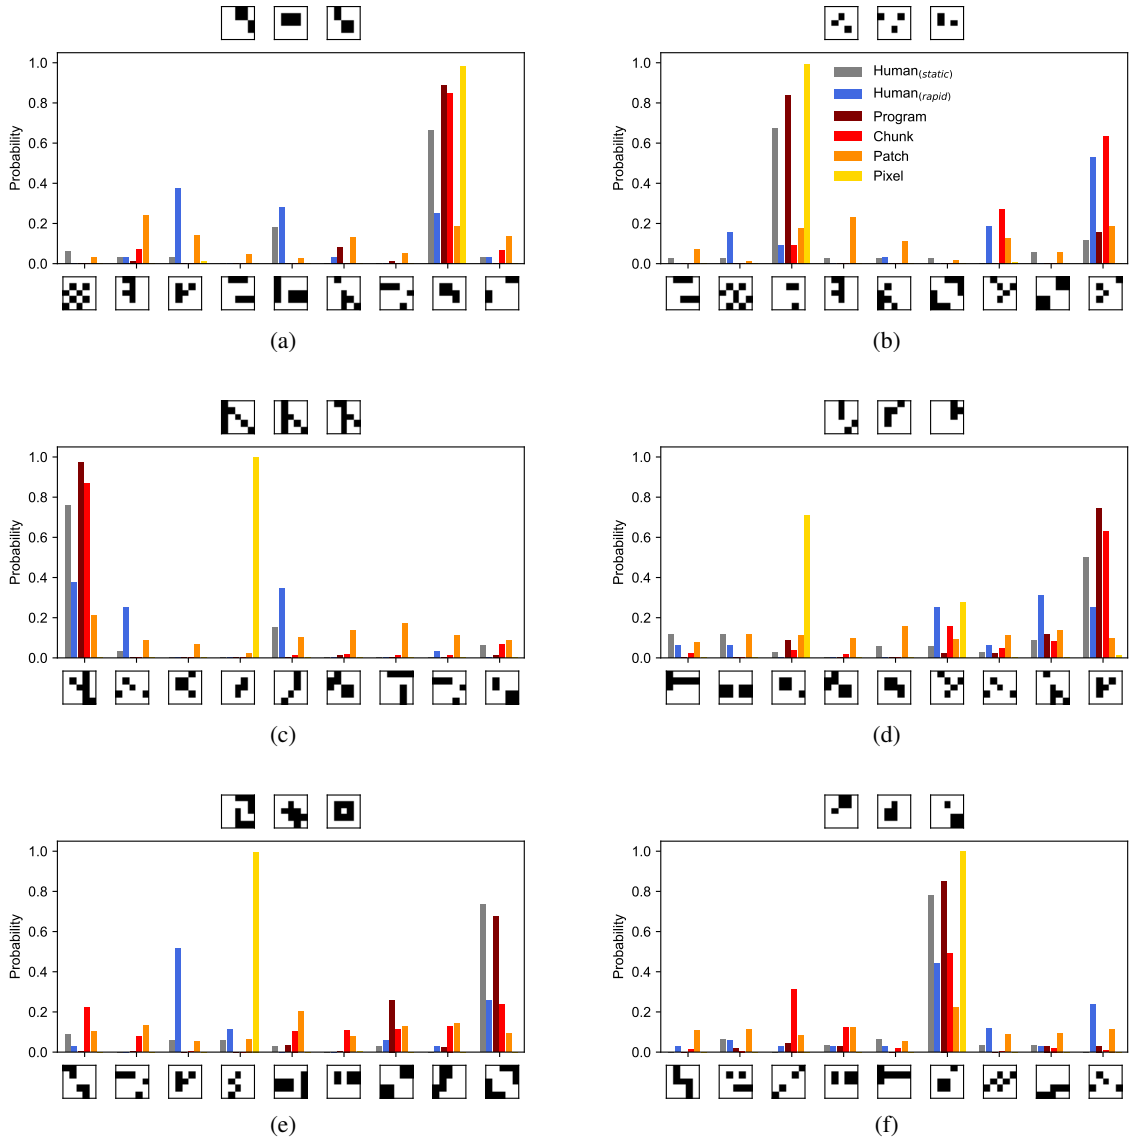


Figure 4: Fine-grained comparison of model responses to human responses.

concept learning (Tenenbaum, 2000; Tenenbaum & Griffiths, 2001; Kemp, Bernstein, & Tenenbaum, 2005; Goodman et al., 2008; Stuhlmuller, Tenenbaum, & Goodman, 2010) in computational cognitive science. We investigated visual concepts with more abstract, relational, compositional, hierarchical and object-like structure.

Compared to previous work (Orbán, Fiser, Aslin, & Lengyel, 2008) that studied learning visual scenes in a grid world composed of simple chunks (i.e. the statistical dependencies are simple associations between adjacent objects), this work explores more complex scenes that allow for more abstract (non-statistical) relations between objects in a scene. Further, objects in the visual scenes might occlude each other, which propose yet another challenge for learners, both model and humans, in identifying the latent structure.

Other important related works are Bayesian program learning of hand-written characters (Lake et al., 2015) and abstract visual concepts (Overlan, Jacobs, & Piantadosi, 2017). Our study introduces a richer grid concept domain, and develops computational account of different levels of abstraction. Although Lake et al. (2015) presents a Bayesian program learning model for few-shot learning of hand-written characters, which are images on a larger grid than what we use here, some interesting differences are worth mentioning here. Human might have a lot of practical experience with hand-written characters in daily life. There could be reasonably good prototype for hand-written characters as they are often standardized for communication purpose. People might rely on inferring a single visual prototype and generalize through similarity matching to the prototypical image. In our case, in contrast, it is hard to infer a single visual prototype for many of our concepts, even though there are only a small number

Examples	$\log(P)$	Concepts	Posterior samples
	-1.41	GROW(dl,2) → GROW(u,2) → GROW(ur,2) → START → ADD(2×2)		-1.41	GROW(dl,2) → JUMP(d,1) → GROW(ur, 2) → START → ADD(2×2)	
	-7.65	GROW(any,2) → JUMP(u,1) → GROW(ur,2)→ START → ADD(2×2)	
	-1.47	GROW(ur,2) → JUMP(l,2) → GROW(dl,2) → COPY(1)		-6.43	GROW(dl,2) → JUMP(r,3) → JUMP(u,1) → GROW(dl,2) → COPY(2)	
	-12.66	GROW(dl,2) → JUMP(r,any) → JUMP(u,1) → GROW(dl,2) → COPY(any)	
	-2.12	GROW(dr,3) → START → GROW(dl,3)		-6.28	GROW(dr,any) → START → GROW(ur,3)	
	-8.35	GROW(dl,3) → START → GROW(any,3)	
	-0.42	ADD(2×2) → START → ADD(2×2)		-3.07	ADD(2×2) → JUMP(any,any) → ADD(2×2)	
	-23.04	ADD(2×2) → START → GROW(r,2) → COPY(2)	

Table 3: Programs found by MCMC for several test concepts, with corresponding posterior-predictive samples of new images.

of observations to choose and generalize from.

This work also shows that compositionality is not the only important aspect behind human few-shot learning, in line with previous work (Schulz, Tenenbaum, Duvenaud, Speekenbrink, & Gershman, 2016) that demonstrates human's preferences of compositional pattern in function learning domain. The level of abstraction in the representation also plays an important role in building models that can better match the generalization behaviors observed in human concept learning.

We believe that our visual concept learning task contributes to an understanding of how humans learn and reason about novel visual concepts, addressing two questions: (1) what kinds of representation and architecture support flexible inference of underlying abstract structure, and the impressive generalizations that humans achieve from often minimal data? (2) Is this same architecture necessary, and is it sufficient, to explain the kind of rapid inferences humans are able to make given only a short glimpse of a concept? Comparisons among several Bayesian models with different degrees of abstraction demonstrate that, even in this minimal domain, humans can infer concepts with a rich compositional structure, but that the extent of this structure is dependent on the condition of presentation.

The Expected Unexpected & Unexpected Unexpected:
How People's Conception of the Unexpected is Not Really That Unexpected

Abstract

The answers people give when asked to "think of the unexpected" for everyday event scenarios appear to be more expected than unexpected. There are *expected unexpected* outcomes that closely adhere to the given information in a scenario, based on familiar disruptions and common plan-failures. There are also *unexpected unexpected* outcomes that are more inventive, that depart from given information, adding new concepts/actions. However, people seem to tend to conceive of the unexpected as the former more than the latter. Study 1 tests these proposals by analysing the object-concepts people mention in their reports of the unexpected and the agreement between their answers. Study 2 shows that object-choices are weakly influenced by recency, that is, the order of sentences in the scenario. The implications of these results for ideas in philosophy, psychology and computing are discussed.

Keywords: expectation; explanation; cognitive; judgments

As we know, there are known knowns; there are things that we know that we know. We also know there are known unknowns; that is to say we know there are some things we do not know. But there are also unknown unknowns, the ones we don't know we don't know.

Donald Rumsfeld, Feb 2002, US Secretary of Defence

1. Introduction

In an uncertain and contingent world, our ability to deal with the unexpected often gives us safe passage through the Siren-like obstacles of everyday life (see e.g., Weiner, 1985a). The Cognitive Sciences have often concerned themselves with how people think about the unexpected. However, most of this research relies on theory-driven definitions of the unexpected (e.g., low probability events), rather than simply asking people to "think of the unexpected" and see how they respond[1]. In the present paper, we report two studies that ask people to generate unexpected events for everyday scenarios and then analyse their responses. As the title of the paper suggests, our main finding is that *people's conception of the unexpected is not really that unexpected at all.*

In Cognitive Psychology, *unexpectedness* is often used as a dependent variable in studies of human thinking and decision making. For example, in reasoning research, the unexpected has often been proposed to elicit counterfactual thinking (Kahneman & Miller, 1986; McEleney & Byrne, 2006). In attribution research, the unexpected has been cast as non-normative behavior in others, that elicits spontaneous causal thinking (Hastie, 1984; Weiner, 1985b). And, surprising events are often defined in terms of their unexpectedness (Meyer et al., 1997; Maguire et al., 2011).

However, most of these studies do not actually *ask* people to report unexpected outcomes; rather they adopt *a priori* operational definitions of *unexpectedness* based on the experimenter's theoretical stance. The unexpected is commonly operationalized as (i) an event rated as having a low subjective probability (Maguire et al., 2011; Teigen & Keren, 2003), or (ii) profiles of people with inconsistent traits (Hastie, 1984), or (iii) events that are simply asserted to be unexpected to the actors in a narrative (McEleney & Byrne, 2006). In contrast, we do not use *a priori* definitions but rather, simply, ask people to tell us what they consider the unexpected to be. This sort of behaviour was observed by Foster & Keane (2015, 2019), in studies on surprise, in the form of familiar surprises ("I am surprised my wallet is missing from my trouser pocket, but I am guessing it was robbed") and unfamiliar surprises ("I am surprise my belt is missing from my trousers but have no idea how that could have happened"; see also Maguire & Keane, 2006).

1.1 Thinking About the Unexpected

Consider the simple task used in the current experiments to elicit unexpected events from people. Imagine being told a story about a woman, called Louise, who is going shopping at her favourite clothes store, in which she draws money from an ATM and heads into town on the bus. Now imagine you are told "Something unexpected occurred. What do you think happened?" One could respond with one of the following unexpected events, saying that:

1) Louise lost the money she drew from the ATM.
2) Louise was delayed in traffic, arrived late and the shop was shut.

However, one could also validly say:

3) The bus stopped at a charity bus-wash and Louise got covered in suds.
4) Louise pulled a gun on the driver and robbed him to raise more money for her shopping spree.

Intuitively, as unexpected outcomes, the first two answers (1-2) are quite conservative and mundane and *less* unexpected

[1] Khemlani et al.'s (2011) Expt. 3 is a notable, but rare, exception though it focusses on the issue of latent scope.

than the latter two responses (3-4) which are more inventive and a lot *more* unexpected. We call the former answers the *expected unexpected* and gloss the latter as the *unexpected unexpected*.

Expected unexpected outcomes tend to maintain the original goal of the story scenario (i.e., shopping) and the stated object-concepts associated with the story's goal; these *goal concepts* tend to be re-used in the unexpected event (i.e., *bus*, *ATM*, *money*, *store*) and few new objects are added (e.g., *traffic*). Furthermore, these events are often "common failures" that are familiar to people; losing one's money or being delayed are common reasons for failed plans and goals.

Unexpected unexpected outcomes, in contrast, may establish new goals for the story scenario (e.g., attending a charity event) and, though *goal objects* may be used (i.e., *bus*, *money*), often "new" object-concepts not present in the original story are introduced (e.g., *guns, suds*). Also, these unexpected events are quite unfamiliar to the scenario: getting involved in a charity bus-wash is not a common everyday event for most people who are going shopping. In previous work on surprise using these everyday scenarios (Foster & Keane, 2015), we noticed that people typically produced *expected unexpected* answers rather than *unexpected unexpected* ones. But, why?

Why do people *minimally* perturb the stated scenario, keeping its goals and goal-concepts in these expected-unexpected events that they seem to prefer to generate? One possibility is that when people are thinking about the unexpected, they are essentially trying to explain how current goals might fail; so, unexpected events tend to describe disruptions to a current plan or undoings of assumed facts that enable current goals. Being delayed in traffic disrupts Louise's shopping plan, undoing the assumption that the bus gets her to the shop on time. Losing one's money is an unexpected event that explains how any shopping-goal might fail. From an adaptive perspective, it makes sense to minimally change the current situation when projecting such unexpected futures. In contrast, more creative unexpected-unexpected events, that depart significantly from the current scenario, may never occur and, therefore, seem not to be considered. In short, the former probably have higher predictive value than the latter. Across the Cognitive Sciences, many researchers have highlighted this minimalist stance in people when they encounter the unexpected.

1.2 The Minimalism of the Unexpected

In Philosophy, when reasoning about inconsistencies (such as new, unexpected facts), it has been repeatedly proposed that any change to stated propositions or prior beliefs should be as minimal as possible; observing the "maxim of minimal mutilation" (Quine, 1992, p.14), or the "principle of conservativism" (Harman, 1986, p.46). Similarly, in considering counterfactual situations (of which unexpected situations could be a subclass), Lewis (1986), taking a possible-world perspective, talks of finding the maximally-similar world to the current one.

In Psychology, related ideas arise in considering the *minimal-mutability* of counterfactual scenarios (Kahneman & Miller, 1986). Also, in the psychology of explanation, several researchers have noted how explanations of the unexpected maintain aspects of the original scenario; they preserve the level-of-abstraction of the original scenario rather than identifying new or more specific information (see e.g., Johnson & Keil, 2014) or they favor explanations with a narrow, latent scope (Khemlani et al., 2011).

In Artificial Intelligence, theories of understanding and explanation directly predict *minimalism* and show how the "expected unexpected" might arise (see Leake, 1991, 1992; Schank, 1986; Schank, Kass & Riesbeck, 1994). David Leake's (1992) computational account of understanding gives the most comprehensive account of what people might be doing when asked to "think of the unexpected" (see also Schank, 1986). Leake argues that people store *explanation patterns* to handle plan failures and anomalies encountered in everyday life. These explanation patterns can be thought of as "script-like" structures (Schank & Abelson, 1977), at varying degrees of abstraction, that can account for difficulties that arise in plans; for instance, in considering how a planned shopping-expedition might be disrupted, a number of standard disruption-events suggest themselves from pre-stored explanation patterns (e.g., that I might be mugged, or that I might lose my money or that I might be delayed). To handle a contingent world, it is proposed that we store these pre-canned explanations and retrieve them to quickly explain unexpected happenings[2]. Although these ideas have been referenced in the psychological literature (e.g., Hastie, 1984), they have not been worked up into a psychological model or specifically tested. Here, we propose an initial psychological account, that we then test this model in two experiments.

1.3 Minimal Retrieval Model

Our psychological account for the generating unexpected events is called the Minimal Retrieval Model (MRM). According to this model, when people are asked for unexpected outcomes to everyday scenarios, they retrieve explanation patterns and adapt them to the situation in hand. Specifically, that people build a *cue frame* using the given information in the scenario (e.g., the goals, actors, actions and objects mentioned) to search memory for suitable explanation patterns. For example, when people are told Louise had the goal of going shopping, took money from the ATM and then went to town, it is assumed that memory is searched for explanation patterns involving shopping-goals, female-shoppers, buses, money, and ATMs. Accordingly, unexpected events such as Louise losing her money, having problems with the ATM, or being delayed will tend to be found in memory and returned as responses, rather than more inventive answers.

Minimal Retrieval Model makes several predictions about the nature of the unexpected outcomes reported by people; specifically, it is predicted that (i) reported unexpected events should tend to use the stated object-concepts in the original

[2] Note, both Leake and Schank maintain that not all situations can be handled by these pre-canned explanation-patterns; explaining the unexpected may sometimes involve much more creative uses of prior knowledge, such as analogical explanations.

scenario because memory will be *cued* with these concepts and the retrieved explanation patterns will instantiate these objects, (ii) goal-related objects will be preferred in reported events, over non-goal objects, (iii) people will tend to agree on the reported unexpected events because they are using familiar plan-failures (i.e., explanation patterns). Note, the first two of these predictions basically propose that minimalism is a side-effect of the retrieval process and the third prediction basically says that answers will be expected-unexpected events rather than unexpected-unexpected ones.

Table 1: Louise-Shopping Story & Answer Categories

Sentence Order Used in Study 1 & 2 (Normal Condition)		
Goal	(S1)	Louise wants to shop at an expensive clothes store.
Non-Goal	(S2)	She is wearing her favourite dress and matching shoes.
Goal Step	(S3)	Louise draws money from the ATM.
Sentence Order Used in Study 2 (Reversed Condition)		
Goal	(S1)	Louise wants to shop at an expensive clothes store.
Goal Step	(S2)	Louise draws money from the ATM.
Non-Goal	(S3)	She is wearing her favourite dress and matching shoes.
Answer Categories for Unexpected Events		
ls_neg_ans1		She has insufficient money to buy
ls_neg_ans2		She has problems with the ATM
ls_neg_ans3		She is robbed or loses money/card/id.
ls_neg_ans4		Clothes issues (dress rips, shoe snaps).
ls_neg_ans5		The shop is closed.
ls_pos_ans1		She finds or ATM gives more money.
ls_pos_ans2		She has more money than she thought.
ls_pos_ans3		Good events involving shoes and dress.
ls_pos_ans4		Sale is on at the shop.
ls_other		e.g.; ATM speaks,gives money to charity.

Preference for Stated Object-Concepts. If memory is being searched with the stated goals and object-concepts given in the scenario then the explanation patterns retrieved should reflect these objects/entities and minimally introduce new objects (e.g., ones that mention *money*, *ATMs*, *buses*). This process thus delivers unexpected events that remain close to the original scenario, with perhaps better predictive value. In Quine's terms, the reported unexpected event will *minimally mutilate* the original scenario. In the present studies, we measure this minimalism by recording the frequency of stated objects versus new objects in the reported unexpected outcomes (excluding references to *Louise* who as the main actor will always tend to be mentioned).

Preference for Goal Objects. Within the preference for stated objects, MRM also predicts that goal-related objects will be preferred over less goal-related objects (which we will call *non-goal objects*). For example, if the scenario mentions that "Louise was wearing her favorite dress and matching shoes" (see Table 1), these objects *dress* and *shoes* are less goal-critical. People need *money* to go shopping but what they wear is less critical to the shopping goal [3]. Although, it is feasible to generate unexpected events from these non-goal objects (e.g., "when Louise got on the bus, everyone was wearing the same dress and shoes"), explanation patterns based on non-goal objects are less likely to be retrieved because they are not goal-critical. In the present studies, we check for this preference by recording the frequency of stated goals-objects versus non-goal objects in the reported unexpected outcomes (obviously, again, excluding references to *Louise* who as the main actor will tend to be mentioned anyway).

Agreement. By definition, explanation patterns are explanations for commonly-occurring disruptions to everyday plan-goal sequences; it makes more sense for the cognitive system to assume that disruptions that happened repeatedly in the past will happen again. As such, they should be familiar to people, they should be expected-unexpected events. Hence, there should be a high level of agreement between people in the unexpected outcomes they propose. This means that most answers should fall into a small set of common answer-categories; for instance, we should see many people using answers that describe "Louise losing her money" or "the shop being shut" (see Table 1). In the present studies, we test this prediction by classifying people's responses into answer-categories and recording the proportion of answers that fall into these categories. In the remainder of this paper, we report two experiments designed to test these predictions. To the best of our knowledge, these tests are new, as are the measures used to assess what people report as the unexpected.

2. Study 1: How Unexpected?

The study presented participants with scenarios describing everyday events such as going shopping, doing exams, going on trips and attending business meetings (adapted from Foster & Keane, 2015). Each story was followed by an instruction to think of the unexpected. The unexpected outcomes reported for each scenario were categorized by three judges in terms of object-concepts (i.e., *goal-objects*, *non-goal-objects*, *both* goal- and non-goal-objects and *neither* of the stated objects) and answer-categories used.

[3] Though, obviously, it could be made goal-critical with additional conditions (e.g., if one said "she wanted to be able to match the clothes she was wearing with those in the shop").

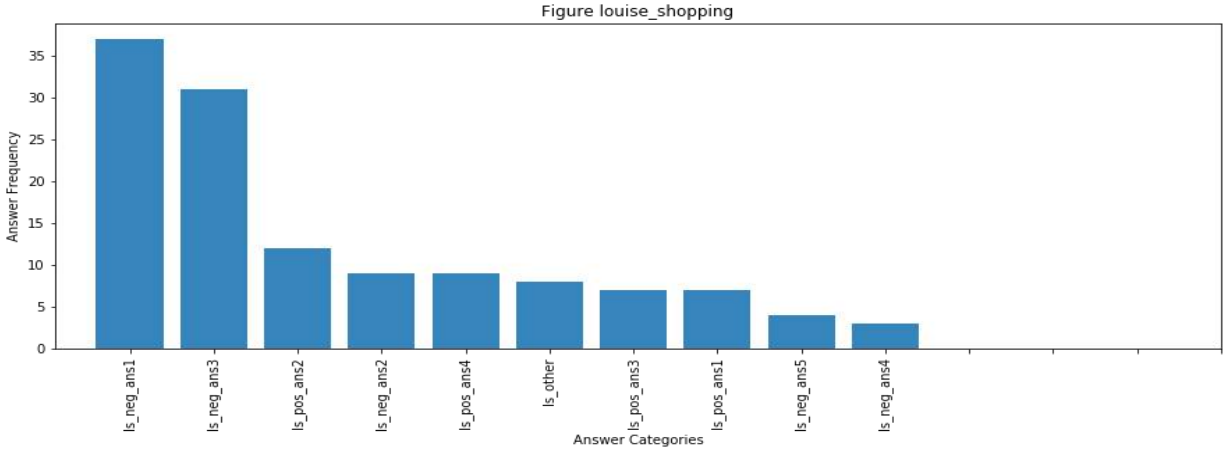

Fig 1. Frequencies for Answer Categories in Louise Story (see Table 1 for Meaning of Answer Code)

2.1 Method

Participants & Design. The study involved 127 participants and was run on the crowdsourcing platform, prolific.com[4]. Participants were native English speakers from Ireland/UK/USA and had not participated in previous studies by the group.

Procedure & Materials. All participants received the same 20 scenarios (randomly re-ordered for each participant), after first being shown two practice materials (these items were not flagged as practice items and not included in the analysis). Participants were presented with a series of web pages, explaining the task and then presented with one scenario after the other, each on its own page. Each material was presented along with the associated instruction to think of unexpected outcomes to the scenario (material lists available on request).

Each scenario was described in three sentences: a setting goal-sentence (S1; Louise going shopping), one giving additional information that was not on the critical path of the plan for the goal (S2; Louise wearing her favourite dress and shoes) and a final one describing some further action taken to achieve the goal (S3: Louise drawing money, see Table 1). Two comprehension questions were asked about the scenario, as a test micro-task, to ensure participants had carefully read and understood the scenario. The instruction to think of the unexpected followed these questions. Participants wrote their responses in a text-field with no upper limit.

Measures & Judgements. In total the study yielded 2,540 responses (127 participants x 20 materials) each of which were judged by three raters (i.e., the three authors) for answer-type and the use of goal-related and non-goal-related objects (the main actor of the scenario was always excluded from this object judgement). Every response was categorized into answer categories specific to the material (e.g., in Louise scenario, answers about losing money, being delayed, the shop being shut). The classification of answers by the three judges revealed high levels of agreement: pairwise comparisons between judgements revealed Cohen's Kappas from K=0.82 to K=0.89. The classification of objects in the answers (as goal, non-goal, both, neither stated object) by the three judges had lower, but acceptable, levels of agreement. Agreement between Judge-1 and Judge-3 was lower (K=0.56) as object classifications were re-defined more tightly for Judge-2 and 3, who agreed more often (K=0.74). The final classifications chosen for all judgements was based on a majority vote from the three judges. Three-way splits (which were rare, N<20) were resolved by discussion.

2.2 Results & Discussion

Overall, the results confirm the predictions made from the Minimal Retrieval Model; the unexpected is really not that unexpected. People tend to (i) stick to the stated objects in the scenario rather than use new objects, (ii) they show a strong preference for given goal-objects over non-goal objects, (iii) they agree on the unexpected events reported, as a few answer-categories cover most responses made.

Preference for Stated Objects. As predicted, people tend to stick to the object-concepts given in the scenario (e.g., the *money*, *buses*, *shoes* of the Louise story), rather than introducing new objects into their answers. Of the 2,540 unexpected outcomes reported by participants, 78% (N=1891) relied on the given objects, while only 22% (N = 649) of answers mentioned none of the stated objects (i.e., "Louise met her best *friend*"). Most unexpected outcomes assert a new relation between the given objects (e.g., "The *ATM* showed *Louise* had more *money"*).

Preference for Goal over Non-Goal Objects. Furthermore, of the 78% (N=1,891) of unexpected outcomes that used the given objects from the scenario, the majority used only goal-objects (80%; N=1,518) with a minority using the non-goal

[4] The original experiment was divided into four conditions that used variants on the main instruction: asking for "something unexpected", "something good and unexpected", "something bad and unexpected", or "what would happen if the goal failed". For brevity, this manipulation is not reported here, as the same pattern of responding is seen across all these four conditions.

objects (14%; N=261) and a few using both stated object-types (6%; N=112). Chi^2 tests performed on frequencies of the four object-types (df=3) for each material were all statistically significant at $p < 0.01$. Also, a by-materials analysis, using Wilcoxen's test, revealed a statistically significant difference in the proportions of goal versus non-goal objects chosen, $z = 3.00$, $p < .001$.

Of course, one could argue that this result is not surprising, as two sentences mentioned goal-objects (S1 and S3) and only one mentions non-goal objects (S2, see e.g. Table 1)[5]. However, even if examine goal and non-goal object choices at the sentence level, the preference for goal-objects remains: on average, goal-objects are chosen from S1 (M=27%) and S3 (M=44%) more often than the non-goal-objects from S2 (M=13%; see Table 2). Chi^2 tests performed on 40 pairwise comparisons of choices, for S1xS2 and S2xS3, found that only 5 comparisons were non-significant (most are $p < .001$). However, it is clear that there is a preference for goal-objects from the final sentence in the scenario (S3 at 44%), suggesting a recency effect, that we explore in Study 2.

Thus far, the evidence suggests that people respond in a minimalist way, sticking close to the original scenario's objects, with a strong preference for stated goal-related objects over stated non-goal objects.

Agreement in Answer Categories. Apart from analysing the object-concepts used in the unexpected outcome, we also categorised responses and noted their frequency of occurrence (e.g. see Table 2 and Fig.1). On average, materials were found to involve 10 answer categories (M=10.68, SD=1.7); Min=6 (*lucy_loan*) and a Max=13 (*robert_essay*; see Table 2). Figure 1 shows a typical distribution of responses across answer-categories for the Louise story; note, the top-3 most-frequently-used answer-categories of 10 categories tend to cover most responses (63%) followed by a long tail of lower-frequencies for other categories. Note, one answer-category was used as a residual one (the *other* category), and it typically also has a low count.

Table 2 shows the percentage of responses that fall into the top-3 most-used answer-categories for each material. In the most extreme case, *lucy_loan*, 89% of responses are covered by the top-3 answer-categories, with the lowest being 49% (for *bill_holiday*). This pattern of responding shows that there are very high levels of agreement between people with respect to the unexpected events they propose. For example, in the *louise_shopping* scenario, 29% of people proposed that Louise had money problems such as spending too much or not having enough money for the clothes (*ls_neg_ans1*), 25% proposed that she lost her money in some way (*ls_neg_ans3)* and 9% said that the ATM told her she had more money than she thought (*ls_pos_ans2).* None of these unexpected events are particularly "unexpected"; they are rather, typical disruptions that occur in everyday plans to achieve mundane goals. They are *expected unexpected* events. Indeed, more inventive answers -- the *unexpected unexpected* -- are quite rare and typically found in the *other* category. For instance, in the Louise story, the *other* category (*ls_other, N=8*) includes responses about (i) Louise deciding to give her money to a charity instead, (ii) Louise being approached by a film director who says she is beautiful and wants to make her a star and, (iii) the wonderful "The ATM opens, and Louise realizes it is a portal to her happiest childhood memory". These sorts of answers are the *unexpected unexpected*, truly unusual possible outcomes but, notably, are rare too.

3. Study 2: The Recently Unexpected?

Study 1 supports the minimalist predictions that people will stick closely to the original scenario, introduce few "new" objects and agree with others when proposing unexpected events for everyday scenarios. However, with respect to the object-concept analyses, the preference for goal-objects (especially, objects from the final sentence, S3) and lack-of-preference for non-goal objects could be due, in part, to a recency effect. That is, maybe people follow on from the last sentence in the story and, hence, use its goal-objects. For example, in the Louise story people do not mention her *shoes* and *dress* (the non-goal objects from S2) but rather follow on from the mention of *ATMs* and *money* (from S3) in proposing their unexpected outcome. If this were true then people's object-choices perhaps hinge less on their goal or non-goal status but more on order of mention. In this study, we put the non-goal sentence last (S3) to check if this changes the object-choices made (see Table 1 for a sample material).

3.1 Method

Participants and Design. The study involved 258 participants on the prolific.com crowdsourcing platform[5,6]. All were native English speakers from Ireland/UK/USA and had not taken part in our previous studies.

Procedure & Materials. All participants received the 20 scenarios used in Study 1, using the same procedure. There were two main conditions of interest: Normal (N = 126) and Reversed conditions (N = 132). Participants in the Normal condition received the same materials as those used in Study 1. Participants in the Reversed condition received variants of these materials, in which the non-goal sentence was moved to the last position in the story (S3; see example in Table 1).

Measures & Judgements. In total the study yielded 5,160 responses (258 participants x 20 materials). Given the very large number of responses in this experiment, we automated the object-judgement process (program and data will be made available on email request). A program, called ObjJudge was developed using the NLTK, Pandas and SciPy python packages to process the answers and identify whether

[5] Also, note the sentences themselves in the original scenarios mentioned equivalent numbers of objects (by-materials, paired t-tests on the object counts in S1, S2 and S3 revealed no differences, all ps > 0.10).

[6] The original experiment had 6 conditions that used (i) the three instructional variants used in Study 1 ("unexpected", "good and unexpected", "bad and unexpected"), crossed with (ii) a variant to think of "bizarre" events. Initial, analyses suggested that these variables do not impact the pattern of responding for object choices and, for brevity, are not reported here.

they mentioned goal-objects, non-goal-objects, both object-types or neither. The program was trained on responses and their respective judgments from Study 1. Using lists of the object-entities (i.e.; object words given in the scenarios and synonyms provided in responses from Study 1), ObjJudge sorts the responses given in Study 2 into goal-object, non-goal object, both, or neither categories.

Stated simply, this program matches object-entities in the response-string against object-lists for each material (including common synonyms that people used in Study 1 answers). With this program, we achieved a high accuracy over all materials comparing its object-judgements against the human-judgments from Study 1 (M=93%; Min=90%, Max = 97%; Cohen's Kappa was K=1). In all other respects, the object-judgement measures were as detailed in Study 1.

3.2 Results & Discussion

The results replicate the findings of Study 1 that people (i) stick to the stated objects in the scenario rather than using new objects, (ii) they show a strong preference for the given goal-objects over non-goal objects. However, it also shows that here is a slight recency effect, in the Reversed condition, where the choice of non-goal objects increased by about 9% relative to the Normal condition.

Preference for Stated Objects. As we saw in Study 1, people tend to stick to the object-concepts given in the scenario (e.g., the *money*, *shoes* of the Louise story), rather than introducing new objects into their answers (e.g., *guns, suds*). Of the 5,160 unexpected outcomes reported by participants, 79% (N=4,098) made use of objects stated in the scenario, while only 21% (N = 1,062) of answers mentioned none of the given objects Most of the unexpected outcomes reported created a new relation between the given objects (e.g., "The *ATM* showed *Louise* had more *money"*).

Preference for Goal over Non-Goal Objects. In a similar vein, of the 4,098 (79% of 5,160) unexpected outcomes that used objects from the original scenario, the majority mentioned only goal-objects (56%; N=2,869) whereas a minority mentioned only non-goal objects (13%; N=688), with some responses mentioning both goal and non-goal objects (10%; N=541). Chi^2 tests performed on frequencies of object-types reported for each material were all significant at $p < 0.05$ (df=3, with corrections for low-valued cells).

However, these analyses collapse across the Normal-Reversed manipulation designed to test for recency. When these conditions are broken out there is a small but statistically-significant increase in the use of the non-goal objects (roughly 9%, with a corresponding reduction in goal-object choices). The following are the relative percentages, for each choice category, $Chi^2(3) = 76.9$, $p < 0.001$:

Cond.	*Goal*	*Non-Goal*	*Both*	*Neither*
Normal	61%	10%	9%	20%
Reversed	51%	16%	12%	21%

In short, when the sentence with the non-goal objects is last in the story, people prefer to use the non-goal objects somewhat more often; showing that they are sensitive, to some degree, to the order in which information is given, though the dominance of goal-object choice still remains.

4. Conclusions

To the best of our knowledge, the current study is the only one simply asking people to "think of the unexpected" when presented with everyday scenarios. Our view is that when people are asked to do this, they tend to recall characteristic explanation patterns that account for common disruptions to everyday plans and goals (e.g., losing a resource, being delayed in executing a plan step). Accordingly, people report unexpected events are not really that unexpected; the *expected unexpected*. This work shows that these are a class of unexpected events -- things that commonly go wrong – that are to be distinguished from "truly unexpected" events (as Foster & Keane, 2015, found for surprising events). These findings should prompt a re-assessment of what we mean by the "unexpected" as a dependent variable in exploring aspects of human thought. It also raises the interesting prospect, that there is a lot more to be discovered about what people conceive the unexpected to be.

Children's Sentential Complement Use Leads the Theory of Mind Development Period: Evidence from the CHILDES Corpus

Abstract

Converging evidence suggests that children's linguistic and theory of mind (ToM) development are linked. Specifically, learning the sentential complement grammatical structure has been shown to play a causal role in the development of some false belief reasoning skills. Here, we extend this line of work to examine this relationship in the wild by means of a corpus analysis of children's speech during the typical period of ToM development. We show that children's use of the sentential complement grammatical structure increases immediately preceding the ToM development period and plateaus shortly thereafter. Furthermore, we find that parents' child-directed speech follows a similar pattern.

Keywords: theory of mind; corpus analysis; sentential complement

Introduction

Most researchers agree that humans' ability to reason about mental states, or their theory of mind (ToM), develops throughout early childhood, with the biggest increases seen during the preschool years, roughly age 3 to 5 (Wellman & Liu, 2004). Other developmental milestones during this time period, such as working memory capacity (Davis & Pratt, 1995), executive control (Perner & Lang, 1999), and language development (de Villiers & Pyers, 1997), have been linked as leading to the apparent improved ToM reasoning ability, either causally or as a side effect. Of these, perhaps the most studied is the role that children's developing language comprehension and production skills play in the development of their ToM (see Milligan, Astington & Dack, 2007).

While some researchers argue that improved language skills merely allow children to express previously-existing ToM concepts (e.g., He, Bolz, & Baillargeon, 2011), it is widely accepted that some interaction between language abilities and performance on ToM tasks exists. In fact, converging evidence suggests that the connection is causal: learning certain linguistic constructions, specifically the sentential complement, is instrumental in children becoming able to perform aspects of ToM reasoning that they were previously unable to perform (de Villiers & Pyers, 1997).

This evidence has taken multiple forms, including (1) a longitudinal study correlating sentential complement use with ToM reasoning ability (de Villiers & Pyers, 2002), (2) training studies that showed children who were trained on sentential complements improved performance on ToM tasks (Lohmann & Tomasello, 2003; Hale & Tager-Flusberg, 2003; Mo et al., 2014), and (3) a computational model of the mechanisms by which children learn ToM from sentential complements (Rabkina, McFate & Forbus, 2018).

Taken together, these studies provide evidence that understanding the sentential complement construction supports ToM development. If this is true, then children's understanding of the sentential complement should precede their ability to pass ToM tests. At a population level, this means that children's use of the sentential complement should begin to increase prior to the ToM development period and plateau by the end. However, prior research has focused on the relationship between children's ToM development and their sentential complement proficiency in a laboratory setting.

Here, we perform a corpus analysis of children's conversational speech (CHILDES; MacWhinney, 2000) to show that the hypothesized pattern exists in the wild. We find that the expected pattern emerges: children's sentential complement use begins just prior to 2 years of age and plateaus around 3 years—just as the ToM development period begins. Furthermore, child-directed speech follows a similar trajectory during the same time period; that is, parents increase their sentential complement use in tandem with their children. These findings support the argument that learning the sentential complement grammatical construction plays an important role in developing ToM reasoning abilities.

We begin with a review of prior work linking ToM development and sentential complement use. We then describe our approach to the corpus analysis and present our findings. We conclude by situating these findings in the context of prior work and outlining steps for future investigation.

Background

A sentence contains a sentential complement if a verb in that sentence takes a full clause as its argument. For example, in the sentence, "Sarah thought the Earth was flat," the clause "the Earth was flat" is an argument to the verb "thought." Crucially, the truth value of the clause is independent of the truth value of the sentence as a whole—the Earth not being flat does not change the fact that Sarah thought it was. De Villiers and colleagues (e.g. de Villiers & Pyers, 1997; de Villiers & de Villiers, 2003) have argued that learning the sentential complement, and the potential

difference in implied truth values between the statement and the embedded clause, is key to ToM development.

Converging evidence supports such a conclusion. In a longitudinal study, de Villiers & Pyers (2002) found a strong correlation between children's performance on a task that measured understanding of sentential complements and their performance on three classic ToM tasks. A hierarchical regression analysis further showed that performance on the understanding of complements task accounted for a significant amount of variance in the ToM tasks, regardless of the order in which variables were presented in the regression. Importantly, this finding was not bidirectional—ToM performance did not predict performance on the sentential complements task.

Intervention studies suggest that the relationship found by de Villiers and Pyers (2002) is causal. Lohmann and Tomasello (2003), Hale and Tager-Flusberg (2003), and Mo et al. (2014) found that sentential complement training leads to improved performance on ToM post-tests in children who failed both sentential complements and ToM pre-tests. Furthermore, Hale and Tager-Flusberg (2003) found that ToM training did not affect performance on sentential complements post-tests, which provides additional evidence that the effect is causal and unidirectional.

Rabkina et al. (2018) proposed a process-level computational model of the effect of sentential complement training on ToM understanding. They argued that, in learning to interpret the sentential complement grammatical structure, children learned a representation that allowed them to separate the truth value of beliefs from reality, analogously to separating the truth value of the sentential complement and the overall statement.

The combination of these studies tells a compelling story of the relationship between ToM development and the sentential complement. However, while the connection has been shown in the laboratory, the story may be different in an everyday setting. Previous work (Koder, 2016) has looked at the developmental trajectory of verbs for reported speech as they appear in children's natural language production in Dutch and German. Others (Gordon & Nair, 2004) have examined more general language use during the ToM development period via corpus analysis. However, to the best of our knowledge, no previous work has addressed the question of sentential complement use in naturally occurring speech.

Here, we perform a corpus analysis of child-directed and child-produced sentential complement use during and immediately preceding the ToM development period. Our results provide further evidence of a link between learning the sentential complement grammatical structure and ToM development.

Approach

If learning the sentential complement grammatical structure bootstraps the development of ToM reasoning skills, then this pattern should hold outside of the laboratory. That is, children's use of the sentential complement in everyday speech should anticipate the developmental trajectory of ToM. Because significant improvements in children's ToM occur between approximately 3 and 5 years of age (Wellman & Liu, 2004), we expect sentential complement use to reach a critical threshold immediately preceding this age range.

To test whether this relationship holds, we performed a corpus analysis of children's use of the sentential complement between 12 and 90 months of age. We also analyzed sentential complement use in child-directed speech (produced by mothers) during the same timeframe.

All data were extracted from the CHILDES project (MacWhinney, 2000), which contains over 130 corpora of child-directed and child-produced speech. A corpus was included in our analysis if it contained speech by a typically developing North American English-speaking child between the ages of 12 months and 90 months. For consistency, only corpora with an available transcript and dependency parse data (Sagae et al., 2007) were included in the analysis. This resulted in a total of 32 corpora, leading to 3982 individual data points[1].

Each corpus included one or more conversations between a child and one or more adults. All conversation transcripts provided the child's age in months and relationship to the adult interlocutor(s) (i.e., mother and/or experimenter).

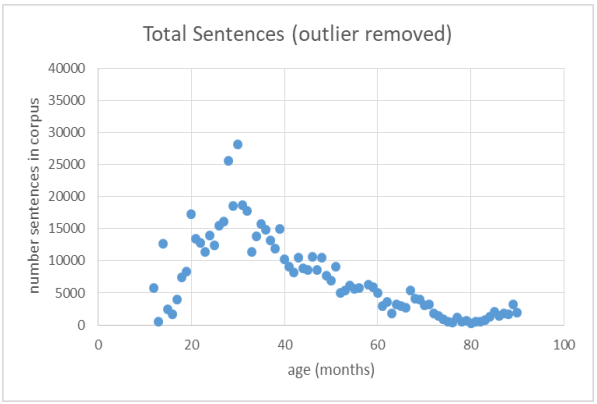
We extracted sentential complements from the children's speech using the "COMP" (finite verb complement) and "XCOMP" (other verb complement) dependency parse tags. Sagae et al. (2007) report overall parse accuracy for children's utterances between 72.7% and 92.3% on varying corpora within CHILDES. Table 1 shows reported precision, recall, and F-score for the "COMP" and "XCOMP" tags in the Eve corpus (Brown, 1973). Overall parse accuracy for the Eve corpus is 92.0%. Note that these analyses include both child and adult utterances.

Because a causal relationship between learning the sentential complement and developing ToM reasoning abilities has been proposed (e.g., de Villier & Pyers, 1997), we expected children's use of the sentential complement to lead their ToM development. To examine this effect, we computed the average number of sentential complements produced per sentence at each age in months. If learning the sentential complement bootstraps ToM reasoning, then children should show an increase in sentential complement use leading into the ToM development period. Moreover, the increase should be specific to this timeframe; that is, children should achieve sentential complement proficiency prior to finishing ToM development.

Table 1: Statistics for COMP and XCOMP tags (Sagae et al., 2007)

	Precision	*Recall*	*F-score*
COMP	0.83	0.86	0.84
XCOMP	0.86	0.87	0.87

[1] For longitudinal studies, a new data point was included for each recorded age in months.



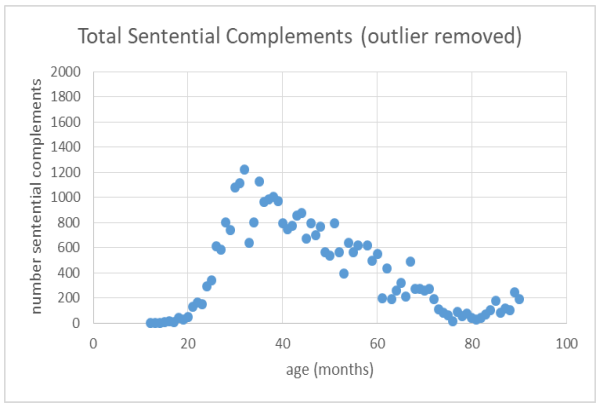


Figure 1: Counts for total sentences (left) and total sentential complements (right) in our corpus at each age in months. Note that one outlier (57 months) was removed from each graph.

Results

Our results indicate a concentrated growth period for children's sentential complement use that begins to plateau at the beginning of the ToM development period, suggesting a causal relationship between the two. Furthermore, this period of increasing sentential complement use coincides with a similar period found in parents' child-directed speech, which suggests a critical role for parents in children's acquisition of this grammatical structure.

Figure 1 shows the total number of sentences in our corpus of child-produced speech at each age in months along with the corresponding counts of sentential complement use. The corpus contains the most data in the range from 25 to 60 months. Note that this is an artifact of the data available and does not necessarily represent an increase in overall speech production during this age range.

Figure 2 shows children's sentential complement production as a proportion of overall sentences produced at a given age. The graph shows a linear increase from approximately 20 months to approximately 40 months of age, with a plateau beginning shortly thereafter. Once this baseline level of sentential complement production is reached, variance visibly increases. However, this variance is likely a byproduct of noise due to lower total sentence counts at later ages (Figure 1).

To determine the period of most concentrated sentential complement development, we isolated the interval with the strongest linear correlation between age and proportion of sentential complements (Figure 3, left). We fixed the starting point at 22 months, the first instance of appreciable sentential complement use (>1%). An endpoint of 38 months produced the strongest correlation, r^2=0.9217, p<0.001. Beginning at 39 months, the distribution plateaus with a slope of approximately 0 (Figure 3, right).

Child-directed adult-produced speech follows a similar pattern (Figure 4). Following a period of linear increase from child's age 12 months to 38 months (r^2=0.8603, p<0.001, Figure 5), sentential complement use peaks and begins to gradually decline. Notably, the absolute

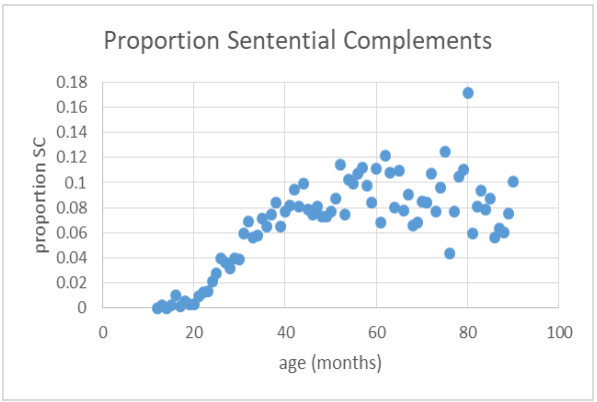

Figure 2: Average number of sentential complements per sentences produced by children at each age in months. No outliers were excluded.

proportion of sentential complements per sentence produced by adults is higher than the proportion produced by children at almost all ages.

As a potential contrast to the sentential complement, we also examined the use of another complex grammatical structure that has been argued to influence ToM acquisition, the relative clause (e.g., Smith, Apperly & White, 2003). However, we found negligible use of the relative clause in both child-produced and child-directed speech. This is consistent with a prior analysis of longitudinal data (Diessel & Tomasello, 2000) which found that children use the relative clause in less than 0.5% of utterances. Absent a direct increase in the use of another such structure in child-produced speech during this period, the sentential complement stands out as the best candidate for a syntactic aid to ToM development.

Discussion

As predicted, children reach a critical threshold of sentential complement use prior to entering the major period of ToM development, typically regarded as 3 to 5 years of age. By

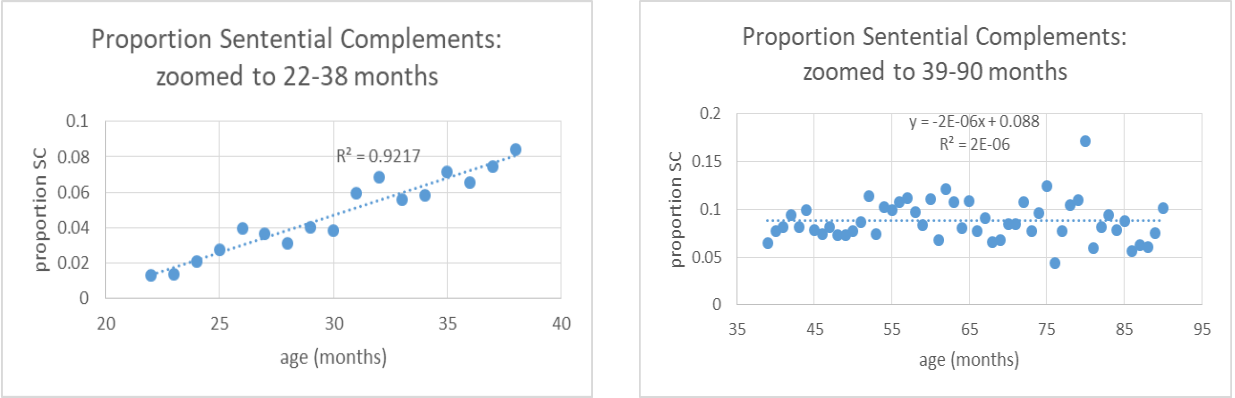

Figure 3: Proportion of sentential complement use by children at each age, zoomed to period of growth (left) and stabilization (right).

36 months children use sentential complements in an average of 6.5% of sentences (Figure 1). Their sentential complement use begins to plateau shortly thereafter, at 38 months and 8.4%.

It is important to note that both the ToM development period and the beginning of the observed plateau in sentential complement use are not hard boundaries. In fact, sentential complement use continues to increase after the onset of the plateau (between 39 and 58 months; r^2=0.3581, p=0.005; Figure 3, right), albeit at a much reduced rate. However, weak correlation and high variance make it difficult to draw firm conclusions about trends within the plateau.

What is clear is that the most concentrated growth occurs before children make significant strides in their ToM development. Previous work has shown that training children to understand the sentential complement leads to improved ToM reasoning skills in a laboratory setting (Lohmann & Tomasello, 2003; Hale & Tager-Flusberg, 2003; Mo et al., 2014). Our results suggest that the same effect occurs outside of the laboratory. Taken together, these findings support the hypothesis that mastery of basic sentential complement use sparks ToM development.

Another finding of note is that child-directed sentential complement use shows a similar pattern of increase to child-produced sentential complement use. Specifically, adult sentential complement use increases from 7.0% at child's 12 months to 16.0% at child's 38 months. This period subsumes the interval of greatest sentential complement development in children and gives way to a period of decline as children's use plateaus. Parents seem to adjust their sentential complement use according to the child's level of proficiency. Moreover, parents' sentential complement use seems to promote sentential complement production in children, as parents consistently overproduce compared to children at a given age.

Several explanations could account for the observed behavior. First, it is possible that parents mirror their children's speech patterns: as the child increases her sentential complement use, so does the parent. Under this hypothesis, other grammatical constructions should follow a similar trajectory. Alternatively, the causality could flow in

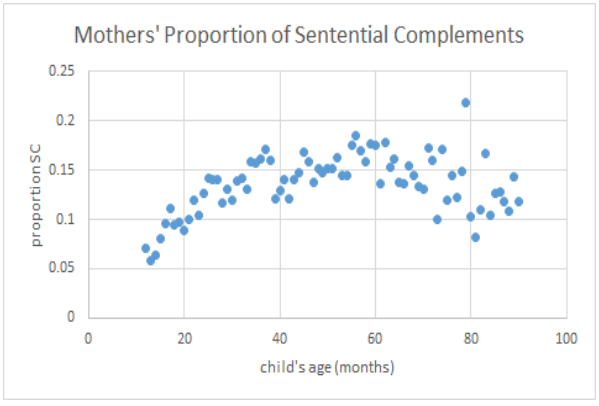

Figure 4: Average number of sentential complements per sentence produced by mothers at child's age in months. No outliers were excluded.

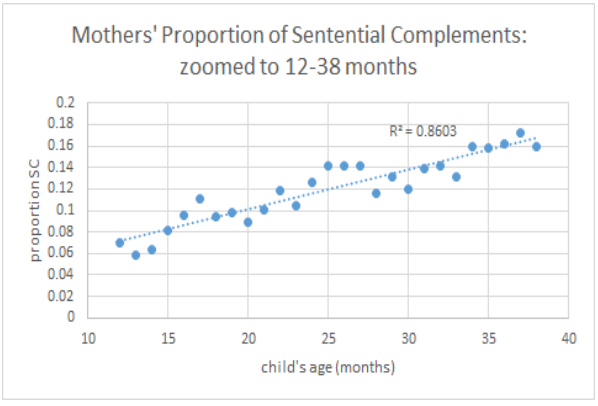

Figure 5: Average number of sentential complements per sentence produced by mothers at child's age in months, zoomed to period of increase.

the opposite direction, with children mirroring their parents. This explanation follows more directly from the present data, since the parents' sentential complement use precedes the children's, but it does not explain why the parents' use increases. Yet another explanation could be a mutual influence effect between children and their parents. As children begin to use the sentential complement, the parents increase their usage of the grammatical form, pacing their children's learning. Identifying the exact relationship at play will require data that can clarify the interaction between children's language use and their parents'.

Overall, our findings paint a picture of parental influence on children's sentential complement development, leading to children's acquisition of ToM. While the corpus analysis is not stand-alone proof of a relationship between sentential complement proficiency and ToM development, it is consistent with prior laboratory evidence of a causal link between the two. This is a step toward showing that such a link exists in the wild.

Limitations

One goal of this paper is to provide evidence in support of the hypothesis that sentential complement acquisition causally drives ToM development. While the evidence presented here supports such a relationship, it is not sufficient to establish causality for two reasons. First, as a correlational study, this can only point to likely interactions and cannot confirm their directionality or factor out potential confounds. Second, our analysis takes the ToM development period as a given and does not examine ToM effects directly.

These limitations mean that our findings cannot be used to draw broad conclusions about the interaction between language and cognition. The observed patterns could arise from effects that contradict the linguistic determinism hypothesis but are not accounted for in the available data. In particular, the lack of explicit ToM performance data means that any conclusions about ToM drawn from this dataset must be based on independently motivated developmental theories. For example, some researchers have found evidence that infants exhibit behaviors consistent with some understanding of ToM (e.g., Baillargeon, Scott & He, 2010). It is unclear how to reconcile such findings with the patterns observed here.

Another caveat to our findings is the potential for noise in the dependency parses we use. Though the analysis in Sagae et al. (2007) shows adequate performance of their parses on the CHILDES dataset (see Approach section for detailed overview), manual inspection showed instances where the dependency parse was inaccurate. It remains to be seen how the overall performance of the parser relates to the specific corpora used in our analysis.

Future Work

This paper considered the relationship between children's sentential complement use and their ToM development. However, evidence exists that a more granular view of the sentential complement might be appropriate. For example, Mo et al. (2014) found that, on ToM post-tests, children trained with sentential complements involving communication verbs outperformed children who were trained with mental state verbs. They note that this may be an artifact of the language used in the study, Mandarin, rather than a more general effect. On the other hand, Hale and Tager-Flusberg (2003) included only communication verbs in their training study of English-speaking children because of the potential confounding factor of the semantics carried by mental state verbs. A deeper analysis of the types of verbs used by children as they learn the sentential complement could shed some light on this question.

Because the effects of sentential complement training on ToM performance have been observed cross-linguistically, it is worth examining whether the patterns found in the present study are consistent across languages as well. Shatz et al. (2003) showed that 3- and 4-year-old speakers of languages with explicit false belief markings outperformed speakers of languages without such markings on some ToM tests. This suggests that other linguistic effects may be at play, and that the sentential complement may not be the sole way ToM is encoded in linguistic structure. For such languages, it is possible that the pattern of sentential complement use found in English may be less strong or entirely nonexistent.

Another question that merits further investigation is the nature of the plateau observed in Figure 2 and Figure 3 (right). A cursory analysis shows a period of continued increase from 39 months to 58 months before a period of mild decrease lasting through the end of the included data. The variance in the available data at this age range precludes a more concrete analysis, but the coincidence of the period of sustained increase in sentential complement use and the period of ToM development points to a tighter connection than can be shown at present.

Current data also does not fully illuminate the relationship between children's sentential complement use and that of their parents. It is curious that the adult-produced speech so closely parallels the patterns observed in children's speech. However, identifying the exact mechanism by which this arises would require paired data to more closely track changes in sentential complement use.

Finally, the questions raised in this paper tie into a broader debate about ToM acquisition as a whole. Although we provide evidence that is consistent with the hypothesis that sentential complement proficiency facilitates ToM development, strict causality has yet to be proven. Further research is required to fully explore this connection.

Abstract

When does a reasoner respond that "no valid conclusion" (NVC) follows in a syllogistic reasoning task? Cognitive theories aim to trace it back to theory specific inference processes. In contrast, systemic theories explain it by depleted cognitive resources among others. This paper investigates possible theories to explain NVC responses in an experiment with 139 participants. Using mixed models we analyze the association of NVC responses with reaction times, the validity as well as the entropy of a syllogism, and how NVC responses change over time. As expected, the number of NVC responses is lower than logically expected, participants respond NVC more often for invalid syllogisms, and the likelihood to respond NVC increases over the time-course of the experiment. Surprisingly, however, only for valid syllogisms, are the entropy and the RTs associated with NVC responses. Consequently, for invalid syllogisms, NVC responses seem to be generated differently as compared to valid ones.

Keywords: Reasoning; NVC; cognitive theories; logic; valid; invalid

Introduction

The psychology of reasoning investigates when and which conclusion is derived from given information. This includes the case when *no conclusion* can be drawn because the information is insufficient or it is too difficult to make an inference. The domain of syllogistic reasoning is probably the best researched domain with most published theories (for an overview see Khemlani & Johnson-Laird, 2012). A *syllogism* consists of two quantified statements. Each statement is formed using one of four quantifiers: All (A), Some (I), Some ... not (O), or None (E). Consider the following syllogistic reasoning problem:

(AA4) All beekeepers are architects.
All beekeepers are chemists.
What, if anything, follows?

The task is to generate a quantified answer using one of the quantifiers A, I, O, E about the two terms architects (A) and chemists (C, in any direction) or to conclude that no logically valid conclusion (*NVC* for short) can be made. Four different arrangements of the terms in the premises, called figures, are possible. The example above, for instance, is a type 4 figure (B-A, B-C). The four quantifiers for each of the two premises times four figures sum up to 64 possible syllogistic problems. Each syllogism can be encoded by a string, describing the quantifiers of the two premises as well as the relation of the used items in a figure. Hence, the syllogism above can be succinctly written as AA4. For the problem (AA4) most of the participants (49% in Khemlani & Johnson-Laird, 2012) infer that *All architects are chemists* and only 16% give one of the logical correct answer that *Some architects are chemists* or that *Some chemists are architects*. However, about 22% of the participants in the metaanalysis (Khemlani & Johnson-Laird, 2012) respond that NVC follows. A *logically valid* problem is one where by applying a logical calculus such as first-order logic allows to infer a conclusion (such as the syllogistic example AA4 above where *Some architects are beekeepers* is one). If this cannot be inferred then it is called *invalid* problem (and the only logical correct answer is NVC). Past research both from a statistical and from a modeling perspective has strongly focused on the case when an inference can be drawn (Oaksford & Chater, 2007; Johnson-Laird, 2006; Costa, Saldanha, Hölldobler, & Ragni, 2017) but less on the case when *no logically valid conclusion* can be inferred. Yet, it is exactly this response that stands out from the rest: Not only is the response NVC a *different class of response*, namely stating that no other conclusion follows, but it is the NVC response, that is the *most frequently observed response* in experiments (Khemlani & Johnson-Laird, 2012). In the current work, we aim to fill the gap of investigations on NVC responses by systematically investigating *when* people respond NVC. In particular, we compare different approaches to explain NVC responses by analyzing experimental data.

When is an NVC response given?

Syllogistic theories have been categorized as heuristic, rule-based, and model-based approaches (Khemlani & Johnson-Laird, 2012): Only few cognitive theories in syllogistic reasoning predict the NVC conclusion at all (e.g., Mental Model Theory, Verbal, Conversion). If a theory does so, it often implies that individuals give NVC as a last-resort, when the inference process yields nothing else (e.g., Mental Logic; Rips, 1994). Most of the heuristic theories do not predict NVC responses, with a rare exception in the case of Conversion and the probabilistic heuristic model (PHM, Oaksford & Chater, 2007, but see Copeland, 2006) that can be extended to predict NVC. The Atmosphere (Woodworth & Sells, 1935) and Matching (Wetherick & Gilhooly, 1995) theories derive only the quantifier in the response from the premise quantifiers. Hence, they do not consider and cannot explain NVC responses. This is remarkable as in the case of syllogisms there are 37 invalid problems (58% of all syllogisms) that would require from a normative logical perspective NVC as the correct response.

In sum, while there are at least twelve cognitive theories about syllogistic reasoning (Khemlani & Johnson-Laird, 2012), there is no explicit cognitive reasoning theory beyond explaining it by a search through the theory specific inference mechanism (e.g., by applying all inference rules or the generation of all models). Beyond explaining NVC by *cognitive reasoning theories*, *systemic theories* can provide alternative accounts emphasizing the role of behavioral response tendencies within experiments. Among others these systemic hypotheses include phenomena such as mental depletion (i.e., with each syllogism the cognitive resources are depleted (e.g., Schmeichel & Vohs, 2018) or cognitive load

*Both authors contributed equally to this manuscript.

(e.g., Sweller, 1994), which lead an individual to stop reasoning as soon as the problem becomes too difficult, or a general aversion to respond NVC (e.g., NVC is interpreted as "giving-up"). These hypotheses including their assumed, underlying cognitive processes are briefly summarized in Table 1. The aim of the current paper is to investigate such cognitive and systemic hypotheses in explaining why a NVC response is given. For the above-mentioned differences in the ability to predict NVC within heuristic theories, we focus on the MMT and mental logic theory in the current paper. Thereby, we aim to provide novel and much needed insights into when participants respond *no valid conclusion*.

Theories, predictions, and hypotheses

We have identified distinctive cognitive theories and systemic hypotheses that can explain when a reasoner responds NVC. In this section, we briefly outline these theories as well as hypotheses and draw implications on five observable patterns of NVC: first, the *response time* (RT) and the *frequency* of NVC response. Furthermore, we investigate the influence of valid and invalid syllogisms (*validity*) and the problem's entropy. The entropy measure (Shannon & Weaver, 1963) has been applied to measure the response diversity of each syllogism (Khemlani & Johnson-Laird, 2012). For each syllogism per study, the authors computed the probability with which each conclusion was drawn and aggregated the probabilities using Shannon's measure. The response diversity demonstrates an uncertainty of reasoners about which conclusion has to be drawn. Last, we analyze how the likelihood to respond NVC changes over the course of 64 syllogisms.

Theory of Mental Models (MMT). The MMT (e.g., Johnson-Laird, 2006) postulates a two-stage process based on the generation of an initial model and a flesh-out process that tests a putative conclusion formed on the initial model by a search for counter-examples (e.g., Bucciarelli & Johnson-Laird, 1999). If the flesh-out process does not yield a conclusion, the reasoner responds NVC. The latest implementation, mReasoner[1], contains a specific parameter that guides the generation of counter-examples. MMT makes the following predictions. *RT of NVC*: On average, the MMT predicts the NVC response at the end of the inference process, hence, responding NVC requires more cognitive steps and thus more time (especially, in the case of multiple model problems, i.e., problems that are invalid). *Frequency of NVC*: The inference process described before, however, can sometimes fail or be stopped early. As a result, not in all cases counter-examples are searched for and putative conclusions are drawn, even in cases where NVC hold. Consequently, less NVC responses are given as required by formal logic. *Entropy and NVC*: In indeterminate cases, the flesh-out process becomes relevant, hence, the more difficult a problem is or the more uncertainty it causes (measured by the entropy), the more NVC responses will be generated. *Time-course of NVC*: The more syllogisms are solved, participants enter more likely the flesh-out process (reasoners become more logical, as it has been recently modeled in mReasoner; Ragni, Riesterer, Khemlani, & Johnson-Laird, 2018). Consequently, participants are more likely to respond NVC for invalid syllogisms over time.

[1] https://mentalmodels.princeton.edu/models/mreasoner/

Theory of Mental Logic (ML). The theory of ML (Rips, 1994) is based on the application of first-order formal inference rules together with the inclusion of Gricean implicature to capture differences between a formal and an everyday language understanding of existential quantifiers. As it is based on formal logic rules, the conclusions are valid and no erroneous results will be predicted. The theory proposes that the erroneous responses generated by human reasoners are due to problems in the recognition, retrieval, or application of the formal rules (Rips, 1994). Following predictions can be derived: *RT of NVC*: ML predicts NVC, if the full application of the inference mechanism does not yield a conclusion. This takes longer than the application of some inference rule in the valid case. *Frequency of NVC*: An NVC response is found in the invalid cases and not in the valid cases. *Entropy and NVC*: A connection has not been reported and so we do not assume a predicted difference. *Time-course of NVC*: The mental logic does not assume a change across time.

Predictions of Mental Depletion. Theories of resource depletion (e.g., Schmeichel & Vohs, 2018) assume that mental activities such as reasoning can deplete cognitive resources. This results in an increase in NVC responses over time due to depletion. This increase appears for valid and invalid syllogisms - due to the depleted cognitive resources. A simple depletion model makes no distinction between logically valid and invalid problems. While combinations with cognitive theory can be thought of, we solely focus on the case where more NVC responses are given over time. Predictions: *RT of NVC*: No effect of NVC-responses on RTs is expected. Depletion processes may result in either generally higher or lower RTs over the course of an experiment, but regardless of an NVC response. *Frequency of NVC*: There are no concrete predictions. *Entropy and NVC*: Entropy has no implications on NVC, but instead generally enhance mental depletion. *Time-course of NVC*: Mental depletion is assumed to strengthen throughout an experiment. Thus, NVC responses should increase across the course of solving the 64 problems, respectively.

Predictions of Early Stoppers. Some syllogisms are more difficult than others and thus require additional cognitive resources. For some syllogisms, reasoners may stop the reasoning process early avoiding the mental effort required by analytic processes by responding NVC. While the application of heuristics would not result in an NVC answer, the early stopping process does (NVC as a last resort). Early stoppers do not necessarily make a distinction between valid and invalid problems as for both types problems with a high entropy exists. Following predictions are derived: *RT of NVC*: An early stopper does not need longer for an NVC response. *Frequency of NVC*: Both valid and invalid problems can be difficult to solve. Therefore, the early stopper hypothesis predicts generally more NVCs as there are logically correct NVC responses. *Entropy and NVC*: Higher entropy resembles a higher uncertainty with the problem at hand, which may lead to more NVC responses the higher the entropy. *Time-course of NVC*: The time-course has no effect.

Predictions of NVC aversion. Logically naive reasoners may interpret responding NVC as "giving up" (similar to the last-resort option as it is assumed in many theories). While participants may

even fear to be regarded as less intelligent or ignorant, they may (at least in the beginning) tend to avoid this answer. The following predictions can be made: *RT of NVC*: NVC aversion leads to higher RTs for NVC responses as the deliberation processes to exclude all other response is time-consuming. *Frequency of NVC*: As NVC is avoided, fewer NVC responses as there are logically correct ones are made. *Entropy and NVC*: It is unclear whether Entropy may have an effect. *Time-course of NVC*: The aversion for NVC may diminish over time due to exposition to invalid syllogisms or because the reasoner learns that some syllogisms do not have a valid response. Hence, NVC responses increase over time.

Hypotheses

The introduced theories and hypotheses differ on predictions for response times, frequency of NVC answers, entropy, and the time-course of NVC. Based on these predictions, we will derive five general hypotheses. The presented cognitive theories and hypotheses do explain an NVC response in one of two ways: by the application of the complete inference mechanism that does not yield any valid conclusion or by a model-based search that yields counter-examples to any putative valid conclusion. This implies, however, that more steps are necessary to infer that nothing follows than to infer that something follows. More cognitive steps, however, require more time. This leads to our first hypothesis: *Hypothesis 1: The RTs significantly increase in trials where a NVC response is given as compared to non-NVC trials.*

Cognitive reasoning theories assume that NVC is a response typically generated after the application of inference rules or through the search through all counter-examples. This process is not necessarily always entered resulting in the miss of NVC responses. Thus: *Hypothesis 2: The number of NVC responses is lower than the number of logically correct NVC responses.*

Since validity is a logical concept, cognitive theories that are closer to logic make a difference between them. Hence, we get as a corollary hypothesis: *Hypothesis 3: The number of NVC responses is lower in the case of valid problems than in the case of invalid problems.*

Moreover, if it is more likely for a reasoner to respond NVC, if there is greater uncertainty operationalized by entropy. *Hypothesis 4: The higher the entropy of a syllogism the higher the likelihood of an NVC response.*

A fifth hypothesis is that across an experiment participants may increasingly respond NVC, which can depend both on cognitive (e.g., MMT) and systemic hypotheses (e.g., mental depletion): *Hypothesis 5: There is an increase in NVC responses across solving more problems.*

The different predictions of the cognitive reasoning theories and systemic hypotheses are summarized in Table 1. In the next section we report experimental data and the analysis.

Table 1: The hypotheses and predictions of the cognitive theories and the systemic factors.

Theories	**Prediction**				
	RT H1	NVC H2	Validity H3	Entropy H4	Time H5
Mental Model	y	y	y	y	y
Mental Logic	y	n	y	n	n
Mental Depletion	n	?	n	n	y
Early Stopper	n	n	n	y	n
NVC aversive	y	y	n	?	y

Explanation of the abbreviation y = the theory predicts yes; ? = the theory does neither predict yes nor no; n = the theory predicts no.

Experiment

Method

The experiment tested 204 participants (125 female and 79 male) on Amazon's Mechanical Turk[2]. They received a nominal fee for their participation. Participants or trials were excluded based on the following criteria: First, in order to identify non-compliers, data from participants that are at or below guessing level were discarded. The cutoff point of 18.8% (n = 64) is calculated as the cumulative binomial probabilities of 1/9 (for 9 possible conclusions) for 64 correct responses. That results in twelve problems correct for the α-value of .05 according to the binomial distribution. Second, trials with exceptionally long response times (RT) were excluded from the analyses: RTs exceeding 10 minutes (n = 1) and RTs deviating more than 3 standard deviations (SDs) from the individual mean RT separated for valid vs invalid syllogisms (n = 147, 1.7% of remaining trials). Last, the first four trials of the experiment were excluded as the four first trials always consisted of the same syllogisms for practice purposes (n = 546). Thus, 139 participants and 8202 observations were included in the following analyses.

Each participant had to select a conclusion from all possible nine response options for all 64 syllogisms (selection task). The order of the problems was randomized for each participant, except that the problems, AA1, AI2, EA3 and IA4, were always presented first in a randomized order, so that participants can familiarize themselves with the experiment. In addition, four single-premise syllogisms (of the four different possible quantifiers) were used as practice trials. Participants received two assertions similar to problem AA4 above. Content was randomly assigned to all 64 syllogisms (thus, valid and invalid problems received the same content with similar premise lengths of the resulting premises). For each set they had to determine which eight possible conclusions logically follow from the assertions by pressing one of the eight keys: 1-4 (the respective quantifier with the conclusion direction A-C) and 7-0 (the respective quantifer with the conclusion direction C-A). If no logical conclusion could be found, participants had to press the space bar. There were eight presentation orders of the conclusion quantifiers to reduce the presentation order effect. Each participant received the same response option order throughout the whole experiment. They could take as much time as they needed, but responses within a second were prohibited.

[2] https://www.mturk.com

Results

The overall percentage of logically correct responses per participant was 38.7% (*SD* = 19.0%), for the 27 syllogisms with valid conclusion(s) 42.1% (*SD* = 15.3%) and for the 37 syllogisms without a valid conclusion (NVC syllogisms) 36.5% (*SD* = 27.1%). On average, for valid syllogisms, participants gave 16.9% NVC responses (*SD* = 16.6%) and 36.5% (*SD* = 27.1%) for invalid syllogisms.

Analysis. Participants' frequency of NVC-responses differed between individuals (*M* = 29.0%, *SD* = 21.4%). In fact, there were a few participants that did not give any ($n = 8$) or less than 10 ($n = 48$) NVC responses. In the following analyses we used (generalized) linear mixed models (short (G)LMM; for an overview see Baayen, Davidson, & Bates, 2008; Judd, Westfall, & Kenny, 2012) as they can handle incomplete and unbalanced data and can account for the multi-level structure of the designs (e.g., multiple measures per participant). GLMMs were analyzed using the lme4 package (Bates, Mächler, Bolker, & Walker, 2015, Version 1.1.19) in the R environment. Models were fit via maximum likelihood (ML). Effect coding was used for all dichotomous fixed effects. Denominator degrees of freedom and *p*-values were estimated via Satterthwaite corrections implemented via lmerTest (Kuznetsova, Brockhoff, & Christensen, 2017, Version 3.0.1). Furthermore, the significance of fixed effect on the model fit was obtained by step-wise removing a fixed effect from the full model and testing whether the exclusion of the variable resulted in a significant loss of the goodness of fit as indicated by likelihood ratio tests and by comparing the Bayesian information criterion (BIC) and the Akaike information criterion (AIC). The reported tables (Table 2 and 3) show the results for the best models.

The analysis of reaction times. For the analysis of RTs, there is currently a debate about whether or not dependent variables should be transformed (Lo & Andrews, 2015). It has been suggested to use GLMMs on the raw RTs to analyze non-normal data that involve random effects (Lo & Andrews, 2015). Here, were use Inverse Gaussian distributions to account for the distinct positive skewed distribution of the continuous, raw RTs (for an overview of this approach, see Lo & Andrews, 2015). However, this approach resulted in a significantly worse fit ($\chi^2 = 156020$, $p < .001$) than the standard logarithmic approach using LMMs (where RTs were logarithmically transformed prior to analyses). As we report only the best-fit models, we therefore only display the LMMs on the logarithmically transformed RTs. However, results were similar both in the transformed and the untransformed analysis. The RTs were analyzed using LMMs with the factors *validity* (invalid = -1 vs. valid = 1), the *"NVC"* response (No NVC = -1, NVC = 1), and the corresponding interaction as fixed factors (1). We implemented the maximal random-effects structure justified by the design (as suggested by Barr, Levy, Scheepers, & Tily, 2013): Participants (including by-participant random slopes for Validity, NVC, and their interaction) and the different syllogism problems were treated as a random factors (2). The trial *"sequence"* (4-64) was added as covariate since it correlated with the NVC response capturing effects due to fatigue or learning (1). All continuous predictor variables were centered and scaled. The full model was specified as follows:

$$log(RT) = NVC * Validity + Sequence \quad (1)$$
$$+ (NVC * Validity | Participant) + (1 | Syllogism) \quad (2)$$

The results of the best-fit model can be taken from Table 2.

Table 2: Fixed-Effect Parameter Statistics for the full/ best-fit Reaction Time model.

Predictors	Estimates	*SE*	*t*	*p*
Intercept	9.43	0.05	176.76	$< .001$
NVC (yes = 1)	-0.02	0.02	-1.12	*.270*
Validity(valid = 1)	0.06	0.02	3.51	*.001*
Sequence	-0.13	0.01	-22.30	$< .001$
NVC:Validity	0.05	0.01	4.80	$< .001$

Hypothesis 1: Other than expected, there was no main effect of NVC on the RT as the RTs did not significantly increase in trials where a NVC response was given as compared to non-NVC trials. However, there was a significant interaction between NVC responses and the validity of the syllogism: the RTs were significantly associated with the occurrence of a NVC responses for valid syllogisms. In trials with NVC responses, the RT increased, but only for valid syllogisms. Any reduction of a parameter (e.g., of the interaction) resulted in a significantly worse model fit as compared to the full model reported. The interaction was also apparent in the mean RTs: For valid syllogisms, the RTs were higher for NVC responses (*M* = 20.17, *SD* = 17.37) as compared to other conclusions (*M* = 16.55, *SD* = 7.64). However, there was no difference for invalid syllogisms (NVC: *M* = 16.42, *SD* = 11.26, Other conclusions: *M* = 16.56, *SD* = 8.30).

The analysis of the likelihood to give a NVC responses. The occurrence of NVC-responses as a bivariate dependent variable was analyzed using GLMMs (NVC response = 1, no NVC response = 0). GLMM estimates were computed with a logit link, binomially distributed residuals using the bobyqa optimizer with 200 000 iterations. Odds ratios (ORs) of the fixed effects coefficients of the full model are reported as effect sizes.

The occurrence of a NVC response was analyzed with the factors Validity (invalid = -1 vs. valid = 1), the Entropy of each syllogism (using the entropy measures computed by Khemlani & Johnson-Laird, 2012), as well as the corresponding interaction and the trial sequence (4-64) as fixed factors (3). We again implemented the maximal random-effects structure justified by the design: Participants (including by-participant random slopes for the factors Validity, NVC, and their interaction) and the syllogism problems (random intercept) were treated as a random factors (4). The entropy variable was centered prior to analysis. The full model of was specified as follows:

$$NVC = Validity * Entropy + Sequence \quad (3)$$
$$+ (Validity * Entropy | Participant) + (1 | Syllogism) \quad (4)$$

Table 3: Fixed-Effect Parameter Statistics for the best-fit NVC model.

Predictors	Estimates	*SE*	*z*	*OR*	*p*
Intercept	1.77	0.19	-9.23	0.17	$<.001$
Validity$_{(valid = 1)}$	-0.77	0.15	-5.20	0.46	$<.001$
Entropy	0.41	0.35	1.15	1.5	*.249*
Sequence	0.18	0.03	5.62	1.19	$<.001$
Validity:Entropy	1.08	0.35	3.05	2.94	$=.002$

Note. OR indicates Odds Ratios.

The results of the best-fit model can be taken from Table 3.

Hypothesis 2. In 53% of the syllogisms a NVC response is the logically conclusion. As hypothesized, in the current experiment, participants gave 28.99% NVC responses (SD = 21.40%) on average which is significantly less than 58% ($V = 382$, $p < .001$; a paired Wilcoxon signed tank test was used due to a deviation from normality). Thus, we can confirm that the number of NVC responses was lower than the number of logically correct invalid syllogisms.

Hypothesis 3. As hypothesized, the occurrence of a NVC response was significantly associated with the validity of the syllogism. NVC responses were more likely to occur for invalid than for valid syllogisms. Excluding this factor from the full model resulted in a significant reduction of the overall fit ($\chi^2 = 189.56$, $p < .001$).

Hypothesis 4. We expected that the higher the entropy of a syllogism was the higher the likelihood of a NVC response would be. Other than hypothesized, there was no significant main effect for entropy on the likelihood to give a NVC response. However, there was a significant interaction between validity and entropy (see Figure 1 for an illustration): Entropy impacted the likelihood to respond NVC, but only for valid syllogisms. Excluding this interaction as well as the entropy factor from the full model resulted in a significant reduction of the overall fit ($\chi^2 = 57.07$, $p < .001$). A post-hoc analysis for the number of NVC responses and entropy also revealed a strong association between entropy and the relative frequency of NVC responses for each syllogisms for valid ($r_\rho = .69$, $p < .001$) but not for invalid syllogisms ($r_\rho = -.27$, $p = .112$).

Hypothesis 5. The effect of the trial sequence on the relative frequency of NVC responses separated for valid and invalid syllogisms is illustrated in Figure 2. The plot highlights that NVC responses do not stay constant over the time-course of the experiment. As expected, there was also a significant main effect of the sequence on the likelihood to give a NVC response in the mixed model (see 3). Excluding the sequence factor from the full model resulted in a significant reduction of the overall fit ($\chi^2 = 30.63$, $p < .001$). Since NVC is a logically sound conclusion only for invalid syllogisms, a simultaneous increase for invalid and decrease for valid syllogisms would indicate a trend towards a support for the theory that reasoners become more logical in the experiment. However, the increase in NVC response probability does not differentiate between valid and invalid syllogisms.

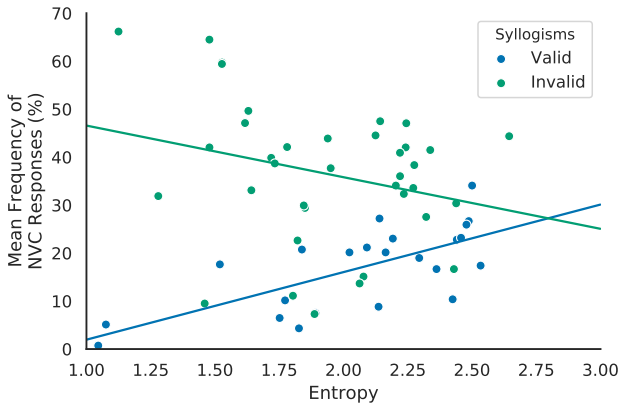

Figure 1: The relationship between the frequency of NVC responses and entropy. Linear regression lines are plotted separately for valid and invalid syllogisms.

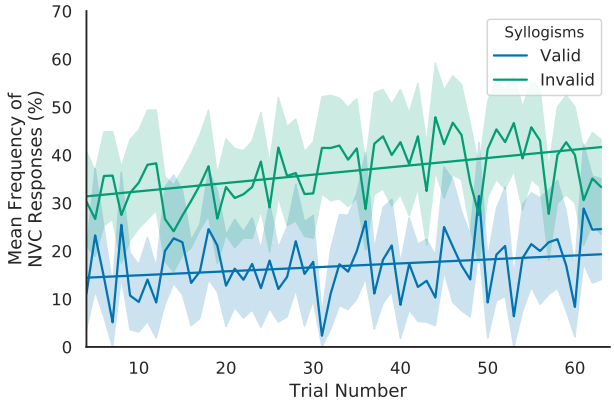

Figure 2: Mean number of NVC responses on valid and invalid syllogisms for the experimental sequence of 64 syllogisms.

An upwards trend can be observed for both. Furthermore, in follow-up analyses the inclusion of an interaction effect for the sequence and the validity of a syllogisms did not result in a fit improvement to the reported best-fit model $\chi^2 = 0.65$, $p = .420$.

Discussion

On which factors does the likelihood to respond NVC depend and how are NVC responses associated with differences in RTs? First, the RTs seem to increase in NVC trials as compared to trials where another conclusion was given - but only (and other than expected) for valid syllogisms. There are various explanations why RTs did not increase for NVC responses in invalid syllogisms. For instance, NVC responses are the "logical" correct response option for invalid syllogisms. Thus, on average, NVC responses for these problems could occur for both logical reasoning and as a consequence of other processes (e.g., guessing, giving-up, etc.). As a consequence, responding NVC may not only be a "last resort" after elaborate reasoning (thus, higher RTs), but also stem from logically correct reasoning. Also, providing any response

other than NVC for invalid syllogisms is logically incorrect and may therefore include deviating processes (possibly leading to prolonged RTs). Therefore, for invalid syllogisms, such effects may mask the effect of NVC responses. Second, while we found a significant main effect of validity on NVC, entropy was associated with NVC responses only for valid syllogisms. The reported interaction between validity and entropy on the frequency of NVC responses is however only logical. As theorized, the frequency of NVC responses seems to be higher for high entropy problems as compared to low entropy problems for valid syllogisms. The opposite relationship observed for invalid problems is logical as naturally for easy invalid syllogisms (reflected in a low entropy), participants should most frequently respond "NVC". The harder an invalid syllogism becomes (possibly reflected by a high entropy), the more the responses spread, and the less often a NVC response is given. Future analyses should investigate whether NVC responses are selected more frequently for high entropy problems in addition to the general benefit or drawback NVC responses receive by a higher variance in responses. Third, as hypothesized, the likelihood to respond NVC increases with the trial sequences during the time-course of the experiment. Surprisingly, this association seems to be apparent for both valid and invalid syllogisms. The effect of trial sequence on NVC responses can thus not be explained by participants becoming more logical. On the contrary, the results point towards other systemic processes taking place during the course of the experiment. Note, that this study used a selection task. It remains an open question how our results relate to tentative studies on generation tasks (for an overview of differences of response formats see Hardman & Payne, 1995). Moreover, variations of the classic syllogism task, such as the countermodel/ "Harry"-task (see Achourioti, Fugard, & Stenning, 2014), would certainly provide additional insights on the questions when participants conclude that "nothing follows" in other test situations.

General Discussion

When does a reasoner respond "nothing follows"? To answer that question we have investigated implications of the mental model (e.g., Johnson-Laird, 2006) and mental logic theory (Rips, 1994) as well as adapted alternative systemic hypothesizes such as the role of mental depletion. First, reasoners seem to take longer when responding NVC only for valid and not for invalid syllogisms. With regard to the proposed theories and systemic hypotheses of interest, this finding poses a challenging novel perspective on NVC responses as this distinction is not yet predicted by cognitive theories: giving a NVC response generally takes longer due to the requirement of more cognitive steps, e.g., by generating all inferences or searching for counterexamples (Khemlani & Johnson-Laird, 2012). So, the time needed to respond "nothing follows" is expected to be independent of the validity of a problem. Moreover, the Early Stopper hypothesis contradicts this empirical finding: An Early Stopper would not need more time for responding NVC. In sum, our assumptions holds true only for valid syllogisms. This raises the question whether invalid and valid syllogisms are processed differently and influenced by other processes such as mental depletion or a NVC aversion. Second, the likelihood to respond NVC increases for both valid and invalid syllogisms over time indicating that these differences cannot be explained by participants becoming more logical within the same experiment. While the Early Stopper hypothesis cannot account for this finding, the results can be well explained by the NVC aversion hypothesis. Participants may have an early aversion to respond NVC. If the NVC response is assigned a meaning of "I give up", participants might need to encounter some of the invalid syllogisms to gain confidence in stating that no conclusion may follow from the premises. It is possible that a reasoner may for instance learn across solving syllogistic problems that for some types of problems a valid conclusion cannot be found. Hence, the reasoner can start to assume that the probability of NVC problems is high (with each such observation). The aversion may however also diminish over time due to depletion or fatigue effects.

What can we conclude regarding our proposed theories and systemic hypotheses based on these findings? We see that cognitive theories seems to be able to provide correct predictions in terms of RTs for NVC responses for valid but does not for invalid syllogisms. The systemic hypotheses proposing an early NVC aversion and a later mental depletion seem to be able to explain why cognitive theories sometimes fail to predict NVC responses correctly: Yet, cognitive theories do not yet take such processes into account. It is noteworthy however, that the systemic hypotheses are unable to explain some of the results found in the present study. Whereas the cognitive theories do at least predict an effect of NVC-responses on the RTs, two of the systemic hypotheses do not necessarily propose higher RTs for such trials. Additionally, one of the systemic hypotheses predicted the main effect of validity on NVC responses.

In summary, with regard to the proposed theories, we see that the cognitive theories seem to be able to provide correct predictions of NVC responses for valid but sometimes not for invalid syllogisms. The strong dependencies on the validity of a syllogism as well as differences over the time-course of an experiment suggest that there are also some other cognitive processes taking place within the individual. The systemic hypotheses can account for some of these effects complementing the cognitive theories. We can conclude that there may indeed be an initial bias against an NVC response, which highly differs between individuals. Hence, more analysis are necessary to analyze the interplay between existing cognitive reasoning theories and possible systemic hypotheses to increase the correct prediction rate of when people answer NVC. Indeed, in parallel to this work, we were able to demonstrate that by attaching heuristic rules for predicting NVC to cognitive models of syllogistic reasoning, their performance can increase up to 20 % on average (Riesterer, Brandt, Dames, & Ragni, in press). Last, the results also highlight that logical correctness need to be used with caution when analyzing syllogistic reasoning data due to the unproportional weight of NVC responses: Such analyses should always consider the validity of the problems.

The Design of the Learning Environment Shapes Preschoolers' Causal Inference

Abstract

In the present study, we examine whether the design of the learning environment can impact causal inference in very young children. Specifically, we assess whether the physical features of a novel toy can facilitate children's recognition of an abstract, relational hypothesis (*same-different*) that they typically fail to discover. Three-year-olds were presented with an identical pattern of evidence that was consistent with a relational hypothesis (i.e., pairs of same or different blocks cause a toy to activate) using one of two causal toys. In the *standard* condition, blocks were placed in pairs on top of the toy, while in the *relational* condition, each block was placed inside one of two transparent openings on either side of the toy. The physical design of the latter toy was intended to highlight the relationship between pairs of blocks. Results suggest that even 3-year-olds' causal inferences are sensitive to design, with children in the *relational* condition more likely to infer the abstract relation than those in the *standard* case. These results provide strong evidence that design serves as a constraint on causal inference in early childhood. Findings are discussed in terms of their implications for creating intuitive learning environments for young children.

Keywords: cognitive development; causal inference; relational reasoning; learning environments; design

Introduction

When reasoning about novel causal relationships, learners must select the most likely hypothesis from a range of underdetermined possibilities. For example, to activate a novel appliance, you might consider several possible interventions: the 'on/off' switch might have to be flipped, the reset button on the circuit interrupter might have to be depressed, or perhaps both the switch and the button together activate the device. Depending on your prior belief in the likelihood of each candidate cause and your subsequent observations, you then select the most likely action. If, for example, the switch is in the 'on' position and the appliance does not activate, it provides evidence that it must be activated in conjunction with the interrupter reset. However, one could also imagine a seemingly infinite number of alternative ways the causal system may work. Perhaps the appliance is voice activated, or the buttons need to be pushed in a particular repeating order, or there is an additional hidden switch somewhere else on the device.

To solve the infinite hypothesis search problem, recent work emphasizing the psychological processes underlying inductive inference has proposed that learners likely "sample" from this vast space of hypotheses, based on prior knowledge (e.g., Bonawitz, Denison, Griffiths, & Gopnik, 2014; Ullman, Goodman, & Tenenbaum, 2012; Tenenbaum, Griffiths & Kemp, 2006). Thus, instead of considering all possible hypotheses and weighing each against the observed evidence, learners may only generate a subset of the most likely candidates to evaluate (Bonawitz & Griffiths, 2010). Critically, the specific subset of hypotheses that is generated for a particular learning problem may depend on a variety of factors, including their prior probability, their relevance to the current problem, priming, and so forth (e.g., Dougherty & Hunter 2003; Flin, Slaven & Stewart, 1996; Klein, 1993; Weber et al., 1993; Schunn & Klahr, 1993; Koehler, 1994). In fact, even young children are sensitive to input that constrains the hypotheses they consider, including information about the problem they are trying to solve, how the data were sampled, who generated the evidence, and why (e.g., Buchsbaum, Gopnik, Griffiths, & Shafto, 2011; Butler & Markman, 2012; Gergely, Bekkering & Kiraly, 2002; Walker, Lombrozo, Legare, & Gopnik, 2014).

Accordingly, any input that changes a learner's prior expectations about the most likely causal structure can influence the hypotheses they privilege, and ultimately apply. Here, we consider a specific environmental cue that, to our knowledge, has not yet been examined: the visible *design* of the object itself. If children use information about an object's design to constrain the hypotheses they generate, changes in the *physical features* of the learning context might influence causal learning and discovery. That is, the design of a causal system may serve to increase or decrease the salience of some hypotheses over others.

Effects of Design on Behavior

Although object design has not been specifically examined in the context of causal learning, there are several reasons to expect that the physical features of the learning context may influence children's causal inference. Indeed, nearly all of the objects we interact with include some element of design, and we often use these cues to infer information about an object's function. For example, if a door has no handle, the only way to enter is to push. While this action seems intuitive, the design is intentional. The creator constructed the door so that its physical features would constrain the permissible actions. Norman (1988) includes such constraints as one of several principles of good design, recognizing that design impacts reasoning about object function. A large body of literature has also explored the ways in which subtle environmental influences, or "nudges," have disproportional effects on human choice (Thaler & Sunstein, 2008), impacting hygiene (Holland, Hendriks, & Aarts, 2005), energy use, (Allcott & Mullainathan, 2010), and health (Thorndike, Sonnenberg,

Riis, Barraclough, & Levy, 2012; van Nieuw-Amerongen, Kremers, De Vries, & Kok, 2011), among others.

Other applied research has also begun to examine whether environmental design can change the way we *learn* in select educational contexts. For example, museum designers have used exhibit access, visibility, and object affordances to encourage visitor exploration, engagement, and understanding (e.g., adding a knob to a display suggests that an object can be moved, adding a glass window on the side of a machine encourages visitors to view the internal mechanism; see Allen, 2004; Wineman & Peponis, 2010; Shin, Park & Kim, 2014). Here, we go beyond this past applied work to consider whether similar cues can influence the salience of certain concepts or reasoning strategies in the context of causal learning. That is, we test whether elements of design influence a learner's prior beliefs about the likelihood of a particular causal hypothesis, given some pattern of evidence.

To illustrate how the design of an object might impact a learner's beliefs about its function, we return to our novel appliance. If you are familiar with electronic machines, you might believe that before you can turn something on, you must connect its cord to a power source. Once learned, this general principle can be widely applied to novel cases, even before observing any evidence about how a particular appliance functions. However, now consider a situation in which you are confronted with an appliance that has *two* cords. In this case, your prior belief that a single power cord must be plugged in to turn on the machine seems less probable. You might instead form a hypothesis that the two cords must *both* be connected before the machine will turn on. This demonstrates an even more general assumption that the features of an object are relevant to its function. This sort of abstract causal principle, or "overhypothesis," is a belief about the *kinds* of hypotheses that are most likely to be true (Goodman, 1955; Kemp, Perfors, Tenenbaum, 2007). Based on the learner's prior experience, it might seem unlikely to observe a second power cord that is unnecessary for the machine's operation (without an alternative explanation for the presence of the second cord). In this way, the visible features of an object serve as critical design cues that constrain the hypotheses that are generated about its causal structure (Norman, 1988).

Some existing support for the proposal that an object's design serves to constrain inferences about causal structure can be found in the literature examining human reasoning about artifacts (i.e., human-made objects). That is, both children and adults view features of artifacts as reflective of that object's function and intended use (Keil, 1992; Keleman, 1999; Keleman, Seston, & Saint Georges, 2012). For example, Kelemen and colleagues (2012) showed preschool-aged children two objects that were equally optimal for performing a particular function (i.e., both objects featured a flat surface that could be used to crush popcorn), but one of them had additional salient features that suggested it could *also* be used for an additional purpose (i.e., spikes along the object's handle). When asked which object was designed for the target purpose (crushing popcorn), 3- and 4-year-old children privileged the object with a more efficient design.

Magid and colleagues (2015) also provide evidence that children relate an object's design to its function. The authors argue that young learners represent the abstract criteria for solving a problem, before arriving at a precise solution. These criteria are based on how well a particular hypothesis matches the abstract "form" of the problem to be solved. Specifically, 4 and 5-year-olds mapped the *type* of effect produced (a discrete vs. continuous visual effect) to the *type* of mechanism that produced it (a binary "on/off" switch vs. a dial), providing evidence that children relate the physical structure of an object's causal mechanism to its effect. Additionally, 4- and 5-year-olds have also been shown to map the quantity and diversity of object functions (e.g., making cupcakes vs. making cupcakes *and* wrapping presents) to make inferences about the complexity of the design of its internal mechanism (Ahl & Keil, 2016).

The Current Approach

In the prior work reviewed above, learners made inferences about the design of objects, given information about possible functions. Here, we ask whether children can perform a more challenging task -- whether they will be more likely to generate a particular causal hypothesis, given the object's design. In particular, we present a conceptual case in which 3-year-olds typically fail to discover a relational hypothesis. We then assess whether the object's design influences learning by observing whether subtle changes to the physical structure of the causal system leads to the successful identification of the abstract relational cause.

Specifically, we present 3-year-olds with a relational reasoning problem that they systematically fail at this age (Walker, Bridgers & Gopnik, 2016). In this task, children are introduced to a novel toy that plays music for some objects and not for others (i.e., a "blicket detector," Gopnik & Sobel, 2000). They then observe pairs of blocks being placed on top of the toy. When 3-year-olds are provided with evidence that the toy's activation is caused by the relation between the two blocks in each pair (i.e., whether the blocks are the same or different), rather than by individual object kinds (i.e., blocks of a particular shape and color), they failed to make the correct causal inference at test (see Figure 1).

Notably, younger children (18 to 30-month-olds) successfully infer *same-different* relations in this task, suggesting that later failures are due to a difference in tendency, not a lack of relational competence (Walker et al, 2016; Walker & Gopnik, 2017; Walker, Walker, & Gopnik, under review). In other words, these developmental data provide evidence that older children are capable of inferring such relations, even if they do not spontaneously generate them in most learning scenarios. Critically, this proposal contrasts with decades of research suggesting that preschoolers were simply unable to reason on the basis of

these abstract relations (e.g., Christie & Gentner, 2010; 2014).

Based on these findings, it has been proposed that 3-year-olds' long-documented failure to infer *same-different* relations results from a learned bias in the form of an overhypothesis that privileges the role of individual objects over the relations between them (Walker et al., 2016; Carstensen & Walker, 2017). Walker and colleagues (2016, Exp 3) provide additional support for this idea, demonstrating that prompting children to explain during training trials significantly increases their tendency to endorse the relational hypothesis at test. The authors propose that explanation likely serves as an *internal* constraint on hypothesis search, leading learners to privilege more abstract solutions. This domain therefore provides a promising case study to explore the proposal that an *external* constraint, namely the design of an object, can also influence hypothesis generation in causal learning.

In order to assess whether the tendency to discover the relational hypothesis may be sensitive to constraints imposed by physical design, we made one small modification to the standard causal relational task: Rather than placing pairs of blocks on top of the toy on a single, large platform, the blocks were inserted on either side of the toy, into two transparent openings (see Figure 2). By adding these two intentionally designed openings, a learner who treats object design as relevant to their causal inferences might consider *why* the causal system included these features. These two openings therefore not only draw attention to the presence of two objects, but also suggest a particular affordance: that the machine activates by combining the two. As a result, this may raise the possibility that the *relation between* the blocks—rather than the identity of the blocks themselves—is relevant to the causal structure, leading to the discovery of the relational hypothesis. We return to consider the implications of this particular design choice in the discussion.

Alternatively, it may be the case that the design of the causal system has no effect on 3-year-olds' endorsement of the relational hypothesis. As noted, children at this age repeatedly fail to spontaneously privilege relational information (Christie & Gentner, 2010; 2014; Walker et al., 2016), suggesting a strong prior for hypotheses based on individual object kinds. To correctly infer the relational hypothesis in this case, children must integrate information about the object's design with their prior beliefs about likely causes, taking into account why object design is relevant, *and* weighing this information more heavily than their prior commitment to the object-based hypothesis. That said, if children's failure to infer abstract relations indeed results from a difference in *tendency,* rather than a lack of *competence* (as has been suggested)*, and* they are sensitive to the design of the learning context, then we might reasonably expect them to successfully infer the abstract relational hypothesis, even following such a minor modification to the standard task.

Methods

Participants

A total of 152 3-year-olds participated in the study, with 76 children randomly assigned to either the *standard toy* (M = 41.9 months; 36 female) or *relational toy* (M = 41.6 months; 37 female) conditions. Within each condition, half of the children observed evidence consistent with the *same* relation and half observed evidence consistent with the *different* relation. Sample size satisfies a power analysis with power > .8, given an alpha of .05 and an effect size of .3 (medium). An additional 9 participants were excluded due to experimenter error (3), failure to complete the study (4), parent interference (1), or interference by another child (1). Children were recruited and tested in the lab, at preschools, and at museums. All participants were tested in a quiet, private room with the experimenter.

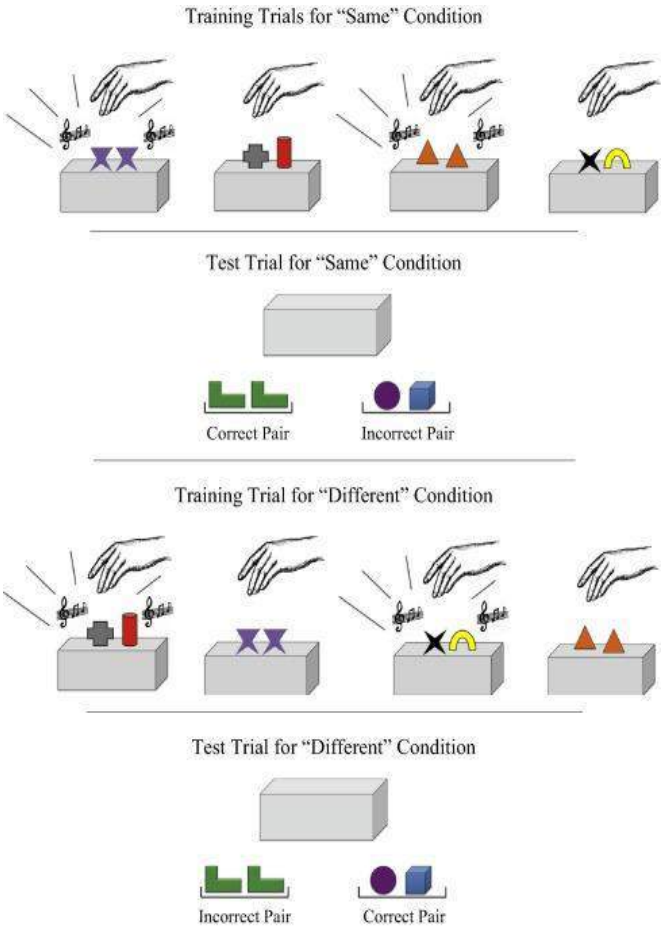

Figure 1. Schematic illustration of evidence presented during training and test trials in the *standard* condition (reprinted from Walker et al., 2016, Exp. 1). Identical pairs and outcomes were presented in the *relational* condition, using the relational toy (see Fig. 2).

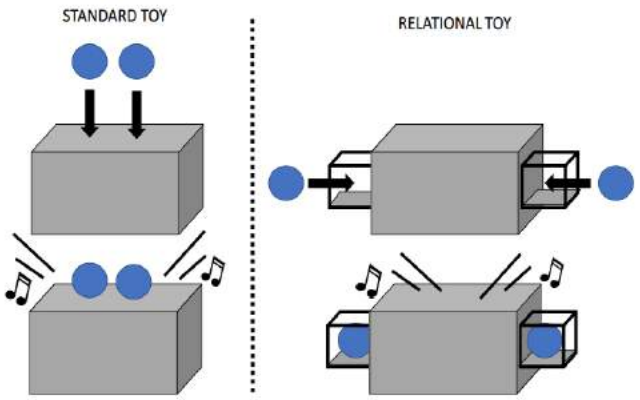

Figure 2. Standard and relational toys

Materials and Procedure

The materials and procedure for the *standard toy* condition replicate those used by Walker et al. (2016, Exp. 1; see Fig. 1). Children were seated at a table across from the experimenter. The experimenter began by placing an opaque cardboard box on the table, saying "This is my toy! Sometimes when I put things on top, the toy will play music, and other times it does not. Should we try some and see how it works?" As in previous research, the toy appeared to activate and play a novel melody in response to certain combinations of blocks. In fact, the experimenter activated a wireless doorbell inside the box by surreptitiously pressing a button.

A total of 4 pairs of *same* and *different* painted wooden blocks (2 pairs of *same* and 2 pairs of *different*) were used during the training trials. After introducing the toy, the experimenter produced two blocks in either the *same* or *different* relation (depending upon the condition), and said, "Let's try!," and put both blocks on top of the toy, simultaneously. The toy played music and the experimenter said, "Music! My toy played music!" The experimenter then picked up the blocks and set them back on the toy, which again played music, saying "Music! These ones made my toy play music!" She then repeated this procedure with a new pair of blocks in the opposite relation. The new pair did not make the toy play music, and the experimenter responded to the first try with, "No music! Do you hear anything? I don't hear anything," and after the second try, said "No music. These ones did not make my toy play music." This pattern was repeated with two additional pairs of blocks, one in each relation. The experimenter always began with a causal pair (identical blocks in the *same* condition and blocks of unique colors and shapes in the *different* condition), and then alternated inert, causal, inert, using novel blocks in each new pair, and randomizing the specific blocks between participants.

After the four training trials, the experimenter said "Now that you've seen how my toy works, I need your help finding the things that will make it play music. I have two choices for you." The experimenter presented the child with two new pairs composed of novel blocks, one "same" pair and one "different" pair. Each pair was presented on a plastic tray, which the experimenter held up, saying, "I have these, and I have these (directing the child's attention to each pair). Only one of these trays has the things that will make my toy play music. Can you point to the tray that has the things that will make it play?" The trays were then placed out of the child's reach, on either side of the toy, with each pair set an equal distance from the child. The order and side of presentation of the correct pair counterbalanced between participants. The experimenter recorded the child's first point or reach, scoring the response as correct (1) if the child chose the test pair (same or different) that corresponded to her training, and incorrect (0) for the opposite pair.

The materials and procedures for the *relational toy* condition were identical to those in the *standard toy* condition with one critical difference: The design of the toy was modified to include two transparent openings located on either side (see Fig. 2). The openings were constructed using clear, 2" x 2" hard plastic boxes. When children observed each of the training trials described above, pairs of blocks were inserted into the two openings (one block on either side), rather than placed on top of the toy. This was the only difference between the two conditions.

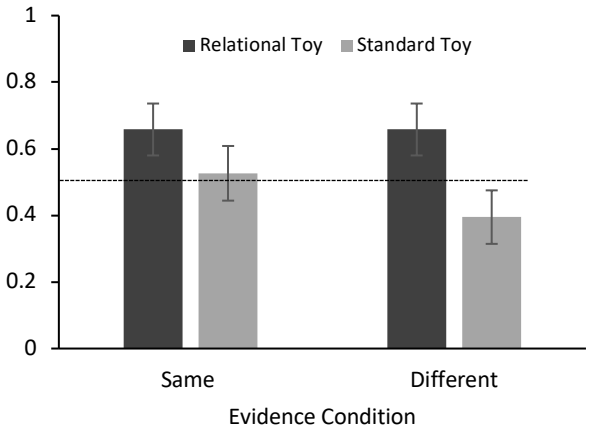

Figure 3. Mean proportion of correct relations by condition. Error bars indicate +/- 1 *SEM*. Chance performance is indicated by the dotted line.

Results

Replicating previous work (Walker et al., 2016), 3-year-old children in the *standard toy* condition responded at chance (46%), p = .57 (two-tailed, exact binomial), with no difference in performance between *same* (53%) and *different* (40%) training trials, p = .35 (two-tailed, Fisher's exact). In contrast, 3-year-olds in the *relational toy* condition succeeded in selecting the test pair that was consistent with their training (66%), p = .008 (two-tailed exact binomial), performing identically in *same* and *different* training trials (p = 1, two-tailed, Fisher's exact). Comparing performance across conditions, children in the

relational toy condition significantly outperformed those in the *standard* condition (p = .022, two-tailed, Fisher's exact) in inferring *same-different* relations.

Discussion

In the current study, we present findings demonstrating that children are indeed sensitive to the physical design of the learning context when reasoning about causal relationships. Although 3-year-olds in the *standard toy* condition failed to recognize the relational hypothesis (replicating prior work), increasing the salience of this hypothesis through the application of a relatively subtle design cue significantly increased their tendency to engage in relational reasoning in this task. In addition to providing evidence for the role of design in constraining causal inference, these data provide additional support for the proposal that children's failure on relational reasoning tasks results from a difference in *tendency*, not a lack of competence (e.g., Walker & Gopnik, 2014; Walker et al., 2016; Carstensen & Walker, 2017; Walker & Gopnik, 2017).

These results are particularly striking given that 3-year-olds have repeatedly failed to spontaneously privilege relational information (Christie & Gentner, 2010; 2014), suggesting a very strong prior to prefer individual object kinds. In order to use the design of the learning context to override this tendency and privilege the relational hypothesis, these very young children had to make a particularly sophisticated inference: They must have noticed this subtle design cue, inferred its relevance to the system's causal structure (i.e., that an object's design is relevant for its function), and weighed this information more heavily than their (strong) prior commitment to the object-based hypothesis.

These surprising findings therefore suggest that relatively minor elements of design can radically change the distribution of a learner's prior expectations, constrain the type of hypotheses that are generated, influence learning outcomes, and even facilitate the early discovery of new causal beliefs. Our results join prior research suggesting that hypothesis generation can be influenced by a variety of cognitive factors (e.g., Dougherty & Hunter 2003; Flin, Slaven & Stewart, 1996; Klein, 1993; Weber et al., 1993; Schunn & Klahr, 1993; Koehler, 1994), prompts (Walker et al., 2014, 2016; Williams & Lombrozo, 2010) and social inferences (Butler & Markman, 2012; Buchsbaun et al., 2011; Gergely, Bekkering, & Kiraly, 2002), and extends this work to include the structure of the learning environment itself. Ongoing work examines whether and how design influences even more entrenched causal beliefs and biases (e.g., in adults; Walker, Rett, & Bonawitz, in prep), and considers how design may interact with other constraints, such as pedagogical cues or prompts to explain. For instance, in some contexts, children privilege an object's visible affordances over an actor's intentional behavior when reasoning about how an artifact is intended to be used (e.g., DiYanni & Keleman, 2008). Future work will explore to what extent learners may be reasoning about the intentions of the designer (as a social agent) when making inferences based on these environmental cues.

There are also open questions surrounding how the particular design modifications used in this experiment influence children's reasoning. One possibility is that the addition of exactly two transparent openings on either side of the toy directly primed the relational hypothesis. Another possibility is that this design cue simply served to disrupt children's initial intuitions about the likely causal mechanism, leading them to consider alternatives more broadly. If so, this may have made it more likely for children to discover the relational hypothesis, albeit indirectly. Future work is needed to address these important questions.

Finally, these results have clear practical implications for early science education, and in particular, the design of formal and informal learning environments intended for children. Our findings dovetail with literature in education pointing to the importance of "mise en place" or setting the stage for learning (Weisberg, Hirsh-Pasek, Golinkoff, & McCandliss, 2014). As demonstrated here, children are sensitive to relatively subtle physical cues in the learning environment when they are engaged in causal reasoning. This simple manipulation led children to consider a relational hypothesis that they typically fail to spontaneously produce. Our findings therefore highlight the importance of careful design when aiming to teach children specific concepts, given that the visible features of objects may increase or decrease the salience of the available evidence, and change the learner's interpretation of their observations. It is impossible to create artifacts without also making specific design choices, so being aware of how these features might be used to facilitate reasoning can have major consequences for learning and instruction. These findings therefore open up new avenues for future work examining how the design of learning environments can be used to support belief revision and guide early learning and discovery.

Acknowledgements

We are grateful to Mike Frank for his early contributions in conceptualizing the methods for this study. We thank Alicia Lunardhi and Emily To for their efforts towards data collection and Nicky Sullivan for facilitating recruitment. We also thank the Fleet Science Center, the Birch Aquarium at Scripps Institute of Oceanography, and the New Children's Museum, as well as all of the participating preschools and families who made this research possible. This research was funded by a Hellman's Fellowship, awarded to C. Walker.

Abstract

The complex judgments we make about the innumerable objects in the world are made on the basis of our representation of those objects. Thus a model of judgment should specify (a) our representation of the many objects in the world, and (b) how we use this knowledge for making judgments. Here we show that word embeddings, vector representations for words derived from statistics of word use in corpora, proxy this knowledge, and that accurate models of judgment can be trained by regressing human judgment ratings (e.g., femininity of traits) directly on word embeddings. This method achieves higher out-of-sample accuracy than a vector similarity-based baseline and compares favorably to human inter-rater reliability. Word embeddings can also identify the concepts most associated with observed judgments, and can thus shed light on the psychological substrates of judgment. Overall, we provide new methods and insights for predicting and understanding high-level human judgment.

Keywords: judgment; semantic memory; machine learning; word embeddings

Introduction

People are constantly perceiving, judging and evaluating entities in the world, on the qualities that these entities possess. They may consider, for example, whether a food item is nutritious, whether a political candidate is competent, whether a consumer brand is exciting, or whether the work of an occupation is significant. Such judgments influence every sphere of life, determining the social, professional, consumer, and health outcomes of individuals, as well as the political and economic makeup of our societies. It is thus of critical importance to cognitive and behavioral scientists to develop predictive and explanatory models of human judgment. To have good empirical coverage and practical utility, such models must apply to naturalistic objects and concepts, i.e., the vast range of entities people encounter every day and have rich knowledge about. They should be able to quantify what people know about these entities, and specify how people map this knowledge onto the diverse array of complex judgments they make on a day-to-day basis.

To date, building such models has been elusive, as it has been difficult to represent the detailed knowledge people have about the millions of entities in the world that they judge. Traditional psychometric methods of formally specifying object knowledge – multidimensional scaling or simply asking people to rate objects on dimensions theorized to be core to a domain – are costly and typically yield sparse representations. Thus, a technique is needed which cheaply delivers rich, high-dimensional knowledge representations for a large number of objects and concepts, which can then be used to model judgments. Fortunately, such a technique can be found in word embeddings, real-valued vector representations of word meaning derived from the statistics of word use in language corpora, such that words that occur in similar linguistic contexts yield similar vectors (see Lenci (2018) for a review). Word embeddings are a useful tool for many practical natural language processing and artificial intelligence applications. However, they also mimic aspects of human semantic cognition: they can be used to predict judgments of word similarity and relatedness, patterns of free word association, strength of semantic priming, and semantic search (Hill, Reichart, & Korhonen, 2015; Hofmann et al., 2018; Hills, Jones, & Todd, 2012; Jones, Kintsch, & Mewhort, 2006). Most relevant, researchers have also found that word embeddings predict certain association-based probability judgments, social judgments, and consumer judgments (Bhatia, 2017, 2018; Caliskan, Bryson, & Narayanan, 2017)

In this paper we show that the structure of knowledge captured by word embeddings can be used to model a very wide range of complex human judgments, including judgments that are not easily captured by association-based measures of vector similarity. More specifically, we find that with some training data in the form of human judgments about a set of words or phrases, it is possible to learn a mapping from these entities word embeddings to the judgment dimension in consideration, and subsequently make accurate predictions for nearly any entity in that domain. In other words, we use word embeddings as feature vectors for supervised machine learning models and predict out-of-sample judgment ratings with high accuracy. We also show that these learnt mappings can be used to identify the concepts that are most related to each judgment, and thus understand the most important psychological factors underlying judgments.

Method

To illustrate the broad applicability of our method, we use study fourteen types of judgment across seven different domains of mental and behavioral life: masculinity and femininity of traits (Bem, 1974), dread and unknowability of potential risk sources (Slovic, 1987), warmth and competence of people (Rosenberg, Nelson, & Vivekananthan, 1968; Cuddy, Fiske, Glick, & Xu, 2002), taste and nutrition of

foods (Raghunathan, Naylor, & Hoyer, 2006), significance and autonomy of occupations (Hackman & Oldham, 1976), sincerity and excitement of consumer brands (Aaker, 1997), and hedonic and utilitarian value of consumer goods (Batra & Ahtola, 1990). The judgment dimensions, items, participant instructions, and various implementation details for this study and for the resulting analysis, have been pre-registered on OSF here and here.

Experimental Details

We recruited 354 participants (mean age = 31.89 years, 46.19% female) through Prolific Academic. We limited our data collection to participants who were from the U.S. and had an approval rate above 80%. Participants were only allowed to participate once, and they were paid $4.40 each. Using a between-subjects design, we randomly assigned each participant to one of the seven judgment domains brands (N = 54), consumer goods (N = 51), traits (N = 46), foods (N = 55), occupations (N = 49), risk sources (N = 49), people (N = 51). These domains were chosen to span a diverse range of cognitive and behavioral sciences. Additional details about the generation of these items and other methodological details can be found on this project's OSF page and especially supplemental information here. After being randomly assigned to one judgment domain, participants were instructed to rate 200 items (e.g., occupations) on two dimensions from -100 (e.g. not at all significant) to 100 (e.g. extremely significant), one item at a time.

Word Embeddings

For our primary analyses, we used a pre-trained word embedding model, word2vec, obtained using the skip-gram technique (Mikolov, Sutskever, Chen, Corrado, & Dean, 2013)[1], applied to a very large dataset of Google News articles. This space has vectors for 3 million words and short phrases, with each vector being defined on 300 dimensions. Although there are other training methods as well as other pre-trained semantic spaces, we base our analysis on the Google News space because of its rich vocabulary, which includes all of the naturalistic entities used in our study (including multiword entities, such as famous people and various consumer brands, which are often absent from other spaces). This pre-trained space has also been shown to accurately capture human ratings on linguistic and semantic judgment tasks (Pereira, Gershman, Ritter, & Botvinick, 2016).

[1]This technique relies on a multilayer feedforward neural network that slides over windows of text in a large corpus, and attempts to predict the words in the periphery of the window, given the word in the center of the window. By learning to predict context words in this way, the weight matrix of the network gradually learns to encode information about the relationships between words, such that semantically related words have similar (weight) vectors. The rows of the weight matrix from the input layer to the hidden layer are precisely the word embeddings we use.

Results

Predictive Accuracy of Mapping Approach

We first evaluated the predictive accuracy of our mapping method for average participant judgments (i.e. averages of the ratings made on each the fourteen judgment dimensions). We tested the ability of a variety of (regularized) regression techniques (ridge and lasso regressions, k-nearest neighbor regression, and support vector regressions with radial basis function, linear, and polynomial kernels), across a range of hyperparameters, to map our word embeddings to judgments in a pre-registered cross-validation exercise (see pre-registration form for more details). A range of models performed well, but we focus here on our best-performing model, a ridge regression with regularization hyperparameter λ set to 10, which achieved an average r-squared of .54 and an average RMSE of 21. Figure 1 shows, for each judgment dimension, scatterplots of actual judgments and predicted judgments, along with Pearson correlation coefficients, for this method. Each predicted judgment in the scatterplot was obtained by leave-one-out cross-validation (LOOCV): we trained our ridge regression model on the vectors for all but one judgment target, and then used the trained model to predict the rating for the left-out judgment target based on the target's vector. As can be seen in Figure 1, our approach was able to predict participant judgments with a high degree of accuracy, with an average correlation rate of .77 across the fourteen judgment dimensions, and all fourteen judgments yielding statistically significant positive correlations (all $p < 10^{-20}$). Our approach can also be applied to individual-level judgments, thereby accommodating participant heterogeneity. We obtain average correlations of .52 for predicted vs. observed judgments, for the individual participants in each of our fourteen tests. These accuracy rates are lower than those obtained on the aggregate level, likely due to the fact that averaging participant ratings reduces variability in data.

Comparison to Model and Human Baselines

We then compared the vector mapping approach with a simpler, baseline approach that relies only on the relative similarity of a judgment target to words denoting high vs. low ends of a particular judgment dimension (Grand, Blank, Pereira, & Fedorenko, 2018). This method works as follows: First, we select words reflective of high and low ends of some judgment dimension. For example, the occupation significance dimension was represented by the words significant, meaningful, important and insignificant, meaningless, unimportant, pointless. Where possible, we chose words used in previous literature to define the dimensions. Then, for each judgment dimension, the average pairwise vector difference between each possible pair of high and low words is computed to obtain a single vector d representing that dimension. Last, to obtain a score for a judgment target entity on that dimension, we compute the dot product between the target entity's embedding x_i and the dimension embedding, $d * x_i$. This method essentially

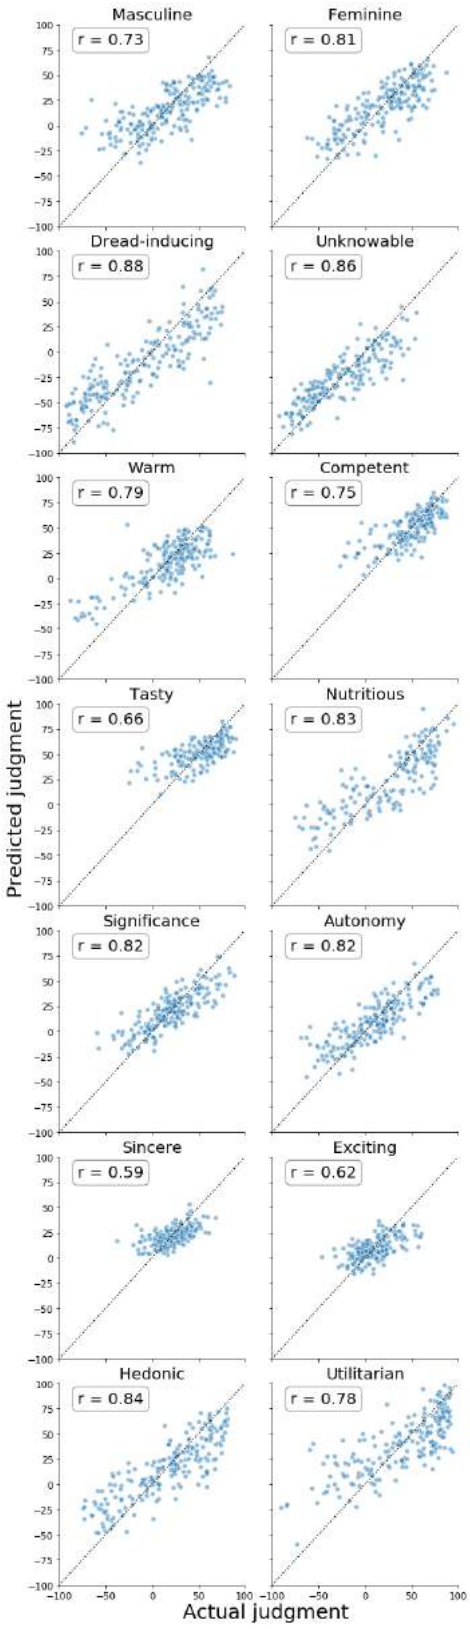

Figure 1: Scatterplots of actual judgments and predicted judgments using leave-one-out cross-validation for each judgment dimension.

computes the similarity of a judgment target (e.g., surgeon) to words high (significant, meaningful, important) relative to words low (insignificant, meaningless, unimportant, pointless) along the dimension of interest. Last, to transform these relative similarities to the range of our human judgment data, we trained OLS models predicting the human judgments from the measures of relative vector similarity, in a leave-one-out cross validation procedure. We found that the average correlation using this method was .30, which is much lower than that obtained using the vector mapping method. Additionally, the similarity method yields significant ($p < .05$) correlations for only eleven out of the fourteen tests. The baseline approach also performs worse on individual-level judgments, for which it generates average correlations of .21. As the baseline approach uses the same distances on the semantic space, for all participants, it cannot substantively accommodate participant heterogeneity (though this approach does allow for different participants to map vector similarities onto responses in different ways).[2]

We also compared the predictive accuracy of our mapping method with human inter-rater reliability, as human inter-rater reliability is often thought to place an upper bound on machine performance (Hill et al., 2015; Grand et al., 2018). To asses models predicting average models, we computed reliability two ways. First, we computed the inter-subject correlation (IS-r, (Grand et al., 2018)), which is the average correlation between one participants ratings and the average of the rest (Hill et al., 2015). This is a commonly used metric in assessing word embeddings' ability to model semantic judgments (e.g., Grand et al., 2018) and is sometimes taken to place an upper bound on machine performance (Pilehvar & Camacho-Collados, 2018). This correlation came out to 0.60, whereas our main model surpassed this with an average correlation of 0.77 across judgments. However, given that our main model is predicting an average judgment rating with word embeddings that more or less constitute the average of human knowledge reflected in word use, it may be more sensible to compare our models' performance to split-half reliability, or the correlation between the average of half the participants with the average of the other half of the participants. Thus, for each judgment dimension, we split participants into two sets, averaged judgment ratings within each set, computed the correlation between the averages, and repeated this process 100 times. The resulting split-half reliability in our judgments averaged across all judgment dimensions is .88, ranging from .69 for taste judgments to .97 for dread-inducing judgments. To assess the individual-level models relative to inter-rater reliability, we again computed reliability two ways. First, we computed the average pairwise correlation between raters (Hill et al., 2015). This correlation

[2]It is perhaps unsurprising that our baseline approach, an unsupervised method, is not as accurate as the mapping method, which is supervised. However, we maintain that this approach is the appropriate baseline to the extent that most previous applications of word embeddings in cognitive science rely on simple relative similarities like our baseline approach does.

came out to 0.34, whereas our individual-level model predictions correlated with actual judgments at an average correlation of 0.53. We can also compare individual-level model accuracy with IS-r rates, since IS-r reflects the ability to predict an individual judgment from the mean of other judgments. As stated above, mean IS-r was .60, somewhat above our average individual-level model accuracy of .53. Overall, for both average- and individual-level judgments, our model performs favorably in comparison to human inter-rater reliability, either exceeding inter-rater reliability or approaching it, depending on choice of inter-rater reliability metric.

Amount of Information Required for Prediction

A natural question for the present work is how much information in the 300-dimensional embeddings is actually required to represent our judgment targets, and hence predict our participants judgments. To this end, we measured predictive accuracy through leave-one-out cross-validation with our primary ridge model ($\lambda = 10$) after reducing the embedding spaces with principal components analysis. Specifically, for each domain, we fit a PCA on the training data design matrix (approximately 199 items, by 300 word2vec dimensions), applied the learned transformation to both the training and held-out data, discarded all but a certain number of initial principal components, and then tested how our ridge model trained on these dimension-reduced matrices predicted the held-out judgment. We emphasize that this approach obtains a *different* reduced space for every domain (cf. retraining word2vec models *for the entire vocabulary* at lower dimensional hidden layers). Figure 2 has predicted vs. actual Pearson correlations for every judgment dimension and number of retained principal components we tested. As can be seen, the 300-dimensional word embeddings can be compressed drastically to $< 10\%$ of their initial dimensionality while preserving predictive performance, with only, on average, a 3-point drop in correlation strength when retaining only the first 25 PCs, and a 7-point drop when retaining only the first 10 PCs. This suggests that, within a domain, the representational space needed to predict the present kinds of judgments is much sparser than the space provided by word2vec. Theoretically, this shows that people may only be evaluating a relative handful of (latent) dimensions when making the kinds of judgments studied here. At the same time, that much of the information relevant to making these judgments is present in the initial principal components further validates previous claims that these 14 dimensions are core dimensions along which we represent objects in these seven domains (Bem, 1974; Slovic, 1987; Rosenberg et al., 1968; Cuddy et al., 2002; Raghunathan et al., 2006; Hackman & Oldham, 1976; Aaker, 1997; Batra & Ahtola, 1990). Practically, these results indicate that future applications of the tested method need not utilize all 300 dimensions, and that successful predictions can be obtained using standard, non-regularized regression methods in the behavioral sciences applied to 10- or 25-dimensional target spaces. What kinds of information the individual principal components represent is an important question for future research, but we believe these dimension-reduced spaces are a step towards more interpretable yet highly predictive models of judgment, as a modeler now has far fewer dimensions (10 to 25, vs 300) to examine or relate to interpretable psychological quantities (by, for example, extracting the words that project onto high and low ends of the principal component's).

Psychological Substrates of Judgment

The ridge regression approach used in most of the above tests involves learning a (regularized) linear mapping from the semantic space to the judgment dimension. The best-fit weights for this mapping have the same dimensionality as the semantic space, and can thus be seen as representing a vector in this space. Judgment items whose vectors project strongly onto the weight vector (typically judgment items whose vectors are highly similar to the weight vector) will be predicted to have the highest judgment ratings. Given this interpretation, we can ask what other objects and concepts (that may not necessarily be judgment targets themselves) project strongly onto the weight vector. Intuitively, these would be the objects and concepts that are most related to the judgment, and may correspond to the judgment-relevant qualities that people evaluate when generating their responses. Thus, we took the 5000 most frequent words in the Corpus of Contemporary American English that were not also judgment targets, and fed their word2vec embeddings through our trained ridge regressions to determine their association with our 14 judgment dimensions. We then computed the difference between a words predicted association with one dimension (e.g., masculinity) and its predicted association with the complementary dimension (e.g., femininity), to find the words most strongly associated with one dimension relative to the other. Figure 3 has word clouds of these words, sized according to the strength of their association with one dimension relative to the other. These word clouds conform with expectations of the bases of these judgments. For example, traits seem to be masculine to the extent they suggest aggression, and feminine to the extent they suggest pro-sociality. A degree of artistry in a job may contribute to perceptions of autonomy, while directly guiding or helping others especially in a medical setting makes for perceptions of significance. Perceived brand sincerity may depend on brand proximity to food, family, and home; perceived brand excitement may depend on brand proximity to science, technology, and the arts.

Discussion

Despite the ubiquity of human judgment, until now we have had limited ability to predict arbitrary human judgments of objects and concepts, as capturing the rich knowledge used to make predictions has been difficult or impossible. Here we demonstrated in a pre-registered study that word embeddings, vector representations for words and concepts based on statistics of language use, proxy this knowledge and can predict 14 diverse judgments across the behavioral sciences with a high degree of accuracy. Our approach to judgment pre-

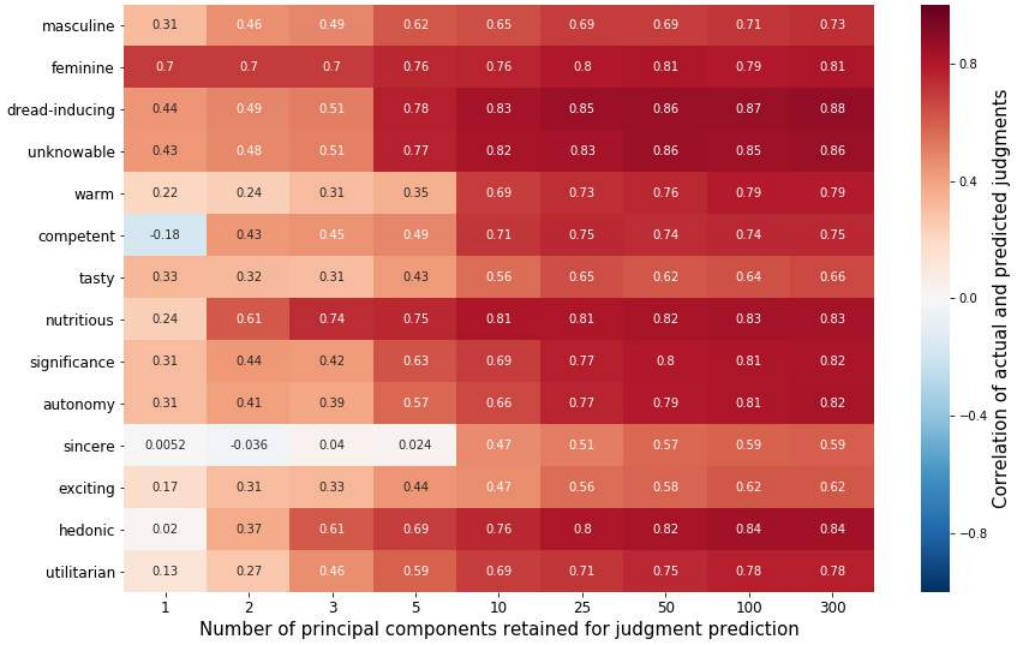

Figure 2: Pearson correlations between predicted and actual judgments for every judgment dimension and varying numbers of retained principal components. Judgment domains (brands, goods, traits, etc.) can be compressed to 5 to 25 principal components while preserving judgment prediction accuracy.

diction learning a (linear) mapping directly from word embeddings to judgment ratings surpassed a similarity-based baseline and compared favorably to human inter-rater reliability. We also showed that, despite our word embedding space (word2vec) being very rich (300 dimensions), predictive accuracy barely dropped when reducing this space to 25, 10, or even fewer dimensions, suggesting that people may only be evaluating a relative handful of pieces of information when making the present kinds of judgments. Finally, we showed that the learned mapping from word embeddings to judgments can also be used to explore the conceptual underpinnings of judgments, by mapping non-judgment target entities onto the judgment dimension.

We view the present approach as a modern extension to classical psychometric approaches used to uncover the underlying representations used for making judgments (Shepard, 1980; Slovic, 1987). However, the present approach offers several advantages over classical techniques. First, the only human data that our approach requires is a (relatively) small number of judgment ratings to train a predictive model. Once a satisfactory model has been trained, no new human psychometric data is required to predict judgments for new entities. Second, word embeddings capture more knowledge about judgment targets than can realistically be collected from human participants, especially when the relevant knowledge used to make a particular judgment is not already theoretically well-understood and thus surveyed from human participants. Capturing a great degree of knowledge leads to the high predictive accuracy we have achieved here, which we suggest may be high enough for applications in downstream behavioral sciences and technologies. For example, marketers could use predicted hedonic and utilitarian values for consumer goods to optimally advertise each of their hundreds or thousands of products, while health policy designers could use predicted risk and food perceptions to guide risk education or nutrition intervention campaigns tailored to individual perceptions.

The present research can be extended in many directions. Besides simply modeling new judgment dimensions for additional domains and entities, one promising avenue is to attempt to model different subpopulations judgments. One way to do this is simply training different regression models for different subpopulations of participants (e.g., Democrats and Republicans), but another is training word embeddings on different corpora more reflective of one population than another (e.g., MSNBC vs. Fox News articles). Under this approach, words and concepts that have somewhat different meanings and associations for different subpopulations, like the word immigrant may for Democrats and Republicans, will be located in different parts of the word embedding spaces for the corresponding representative corpora. Thus, differences in judgments about, say, the warmth and competence of immigrants, elicited from Democrats and Republicans could be predicted from their different word embeddings.

Despite the strength of our approach, it is not without limitations. Cognitive scientists, who are accustomed to inter-

Figure 3: Non-judgment target words with strong association with one judgment relative to its within-domain complement. These suggest potential conceptual underpinnings of judgments.

pretable models, may be most concerned that the dimensions of the most common word embedding techniques including word2vec, which we use here are not themselves interpretable. We attempted to mitigate this problem by using our learnt mappings to predict judgment associations for non-judgment targets, and we suggested that our PCA results were a step towards interpretable models, insofar as they reduced the number of dimensions a modeler would need to examine and relate to psychologically meaningful quantities. Another approach is to train models that predict interpretable psychological qualities that are theorized to subserve different judgments. For example, the unknowability of a potential risk source is theorized to be a composition of its observability, knowledge to the exposed, the delay of their effects, and other specific factors. Thus, one could train a model to predict these quantities from word embeddings, and then train a model predict unknowability from these predicted quantities. It is also worth pointing out that classic psychometric techniques do not always avoid this problem; multi-dimensional scaling is not guaranteed to uncover dimensions corresponding to meaningful psychological qualities. Thus, word embeddings are not always a step down in interpretability relative to other empirical methods of quantifying conceptual knowledge. Finally, cognitive scientists have traditionally focused on interpretable, explanatory models, at the expense of models that make accurate out-of-sample predictions (Yarkoni & Westfall, 2017). Of course, this is undesirable to the extent that we think a good model requires external validity; having statistically significant, interpretable model coefficients is ultimately of limited use if a model cant predict new behavior with any accuracy. Thus, our work can be seen as part of the trend to rebalance the concerns of prediction and explanation in cognitive science.

Agency Drives Category Structure in Instrumental Events

Abstract

Thematic roles such as Agent and Instrument have a long-standing place in theories of event representation. Nonetheless, the structure of these categories has been difficult to determine. We investigated how instrumental events, such as someone slicing bread with a knife, are categorized in English. Speakers described a variety of typical and atypical instrumental events, and we determined the similarity structure of their descriptions using correspondence analysis. We found that events where the instrument is an extension of an intentional agent were most likely to elicit similar language, highlighting the importance of agency in structuring instrumental categories.

Keywords: thematic roles; events; categorization; tools; language production; English

Introduction

Events have event participants – an eating event, for example, involves someone who eats and something that gets eaten. There is extensive evidence that such event participants are represented in terms of abstract event participant categories, sometimes called "thematic roles" (Hafri, Trueswell & Strickland, 2018; Kako, 2006; Lakusta, Spinelli & Garcia, 2017). The category Agent, for example, contains not only the person who eats in an eating event but also the person who cooks in a cooking event and the person who builds in a building event. Thematic roles have been argued to be cross-culturally universal and part of innate knowledge (Carey, 2009; Fillmore, 1968; Strickland, 2016). At the same time, thematic roles have been persistently difficult to define in terms of necessary and sufficient conditions (Cruse, 1973; Dowty, 1991; Levin & Rappaport-Hovav, 2005). For example, the person who sees in a seeing event has fewer agentive properties than the person who eats. The upshot of this prior research is that although humans represent event participants in terms of abstract categories, the structure of these categories is not well understood.

A prominent proposal is that thematic roles have prototype structure (Ackerman & Moore, 2001; Dowty, 1991; Lakoff & Johnson, 1980). Dowty (1991), for example, explains how the arguments of English verbs appear in Subject vs. Object position in terms of Proto-Role properties. The argument with the most Proto-Agent properties (e.g., being sentient, having intention, being a causer) surfaces as Subject, whereas the argument with the most Proto-Patient properties (e.g., undergoing a change of state, being causally affected) surfaces as Object. Ackerman and Moore (2001) argue that being a bounded entity is another Proto-Patient property. Given these properties, the person who sees is a less prototypical Agent than the person who eats because it is sentient but not also a causer. While these proposals have made significant progress in understanding thematic role structure, they are limited in several ways. To fully understand how event participant categories are represented, we first need to investigate a more diverse set of categories beyond Agent and Patient, which have received the most attention. We also need to draw on more diverse forms of evidence, e.g. online psycholinguistic data. The present study achieves both of these goals: we investigate the structure of the English thematic role category Instrument, as in *Marnie sliced the bread with a knife*, using a language production task in which adult speakers described live action videos. We submitted this language description data to correspondence analysis (Greenacre, 2007), allowing us to identify similarity structure within a diverse set of instrumental events.

Within linguistics, thematic roles are often understood to be linguistic objects whose theoretical function is to explain linguistic behavior, such as argument realization. In this paper, we assume that while there may be such domain-specific role representations, there are also domain-general event participant categories that are relevant to both the syntax~semantics interface and non-linguistic event cognition. We take the more conservative position that speakers' descriptions of instrumental events reflect domain-general thematic roles.

Instrument as a Thematic Role

The Instrument role appears frequently in lists of thematic roles, dating back to the ancient Sanskrit grammarian Pāṇini. Like the roles Agent and Patient, Instrument has been characterized as having prototype structure. For example, Luraghi (2001: 388) characterizes a prototypical instrument as "an inanimate manipulable entity which occurs in a controlled state of affairs, where an agent acts intentionally." The prevalence of the Instrument role in linguistic analyses perhaps reflects the importance of tool use for building human culture. In the literature on how tool use differs across human and non-human animals (Plotnik & Clayton, 2015; Seed & Byrne, 2010; Vaesen, 2012), a tool is typically defined as a physical object distinct from the body, that an individual wields intentionally, causing a change in another object or person. We adopt this definition of tool use in the present study. Tools are important because they allow us to

extend the capabilities of our own body, allowing us to solve problems "for which evolution has not provided a rigid morphological or behavioral adaptation" (Seed & Byrne, 2010: R1032).

This definition of tool use does not directly correspond, however, to the event participant categories carved out by human language (Koenig, Mauner, Bienvenue & Conklin, 2008; Lakoff, 1968; Rissman & Rawlins, 2017). English, for example, has two primary morphosyntactic devices for talking about instruments: prepositional *with* (*Remi cut the cake with a knife*) and periphrastic *use* (*Remi used a knife to cut the cake*). In these examples, the knife is an example of a tool. When an object is being used as a tool, both *with* and *use* are appropriate to describe its role. Neither *with* nor *use*, however, is restricted to only the set of tools. *With* is possible for unintentional events (e.g., *Remi tripped and cut her dress with the scissors*). In addition, *use* is possible for instruments that play only a causally indirect role (e.g., *Remi used a stepladder to paint the ceiling*). Both *with* and *use* are also possible for body parts, where no external object extends the reach of the human body (*Remi was eating with her hands*; *Remi was using her hands to eat*). Rissman and Rawlins (2017) ultimately do not use the role Instrument in their analysis of the meanings of *with* and *use*. Thus the boundaries and structure of the Instrument category have been difficult to identify, as with other thematic roles. There is also little empirical evidence that the notion of a tool, as defined above, is a central reference point within this category.

Event Categories and Instruments

Neither *with* nor *use* map onto the category of a tool, and current analyses of the meanings of these words suggest that Instrument is not part of the grammar of English. Nonetheless, there may still be an instrumental category that speakers represent when viewing actual events in the world, and tools may be prototypical members of that category. Events can be construed in multiple ways (DeLancey, 1991). An event of someone pouring orange juice into a glass, for example, can be construed as a caused change of the orange juice from one location to another, or as a caused change to the glass by means of the orange juice. Language provides a window into the construal that is chosen by a speaker at a particular time: the description *Tito poured the orange juice* emphasizes the change of location of the juice. By contrast, *Tito filled the glass with orange juice* emphasizes the change of state of the glass and the causal role of the juice. These two descriptions reflect different ways of construing the event and thus different ways of categorizing the event participants. In this study, we take advantage of this variability to investigate semantic similarity across different types of instrumental participants. To the extent that speakers favor a particular construal of an event, as evidenced through their language, this indicates a dominant way of categorizing the participants in the event. To the extent that speakers use similar language for tools and quasi-tool participants (such as body parts), this suggests that tools and quasi-tools are represented as relatively similar semantically, and may be part of a single event participant category.

We showed adult English speakers videos of tool use as well as seven types of events in which one of the participants shares some but not all of the properties of a tool. These event conditions are displayed in Table 1. For each video, there was a Target participant: we compared linguistic encoding of the Target across all conditions. The Target participants for the example videos are underlined in Table 1. In the No State Change condition, the patient is minimally affected – this contrasts with tool use, where tools bring about a specific

Table 1: Experimental conditions. Target participants are underlined.

	Condition	Description of example video
	Tool	A woman slices a baguette with a knife
Quasi-tool actions	No State Change	A woman hits a box with a pen
	Body Part	A man knocks over a music stand with his hand
	Accidental Agent	A woman sweeps the floor with a broom, accidentally knocking over a bottle
	Causally Indirect	A woman climbs a ladder to open a window
	Locatum	A woman fills a glass with orange juice
	Means of Transit	A trip on Google Maps from Rome to Moscow by plane
	Inanimate Agent	A train rolls down a track, which bumps a red car, which moves a truck
Non-tool actions	Put Theme	A man puts a box on a shelf
	Give Theme	A woman gives a mug to another person

change in an object. In the Body Part condition, the Target is not external to the agent's body. As described above, Accidental Agent events can be described with *with* but not *use*, and Causally Indirect events, where the Target is peripheral to the force exerted on the patient, can be described with *use* but not *with*.

Locatum events are of theoretical interest because some researchers have analyzed such events (e.g., filling a glass with orange juice) in terms of a schema where a substance crosses space, rather than a tool use schema (Jackendoff, 1990). By contrast, Koenig et al. (2008) analyze such events as instrumental, as both a locatum (the orange juice) and a tool are used by an agent to achieve a goal. Similarly, Means of Transit, such as taking a trip by plane, are used by an agent to achieve a goal but are not physically manipulated. Finally, the property of being a causal intermediary has been argued to be essential to instrumentality (Croft, 1991; Talmy, 1976). In Inanimate Agent events, the Target is a causal intermediary but is not manipulated by an animate agent.

We also tested two non-tool-use conditions. In Put Theme events, an agent moved an object to an inanimate location, and in Give Theme events, an agent transferred a physical object to another agent. The Target in both of these events was the theme: themes are intermediary between a source and goal and therefore provide a parallel with tools, which are intermediary between an agent and a patient. Nonetheless, based on prior research on thematic roles (Jackendoff, 1990) we did not expect that participants would use instrumental language to describe the themes in these events.

Method

Participants

43 native speakers of British English participated. An additional four participants were tested but excluded for being native speakers of American English. Participants were tested at Radboud University in the Netherlands and at the University of York in the UK and received either course credit or £5/€5.

Design and Materials

Participants described five videos from each of 10 conditions In Table 1. Each participant saw these 50 videos in a unique random order. The events were live-action videos each lasting 4-5 seconds, with the exception of Means of Transit events. For this condition, we asked participants to describe events in which the mode of transit (e.g., train, bicycle) was construed as a means of getting from one place to another. This construal is difficult to access if participants only see a live-action event of someone riding on a train, for example. We therefore showed a video of someone planning a trip on Google Maps, with a screen capture showing someone typing in a starting point, then a destination, then a means of travel (e.g., walking, driving).

Pilot studies showed that when speakers describe instrumental events, they often omit the instrument from their descriptions (e.g., an event of a man cutting bread with a knife would simply be described as *a man was cutting some bread*). Given this tendency, we highlighted the event participants that we wanted speakers to mention by drawing red circles around them. Circles were drawn around the Target as well as around the agent and patient (or source and goal, as appropriate). A still image of the red circles appeared for two seconds prior to the beginning of the event, as in Figure 1. The circles disappeared as the video began. Means of Transit events did not include red circles.

Figure 1: Initial still image from a video of a woman slicing bread (Tool condition)

Procedure

Participants viewed each of the 50 events on a computer screen and described the events out loud. We gave participants four practice videos to familiarize them with the red circles and Means of Transit events. Speakers were told they could describe the videos in any way they liked, but they needed to mention the three objects in red circles. If a participant failed to mention one of the circled objects during a practice video, they were corrected and given another opportunity to describe the video. Participants were not corrected in the experimental trials. For the Means of Transit events, participants were told that they would see someone planning a trip on Google Maps, and they should describe the trip as if they took it themselves, as if it actually happened. The task itself took about 15 minutes.

Coding

We transcribed speakers' utterances and coded how speakers described the Target in each video (what "term" was used). In syntactic terminology, we coded the lexical item that the Target DP was a complement of. Example terms are shown in (1); these sentences are actual recorded descriptions. The Targets are underlined, terms are noted in boldface and Condition in parentheses. If a speaker described the Target in multiple ways, as in (1f), each of these terms was included. We included all terms to avoid making *a priori* assumptions about which linguistic devices would be relevant for categorizing instrumental events. As we describe below, low-frequency terms were excluded from analysis.

(1) a. The lady smashed the plate **with** a hammer. (Tool)
b. Unfortunately the man **placed** his cup onto the cupcake. (Accidental Agent)
c. A sitting man passes a scarf over to a nearby lady **using** his foot. (Body Part)
d. A woman **used** a toy stick to tap a cat on the head. (No State Change)
e. A lady wrapped the baby **in** the cloth. (Locatum)
f. A man is **holding** a cardboard box. He **lifts** it onto a shelf at about head height and **places** it on that shelf. (Put Theme)

We did not code tense and aspect markings on the verb (e.g. 1b and 1f both included the term *place*). We coded verb and verb-particle constructions as having the same term (e.g., for both *the man held the scarf* and *the man held out the scarf*, the coded term was *hold*).

We excluded trials in which the participant did not mention the Target (e.g., saying *the woman chopped up the carrot* when the Target was the cutting board). We also excluded trials in which the Target was only mentioned as the subject of a clause (e.g., saying *the woman juggled and the ball fell and knocked over the bottle* when the Target was the ball). A total of 4% of all trials were excluded for these reasons.

Results

Descriptive statistics

Across all remaining trials, participants produced 2426 term tokens and 108 term types. Given the high number of term types produced, and the resulting complexity of correspondence analysis models of these data, we focus on only the most frequently produced terms here. We selected the top 16 terms: this was the smallest number of terms needed to ensure that data from all 50 videos were included in the analysis. These top 16 terms constituted 72% of all tokens produced. The 16 most frequent terms were, from most to least frequent: *with, use, put, pick-up, on, take, place, hit, using, knock, drop, in, throw, pass, by* and *into*.

Dimensions of variation

We used correspondence analysis (Greenacre, 2007) to analyze semantic similarity across the descriptions of the 50 videos. We constructed a 16 × 50 matrix in which each cell of the matrix contained a count of how often a particular term was used to describe a particular video. From this high-dimensional space, correspondence analysis extracts dimensions such that the majority of the variance in the data set can be captured using a relatively small number of dimensions. We used the *FactoMineR* package for R (Lê, Josse, & Husson, 2008; R Core Team, 2017). Figure 2 shows the eigenvalues of each of the dimensions in the correspondence analysis, as well as the cumulative variance accounted for with each dimension. Dimensions with higher eigenvalues are more important in interpreting the structure in the semantic space. Drawing on Figure 2, we interpreted the first eight dimensions of the model, which collectively accounted for 86% of the variance.

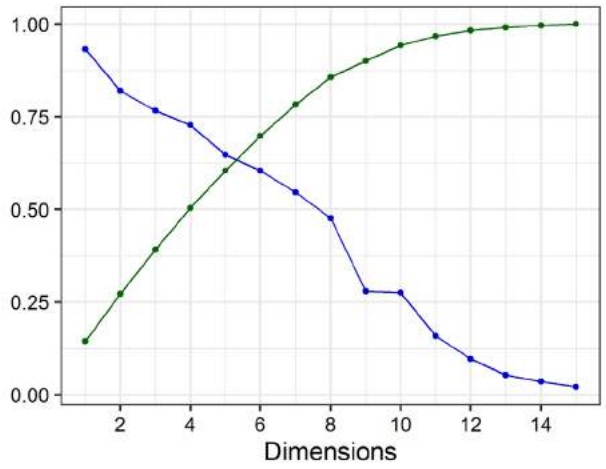

Figure 2: Eigenvalues (blue) and cumulative variance explained (green) for each of the dimensions in the analysis. The y-axis is the same for both values.

We explored how videos in the Tool condition were distinguished in this model from the other conditions. The first dimension distinguished Inanimate Agent videos from the other conditions. The most common terms for Inanimate Agent videos were *knock, hit* and *into*, terms which were rarely used for other videos. The second dimension distinguished videos involving ballistic motion, labeled with the terms *throw* and *drop*, from other videos. These ballistic motion videos came from the Put Theme and Give Theme conditions, as well as the Accidental Agent condition. In one accidental video, for example, a woman tries to juggle three balls but she accidentally drops one of them, knocking over a plastic bottle.

The third dimension grouped Give Theme and Means of Transit videos together, distinguishing them from other videos. The terms distinguished by this third dimension were *take* (e.g., *take a soda can from a woman* but also *take a train to Edinburgh*), *by* (e.g., *go to Paris by car*) and *throw* (e.g., *throw an apple to the man*). The fourth dimension distinguished two conditions from the others, but at opposite ends of the axis: Give Theme videos on one end (labeled by the term *pass*) and Causally Indirect videos on the other (labeled by the term *on*, as in *a woman chops a carrot on a cutting board*). Summarizing the first four dimensions, we see that Inanimate Agent videos are most distinct from Tool videos, followed by Give Theme, Accidental Agent and Means of Transit videos, followed by Causally Indirect videos.

The fifth dimension distinguished the terms *put* and *place* from other terms. These terms were used most often in the Put Theme condition, but also in the Locatum condition (e.g., *place groceries into a basket*) and for one of the Accidental Agent videos, as in (1b). Figure 3 shows a map of the spatial

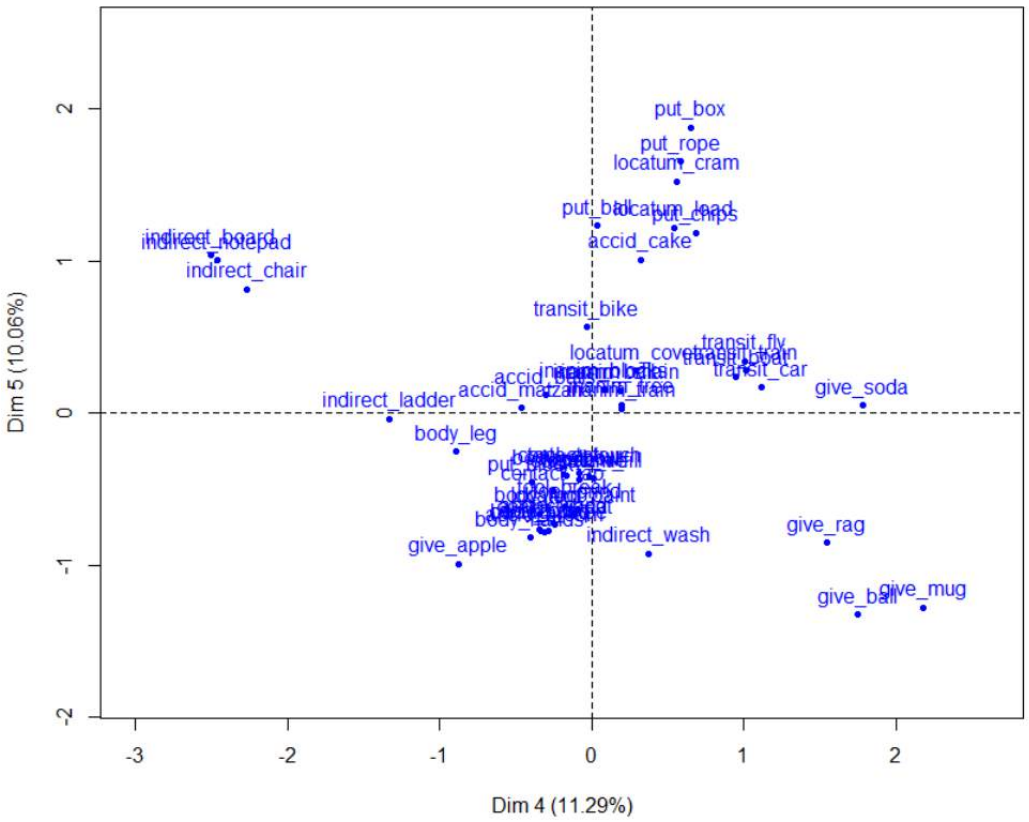

Figure 3: Individual videos plotted on Dimensions 4 and 5 of the correspondence analysis

arrangement of videos as plotted on the fourth and fifth dimensions of the correspondence analysis.

Through five dimensions, all conditions have been distinguished from the Tool condition except for No State Change and Body Part. These two conditions are not, however, distinguished by Dimensions 6-8. Dimension 6 separated transfer events in the Give Theme condition from Means of Transit events. Dimension 7 distinguished a single video in the Causally Indirect condition, where the most frequent term was *in* (e.g., *someone washed spinach in a colander*). Dimension 8 distinguished *throw* from *drop*. The correspondence analysis therefore indicates that No State Change and Body Part events have high semantic similarity to Tool events.

Focus on Tools

We further test this interpretation by analyzing in detail the data from Tool, No State Change and Body Part events taking into consideration the data which was omitted in the above analysis. As described above, 28% of the data was excluded in the correspondence analysis, and these data may reveal that English speakers do in fact categorize the Target in divergent ways across these three events. We calculated how often each term was used in each of these three conditions, as shown in Figure 4. For purposes of visualization, only the 16 most frequent terms are displayed, comprising 93% of all tokens for these three conditions. Black boxes indicate those terms which were not part of the correspondence analysis.

Figure 4 shows that the distribution of terms is similar across Tool, No State Change and Body Part conditions, the most frequent terms being *with, use* and *using*. Smaller differences are also apparent: *pick-up* was relatively common in the Tool and No State Change conditions, but not the Body Part condition. *Over, against* and *elbow* were used for Body Part events but not the other two types of events. Despite these differences, the data in Figure 4 suggest that the similarity across these three conditions observed in the correspondence analysis is not an artefact of 28% of tokens being excluded.

Discussion and Conclusion

In this study, we investigated the structure of thematic roles, focusing on participants that have been classified as Instruments in previous linguistic analysis. We showed live action videos to English speakers, and inferred how participants categorized the events based on the language they used in their descriptions. Correspondence analysis revealed which types of Target participants were described in similar ways to Tools, and which were most distinct. Inanimate Agent events were least similar to Tool events. By contrast, Causally Indirect events were more similar to Tools,

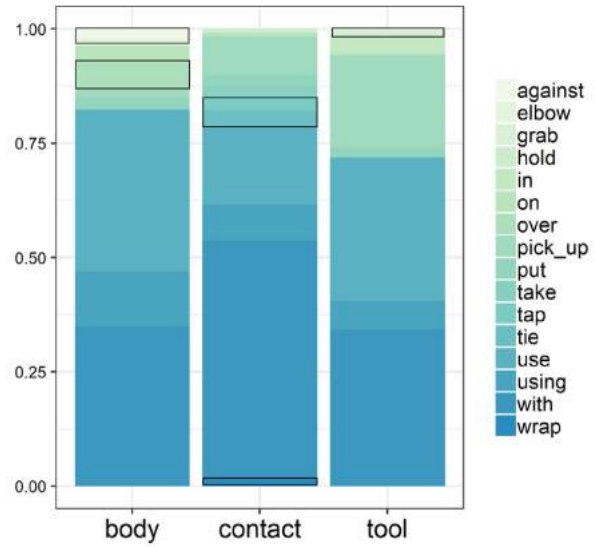

Figure 4: Distribution of the 16 most frequent terms across the Tool, No State Change and Body Part conditions. Black boxes show which terms were excluded from the correspondence analysis

distinguished only by the fourth dimension in the correspondence analysis. Although being a causal intermediary has been argued to be definitive for the Instrument category (Croft, 1991; Talmy, 1976), these results suggest that this property in fact plays a relatively weak role in shaping the categories formed by English speakers.

The results also showed that Put Theme events were more similar to Tools than Give Theme events were to Tools, although neither type of event was predicted to elicit instrumental language. This suggests a relationship between a change of location schema and a tool use schema. In an event of an agent breaking a plate with a hammer, the agent moves the hammer to the location of the plate. And although Tool events were predominantly described with *use* and *with*, not with the locative terms *put* and *place*, Locatum events formed a semantic bridge between Tool events and Put Theme events. Locatum events, such as someone putting a towel over a baby, alternated between locative encodings (e.g., *A woman picked up a towel and placed it onto a toy doll*) and Tool encodings (e.g., *The woman covered the baby with the blanket*). This semantic relationship between Instruments and Themes has been documented cross-linguistically (Bickel, Zakharko, Bierkandt & Witzlack-Makarevich, 2014), but has not been clearly noted for English before.

Previous studies of English have more often emphasized that an Instrument is an extension of an Agent (Rissman & Rawlins, 2017), and we see clear evidence for this relationship in our data. Surprisingly, the terms used for Body Part events were highly similar to the terms used for Tool events. The idea that tools are external to our body, and can therefore extend our reach, is crucial to the role of tools in the development of human culture. *A priori*, we therefore expected that Tool and Body Part events would be categorized in different ways. We did not find a strong distinction between these events, however, suggesting the importance of conceptualizing Instruments as an extension of the Agent. The fact that No State Change events were also similar to Tool events supports this conclusion: the intention and actions of the Agent are more important than the actual outcome. To the extent that tools are prototypical instances of instrumental events, the instruments in Body Part and No State Change events are no less prototypical.

In the video stimuli in this study, we circled the Target participants, in addition to agents, patients, sources and goals, in order to prompt speakers to mention these participants. This likely did affect speakers' construal of the events – in fact, it was our goal to direct speakers to a construal where the Target had high prominence, high enough to be mentioned. We do make the assumption that the descriptions we elicited using these circles would not differ significantly from descriptions where speakers mention the Targets spontaneously, without prompting.

In conclusion, we find that agency plays a prominent role in determining similarity across instrumental events. These conclusions, however, only extend as far as English, and how English speakers conceptualize events. Future research can determine the extent to which similar principles guide categorization in other languages and other cultures.

Abstract

The current study used an eye tracker to examine how auditory input affects the latency of visual fixations and speeded responses on a Serial Response Time Task (SRTT). In Experiment 1, participants viewed a sequence of visual stimuli that appeared in different locations on a computer monitor and the same sequence repeated throughout the experiment. The visual sequence was either presented in silence or paired with uncorrelated sounds (i.e., sounds did not predict visual target location). Participants made more fixations and were more likely to fixate on the visual stimuli when visual sequences were presented in silence than when paired with sounds. Participants in Experiment 2 were presented with the same sequences, but they also had to determine if each visual stimulus was red or blue. The presence of auditory stimuli had no effect on accuracy (red vs. blue), however, there was some evidence that auditory stimuli delayed the latency of first fixations to the visual stimuli and discriminating the images as red or blue was also slower relative to the unimodal visual baseline. While visual stimuli often dominate auditory processing on spatial tasks, the current findings show that auditory stimuli can also slow down visual detection on a task that is better suited for the visual modality. These findings are consistent with a potential mechanism underlying auditory dominance effects, which posits that auditory stimuli may attenuate and/or delay the encoding of visual information.

Keywords: Attention, Multisensory Processing, Auditory Dominance

Introduction

Over the last 40 years, there has been a considerable amount of research examining how individuals process and integrate multisensory information (see Bahrick, Lickliter, & Flom, 2004; Calvert, Spence & Stein, 2004; Robinson & Sloutsky, 2010; Spence, Parise, & Chen, 2012; Stein & Meredith, 1993, for reviews). Much of this research focuses on multisensory integration where information from different sensory modalities is quickly, if not automatically, bound into a multisensory percept in which processing and responding to these multisensory percepts is often faster and more efficient than responding to the unisensory information (Bahrick, Flom, & Lickliter, 2002; Fort, Delpuech, Pernier, & Giard, 2002; Giard & Peronnet, 1999; Miller, 1982). For example, localizing a visual stimulus paired with a sound is often faster than localizing a visual stimulus presented in silence.

However, there are also many situations where multisensory information is arbitrary in nature and information presented to one sensory modality is unrelated to the information presented to the other sensory modality (e.g., listening to music while visually navigating traffic). Under these situations, multisensory presentation can sometimes disrupt encoding, learning, and/or responding, with one sensory modality dominating processing of the other sensory modality. For example, modality dominance research in adults often shows that when auditory and visual stimuli are presented simultaneously, visual input often dominates processing of auditory information (Colavita, 1974; Sinnett, Spence, & Soto-Faraco, 2007; see also Spence et al., 2012, for a review).

There is recent evidence of auditory dominance in adults (Barnhart, Rivera, & Robinson, 2018; Dunifon, Rivera, & Robinson, 2016; Robinson, Moore, & Crook, 2018), however, research pointing to auditory dominance in adult populations typically relies on temporal tasks (e.g., Parker & Robinson, 2018; Robinson & Sloutsky, 2013; Shams et al., 2000; 2002). More specifically, while the auditory modality can sometimes dominate visual processing on temporal tasks, the visual modality typically dominates auditory processing on spatial tasks (Welch & Warren, 1980). These findings suggest that modality dominance effects are flexible in nature and vary as a function of response demands (Robinson, Chandra, & Sinnett, 2016), nature of the task (Welch & Warren, 1980), and signal strength (Alias & Burr, 2004).

Given that auditory dominance effects are less prevalent in the adult literature, the primary goal of the current paper was to focus on these effects. One potential mechanism underlying auditory dominance is that sensory modalities might be competing for attention (Robinson & Sloutsky, 2010; see also Duncan, Martens, & Ward, 1997; Eimer & Driver, 2000; Sinnett et al., 2007; Wickens, 1984, for related discussions). Moreover, because auditory stimuli are often dynamic and transient in nature, it would be adaptive to first allocate attention to this information before it disappears. Attentional resources automatically deployed to the auditory modality might come with a cost - disrupted or delayed visual processing. There is some support for this claim from studies using temporal and recognition tasks (Barnhart et al., 2018; Dunifon et al., 2016; Parker & Robinson, 2018; Robinson et al., 2018, Robinson & Sloutsky, 2013; Shams et al., 2000; 2002), however, a stronger test of this proposed mechanism would be to examine if auditory stimuli also delay visual

processing on a visuospatial task, a task better suited for the visual modality.

A recent study presented adults with a SRTT, which was administered on a touch screen computer (Robinson & Parker, 2016). As in previous research using variations of this paradigm (e.g., Dennis, Howard, & Howard, 2006; Nissen & Bullemer, 1987; Song, Howard, & Howard, 2008), Robinson and Parker (2016) presented visual information to spatially distinct locations, and participants had to quickly respond to this information (i.e., they had to touch each stimulus when it appeared on the touch screen monitor). Unbeknownst to participants, the visual sequences were structured and followed the same sequence throughout the experiment. Motor responses sped up over the time suggesting that, at some level, participants were learning the sequences. More relevant to the current study, motor responses to the visual stimuli were slower when the visual stimuli were paired with uncorrelated sounds (i.e., sounds that did not predict/correspond with location of the visual stimulus).

The current study expands on this research by using variations of a SRTT administered on an eye tracker to examine patterns of visual fixations over time. In both reported experiments, participants were shown two visual sequences of 12 stimuli, and the same sequences repeated throughout the experiment. In one condition, the sequence was presented in silence (unimodal condition) and in the other condition, the visual sequence was paired with sounds that were not correlated with the spatial location of the visual stimuli (cross-modal condition). Participants either counted the number of visual stimuli (Experiment 1) or they responded to each stimulus by quickly making a distinction on whether visual stimulus was red or blue (Experiment 2). If auditory stimuli are disrupting visual detection/encoding, then latency of first fixations to the visual stimuli should also be delayed. However, if auditory stimuli are disrupting later stages of visual processing (e.g., response/decision phase), then auditory interference should only be found in Experiment 2 when participants are making explicit responses to each stimulus.

Experiment 1

Method

Participants Forty undergraduate students (M = 19.41 years, SD = 1.61 years, 22 Females, one person did not disclose gender or age information) from The Ohio State University at Newark participated in the experiment for course credit. Data from 11 other participants were excluded from the study due to technical difficulties such as poor calibration, software crashes, etc.

Apparatus Participants were centrally positioned and seated approximately 65 cm in front of an EyeLink 1000 Plus eye tracker with desktop mount and remote camera. The eye tracker computed eye movements at a rate of 500 Hz, and Experiment Builder 1.10.165 controlled the timing of stimulus presentations. Visual stimuli were presented on a BenQ XL2420 24" 1920 x 1080 monitor and auditory stimuli were presented via Kensington 33137 headphones. Eye tracking data were collected and stored on a Dell Optiplex 7010 computer. Gaze fixation positions, Areas Of Interest (AOIs), and fixations were identified by the EyeLink system and data were exported using Data Viewer. The eye tracker, stimulus presentation computer, and eye tracking computer were stationed in a quiet testing room and a trained experimenter oversaw the entire duration of each participant's study.

Materials and Design Visual stimuli were solid red and blue circles (100 pixels in diameter) and were presented on a white background. Visual stimuli were presented for 700 ms and were presented one right after another with no interstimulus interval. Auditory stimuli were 6 sine waves (500 - 3000 Hz, each stimulus increasing by 500 Hz) and 6 sawtooth waves (250 - 2750 Hz, each increasing by 500 Hz) Auditory stimuli were created in Audacity and were presented via headphones at a comfortable level - approximately 65 dB. Auditory stimuli were presented for 500 ms, and the auditory and visual stimuli shared the same onset.

The experiment consisted of two within-subjects conditions: a unimodal condition and a cross-modal condition. We presented two visual sequences of 12 distinct circle locations that repeated 20 times (see Figure 1 for sequences). In the unimodal condition, the sequence was presented in silence, and in the cross-modal condition, the visual sequence was paired with sounds. The color of the circles in both conditions was random (not correlated with the location of the circle), as were the sounds in the cross-modal condition. The order of the two sequences and the sequence-condition pairings were counterbalanced across participants.

Procedure Participants were told that they would see red and blue circles appear one at a time in different locations across the screen. They were instructed to look at the circles as they appear and respond by pressing a USB button placed in front of them after every 10 circles that they saw. Participants were not told that the circles would appear in the same sequence of 12 locations, however, they were informed that the study was split into two parts, a silent condition and a sound condition. Participants were given a consent form and demographics form to fill out before the study began.

After completing the consent and demographic forms, participants were calibrated on the eye tracker. Drift correction occurred every 50 stimuli (approximately 40 s), and we recalibrated the eye tracker every 100 stimuli (approximately 80 s). When the experiment concluded, the participants were given a three-question survey. On each item, they had to determine if they thought the order of the visual sequence, the order of the visual sequence paired with the sounds, and the order of the auditory sequence, was random or followed a pattern which repeated throughout the experiment. Question order was counterbalanced across participants (e.g., participants who received the unimodal

condition first were first asked about the unimodal sequence and vice versa).

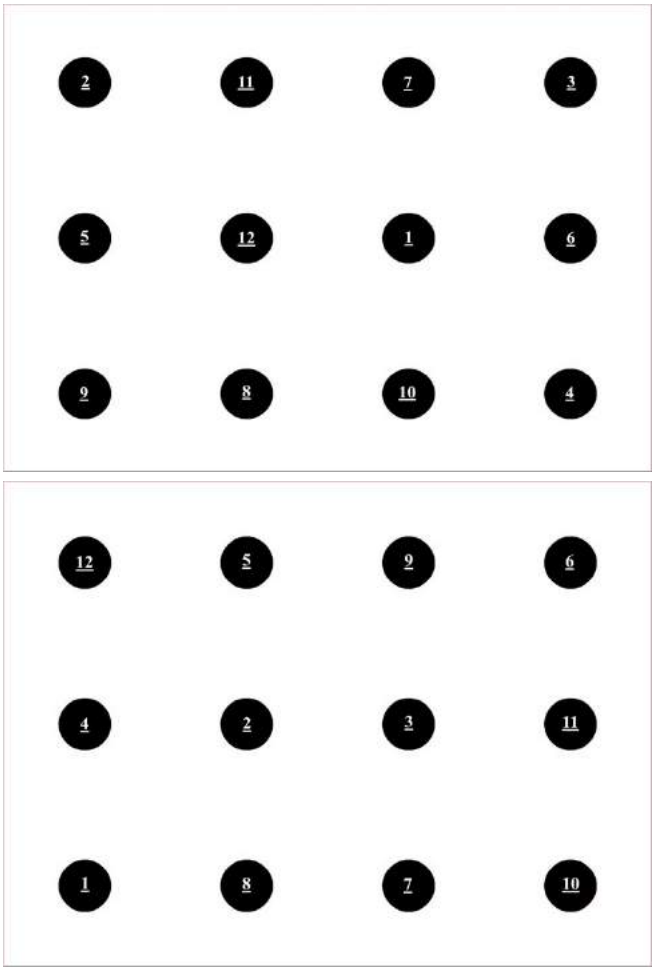

Figure 1: Order of the two visual sequences.

Results

We examined three different eye tracking variables which might be affected by the presence of auditory stimuli. First, we examined the latency of first fixations, which are sometimes slowed down on recognition tasks when visual stimuli are paired with sounds or words (Barnhart et al., 2018; Dunifon et al., 2016). Second, we examined the proportion of stimuli where participants made a fixation to the target location. If auditory stimuli disrupt visual encoding, there should be fewer fixations to the visual targets in the sound condition. Finally, we examined the number of fixations on each trial, however, these predictions are less clear. For example, attention automatically deployed to the auditory modality (or away from the visual modality) could reduce the overall number of fixations or it could make the visual task more challenging and require more fixations before detecting the visual target.

Each participant reported in the final sample completed the unimodal condition and the cross-modal condition, and in each condition, participants were presented with an ordered sequence of 12 visual stimuli, which repeated 20 times. Each sequence of 12 stimuli was considered as a trial, and to reduce noise, we created four blocks by averaging across five trials (60 stimuli). Thus, each condition consisted of four blocks of five trials, with 60 stimuli per block (e.g., Block 1 = first 60 stimuli, Block 2 = 61 - 120, etc.).

Every 700 ms a visual stimulus appeared in one of 12 pre-specified locations on the monitor and we recorded the latency first fixation to the visual stimulus (timestamp of first fixation to AOI - timestamp of stimulus onset). AOIs were created in Data Viewer and were 300 x 300 pixel squares centered around each visual stimulus. We submitted the mean latency of first fixations to a 2 (condition: unimodal, cross-modal) x 4 (block: blocks 1-4) repeated measures ANOVA. Mean latency of first fixations across condition and time ranged from 256 - 261 ms. There were no significant effects and the interaction did not reach significance, *p*s > .31.

We also examined the proportion of stimuli where participants made a fixation to the AOIs. If a participant made a fixation to the location of the target from stimulus onset to stimulus offset, then we coded that stimulus as a 1. If a participant did not make a fixation to the AOI during this time window, then we coded that stimulus as a 0. Proportions of fixations to the AOIs were averaged within each block and we submitted these values to a 2 (condition: unimodal, cross-modal) x 4 (block: blocks 1-4) repeated measures ANOVA. The analyses only revealed a marginally significant effect of condition, F (1, 39) = 3.95, p = .054, η_p^2 = .092, with participants making a higher proportion of fixations to the AOIs in the unimodal condition (M = .94, SE = .01) than in the cross-modal condition (M = .92, SE = .02).

The number of fixations from stimulus onset to stimulus offset (to any location on the monitor) was collected and we submitted these values to a 2 (condition: unimodal, cross-modal) x 4 (block: blocks 1-4) repeated measures ANOVA. The analysis only revealed an effect of condition, F (1, 39) = 5.66, p = .022, η_p^2 = .127, with participants making more fixations in the unimodal condition (M = 2.42, SE = .03) than in the cross-modal condition (M = 2.39, SE = .03).

Finally, at the end of the experiment, participants completed a three-item questionnaire. Random and Patterned responses for the unimodal and cross-modal conditions were analyzed using a McNemar's Chi-square. The McNemar Chi-square was significant (N = 40), p = .049, and one sample binomial tests compared to chance revealed that a majority of the participants thought the unimodal visual sequences were random (M = 68% reported random, p = .04), whereas, only 45% of the participants indicated that the visual sequences paired with sounds were random, which did not differ from chance, p = .64. Forty-five percent of participants also reported that the order of the auditory sequence was random.

In summary, while previous research demonstrated that auditory stimuli can slow down first fixations on recognition tasks (Barnhart et al., 2018; Dunifon et al., 2016) and slow down motor responses on a touch screen SRTT (Robinson & Parker, 2016), the current study found only weak support for

auditory interference. More specifically, participants in the current study were slightly less likely to make a fixation to the visual stimulus when it was paired with a sound and they also made fewer fixations (to any location on the monitor). However, unlike Robinson and Parker (2016), there was no evidence that participants learned the visual sequences. Recall that latency of first fixations to the target locations did not speed up across training, whereas, motor responses sped up in Parker and Robinson (2016). Finally, while a majority of participants thought the unimodal visual sequences were random, participant responses did not differ from chance when sequences were paired with sounds. It is unclear if the uncorrelated sounds increased the perceived structure of visual input or if the sounds simply increased chance responding. However, if the sounds did increase the perceived structure of visual sequences, it did not result in faster or more fixations to the visual targets.

Experiment 2

The primary aim of the Experiment 2 was to further examine possible effects of auditory stimuli on visual sequence learning. Are interference effects restricted to tasks that require an explicit response? To address this aim, we presented participants with structured visual sequences in silence or paired with sounds, however, in contrast to Experiment 1, participants were required to make a response to each visual stimulus (i.e., indicate if the visual target was red or blue). If auditory stimuli interfere with visual processing during the decision/response phase, as opposed to disrupting encoding, then response times should slow down in the cross-modal condition in Experiment 2 while having no negative effect on the latency of first fixations. However, slowed response times and delayed first fixations would be consistent with the claim that auditory stimuli are disrupting visual encoding (Robinson & Sloutsky, 2010a).

Experiment 2 was not originally designed to examine the effects of engagement on sequence learning, however, requiring participants to make an explicit response to each stimulus should make the task more engaging. Thus, it is also possible to examine if poor engagement could account for the lack of learning in Experiment 1. While visual sequence learning on SRTT and statistical learning tasks are often thought to be implicit in nature and not dependent on attention (e.g., Nissen & Bullemer, 1987; Saffran, Newport, Aslin, & Tunick, 1997), it is possible that learning would be more robust if participants were more engaged throughout testing. Requiring participants to indicate if each visual stimulus is red or blue should make the task more engaging, which could result in better learning (i.e., faster response times and/or fixations across time).

Method

Participants, Materials, Design, and Procedure Thirty undergraduate students (M = 20.19 years, SD = 2.51 years, 20 Females) from The Ohio State University at Newark participated in the experiment for course credit. Data from eight other participants were excluded from the study due to technical difficulties, such as software/system crashes, computer lagging, or poor calibrations.

The procedure and design of Experiment 2 were identical to Experiment 1, except that in Experiment 2, a choice response task paradigm was used. Participants were required to make a color distinction with each stimulus by responding with one of two external USB buttons, labeled "RED" and "BLUE" respectively. Participants were instructed to respond as fast and as accurate as possible. The left-right locations of the buttons were counterbalanced across participants.

Results

As in Experiment 1, we examined the latency of first fixations, the proportion of stimuli where participants made a fixation to the visual target, and the number of fixations between stimulus onset and stimulus offset, however, we also examined response times and accuracies on the primary task.

First, as in Experiment 1, we submitted the mean latency of first fixations to a 2 (condition: unimodal, cross-modal) x 4 (block: blocks 1-4) repeated measures ANOVA. The analyses revealed a marginally significant effect of condition, F (1, 29) = 3.62, p = .067, η_p^2 = .111, and a significant time x condition interaction, F (3, 87) = 3.28, p = .025, η_p^2 = .102. While latency of first fixations were numerically faster across all blocks in the unimodal condition, simple effects with Bonferroni adjustments revealed that the difference between unimodal and cross-modal means only reached significance in block 3, p = .012 (see Figure 2).

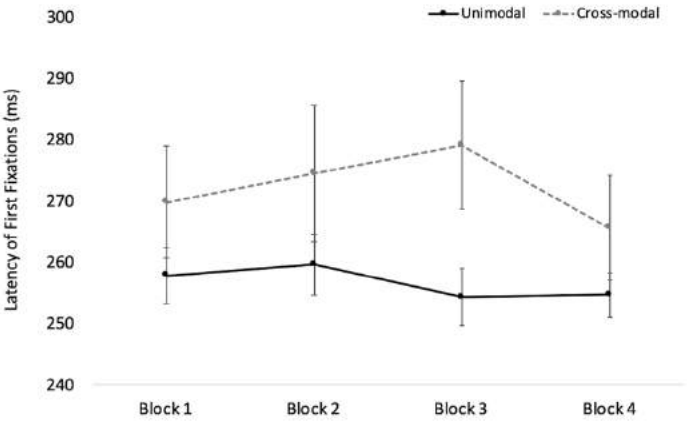

Figure 2. Latency of First Fixations (ms) across condition and time. Error bars denote Standard Errors.

Response times were also submitted to a 2 (condition: unimodal, cross-modal) x 4 (block: blocks 1-4) repeated measures ANOVA. The analysis revealed an effect of condition F (1, 29) = 5.90, p = .022, η_p^2 = .169, with response times being faster in the unimodal condition (M = 584 ms, SE = 19.85) than in the cross-modal condition (M = 624 ms, SE = 28.56). The analysis also revealed an effect of time, F (3, 87) = 16.04, p < .001, η_p^2 = .356. See Figure 2 for response

times across condition and time. Pairwise comparisons with Bonferroni adjustments revealed that mean response times on Block 1 (M = 637 ms, SE = 27.92) were significantly slower than Block 2 (M = 600 ms, SE = 24.18), Block 3 (M = 592 ms, SE = 22.72), and Block 4 (M = 587 ms, SE = 19.48), ps < .001. Blocks 2-4 did not differ, ps > .56. Also note that accuracies (i.e., discriminating red vs. blue stimuli) exceeded .96 across all conditions with no significant effects or interactions, ps > .22.

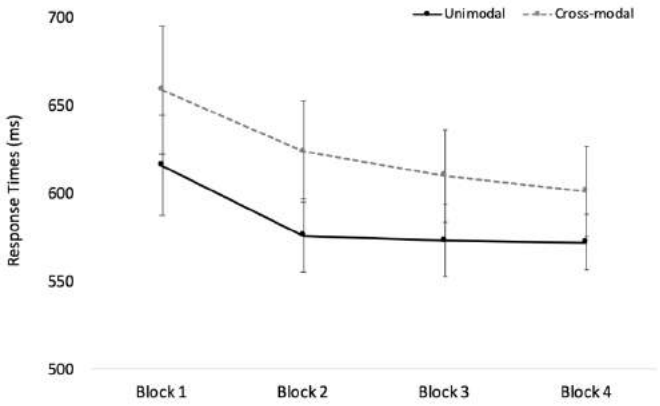

Figure 3. Response times (ms) across condition and time. Error bars denote Standard Errors.

The proportion of stimuli where participants made a fixation to the AOI were submitted to a 2 (condition: unimodal, cross-modal) x 4 (block: blocks 1-4) repeated measures ANOVA. Mean proportion of fixating to the visual stimuli ranged from .93 - .97, and the analysis revealed no significant effects or interactions, ps > .32.

The mean number of fixations between stimulus onset and offset were submitted to a 2 (condition: unimodal, cross-modal) x 4 (block: blocks 1-4) repeated measures ANOVA. The analysis only revealed a marginally significant effect of time, F (3, 87) = 2.62, p = .056, η_p^2 = .083. Pairwise comparisons with Bonferonni adjustments revealed that participants made more fixations on block 1 (M = 2.24, SE = .05) than on block 2 (M = 2.18, SE = .05), p = .023. Block 1 did not differ from block 3 (M = 2.20, SE = .05) or block 4 (M = 2.19, SE = .05), and blocks 2-4 did not differ, ps > .323.

Finally, we also examined responses on the three-item questionnaire, which was administered at the end of the study. Two participants did not complete the questionnaire. Patterned responses for the unimodal visual and visual sequence paired with sounds were analyzed using a McNemar's Chi-square. The McNemar Chi-square was not significant (N = 28), p > .99, Binomial tests compared to chance revealed that 78% of the participants thought the order of the unimodal visual sequence was random, different from chance, p = .004, and 82% of the participants reported that the order of the visual sequence paired with sounds was also random, different from chance, p = .001.

General Discussion

In both reported experiments, participants were shown two visual sequences, and each sequence repeated 20 times over the course of the experiment. One sequence was presented in silence, whereas, the other sequence was paired with sounds, which were not correlated with the location of the visual stimulus. In Experiment 1, participants simply counted the number of visual stimuli, pressed a button after every 10 stimuli, and we examined visual fixations throughout the procedure. Experiment 2 was more engaging, as participants were required to quickly determine if each visual stimulus was red or blue.

Auditory interference effects were found in both experiments. More specifically, in Experiment 1 when participants counted the number of visual stimuli, participants were more inclined to fixate on the visual stimuli in the unimodal condition and also made more overall fixations in the unimodal condition. When participants had to determine if each visual stimulus was red or blue, both latency measures showed some evidence of a slowdown/delay in the cross-modal condition. More specifically, latency of first fixations to the visual stimuli was slower in the cross-modal condition compared to the unimodal baseline, especially in block 3 (see Figure 2). In addition, overall response times were also slower in the cross-modal condition than in the unimodal condition.

The current study contributes to modality dominance research in the following ways. First, most research examining modality dominance in adults often points to visual dominance, with the visual modality dominating auditory processing (Spence, 2009; Spence et al., 2012, for reviews). While the current study did not examine the effects of visual input on auditory processing, the findings provide support for auditory dominance with auditory stimuli slowing down visual fixations and responding. These findings are remarkable given that spatial tasks are typically better suited for the visual modality (Welch & Warren, 1980). Moreover, the current study examined latency of first fixations as well as response times. If sounds were simply interfering during the response/decision phase, then only response times should have been slowed down. Finding evidence that first fixations to the stimuli were also delayed suggests that interference effects are happening early in the course of visual processing (i.e., during the detection phase).

While these findings shed light on the dynamics of multisensory processing, there are some limitations to the current study. First, while response times sped up in Experiment 2, there was no evidence in the eye tracking data that participants were learning the sequences. There are several reasons why learning may have not occurred. First, in both reported experiments, the color of the visual stimuli added noise to the sequences and the sounds in the cross-modal conditions also added additional noise (i.e., participants may have focused on these irrelevant variables and failed to learn the sequences). However, this additional information should not have affected sequence learning if the task is assessing implicit learning. It is also possible that

participants were learning the sequences, but we failed to capture this learning because we primarily focused on participants' responses to visual stimuli and not on their anticipations (fixations before stimulus onset). These possibilities need to be addressed in future research.

In summary, the current study demonstrates that sounds can disrupt visual stimulus detection and response times. These effects have implications on tasks that require processing of multisensory information and shed light on possible mechanisms underlying auditory dominance effects.

Abstract

Creative ideas emerge from a meshwork of dynamic elements. Resources internal and external to the agent configure a cognitive ecosystem that scaffolds performance. In addition, capitalizing on fortuitous external cues may trigger new ideas. We examined these elements to determine how they come into play during a simple word production task. Participants were video recorded as they generated new words from 7 letter tiles in three different environments (i) high interactivity where the titles could be moved at will (ii) low interactivity where they could not, and (iii) low interactivity where the order of the tiles could be shuffled but once shuffled no additional actions were allowed. Overall, interactivity had a marginally positive impact on performance, while independent measures of participants' verbal fluency were strong predictors of performance in all environments. Based on a detailed coding of the video data, a finer-grained analysis of behaviour in the high interactivity condition revealed that the time participants spent manipulating the tiles was a significant predictor of performance. The video data also allowed us to measure the average latency to the production of a new word after shuffling the letters in the low interactivity condition as an index of how 'lucky' the reset was: Shorter average latencies were a significant predictor of overall word production. These data indicate that interactivity, serendipity, and internal cognitive resources determine problem-solving performance in this task.

Keywords: Creativity; interactivity; serendipity; cognitive eco system.

Introduction

Problem solving is an activity that takes shape in a dynamic meshwork of resources and processes, configured from internal mental resources, embodied actions and environmental affordances. To better appreciate the role of interactivity in problem solving it is important to contrast problem solving performance in task ecologies that differ in the degree to which a problem solver can 'think' through the manipulation of a physical model of the problem. In a low interactivity task environment, the problem solver is decoupled from her immediate environment: She is invited to solve a problem without using her hands to support thinking either through gesture or rearranging the physical elements that configure a model of the problem (such task environments are often the default procedure employed in problem solving research, Vallée-Tourangeau & March, 2019). In other words, problem solving proceeds from mental simulations of possible solutions. In contrast, a high interactivity task environment places no such constraints on her: Participants are presented with physical elements of the problem that can be manipulated to arrive at a solution. In such environments, proto solutions are boundary objects of sorts (Fiore & Wiltshire, 2016) that are physically constructed and perceived, unveiling action affordances and guiding attention in ways that are simply not possible in low interactivity conditions. Creative problem solving in a task ecology that favours interacting with the physical elements of a problem, is driven by three factors: the internal resources of the problem solver, her embodied behaviour and the environmental affordances that unfold dynamically as the physical model of the problem is modified. A full account of these aspects helps better appreciate their transactional nature.

Interactivity in the Word Production Task

The game of Scrabble has been modified to assess whether manipulating the letter array supports word production (see Maglio, Matlock, Raphaely, Chernicky & Kirsh, 1999; Webb & Vallée-Tourangeau, 2009; Vallée-Tourangeau & Wrightman, 2010; Kirsh, 2014; Fleming & Maglio, 2015). In this modified task participants are given 7 letters and invited to generate words. With an open problem of this sort, the dependent measure offers a more nuanced measure of the benefit or otherwise of interactivity. Additionally, letter set difficulty can be manipulated by selecting sets of letters that generate more or fewer words.

There are clear theoretical reasons to suppose that interactivity would benefit solvers in a word production task of this kind. By extending the mental workspace outside of the head, the internal letter representations are reified and are easily manipulated freeing up and scaffolding participants' internal resources (Gavurin, 1967; Webb & Vallée-Tourangeau, 2009; Vallée-Tourangeau & Wrightman, 2010). Furthermore, interactivity allows the solvers to move with less effort through the problem space and even to jump to new places with, at times, unplanned moves (Maglio et al., 1999). Thus, the tiles may either be recruited strategically or, more serendipitously, non-strategic moves may yield lucky combinations of letters.

Empirically, however, the data are less clear than may be imagined. The only study that demonstrates an unequivocal benefit is Flemming and Maglio (2015) where interactivity not only led to an increase in word production but also to rarer (less frequent) words being produced. While Maglio et al. (1999) documented a small overall benefit for interactivity, when this was broken down into the two different letter sets used, interactivity led participants to produce more words with one letter set but fewer words with another, easier, letter

set. With an easy letter set, participants are more capable of generating words without help so the added cost of manipulating tiles may actually slow down word generation. In addition, the serendipitous jumps proposed by Maglio et al. (1999) are less likely to occur when a participant can easily produce words.

Individual Differences

Where the participants have been profiled, the existing data show a clear interaction between the individual resources of the problem solver and the effect of interactivity. Vallée-Tourangeau and Wrightman (2010) found that there was a statistically significant benefit in the high interactivity condition for participants categorised in the low verbal fluency group while the benefit for those in the high verbal fluency group was negligible. This mixed story is echoed by Webb and Vallée-Tourangeau (2009) who manipulated the difficulty of level sets across two groups, children with and without developmental dyslexia. Here the number of words produced by each group depended on the difficulty of the letter set: Interactivity only benefitted the control group with the harder letter set and the children with developmental dyslexia only benefitted from interactivity with the easy set. The evidence to date suggests that interactivity scaffolds the performance of those who have lower verbal fluency or working memory and acts as an additional, reciprocal and non-linear processing loop (Vallée-Tourangeau & Vallée-Tourangeau, 2017) but it appears to confer little benefit when the task is within the capability of the participants either because of their skills or the nature of the letter set employed.

Environmental Affordances

For Maglio et al. (1999) the benefit of high interactivity was in no small part due to the introduction of randomness that seeds intelligent behaviour. Randomness is generated by the external environment and interactivity research explores the way problem solvers both recruit and are entangled with this environment (Ingold, 2017). Kirsh (2014) explicitly examined this role of randomness in the word production task. The participants were invited to take part in a task on a computer with an additional shuffle condition where one click shuffled the letters randomly. He found that the shuffle condition encouraged the production of a significantly higher number of words (M = 18.9) than both the static (M = 16.6) and the interactive (M = 17.7) conditions.

If we consider the constraints in place across Kirsh's three conditions, this becomes a more surprising result. As there were no reported constraints in the high interactivity condition, it theoretically provides the widest range of possible strategies. Participants are not prevented from shuffling the tiles randomly, just such shuffling would have to be self-generated. In practice, it seems unlikely that participants could have fully used the range of possibilities of the high interactivity version. Indeed, the number of shuffles described by Kirsh—the best performing third shuffled once every 3.7 seconds, the worst performing third once every 1.9 seconds—demonstrate the incredibly low cost of shuffling to generate hints in this task environment. In practice, it would be impossible to mimic this strategy with the high interactivity version in the same time.

Just as the skills of the problem solver are important when we consider the ways cognition arises from the interplay between person and external artefacts, so too are the affordances for action offered by the artefacts. Taking the cognitive ecology of this task seriously, requires taking the affordances of the external environment seriously. Rather than making the implicit assumption that the problem solver imposes her will on an inert and indifferent environment, we suggest that the nature of the artefacts selected will determine to some extent the actions undertaken (Steffensen, Vallée-Tourangeau & Vallée-Tourangeau, 2017).

It is our hypothesis that in Kirsh (2014) the low cost of shuffling the tiles with one click on a computer compared to the relatively high cost of moving tiles with a mouse, meant that shuffling functioned as an epistemic action (Kirsh & Maglio, 1994) more closely resembling the actions of a Tetris player who chooses a tretromino drop location based on what she sees *after* multiple physical rotations rather than a true test of luck. Indeed, Kirsh (2014, p. 19) acknowledges this: "the cost in time and mental effort must be sufficiently low that it pays to keep fishing for hints". The benefits of interactivity are only useful when they outweigh the costs of that interactivity (Maglio et al, 1999) and the shuffle condition reported in Kirsh (2014) is incredibly low in cognitive cost. Thus, while environmental randomness was examined it remains to be seen to what extent its benefit resulted from the low cost involved in monitoring the usefulness of a change in the letter array rather than having to take the time or make the mental effort to produce different arrays.

Participant Behaviour

The manipulation of chance by Kirsh (2014) also highlights differences in participants' behaviour. The number of shuffles varied across shufflers. Indeed, the better word generators shuffled "about 50% less" (p.18) than those who produced the fewest words. So, while the shuffle condition produced a higher overall mean of words, when the behaviour of the participants is taken into account, a more nuanced and accurate account of the role of chance is possible. Shuffling did not confer an indiscriminate benefit across all participants.

This difference in the behaviour of the participants is also acknowledged in a footnote in Maglio et al. (1999, footnote 2, p. 330): roughly a third of the participants did not consider it worth using their hands to structure their thoughts in an ostensibly high interactivity environment. This footnote requires us to consider to what extent the participants in this experimental condition could be said to be using interactivity; rather the condition might be more aptly renamed *potential* for high interactivity.

In various experiments investigating the role of interactivity in problem solving (e.g., Vallée-Tourangeau, Sirota & Vallée-Tourangeau, 2016), the low interactivity

condition is invariably tightly controlled, and participants' movements are constrained with them often being requested to lay their hands flat on the work surface. However, there are few controls and rarely any consideration of the manner in which participants recruit resources in a task environment labelled as high interactivity. Only Fleming and Maglio (2015) have taken a closer look at the behaviour of participants in a high interactivity condition. In contrast to Maglio et al. (1999), they suggest that all their participants moved the tiles. However, as the focus of their paper was strategy selection rather than the time spent interacting, the detailed analysis required restricted their coding to the behaviour of 8 participants in the final block with a specific aim of looking for and coding word production strategies. If we are to profile the whole system (Vallée-Tourangeau & Vallée-Tourangeau, 2017) then the level of interaction becomes important each time the participants encounter the tiles as a measure in itself rather than solely as an indication of strategy, especially if the different levels of interactivity designed in these environments do not result in differences in participants' behaviour.

It is further unclear how much participants' behaviour differs as a function of their individual differences. It is plausible that those who do not need the help of the tiles recruit them less. Research on expert Tetris players suggests an inverted U shape relationship of action and expertise with complementary actions decreasing as expertise increases (Destefano, Lindstedt & Gray, 2011). It is not unreasonable to expect a similar relationship in this task.

The Current Experiment

We examined the role of interactivity and chance in a word production task as well as the moderating properties of participants' verbal fluency. Rather than a computer and mouse we employed physical letter tiles. These artefacts more naturally invite interaction in the high interactivity condition and conversely increase the cost of movement in the shuffle condition testing if the benefits of shuffling hold when the nature of the artefacts are taken into consideration. We video recorded participants to undertake a more granular analysis of their behaviour in the high interactivity condition. This allowed us to assess the number of participants in the high interactivity condition who actually chose to move the letter tiles and determine the amount of time they actually interacted with the tiles. In this way, we can begin to disentangle some of the complexities that underlie the reported aggregated means in the high interactivity and the shuffle conditions.

We hypothesised that the increased time and cognitive cost of shuffling would lead to a reduction in the average number of shuffles and so, contrary to Kirsh's findings, we further hypothesised that the high interactivity condition would yield the most words followed by the shuffle condition reflecting the relative cognitive and time costs of each condition. Further, that video data would reveal a range of engagement with the tiles and capture the participants who do not avail themselves of the affordances for creativity in a high interactivity task environment. In line with the data reported for shuffling in Kirsh (2014), we expected an optimum level of interactivity beyond which there would be no further benefit. We hypothesised that verbal fluency would significantly moderate not only the total word count but participant behaviour, that is that high verbal fluency participants might not interact with the letter tiles to the same degree as low verbal fluency participants.

Method

Participants

Forty-two participants took part in the experiment in exchange for course credits. Two participants did not consent to be filmed and still received credit but as their behaviour could not be coded, their data were excluded. This left data for 40 participants (32 females, M_{age} = 25.65, SD = 7.17).

Design

The experiment used a repeated measures design with the order of the three experimental conditions counterbalanced across participants. The three conditions were high interactivity, low interactivity, and low interactivity + shuffle.

Materials and Measures

Three sets of 7 letters (COTFAED, NDRBEOE and TVAERWI) were created with similar average number of possible words of similar frequencies[1] piloted in a prior norming task. In each condition, the participants were given 5 minutes to call out as many words as they could from a set of 7 letter tiles (2cm * 2cm) initially presented in a straight line with the following constraints (i) the words must be at least three letters long and (ii) proper names and acronyms were not allowed. In the high interactivity condition, participants were invited to move the tiles as they saw fit. In the low interactivity condition, they were asked to not move or interact with the tiles in any way. Finally, in the shuffle condition, they were invited "whenever you want to and as many times as you want to" to collect all the tiles up, shake them in closed hands and lay the tiles out again in the new, randomly generated order. In the shuffle condition, when not shuffling the tiles, participants' movements were constrained in the same way as in the low interactivity condition. The dependent variable was the number of words generated by the participants in the three task environments.

Participants were also profiled along three further measures. First, performance on a modified version of the Thurstone (1938) test, which involves writing as many words with the letter S in five minutes and then as many words with the letter C in four minutes, was used to index participants'

[1] Frequencies taken from Zipf scores presented in the SUBTLEX-UK database (Van Heuven, Mandera & Keuleers (2014).

verbal fluency. Second, participants were invited to complete 12 5-letter anagrams taken from a larger set in Webb, Little and Cropper (2016) to assess their skills at anagramming. Finally, their levels of openness to experience was measured using the relevant items from the scale used in Lee and Ashton (2004); although there is little firm evidence on the role of personality traits and luck, this trait has been previously linked to a propensity to experience luck (McCay-Peet, Toms & Kelloway, 2015) and was added as an exploratory measure to assess if participants high on this trait would leverage the luck or otherwise of the shuffle condition.

Procedure

The anagram and verbal fluency tests were used as warm up tasks before the three main experimental conditions. The measure of extraversion was placed at the end of the study producing the following order:

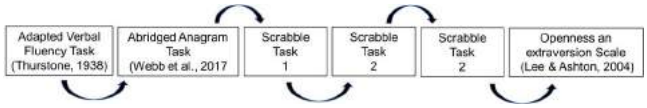

Figure 1: The order of the tasks.

The order of the conditions was counterbalanced across participants as was the set of letter tiles associated with each condition.

Qualitative Coding

In the high interactivity condition, the amount of time participants spent moving the tiles was coded using ELAN. The total time interacting with the tiles was assessed from when a participant touched a tile to when he or she stopped touching it. As there were many moments when a participant touched a tile but did not move it, this was further split into neutral moves (which did nothing to alter the array) and active moves (which changed the array in some way, either deliberate or random). Active moves were considered a reflection of interactivity. In the shuffle condition the number and timing of the shuffles was also recorded in ELAN. The timing of the shuffle was calculated from the moment participants touched the tiles until they had re-laid the array. In some instances, participants generated a word while relaying the tiles after the shuffle and therefore before the end of the full shuffle process; in these cases, the shuffle-new word latencies were negative.

Results

There was broadly similar performance in each experimental condition. Participants produced the highest number of words in the high interactivity condition ($M = 18.4$, $SD = 8.5$). There was virtually no difference between the performance in the low interactivity ($M = 17.0$, $SD = 6.2$) and shuffle ($M = 17.2$, $SD = 6.2$). While there was a slight benefit of interactivity, a one-way repeated measures analysis of variance revealed this to be non-significant, $F(2, 78) = 1.97$, $p = .146$, $\eta p^2 = .048$.

Correlations among measures of verbal fluency, anagram performance, openness and word production in the three experimental conditions are reported in Table 1 (df = 38). As expected, verbal fluency significantly correlated with performance in the high condition, $r = .717$, $p < .001$, the low condition, $r = .734$, $p < .001$ and the shuffle condition, $r = .745$, $p < .001$. Anagram skill also correlated highly with performance in the high, $r = .601$, $p < .001$, low, $r = .679$, $p < .001$ and shuffle conditions, $r = .630$, $p < .001$. There were no significant correlations between the measure of openness to experience and performance in any of the conditions.

Performance in the High Interactivity Condition

The video data enabled us to examine and analyse in finer detail the behaviour of the participants in the high interactivity condition. As we reviewed in the introduction, not all participants avail themselves of the opportunity to interact with the external environment. It is insufficient to analyse group level performance to determine the benefits of interactivity in the absence of a more detailed analysis of individual behaviour and performance. As expected, the video data revealed large differences in the behaviour of the participants in the high interactivity task environment. Active moves constituted 86% of the total time spent touching the tiles. Two participants opted not to interact with the tiles at all. The range of the time spent actually interacting with the letter tiles was 2.9 seconds to 226.9 seconds with a mean time of 106.4 seconds ($SD = 65.10$). The relationship between time interacting and the number of words produced is displayed in Figure 2. As the scatterplot reveals, the longer the participants interacted with the tiles the more words they produced. This relationship was significant, $r(38) = .329$, $p = .038$ and indeed becomes stronger when the effects of anagram skills and verbal fluency are partialled out, $r(38) = .439$, $p = .006$ offering a more direct measure of the impact of interactivity on word production. Contrary to our prediction and the observed shuffling behaviour in Kirsh (2014), interactivity conferred a steady benefit with no tailing off.

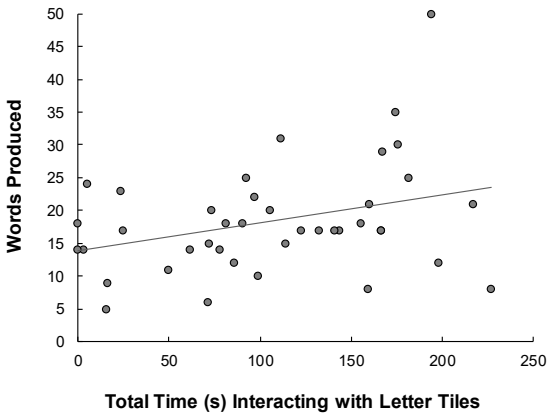

Figure 2: Number of words produced in the high interactivity condition as a function of the time (in seconds) spent interacting with the letter tiles.

Table 1: Descriptive statistics for and correlations among measures of verbal fluency, anagram performance, openness, and word production performance in the three experimental conditions.

	M	*SD*	1	2	3	4	5	6
1. Fluency score	88.30	25.15	-					
2. Anagram total	8.90	2.73	.493 **	-				
3. Openness	102.75	15.25	-.018	-.046	-			
4. High word count	18.35	8.49	.717 **	.601 **	-.230	-		
5. Low word count	17.03	6.59	.734 **	.679 **	-.173	.819 **	-	
6. Shuffle word count	17.23	6.23	.745 **	.630 **	-.019	.848 **	.796 **	-

** $p < .001$ level (2-tailed).

Finally, in contrast to our prediction, the extent to which a participant recruited the letters to aid thinking did not significantly correlate with either verbal fluency, $r(38) = .111$, $p = .481$, or anagram skills, $r(38) = -.032$, $p = .844$.

Performance in the Shuffle Condition

Participants shuffled an average of 1.58 times; there was, however, a wide variation in the number of shuffles. Twenty five percent of the participants opted not to shuffle at all, 17.5% of participants opted to shuffle once, 30% twice and a further 27.5% opted to shuffle 3 times.

As predicted, there was a large time cost to shuffling. The average shuffle took 17.51 seconds ($SD = 3.51$) with the fastest shuffle being 10.22 seconds and the slowest taking 24.64 seconds. Overall, shuffling appeared to be an unhelpful strategy. Participants' word production performance did not differ among those who did not shuffle ($M = 17.81$, $SD = 6.58$), shuffled once ($M = 17.12$, $SD = 5.02$), twice ($M = 16.58$, $SD = 7.35$) or three times ($M = 16.81$, $SD = 6.30$), $F < 1$.

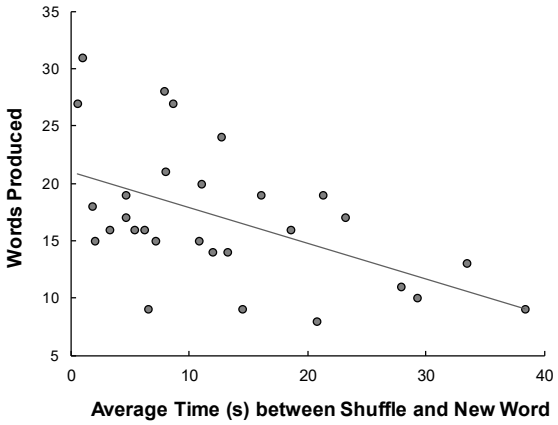

Figure 3: Number of words produced in the shuffle condition as a function of the average time (in seconds) before a word is produced after shuffling the letter tiles.

The effect of the shuffles also varied widely. The average time after the end of shuffling to generate a word was 11.69 seconds ($SD = 13.77$). The minimum time after shuffling to produce a word was -5.05 seconds (producing a word while relaying the tiles after the shuffle) whereas the maximum time after the shuffling had ended to producing another word was over a minute (61.72 seconds). Only one participant did not produce any words after her first shuffle and went on to shuffle again.

It seems likely that a word produced directly after a shuffle has been stimulated by that shuffle whether that shuffle directly yielded the word or whether the act of shuffling and laying out of the tiles stimulates further thought. We thus measured how long after a shuffle a word was produced as a proxy measure of the luckiness of the shuffle – the faster a word was produced the luckier the shuffle. The relationship between this time (averaged out for those participants who had more than one shuffle) and the total number of words produced overall in the shuffle condition is illustrated in Figure 3. The correlation was significant, $r(27) = -.520$, $p = .004$ even when controlling for verbal fluency and anagram skill, $r(27) = .422$, $p = .028$, suggesting that the nature of the array produced by the shuffle and the words it stimulated was important to the overall number of words produced in that condition.

Discussion

This experiment was designed to trace the influence of interactivity, serendipity and verbal fluency in a word production task. These three elements create a dynamic meshwork from which word production skills are enacted. The differences in the mean number of words produced in the three experimental conditions were marginal albeit showing a general trend in line with past findings favouring high interactivity. When performance is viewed through the lens of a condition's mean score with individual variation in behaviour and cognitive skills flattened, the benefits of interactivity in this task are not clearly revealed. While there has been some examination of cognitive profiles which benefit from interactivity, the implicit assumption in previous research has been that there has been no difference in participant behaviour in the high interactivity condition.

However, by subjecting participant behaviour to a finer granularity of analysis, we can start to disentangle how that behaviour affects the numbers of words produced and isolate a purer effect of interactivity. Given that two participants did not interact with the letter tiles at all, it is illogical to attribute

their scores in both the low and high interactivity conditions to different factors (in effect, despite our best efforts to change the task ecology, these participants approached the high and low interactivity conditions in the same manner). Again, those participants who chose not to shuffle essentially participated in an additional low interactivity experimental condition. It is meaningless to assign one score to low and one to shuffle unless we are measuring the effect of experimental instructions.

When the behaviour of the participants is taken into account, there was a significant correlation between the time spent interacting with the letter tiles and the number of words produced in that condition even when controlling for verbal fluency skills. This suggests that interactivity boosts word production only when a participant fully engages in that condition. Measuring participants' behaviour is important and designing a high interactivity task environment does not guarantee that the affordances inherent to a dynamic problem-solving environment will be perceived and exploited to boost performance. Contrary to expectation, there was no relationship between verbal fluency and the time spent interacting. This is in contrast to prior observations on the different effect of interactivity on different individual difference profiles: interacting with the tiles helped everyone.

Further, there was failure to replicate Kirsh's (2014) observation that engineered randomness boosts performance. However, the nature of the current experiment increased the impact of an unlucky shuffle by increasing the time and cognitive cost of shuffling as the materials were moved from a digital to a material environment. This led to a predicted decrease in the number of participants who opted to shuffle and the number of times they shuffled along with a much higher investment in the array produced by the shuffle than that reported by Kirsh. The inherent contingent and transactional nature of luck in this task was partly captured by the latency to first word produced after a random re-arrangement. These average latencies were significant predictors of how many total words would be produced in this otherwise low interactivity environment. It would be interesting to couple the luck and high interactivity manipulation in future research.

The current results suggest that previous research into interactivity may have underestimated its benefit by failing to subject behaviour to a sufficiently granular analysis which can only be done with detailed video coding of behaviour (see also Steffensen, Vallée-Tourangeau, & Vallée-Tourangeau, 2016). A problem solver's trajectory is unique and the interaction with a richer set of environmental resources will trigger more complex behaviours. Thus, it behoves us to take a closer look at what is actually happening in a task environment that fosters interactivity. Interactivity is contingent and messy: its study must take into account the behaviour of the participant and the nature of the materials being used to more accurately capture the factors that drive creative problem solving.

Modelling semantics by integrating linguistic, visual and affective information

Armand S. Rotaru (armand.rotaru.14@ucl.ac.uk) **Gabriella Vigliocco (g.vigliocco@ucl.ac.uk)**

Abstract

A number of recent models of semantics combine linguistic information, derived from text corpora, and visual information, derived from image collections, demonstrating that the resulting multimodal models are better than either of their unimodal counterparts, in accounting for behavioural data. However, first, while linguistic models have been extensively tested for their fit to behavioural semantic ratings, this is not the case for visual models which are also far more limited in their coverage. More broadly, empirical work on semantic processing has shown that emotion also plays an important role especially for abstract concepts, however, models integrating emotion along with linguistic and visual information are lacking. Here, we first improve on visual representations by choosing a visual model that best fit semantic data and extending its coverage. Crucially then, we assess whether adding affective representations (obtained from a neural network model designed to predict emojis from co-occurring text) improves model's ability to fit semantic similarity/relatedness judgements from a purely linguistic and linguistic-visual model. We find that adding both visual and affective representations improve performance, with visual representations providing an improvement especially for more concrete words and affective representations improving especially fit for more abstract words.

Keywords: language; vision; emotion; distributional models; multimodal models; similarity/relatedness; concreteness.

Introduction

Despite the success of distributional, linguistic models in accounting for behavioural effects in a variety of semantic tasks, all these models suffer from the *symbol grounding problem* (Harnad, 1990). As a solution to this problem, embodied theories of semantics (e.g., Glenberg, Graesser, & de Vega, 2008) have argued that the sensory-motor representations generated by our experiences with the world play an important role in determining word meaning. Recent computational models of semantics reconcile distributional and embodied theories, by combining linguistic and perceptual (i.e., visual) representations. The fact that language and vision provide complementary sources of information is best illustrated by the finding that multimodal, linguistic-visual models outperform both purely linguistic and purely visual models, in a wide range of tasks (see Bruni, Tran, & Baroni, 2011; 2014; Kiela, Verő, & Clark, 2016).

However, empirical work has shown that semantic representations are not only grounded in sensory-motor experience but also in emotion. A vast literature supports the finding that emotion plays a significant and pervasive role in human cognition (for a review, see Dolan, 2002). Emotion is an important factor in memory (Blaney, 1986; Eich, Macaulay, & Ryan, 1994), and in processing words (e.g., Kousta, Vinson, & Vigliocco, 2009). Kousta et al. (2011) found that a much larger number of abstract than concrete concepts are valenced (have positive or negative emotional associations) and by virtue of being valenced, they are processed faster than neutral matched words. Vigliocco et al. (2014) further showed that because of their greater affective associations, abstract words processing engages the limbic emotional system and Ponari, Norbury, and Vigliocco (2018) showed that emotionally valenced words are learnt earlier and better recognized by children up to 9 years of age. Within a general embodiment framework, the hypothesis is that semantic representations do not only embed sensorimotor properties but also emotional properties. Emotional properties may be especially important for abstract concepts (e.g., *religion*, *society, idea*), however, emotional associations are not limited to abstract words and therefore, we argue, they play a general role in semantic representation.

While many models have integrated linguistic and visual information, only one previous study has considered emotional information along with visual and linguistic information (De Deyne, Navarro, Collell, & Perfors, 2018). De Deyne et al. examined the change in performance for distributional models of semantics, when adding visual and emotional information. They tested the assumption that external language models (i.e., distributional models, trained on word corpora) are relatively poor at representing visual and affective information, in comparison to internal language models (i.e., models based on free association norms). They found that adding visual and emotional information led to little or no improvement for internal language models, but a moderate positive effect for external language models. Here, we develop a quite different multimodal model of semantics that incorporates linguistic, visual and emotional information from corpora of text, images and emoticons, and test the multimodal model against existing datasets of ratings of

semantic similarity/relatedness of words. We use a state-of-the-art emotion model (DeepMoji) and we improve the coverage of the visual model we use. While state-of-the art distributional language models (Pereira et al. 2016) have large coverage of words and have been widely tested for their ability to fit human semantic similarity/relatedness data, this is not the case for visual models. Thus, before being able to develop models that embed linguistic, visual and emotional information, we extend the coverage of existing visual models and carry out their evaluation in order to decide which one to use for our multimodal models. We expect that the integrated model will outperform a purely linguistic, as well as models that combine linguistic-visual and linguistic-emotional information. In addition, we expect that adding visual or emotional representations will especially be beneficial for more concrete concepts whereas emotional information will especially be beneficial for more abstract concepts, in line with the empirical evidence reviewed above (and with initial findings from De Deyne et al, 2018).

Methods

Datasets of behavioural data

We use four datasets of similarity/relatedness ratings to carry out evaluation of the models. The datasets are: SimLex999 (999 pairs of nouns, verbs, and adjectives; Hill, Reichart, & Korhonen, 2015), SimVerb3500 (3500 pairs of verbs; Gerz et al., 2016), MEN (3000 pairs of nouns, verbs, and adjectives; Bruni, Tran, & Baroni, 2014), and SL (7576 pairs of nouns; Silberer & Lapata, 2014). We chose these norms mainly because they are some of the largest datasets currently available, but also because the word pairs they contain cover are very diverse in terms of concreteness and valence, as well as parts of speech. In terms of word pair concreteness, SimLex999 (M = 3.62, SD = 1.07) and SimVerb3500 (M = 3.1, SD = 0.7) cover a broad range of values, whereas MEN (M = 4.4, SD = 0.49) and SL (M = 4.83, SD = 0.14) consist predominantly of concrete words.

Model choice

Language Model. Our language model of choice is GloVe (Pennington, Socher, & Manning, 2014), trained on a corpus of 6 billion words, using 300-dimensional representations. GloVe has been shown to have a performance better than, or equal to, several other state-of-the-art distributional models (Pereira, Gershman, Ritter, & Botvinick, 2016), which makes it one of the best linguistic models available.

Emotion Model. The emotion model that we use is DeepMoji (Felbo et al., 2017), trained on 1.2 billion tweets. This model has been shown to obtain state-of-the-art performance in tasks involving emotion and sentiment analysis, as well as sarcasm detection. DeepMoji is similar to a number of recent approaches, which employ emotional expressions co-occurring with text fragments, such as positive/negative emoticons (Deriu et al., 2016), hashtags (e.g., #anger, #joy; Mohammad, 2012), or mood tags (Mishne, 2005). This model is very different from the one by De Deyne et al. (2018), which was constructed by concatenating valence, arousal, and potency ratings, for men and women separately (i.e., 6 dimensions), from the study by Warriner, Kuperman, and Brysbaert (2013), with valence, arousal, and dominance ratings, from the study by Mohammad (2018). DeepMoji provides better represetations for our purposes than ratings because firstly, a model trained over a corpus of tweets, rather than subjective ratings, makes the emotion model more comparable to the linguistic and visual models, both trained over corpora. Secondly, DeepMoji covers 50,000 words, whereas the combined affective norms cover less than 14,000 words. Finally, the model operates with 256-dimensional vector representations, and is trained to predict the occurrence of 64 types of emoticons, and thus it is able to represent complex patterns of word similarity, driven by richer emotional information than that captured by subjective norms.

Visual Model. To select the best model, we compared five models, based on their performance in predicting subjective similarity/relatedness ratings. The first model (K&B) is the convolutional model employed by Kiela and Bottou (2014; 6144 dimensions), trained on the ESP Game dataset (Von Ahn & Dabbish, 2004), using the mean of the feature vectors per each word. The second, third, and fourth models are AlexNet (Krizhevsky, Sutskever, & Hinton, 2012; 4096 dimensions), GoogLeNet (Szegedy et al., 2015; 1024 dimensions), and VGG-19 (Simonyan & Zisserman, 2014; 4096 dimensions), trained on images obtained from Google Image Search, following the approach used by Kiela, Verő, and Clark (2016). The fifth model uses SIFT descriptors (Lowe, 2004), computed over the NUS-WIDE dataset (Chua et al., 2009; 500 dimensions). The models were tested on similarity/relatedness ratings for 7611 word pairs, covered by all models and obtained by merging the four sets of ratings. Before merging, the scores in each set were linearly rescaled to fall in the interval [0,1], to make them comparable across datasets. The performance of the models was evaluated using the Spearman correlation between the cosine similarity of the model representations, and the similarity/relatedness ratings from the norms. The results are shown in Fig. 1.

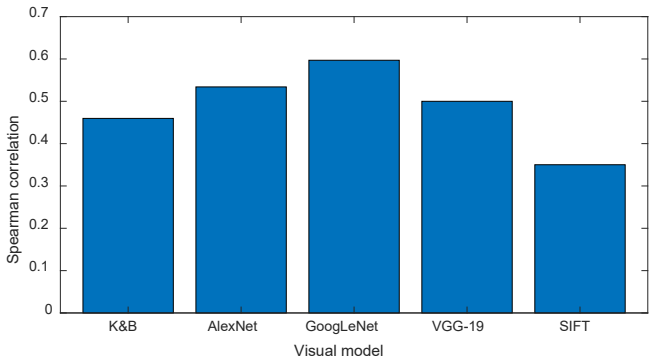

Figure 1. Spearman correlations between model cosine similarities and subjective similarity/relatedness ratings.

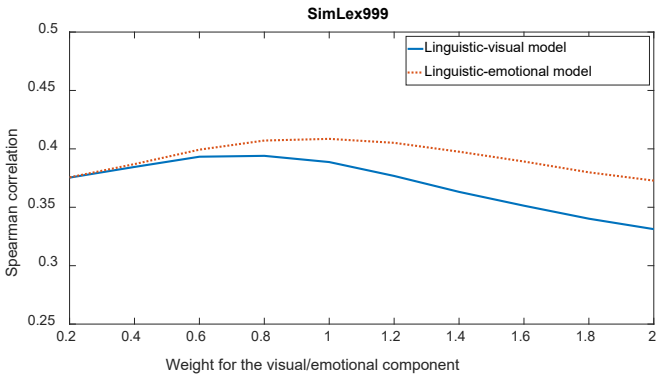
All the correlations are significant[1] ($p < .001$), suggesting that model-based similarities are reliable predictors of subjective similarity/relatedness ratings. Since we want to find the best model, we apply the Fisher Z-Transformation and then run two-tailed Z-tests for all the 10 possible pairings of models. All the differences are significant ($p < .004$), and they reveal that GoogLeNet has the highest performance, followed by Alexnet, VGG-19, K&B, and SIFT. Thus, we use GoogLeNet.

Results

We tested whether linguistic-visual and linguistic-emotional models are indeed better than a purely linguistic one, as well as whether it is the case that linguistic-visual-emotional models are better than linguistic-visual, linguistic-emotional and purely linguistic ones. We also examined whether the models behave differently for concrete and abstract word pairs.

Linguistic-visual and linguistic-emotional models vs purely linguistic model.

To evaluate the change in goodness of fit associated with adding a visual component to the purely linguistic model, we began by normalizing the linguistic and the visual representations to unit length. Next, we concatenated the linguistic representations with the visual ones, assigning a weight of 1 to the linguistic components, and weights from 0.2 to 2, in steps of 0.2, to the visual components. Both here and in our further analyses, we tested various weights, since it was not clear which weight would produce optimal results. Finally, for each of the four similarity/relatedness datasets, we compared the 10 resulting linguistic-visual models with the purely linguistic model, by normalizing the correlations and using two-tailed Z-tests. The same type of analyses were run for the linguistic-emotional models. Results are in Fig. 2.



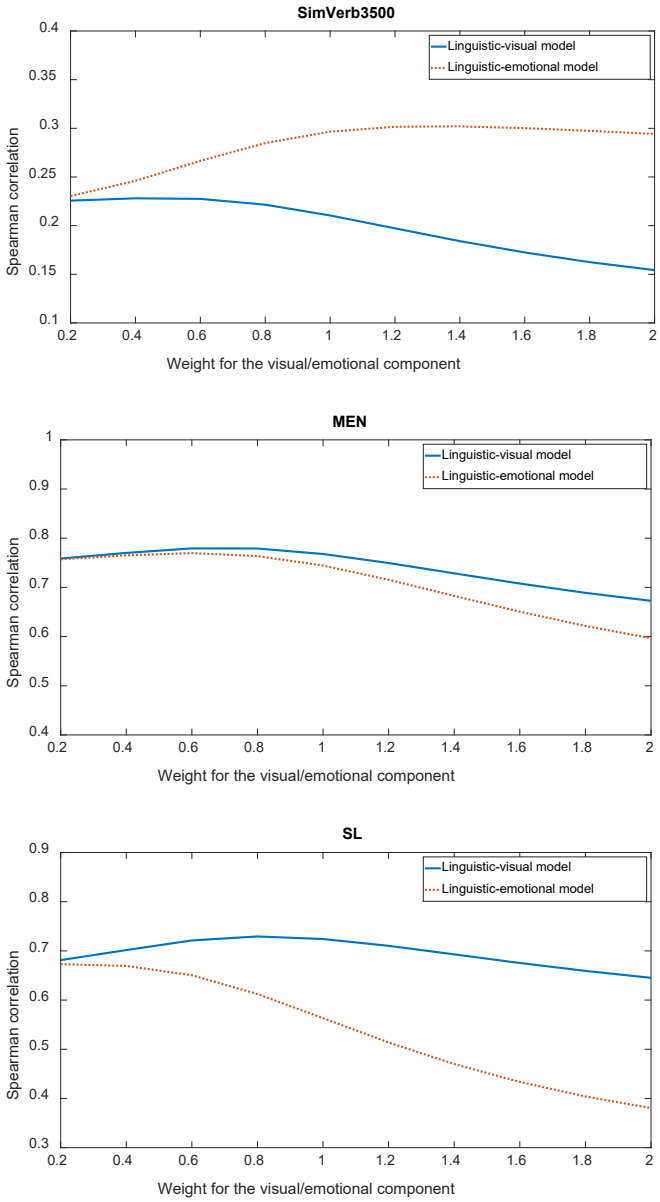


Figure 2. Model performance for the linguistic-visual and linguistic-emotional models. The weights assigned to the visual/emotional component vary from 0.2 to 2, in steps of 0.2

The tests indicate that adding visual information has a significant positive effect only for the SL dataset ($p < .001$), for weights ranging from 0.6 to 1.2, and a significant negative effect for the MEN dataset ($p < .001$), for weights between 1.6 and 2. These results seem to be at odds with previous studies showing that linguistic-visual models always perform slightly better than purely linguistic ones. However, firstly, in almost all the other studies, the authors either weigh the linguistic and visual representations equally, by default (e.g., Kiela, Hill, Korhonen, & Clark, 2014; Silberer, Ferrari, &

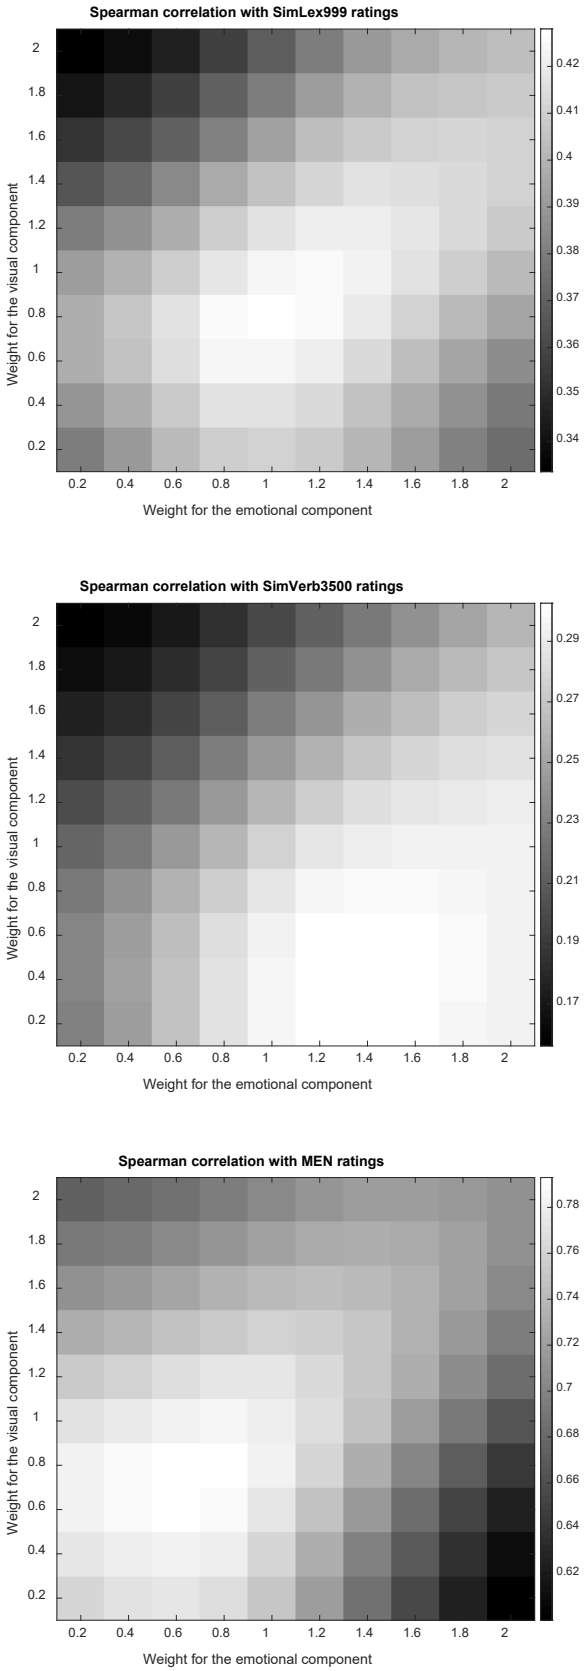
[1] The Bonferroni correction was applied when assessing the statistical significance of all the results presented in this study.

Lapata, 2013), or they only employ the weight that gives the best results for the integration (e.g., Bruni, Tran, & Baroni, 2014; Bruni, Uijlings, et al., 2012), which leaves room for null or detrimental results of linguistic-visual integration, when employing sub-optimal weights. Secondly, we use a linguistic model that is trained over a corpus of 6 billion words, whereas other studies (e.g., Hill & Korhonen, 2014; Kiela & Bottou, 2014; Silberer & Lapata, 2012) typically employ considerably smaller corpora (i.e., containing between 80 and 800 million words). Since smaller corpora lead to a poorer performance of the linguistic model, this leaves more room for a beneficial effect of adding visual information in the other studies, as compared to our study.

Adding emotional information is significantly beneficial only for the SimVerb3500 dataset ($p < .00125$), for weights ranging from 1.2 to 1.6, while it is significantly detrimental for the MEN dataset ($p < .001$), for weights between 1.4 and 2, and for the SL dataset ($p < .001$), for weights between 0.6 and 2. The SimVerb3500 dataset is different from all the others in that it is the only one including only verbs (which are not highly represented in any other dataset). As verbs (words referring to events) are considered to be more abstract, this finding is in line with the view that emotional information is especially important for abstract words (Kousta et al., 2011).

Linguistic-visual-emotional model vs linguistic-visual, linguistic-emotional, and purely linguistic models.

In order to compare the trimodal model with the bimodal and unimodal ones, we again start by normalizing the linguistic, visual, and emotional representations, to unit length. We then construct trimodal models by assigning a weight of 1 to the linguistic components, and weights from 0.2 to 2, in steps of 0.2, to the visual and emotional components, in all pairwise combinations for the last two components. Next, for each dataset, we select the best five and worst five trimodal models, in terms of performance, and compare them to their corresponding linguistic-visual models (i.e., obtained by removing the emotional component), linguistic-emotional models (i.e., obtained by removing the visual component), and purely linguistic model (i.e., obtained by removing both the visual and emotional components). The results are shown in Fig. 3.



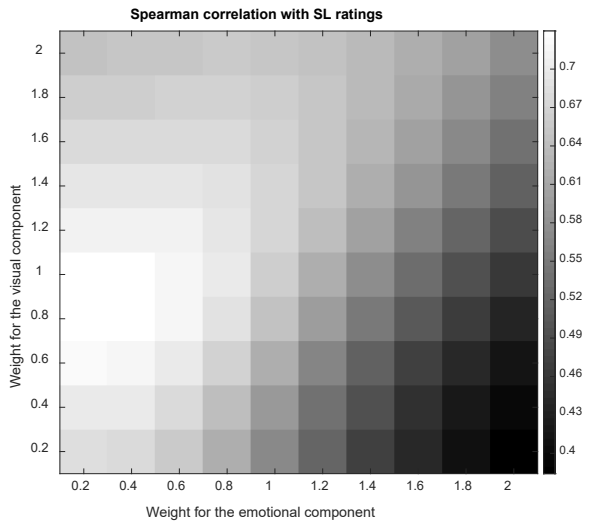


Figure 3. Model performance for the linguistic-visual-emotional model. The weights assigned to the visual/emotional component vary from 0.2 to 2, in steps of 0.2

When comparing the performance of the trimodal models to that of their corresponding linguistic-visual models, the addition of an emotional component has a significant positive effect for the best models on the SimVerb3500 dataset ($p <$ .0016), and a significant negative effect for the worst models on the MEN and SL datasets ($p <$ .001). These results are very similar to those found when comparing the linguistic-emotional models to the purely linguistic one, and might be explained by the fact that verbs, such as those that make up the SimVerb3500 norms, are relatively abstract. In contrast, for concrete nouns, which form the majority of pairs from the MEN and SL norms, emotion should not have a positive effect (the finding of a detrimental effect is unexpected but potentially interesting as may indicate that adding affective information may reduce the separation between different types of words).

The comparison between the trimodal models and their corresponding linguistic-emotional models reveals that including a visual component is significantly beneficial for the best models on the SL dataset ($p <$ .001), but significantly detrimental for two of the worst models on the SimVerb3500 datasets ($p <$ .001). Again, SL consists only of concrete nouns, for which visual information is very salient, while SimVerb3500 consists only of verbs, the semantics of which is likely not to be properly captured in a few tens of images per word, due to its complexity.

Finally, contrasting the trimodal models with the purely linguistic one, we find that bringing in both visual and emotional information significantly increases performance for the best models on the SimVerb3500, MEN, and SL datasets ($p <$ .0016), while it significantly decreases performance for the worst models on the MEN and SL datasets ($p <$ .001). These results are a combination of the partial results regarding the effects of appending visual and emotional components to the purely linguistic and bimodal models, which indicates little overlap between vision and emotional representation.

Comparing the models for concrete and abstract words

In order to test whether visual content is more important for more concrete words, while emotional content for more abstract words, we first combined the SimLex999 and SimVerb3500 datasets, as they cover a broader range of concreteness ratings than MEN and SL. Then, we divided the merged dataset into a low and a high concreteness subset. More specifically, we selected the bottom 25% and the top 25% of pairs, based on the mean concreteness of each word pair covered by the concreteness norms of Brysbaert, Warriner, and Kuperman (2014). We then tested the performance of the emotional and visual models, the two bimodal models, and the trimodal models, setting all the weights set to 1. The results are displayed in Fig. 4.

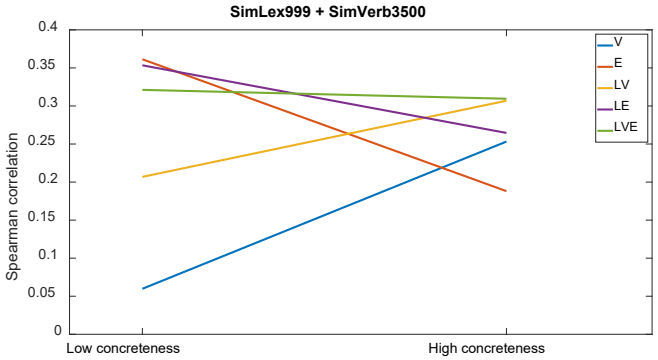

Figure 3. Model performance for low and high concreteness word pairs.

Using one-tailed *Z*-tests, after normalizing the correlations, we found that the performance of the visual model is higher for more concrete pairs, in comparison to the less concrete ones, for the visual ($p <$ .001) and linguistic-visual ($p <$ .01) models. Also, the emotional model has a better performance for the more abstract pairs, as opposed to the less abstract ones. Non-significant results were obtained for the linguistic-emotional and trimodal models. These results seem to suggest that the positive effect of adding visual information should be greatest for datasets consisting mainly of more concrete words, such as MEN and SL, while the beneficial effect of including emotional information should be largest for datasets made up mainly of more abstract words, such as SimLex999 and SimVerb3500.

Discussion

A first goal of this paper was to present an evaluation of visual models in order to identify the model(s) better fitting behavioural semantic data. We found that convolutional neural networks models (i.e., K&B, Alexnet, GoogLeNet, VGG-19) have a better performance than a classical, bag-of-visual-words model (i.e., SIFT), when tested over a large dataset of similarity/relatedness ratings. Among the

convolutional models, GoogLeNet gave the best results, followed by AlexNet, VGG-19, and K&B.

The second, and main goal was to develop models that integrate linguistic, visual and emotional information and to assess their performance against purely linguistic models and models that only include either visual or emotional features. We chose the DeepMoji model for a number of reasons, namely: its state-of-the-art performance in a number of emotional tasks; its distributional nature, since it predicts the occurrence of an emoticon based on its immediate linguistic context; its capacity to use rich emotional information, as it is trained on tweets containing 64 types of emoticons; its high dimensionality, which allows it to encode complex patterns of emotion-based word similarity.

In order to better understand the relative importance of each visual and emotional component, we carried out comparisons in which we parametrically varied the weight of visual and/or emotional information. In this manner, we can see when adding this information leads to better or worse performance. In general, we found that including non-linguistic information has a positive impact. However, first, this impact is modulated by whether the dataset includes predominantly concrete or abstract words. As expected on the basis of previous literature (e.g., Kousta et al., 2011) we see that including visual information is particularly beneficial to more concrete concepts whereas including emotional information is particularly beneficial to more abstract concepts. This is clearly visible when we assess model performance separately for more concrete and abstract words (see Fig 4). It is also clear from the comparison between MEN (only concrete words) and SimVerb3500 (only verbs, hence more abstract): across comparisons, we see that indeed visual information brings more benefit to the former, whereas emotional information brings more benefit to the latter.

Second, the effect is modulated by the weights attributed to the different types of information. While the theoretical interpretation of the differences we found related to weights is not immediate, this finding may have practical value for future modelling.

As mentioned in the introduction, a previous study (De Deyne et al., 2018) also examined the change in performance for distributional models of semantics, when adding experiential (i.e., visual and emotional) information. They found that adding experiential information led to little or no improvement for internal language models, but had a moderate positive effect for external language models. Moreover, they also found that adding visual information had the greatest effect for concrete words, while introducing affective information had the largest impact for abstract words. This finding mirrors our own, when comparing the linguistic-visual and linguistic-emotional models to the purely linguistic model.

However, there are a number of key differences between their approach and ours. Firstly, we avoided the potentially controversial distinction between external and internal language models, focusing on an objective corpus-based approach. Secondly, in a similar vein, we decided to use an emotional model that learns affective information indirectly, by predicting the co-occurrence of emojis and text in a corpus, rather than using emotional representations derived directly from valence, arousal and dominance norms (Mohammad, 2018; Warriner, Kuperman, & Brysbaert, 2013). This also increases the coverage of our model. Finally, since the resulting representations in our model are high-dimensional, they might provide more fine-grained information than representations with only three dimensions.

Abstract

Models of visual saliency normally belong to one of two camps: models such as Experience Guided Search (E-GS), which emphasize top-down guidance based on task features, and models such as Attention as Information Maximisation (AIM), which emphasize the role of bottom-up saliency. In this paper, we show that E-GS and AIM are structurally similar and can be unified to create a general model of visual search which includes a generic prior over potential non-task related objects. We demonstrate that this model displays inattentional blindness, and that blindness can be modulated by adjusting the relative precisions of several terms within the model. At the same time, our model correctly accounts for a series of classical visual search results.

Keywords: Inattentional Blindness; Conjunction Search; Visual Attention; Bayesian Modelling; Predictive Processing

Introduction

Visual search, where agents search for a target amongst distractors, is an important paradigm in the study of human attention (Wolfe, 1994) (see Figure 1 for an example trial). Inattentional blindness, where unexpected objects fail to capture attention, provides a useful insight into how constraints of processing and access lead to failures in the visual system (Simons, 2000). The literature on the two domains is distinct; in this paper we show that extending a model of visual search by adding an environmental prior produces a model that can reproduce empirical results from both domains.

The motivation for our extension hinges on the idea that the brain, due to the pressures of an ever changing environment, never *solely* models a task; it must always additionally maintain what are effectively generic, non-task-specific prior expectations about possible interesting states of the world. For example, in conjunction search (Nakayama & Silverman, 1986), where participants search for a target amongst distractors, a simple model of the search environment should include both "targets" and "distractors" (the statistics of which are learned during training), and "non-task entities" (which are unrelated to the task), as possible kinds. Ignoring non-task entities allows the brain to attend to (and successfully perform) a task, at the expense of potentially missing useful information about the world.

The contributions of this work are threefold. We demonstrate a successful joint model of visual search and inattentional blindness in which search is driven by saliency, generated using precision-weighted error terms. We show the structural equality of two distinct models of saliency, one top-down, and the other bottom-up. Finally, by constructing a model where both task relevant and task irrelevant stimuli contribute to saliency, we shed light on what it means to perform a task – namely, for an agent to have high confidence in its model of those stimuli that constitute the task, compared with its model of other possible stimuli.

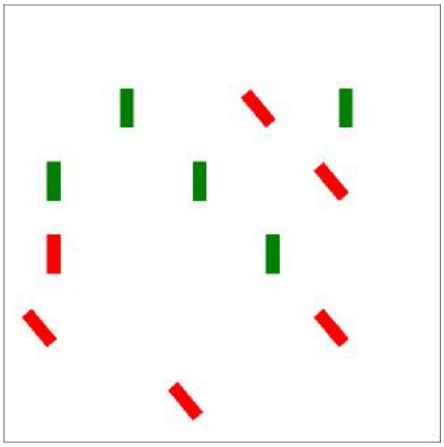

Figure 1: Example trial taken from Task 5 (see Results, below). Task is to find red vertical target amongst green vertical and red titled distractors.

Related Work

Conjunction Search

Empirically, we can distinguish between five forms of guidance in visual search (Wolfe & Horowitz, 2017). The two of interest to this work are bottom-up (where visual properties of aspects of a scene attract more attention than others, Koehler, Guo, Zhang, & Eckstein, 2014), and top-down (where executive control drives attention towards desired targets, Maunsell & Treue, 2006).

The majority of the many models of top-down visual search (Itti, Koch, & Niebur, 1998; Torralba, Oliva, Castelhano, & Henderson, 2006; Navalpakkam & Itti, 2006; Cave, 1999; Choi, Torralba, & Willsky, 2012)[1] share the basic structure of

[1] We cite Itti and Koch's work here, as well as in the section on bottom-up drivers of saliency, because whilst their work focusses on

Guided Search (GS; Wolfe, 1994): primitive visual features are detected across the retina by feature maps, which represent features via a coarse (i.e., highly overlapping) encoding. These feature maps are then passed through a local differencing operator, which enhances local contrasts, and the feature maps are combined using a top-down, task specific weighting to produce a saliency map. A Bayesian treatment of GS called Experience-Guided Search has been proposed by Mozer and Baldwin (2007).

There is also a body of work that focuses specifically on the bottom-up drivers of saliency (Koehler et al., 2014; Itti & Koch, 2001), an example of which is Attention as Information Maximisation (AIM), proposed by Bruce and Tsotsos (2009). These authors argue that the self-information of a location in an image, estimated on its surrounding context, is a good measure of its visual saliency.

Bottom-up models can be thought of as mapping the saliency of a task-neutral environment; but they provide no account of the relationship between this base saliency and the task at hand. Top-down models provide a qualitative account of various phenomena in visual search (see Results for a detailed discussion of relevant phenomena). However, a limitation of these models is that they do not attempt to model tasks as situated in a wider environment containing task-irrelevant stimuli, or competing tasks. A paradigm where modelling the relative saliency of task-relevant and task-irrelevant items becomes important is that of inattentional blindness (IB; Mack & Rock, 1998).

Inattentional Blindness

To model IB in the context of visual search, we use an "additional singleton" approach (see, e.g., Simons, 2000), where an unexpected single item has a distinctive unique feature, and that item is never the target item. There are several factors which have been shown to affect the rate of unexpected object detection when performing a task: increased cognitive load increases blindness (Kreitz, Furley, Memmert, & Simons, 2016), the similarity of the unexpected object to task-relevant objects increases the probability that the unexpected object will capture attention (Most et al., 2001; Simons & Chabris, 1999), as do shared features between task relevant objects and unexpected objects (Koivisto & Revonsuo, 2009).

Models of the causes of inattentional blindness range from claims of inattentional amnesia (we see the object, but fail to report it after the trial, Wolfe, 1999), to arguments that we are blind to objects we do not expect to see (Braun, 2001). More recent accounts have focused on the relationship between bottom-up saliency (which drives transient attentional capture) and a top-down attentional set, which governs whether transient attention is sufficient to generate sustained attention, and subsequent awareness (Most, Scholl, Clifford, & Simons, 2005). In spirit, our approach falls under this latter umbrella, but we show that blindness can be explicitly thought of as a result of a ratio of precisions in a mathematical model that extends the conjunction search literature (and is also able to replicate standard results in that domain).

saliency maps, they assume that these maps are combined according to top-down attentional drivers, which makes them less purely bottom-up than AIM, for example. See the section on bottom-up visual attention, below.

Model

Our starting point is Experience-Guided Search (E-GS; Mozer & Baldwin, 2007), a Bayesian treatment of GS developed to overcome a shortcomings of GS (Wolfe, 1994; Wolfe & Horowitz, 2017), namely that GS produces better than human performance without the addition of noise or regularising constraints on the top-down weighting of features. Mozer and Baldwin's premise is that a location in the visual field is salient if a target is likely to be at that location. They define $P(T_x = 1|\boldsymbol{F}_x)$ as a measure of saliency computed using statistics obtained from recent experience performing the task:

$$P(T_x|\boldsymbol{F}_x,\boldsymbol{\rho}) = \frac{P(T_x)\prod_i P(F_{xi}|T_x,\boldsymbol{\rho}_i)}{\sum_{t=0}^{1} P(T_x = t)\prod_i P(F_{xi}|T_x = t,\boldsymbol{\rho}_i)} \quad (1)$$

Here, $\boldsymbol{F}_x$ is the feature activity vector at retinal location x, T_x is the binary indicator of targethood, $\boldsymbol{\rho}$ parameterises the stimulus environment, and F_{xi} is the feature vector corresponding to feature i.

Whilst we lack the space to give a full treatment here, by assuming a generative model with $F_{xi}|\{T_x = t,\boldsymbol{\rho}\} \sim \text{Binomial}(n,\rho_{it})$, where ρ_{it} is the parameterising spike rate associated with feature i for target and non-target items ($t = 1, t = 0$), in the limit of reasonably large n we can approximate $P(F_{xi}|\ldots)$ as Gaussian, with mean $n\rho_{it}$ and variance $n\rho_{it}(1-\rho_{it})$. This allows the authors to derive a measure of saliency, S_{EGS}, as:

$$S_{EGS} = \sum_i \left[\Lambda_{\rho i0}(f_{xi} - n\rho_{i0})^2 - \Lambda_{\rho i1}(f_{xi} - n\rho_{i1})^2\right] \quad (2)$$

Where $\Lambda_{\rho it}$ denotes the precision (inverse variance) of the model's current estimate of ρ_{it}.[2]

This is a sum of terms, two for each feature i, which capture how surprising the activation corresponding to that feature, f_{xi}, is with respect to the target or not-target cases, the model's beliefs about which are parameterised by ρ_{i1} and ρ_{i0} respectively. The saliency of feature i increases if the observed activation is distant from the mean activity observed in the past in the absence of a target. It decreases if the observed behaviour is distant from the mean activity observed its presence. This surprisal is weighted by observed precisions: high variance features contribute less to saliency.

This remains a strictly task-based model, however. To expand it, we need to consider how the saliency of a feature changes under a generic, non-task specific prior. To do this, we turn to the literature on bottom-up measures of saliency,

[2] A difference between this presentation and that in Mozer and Baldwin is that we have not ignored the scaling n; whilst in E-GS only the relative magnitude of the terms in (2) is relevant, here we do care about how much data the model has seen.

in particular AIM (Bruce & Tsotsos, 2009). In doing so, we note the structural similarity between AIM and E-GS.

The premise of AIM is that those areas of an image that contain the most Shannon self-information are those that contain content of interest. Hence visual saliency is driven by surprise with respect just to visual input. First, "a sparse spatiochromatic basis" is generated in an unsupervised fashion using ICA, such that every image patch can be expressed as a vector of coefficient contributions (if projected back into image space, the coefficients, not incidentally, look a lot like Gabor filters and colour opposition patches[3]).

For each location x we can characterise the content of the local neighbourhood C_x by a vector $\boldsymbol{\alpha}_x$. For each of the i features, the p.d.f of the surround is estimated by making a histogram of all α_i values for every nearby patch. Then α_{xi}'s likelihood $P(\alpha_{xi})$ can be estimated from the histogram and thus its Shannon information content computed by $\log(1/P(\alpha_{xi}))$. Adding the Shannon information from each coefficient in $\boldsymbol{\alpha}_x$ gives us an estimate of the Shannon information contained in patch x, and hence the saliency of that patch:

$$S_{\text{AIM}} = -\sum_i \log P(\alpha_{xi}) \tag{3}$$

We then approximate the histogram $P(\alpha_{xi})$ as Gaussian distributed with mean $\bar{\alpha}_i$ and variance $\sigma^2_{\alpha i}$, which are the statistical mean and unbiased variance computed from the activations of surrounding patches for feature i.

This means we can rewrite (3) as:

$$S_{\text{AIM}} = \sum_i \left[\frac{1}{\sigma^2_{\alpha i}} (\alpha_{xi} - \bar{\alpha}_i)^2 \right] \tag{4}$$

Comparing to (2), we can see that if we make the same assumptions about the form of the likelihood of our incoming data, the measures of saliency used by E-GS and AIM are both sums of precision-weighted errors. The main difference is that AIM learns its model statistics from surrounding, synchronic activations, whereas E-GS learns its statistics diachronically, and with respect to the pertinent categories of a task oriented model.

Our final step is to argue that true saliency is a combination of many such terms, driven by the pressure to balance attention between task-driven stimuli and the world in which a task takes place. We therefore propose the following measure of saliency of location x, $\boldsymbol{S}_x$:

$$\boldsymbol{S}_x = \sum_i \left[-\Lambda_{i,1}(f_i - \mu_{i,1})^2 + \Lambda_{i,0}(f_i - \mu_{i,0})^2 + \Lambda_{i,\alpha}(f_i - \mu_{i,\alpha})^2 \right] \tag{5}$$

Where for clarity we have simplified the learned means to μ, and the learned precisions to Λ, for target, 1, distractors, 0, and non-task foils, α.

[3] AIM uses ICA to find a roughly orthogonal basis which the authors argue can be usefully compared to sparse coding in early visual cortex. E-GS uses the handcrafted sparse basis from GS. Both can summarised as: response activity is computed **in parallel** for multiple features. Activity which is surprising on a feature is salient.

We might think of the third term in (5) as constant: in the absence of any task, this is likely the term that dominates saliency. However, once I have a particular task, then the other terms will contribute to my estimate of the saliency. Rather nicely, we can also see how expertise might play a role: if a task has been repeated many times, then the precisions associated with those task-relevant features will be high, and so will dominate the saliency computation.

It is easy to see how this formulation could give rise to inattentional blindness: if a surprising object is neutral with respect to a task, then whether it affects the overall saliency measure will depend on the relative precision weighting of the first two terms and the third (if it is extremely surprising because it is blue, for example, but our task is clear-cut so the precisions associated with the top-down terms is high, then it still might not be that salient overall – if it is the only blue object we have seen, then its associated precision may be quite low). In a free viewing paradigm, the search task-relevant terms would be absent, the model would collapse to AIM, and unexpected objects would be salient. If the object possesses some task relevant features, then the first and second terms will contribute to its saliency, and it is more likely to be attended.

The leveraging of precision weighted errors to produce different effects can also be related to the predictive coding work of Friston and colleagues (Friston, Adams, Perrint, & Breakspear, 2012), where a free-energy minimising agent passes precision-weighted surprisals up a processing hierarchy, and expectations down. Indeed, Friston has explicitly claimed that (covert) attention can be thought of as precision weighting (Feldman & Friston, 2010), which our simple model certainly aligns with.

Methods

To test our model in a conjunction search paradigm, we simulated image environments of distractor and target objects on a 5×5 grid with a white background (See Figure 1 for an example trial). We represented images both at the object level and the pixel level (see Feature Spaces, below); in either case, at test time a vector valued representation $\boldsymbol{F}_x$ scaled to [0,1] was passed to a learned model, which returned the saliency score for each location x by computing $\mathbb{E}_\rho[\boldsymbol{S}_x]$, where we assume Beta priors over the expected activations, such that $\rho_{i,t} \sim \text{Beta}(\alpha_{i,t},\beta_{i,t})$, $\rho_{i,d} \sim \text{Beta}(\alpha_{i,d},\beta_{i,d})$ and $\rho_{i,nt} \sim \text{Beta}(\alpha_{i,nt},\beta_{i,nt})$. We used a Beta prior as the model assumes f_{xi} are rate activations, and hence fall in [0,1].

$\mathbb{E}_\rho[\boldsymbol{S}_x]$ is the sum of the expected value of each of the terms in (5). For the i^{th} feature of the k^{th} term at location x, this is:

$$\mathbb{E}_{\rho k}\left[\Lambda_{i,k}(f_{xi} - \mu_{i,k})^2\right] = n_k \Big[f_{xi}^2 \frac{(\alpha_{ik}+\beta_{ik}-1)(\alpha_{ik}+\beta_{ik}-2)}{(\alpha_{ik}-1)(\beta_{ik}-1)} - f_{xi} \frac{2(\alpha_{ik}+\beta_{ik}-1)}{\beta_{ik}-1} + \frac{\alpha_{ik}}{\beta_{ik}-1} \Big] \tag{6}$$

In the case of an object-level representation, x corresponds to an object in the image. In the case of the pixel-level representation, we computed saliency for every second pixel, which

gave reasonable results and was less costly than computing for every pixel.

For each task, the posterior beliefs of the model were learned from 100 labelled example trials. The learned model was then used to generate saliency maps for 1000 unlabelled trials, where, for object-level saliency maps, rank order of objects by saliency was taken to be directly proportional to response time (RT).

When pixel-level saliency maps were generated, we explicitly "saccade" through the most salient pixels in order, and introduce inhibition of return, which depresses the saliency S at pixel i at step t according to:

$$\begin{aligned} S_{i,t} &= S_{i,t} - (S_{i,t} \cdot R_{i,t-1}) \\ R_{i,t-1} &= \mathrm{G}(S_{i,t}) + \frac{1}{2} R_{i,t-2} \end{aligned} \tag{7}$$

where $\mathrm{G}(S_{i,t})$ is a Gaussian function, with a standard deviation $1/16$ the size of the image, of the distance of i from the target of the t^{th} saccade. The sequence of response times to any particular object is then taken to be proportional to the value of t when a pixel of that object is first visited.

Feature Spaces

Our saliency measure relies on the assumption that we have access to a sparse, independent feature representation of the visual space; either at the object level or at the pixel level. In principle, both should perform similarly, and so we tested our hypotheses (see Results) against both a variant of Guided Search's handcrafted approach to generating activations from features (Wolfe, 1994), and AIM's unsupervised approach (Bruce & Tsotsos, 2009), which uses ICA to generate a vector of activations from an image patch.

Guided Search has an eight-dimensional feature space: four activations correspond to colour, four to orientation. The four orientation dimensions are given by:

Steep: $\cos(2x)^{0.25}$, $-45 < x < 45$
Shallow: $|\cos(2x)|^{0.25}$, $-90 < x < -45$ and $45 < x < 90$
Left: $|\sin(2x)|^{0.25}$, $-90 < x < 0$
Right: $\sin(2x)^{0.25}$, $0 < x < 90$

The four colour receptors are red, yellow, green, and blue, described as the "quite arbitrary ... third root of triangluar functions" (Wolfe, 1994) that have peaks at positions evenly spaced at their ordinal positions in the spectrum. These activations are then passed through a local differencing operator to yield a bottom-up activation.

For unsupervised extraction of a sparse basis, we sampled 250,000 image patches of size 21×21 from a dataset of natural images (Hodosh & Hockenmaier, 2013), and used JadeICA (Cardoso, 1999), preserving 90% variance to extract an independent basis (27 dimensions were retained). ICA infers the mixing matrix, $\boldsymbol{B}$, between the independent causes and the perceived data (the patches). We then use $\boldsymbol{B}^{-1}$ to produce a vector of activations for any new patch.

Both approaches are claimed to produce activations corresponding to neuronal activity; Wolfe (1994) chose the eight features of Guided Search accordingly, and Bruce and Tsotsos (2009) argue that the roughly orthogonal basis learned by ICA can be usefully compared to sparse coding in early visual cortex. Hence it should be the case that our model produces similar performance from both forms of preprocessing.

Learning

The posteriors are computed using:

$$\begin{aligned} \rho_k | F_{xk} \sim \mathrm{Beta}\Big(&\lambda\alpha_k^0 + (1-\lambda)\Big[\alpha_k + \sum_{x \in X_k} f_{xk}\Big], \\ &\lambda\beta_k^0 + (1-\lambda)\Big[\beta_k + \sum_{x \in X_k} 1 - f_{xk}\Big]\Big) \end{aligned} \tag{8}$$

where X_k denotes the set of points labelled k in the training examples. This, as in Mozer and Baldwin (2007), interpolates between the prior distribution $\sim \mathrm{Beta}(\alpha_k^0, \beta_k^0)$ and the empirical posterior. This interpolation regularises the model's fit to the data, and improves its performance.

For all experiments, $\alpha_{id}^0 = \beta_{jt}^0 = 10$, $\alpha_{it}^0 = \beta_{jd}^0 = 25$, for all i and j, $\alpha_{int}^0 = \beta_{int}^0 = 10$, and $\lambda = 0.3$. These parameter values are mostly taken from Mozer and Baldwin (2007), as there was no reason to change them.

Results

We tested two hypotheses: that our model would reproduce a range of standard effects in visual search, and that our model could reproduce two standard results from the inattentional blindness literature.

Visual Search

To evaluate the performance of the model in the visual search paradigm, we followed Wolfe (1994) and Mozer and Baldwin (2007), and tested our model against six search tasks used to evaluate the original guided search model. These tasks are as follows. All graphs shown are using the eight simple features of guided search. Standard error bars are included.

1. Vertical target among homogeneous distractors (Figure 2): As the angle of the distractors increases from 0–55 degrees (where 0 is vertical), time to target should become constant with respect to the number of distractors (i.e., pop-out occurs).
2. Categorical search (Figure 3): Target among two types of distractors defined with respect to a single feature (angle of orientation). Distractors are 100 degrees apart, and target is 40/60 degrees from the distractors in two cases, but in the third case it is the only near vertical item, allowing pop-out.
3. Target-distractor similarity (Figure 4): Search efficiency for target among heterogeneous distractors. There are two target orientations, and two degrees of target similarity. For each orientation, search should be more efficient when target and distractors are dissimilar.

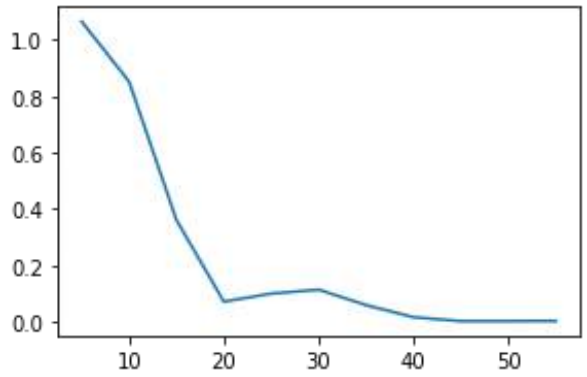

Figure 2: (Task 1) Horizontal; distractor orientation (degrees). Vertical; Gradient of time-to-target against number of distractors. Pop-out clearly occurs at around 20 degrees from the vertical.

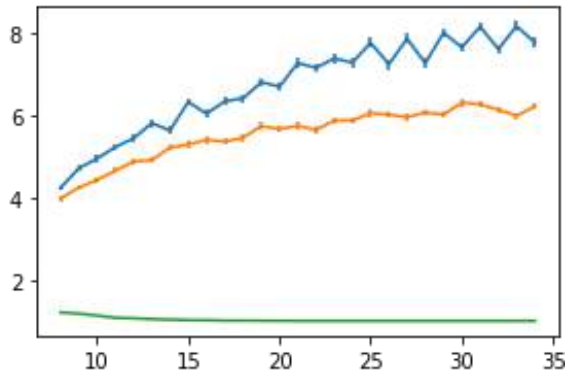

Figure 3: (Task 2) Horizontal; total number of distractors. Vertical; response time/time-to-target (in fixations, t). Blue; target at 10, distractors at -30 and 70 degrees. Orange; target at 20, distractors at -20 and 80 degrees. Green; corresponds to case where distractor is the only near-vertical item. Target at 10, distractors at -50 and 50 degrees.

4. Feature search asymmetry (Figure 5): It is more efficient to find a tilted bar among verticals than a vertical among tilted. This is because tilted items activate features that make them more discriminable; for example in the 8 dimensional feature space described above, one feature activates when presented with vertical objects, but two activate when presented with objects at 20 degrees.

5. Conjunction search – distractor confusability (Figure 6): Red vertical target among green vertical and red tilted distractors. Red tilt can be 90 or 40 degrees: both are inefficient, but should vary in relative difficulty.

6. Distractor ratio effect (Figure 7): Response times for red vertical target amongst red tilted and yellow vertical distractors, as a function of ratio of distractor types. Search should be most efficient in the extremes, where there are a minimum of distractors of one particular type.

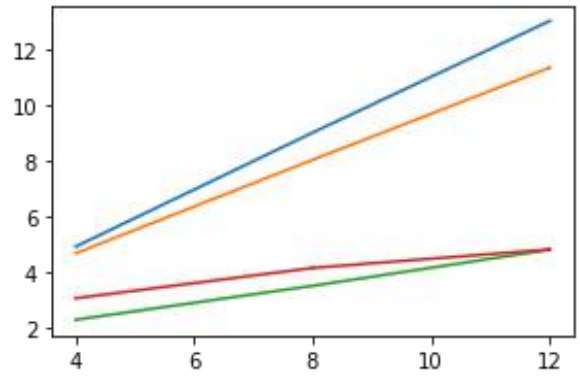

Figure 4: (Task 3) Horizontal; total number of distractors. Vertical; response time/time-to-target (in fixations, t). Blue and Orange; target at 0, distractors at -20 and 20 degrees, and -40 and 40 degrees respectively. Green and Red; target at 20, distractors at 0 and 40 degrees, and -20 and 60 degrees, respectively.

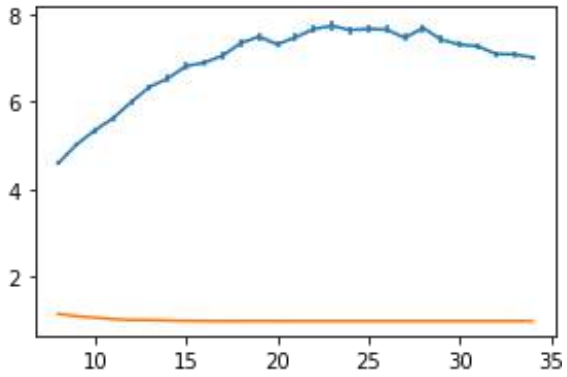

Figure 5: (Task 4) Horizontal; total number of distractors. Vertical; response time/time-to-target (in fixations, t). Blue; Target at 0, distractors at 20, orange; target at 20, distractors at 0.

Inattentional Blindness

We aimed to test two basic results in the inattention blindness literature. First, that performing a task reduces the probability of fixating or reporting unexpected objects, when compared to a task-free control (Simons & Chabris, 1999).

With reference to Equation (5), we assume that $\Lambda_{i,1} \approx \Lambda_{i,0} = \Lambda_T, \forall i$ (i.e., the two task-specific confidences are similar), the relative magnitude of Λ_T to Λ_α should be central to the relationship between performing a task, and corresponding inattentional blindness. This is because if Λ_T is much larger than Λ_α then the task-specific terms dominate the saliency score, and objects which are surprising in features that are not task specific have lower probability of detection.

In free viewing, however, where Λ_α is larger than, or equal to Λ_T (the task does not dominate attention), the context-dependent surprisals should contribute to the overall saliency, and generically unexpected objects (persons in gorilla suits, for example), are more likely to capture attention.

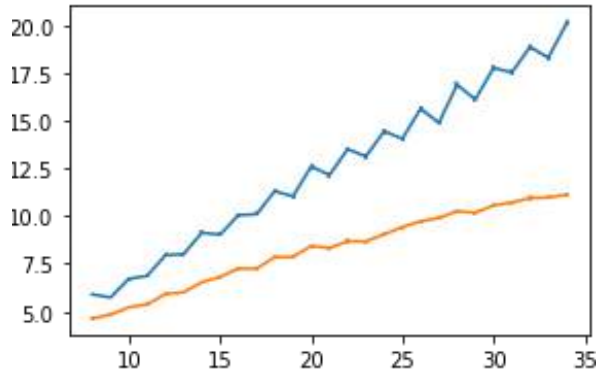

Figure 6: (Task 5) Horizontal; total number of distractors. Vertical; response time/time-to-target (in fixations, t). Red targets at 0 degrees, one set of green distractors at 0 degrees. Blue; second set of red distractors at 40 degrees. Orange; second set of red distractors at 90 degrees.

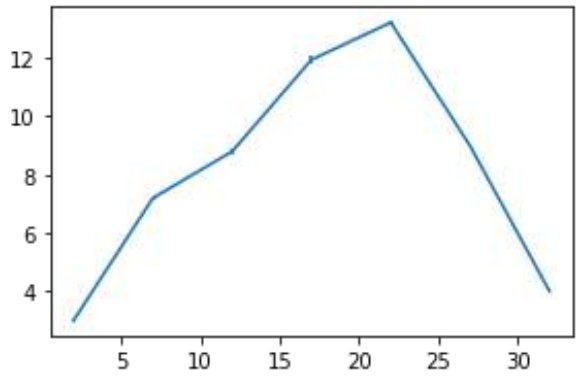

Figure 7: (Task 6) Horizontal; number of red tilted distractors (of a total 35 distractors). Vertical; response time/time-to-target (in fixations, t). Distractors were yellow vertical, and red 60 degrees. Target was red vertical.

To test this we introduced critical trials into our normal experiment. On a critical trial an unexpected (blue, left-leaning) object (see Figure 8a for an example) is also present along with the normal distractors and target. We varied the ratio n_T/n_α between 0.005 and 20. Figures 8b and 8c show a clear transition between the scenario in which the $\boldsymbol{\alpha}$ term dominates the saliency computation – in which the unexpected item pops out amidst the red task-relevant objects – and that in which the $\boldsymbol{T}$ terms dominate – where the same object does not pop out of the target and distractors, even though it is clearly surprising to an outside observer.

Second, we checked that if an unexpected object possesses features that are also task relevant, it is more likely to be fixated or reported (Most et al., 2001). We modified Task 2 (see Visual Search, above), as here the target and distractors are defined with respect to only one feature dimension. For a critical trial with a red target at 10 degrees, and red distractors at 30 and 70 degrees, we added an unexpected blue singleton at −70 or 15 degrees. Average number of fixations to target for the singleton at a task-relevant angle (70 degrees) was 13.99 ± 0.002. For the singleton at a task-irrelevant angle it was 2.0 ± 0.001. This was for a constant 12 distractors, and the ratio n_T/n_α was set to 100. This is quite a substantial difference (probably because the experimental set-up was as simple as possible), but it bears out our hypothesis.

Conclusion and Future Work

A weakness of this work is that as it is intended as a theoretical starting point, our analysis is primarily qualitative, and we have not compared the original predictions of our model to data from human participants. We will focus on these deficiencies in upcoming work via two main avenues.

The first approach is to test human participants to show that modulating the relative model precisions of (i.e., confidences in) targets specifically affects the probability that unexpected objects might be detected. If, for example, participants were initially provided only with a verbal descriptions of a visual target, we would expect probability of inattention to a non-target singleton to increase over the course of several trials, as participants became more confident in the target of their search task. We would also expect probability of inattention to be greater for a comparable task where participants are provided with a visual example of their target.

Our second approach, which lies solely in the conjunction search paradigm, would be to include distractors in a conjunction search task that shared no features with the target. We hypothesise that both overt indications of attention (fixations) and covert indications of attention (average time to target) to these non task-relevant objects would decrease over the course of several trials.

We have made three distinct contributions; we have presented a model of visual search that exhibits inattentional blindness, we have shown the equivalency of AIM and E-GS under certain assumptions, and we have argued that an interpretation of what it is to "perform a task" should be grounded on the relative precisions of parts of the brain's generative model.

We conclude that modelling task-based behaviour as explicitly located in a wider context can bear explanatory fruit.

Abstract

In software development, deliverables in an upstream process are reviewed to ensure their quality and to reduce error propagation to the downstream process. Methods are available for evaluating the review quality. In this study, we considered the defect detection process in a review of Requirement Definition Documents and tested a potential relationship between the gaze patterns and review quality. Specifically, we analyzed the relationship between the gaze patterns, with a primary focus on the blink rate, in a review of RDDs and detection accuracy. A significant nonlinear correlation between the blink rate and the detection accuracy was observed; moreover, the subsequent regression analysis also verified the blink rate as the best predictor of the review quality, notwithstanding the use of other gaze patterns. This result indicates that the blink rate is a major predictor of a type of review performance.

Keywords: gaze; blink rate; document review; review quality; signal detection theory; machine learning;

Introduction

In software development, it is important to ensure the quality of the specification and design document in the upstream process because they affect the quality of the deliverables in the downstream process. It is five to 200 times more expensive to correct defects in the downstream process than in the upstream process when we correct a low-quality deliverable affected by an ineffective specification (Boehm, 1981). Thus, it is preferable to maximize the defect detection in the upstream process.

In order to remove potential defects, it is common to review a document in an upstream process; moreover, numerous review methods have been used. However, individual differences in the review performance are likely to influence the review quality to a higher degree than the differences among the review methods (Uwano, Nakamura, Monden, & Matsumoto, 2007). A reviewer's performance also depends on the time limit for the task and the degree of the reviewer's concentration. Furthermore, although the defect detection rate based on the items indicated and the review rate are used for quantitatively evaluating the review quality, these indices by themselves are not adequate for accurately evaluating the review quality. First, the defect detection rate, for example, depends both on the quality of the reviewer and the quality of the document reviewed. As a result, we cannot assess whether a low detection rate implies low quality of the reviewer or high quality of the document. Second, these available indicators do not capture the different types of defects, such as simple typos, missing information, ambiguity, and misleading sentences. Accordingly, in this study, we explored a new indicator of the review quality, which characterizes the reviewer's performance and the potential types of defects. As a potential candidate for this indicator, we studied the gaze behavior in the document review task.

Recently, gaze data have been studied in software engineering (SE) to elucidate the cognitive process in various SE tasks such as code review (Sharafi, Shaffer, Sharif, & Gueheneuc, 2015). In SE, there are numerous studies targeting the review of a source code in the downstream process or review of "box and arrow" diagram such as Unified Modeling Language (UML). However, there are few studies on the review of documents in the upstream process (Sharafi, Guéhéneuc, & Soh, 2015). In fields other than SE, there has been studies on reading and understanding of narratives using gaze data (Augereau, Kunze, Fujiyoshi, & Kise, 2016; Campbell & Maglio, 2001; Okoso et al., 2015); however, there are few studies on the review process for detecting defects in a document.

Uwano et al., (2007) have defined the review process: "In the software review, a reviewer reads the document, understands the structure and/or functions of the system, then detects and fixes defects if any." They classified it into the three sub-processes: (1) reading, (2) understanding of the structure, and (3) detection/correction of defects.

Relevant to the three sub-processes above, past literature has reported the three major characteristics of eye blink as follows:

(A) An adult subject typically exhibits 20 eye blinks per minute (Bentivoglio et al., 1997).
(B) A task requiring certain external information such as reading tends to enhance external attention and reduce the number of eye blinks per unit time (Cho, Sheng, Chan, Lee, & Tam, 2000; Karson et al., 1981).
(C) A task requiring internal attention, such as mental arithmetic and association, increases the number of eye blinks per unit time (Cho et al., 2000; Karson et al., 1981).

In light of these observations, we hypothesize that the three sub-processes in the review process are related to the eye gaze patterns as follows: Process (1) is supposed to be associated with observation (B), wherein the rate of eye blinks would be reduced as it requires external information.

Processes (2) and (3) are supposed to be associated with observation (C), wherein the rate of eye blinks would be increased as it requires internal attention. Moreover, we suppose that both effective and ineffective reviewers are largely similar in the sub-process of reading (1); however, they would be different in the sub-processes of understanding (2) and detection (3). More specifically, we suppose that an effective reviewer would utilize more cognitive resources for the two sub-processes (2) and (3) than an ineffective one; as a result, a better reviewer would exhibit a higher rate of eye blinks per time.

Therefore, in this study, we executed an experiment that simulated a review process of a set of Requirement Definition Documents (RDD) and measured the reviewer's gaze patterns during the experiment. Then, we tested our above hypothesis by analyzing the relationship between the eye blinks and the review quality. In this experiment, we prepared a RDD material, to which we introduce defects; moreover, the review quality was defined based on whether these presumed defects were detected or not.

Our analysis of the review quality by using the gaze data revealed that the blinks were the most important component of the gaze data; a significant nonlinear correlation between the blink rate and the detection accuracy was apparent.

Experiment

In the experiment, each of the participants underwent two sessions: the review session and post-review session. In each trial in the review session, they were asked to review one page of the three types of the RDDs and then to mark the sentences with defects. After finishing 11 trials of the review session, they were asked to fill the demographic questionnaire.

Participants

We recruited 19 Japanese adults as the participants (16 male and three female) and the average age of them was 42.2 years (SD = 9.1), with nine of them in their 30s, four in their 40s, and six in their 50s. All of them were system engineer and nine of them had no RDD review experience. All of them had normal (corrected) vision.

Material

The set of original documents used in the review session were based on three types of RDDs that were in actual use at Nihon Unisys, Ltd. Each of the original RDDs was re-arranged such that each document had three pages of summary, three pages of functional requirement, three pages of non-functional requirement, and two additional sample documents—eleven pages in total. They were all in Japanese. On each page of a re-arranged RDD, we introduced a defect that was absent in the original document. In this study, the type of defects was the "omission" of certain necessary piece of information for requirement definition. A part of an original sentence was removed, which made the original definition ambiguous. In order to simulate a natural review process, we did not add more than a defect per page. As a result, we limited the number of sentences, including the one with a defect, to two per page; there were 17 sentences, including those with the defects, in the 11 pages. The demographic questionnaire included questions on age, gender, RDD review experience, document review experience, degree of concentration during review, and degree of comprehension to documents for review.

Procedure and Apparatus

In each trial, one page of the documents to be reviewed was presented on a computer screen; the participant's gaze patterns were measured by an eye tracker device during the document review. The eye tracker used in this experiment was gazepoint GP3HD eye tracker (Figure 1). The participants could spend as much time as they considered necessary for this review process.

After the review of each page, the participants were instructed to mark the sentences to be improved, on a printed document with the reviewed content; they were not informed about the type of defects introduced. This trial was repeated for 11 pages and the order of page was the same for all participants. The participants were not provided any break during the review trial. Moreover, they were instructed to maintain their head still as much as feasible in order to ensure accurate eye tracking.

After the review session, each of the participants was asked to answer the demographic questionnaire.

Figure 1: (left) Experimental situation, (right) eye tracker (set up at the bottom of the monitor)

Results

In the review session, the average, minimum, and maximum review times of the 19 subjects were 21, eight, and 40 min, respectively. In order to exclude the data with large numbers of eye tracking error, we performed the Smirnov–Grubbs test (Grubbs, 1969) to detect pages with valid fixation points less than 60% (Figure 2). Based on this test, we excluded data worth four pages (out of the total 209 pages—11 pages for each of the 19 subjects) from the rest of our analysis. We performed the subsequent analysis on the 205 pages of data with a sufficiently large rate of fixation.

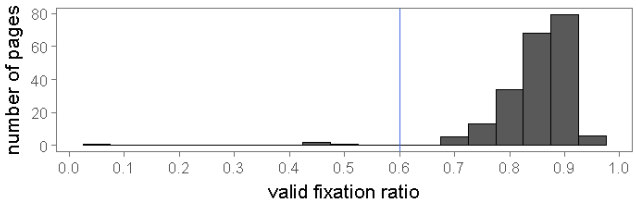

Figure 2: Histogram of valid fixation ratio each page

Review quality

In this study, we defined the correct review report for each unit of document based on the match between the participant's marked sentence and the sentence with a defect. Thus, the defect detection task was formulated as signal detection—the participant report a defect as either being detected or not, given a sentence with defect (signal in the ground truth) or otherwise (noise in the ground truth). We employed the signal detection theory (SDT) (Green & Swets, 1966) and treated the d-prime as an indicator of the accuracy of defect detection or the review quality. In the SDT, the respond bias and the sensitivity (d-prime) are distinguished from the rates of correct rating (the rate of defect detected marked to a sentence with defect) and false alarm (the rate of detect detected marked to a sentence without defect). The d-prime represents the deviation of the signal and noise distribution from the noise distribution as defined by

$$\text{d-prime} = \frac{M_{SN} - M_N}{\sigma_N}, \qquad (1)$$

where M_{SN} is the mean of the signal and noise distribution, M_N is the mean of the noise distribution, and σ_N is the standard deviation of the noise distribution. The d-prime is an indicator of the review quality; it can circumvent the effect of the potential response bias (the behavioral tendency to report detection regardless of the signal).

Analysis

In order to test our hypothesis, we analyzed the relationship between the blink rate and the review quality measured by the d-prime, in Analysis 1. In Analysis 2, we performed a model-based analysis of the relationship between the review quality and the gaze pattern not just the blink rate but also the other types of measurements such as fixation and saccade. The statistical analyses reported here were conducted with the free software R language (R version 3.4.1).

Analysis 1: Is the blink rate related to the review quality?

According to our hypothesis discussed in the introduction, the key sub-process in the review would require internal attention; thus, it would increase the blink rate. In order to verify this relationship between the blink rate and the review quality, the scatter plot of the blink rate and d-prime are shown in Figure 3. The corresponding correlation coefficient and other statistics are listed in Table 1. The maximal information coefficient (MIC) is a correlation coefficient calculated using mutual information; its application is feasible even with a nonlinear relationship. MIC-ρ^2 is an index of nonlinearity, and the maximal asymmetry score (MAS) is an index of non-monotonicity (Reshef et al., 2011). These results are summarized as follows:

- d-primes across the trials of the participants were distributed from - 1 to + 1.
- When d-prime was approximately zero, the blink rate was reduced from the mean blink rate and increased at non-zero d-prime values.
- The Pearson correlation coefficient between the d-prime and the blink rate was significant, although weakly negative.
- Both MIC and MIC-ρ^2 were large, and these together exhibited significant nonlinearity.

From the above facts, it was determined that the relationship between the blink rate and d-prime was a U-shaped or V-shaped nonlinear correlation, in which the blink rate was the smallest for d-primes near zero.

This result, both positive and negative d-primes across the trials, indicates the presence of two distinct groups of participants: One group detected the type of defects incorporated to a few sentences in the experimental manipulation; the other group detected the other type of defect (rather than only random sentences), which were not regulated explicitly in this experiment. Although we incorporated defects to a few sentences in the document, the original document (a RDD in use for some other purpose) is likely to have had certain other type of defects prior to this experimental manipulation. If so, the positive d-prime indicates the sensitivity to the expected type of defects incorporated in this experiment, whereas the negative d-prime indicates the sensitivity to certain unexpected type of defects originally in the RDDs.

Figure 4 shows the relationship between the d-prime and the response to noise in all the trials for each participant. We observed the general trend in these individual differences wherein those who exhibited a negative d-prime tended to detect "noise" as a "signal" (which may be interpreted as a defect by these participants) rather than the signal defined by the pre-experimental manipulation of the RDD. Thus, owing to the ambiguity of definition of the type of defects in the instruction, these participants were likely to detect the other types of defects (which were classified as "noise" by our definition).

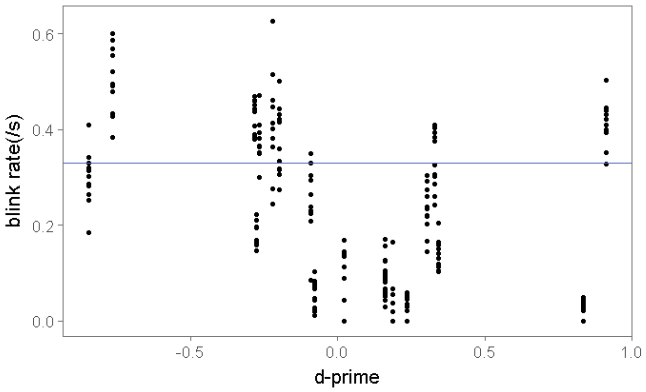

Figure 3: Scatter plot of d-prime and blink rate (blue line: mean blink rate in normal)

Table 1: Correlation coefficient between d-prime and blink rate

		Blink rate
d-prime	Pearson correlation	-.393
	p-value	.000
	MIC	.865
	MIC-ρ^2	.711
	MAS	.450

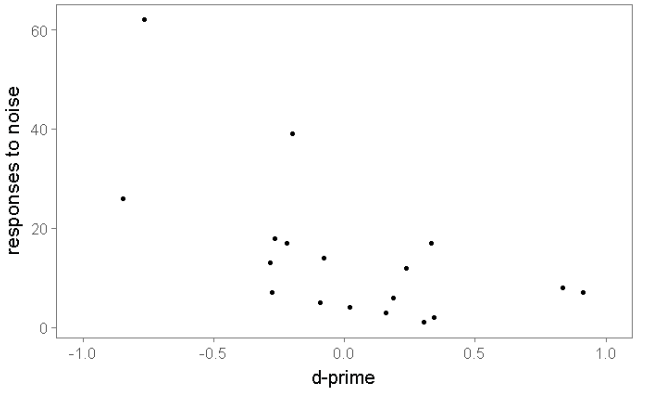

Figure 4: Scatter plot of d-prime and responses to noise

With respect to this interpretation of positive and negative d-primes, both positive and negative (non-zero) d-prime indicate higher sensitivity to certain types of defects; moreover, the blink rate was adequately correlated to the review quality of the potentially mixed types of defects.

This result appears to be evidence supporting for our hypothesis. However, it is likely that this result is caused by a spurious correlation owing to certain other features of gaze patterns, which are also correlated to the blink rate. Accordingly, in Analysis 2, we analyzed the d-primes, the indicator of review quality, with a collection of the other types of gaze features as well as the blink rate. Thereby, we evaluated the significance of the blink rate in the prediction of the d-primes, relative to the other types of gaze features such as fixation and saccade.

Analysis 2: Model-based analysis of review quality

In Analysis2, we constructed a model that predicts the type of detected defects measured by the positivity of the d-prime. Specifically, we employed a machine learning algorithm, random forest (RF) (Breiman, 2001) to predict the d-prime using the blink rate and other gaze patterns as the predictor. First, the set of features were calculated from the gaze patterns. Second, an RF regressor was constructed using the gaze features as a predictor of the d-primes in each trial. Then, we determined which gaze features is more informative for predicting the d-primes.

Extraction of features We extracted a set of 47 gaze features from the four fundamental gaze components: fixation, saccade, blink, and pupil (below). Forty six of these 47 features were originally defined by Bixler & D'Mello (2015); the blink rate was added to the list of features for the purpose of this study.

1. fixation: gazing on a single location
2. saccade: quick eye movement between fixation
3. blink: presence or absence of blink
4. pupil: size of the pupil

For each trial, the gaze pattern was characterized by these 47 features, and it was used to train the RF. As the RF calculated the importance of each feature simultaneously, the feature with low importance (with negligible significance for predicting the d-prime) could be removed.

We employed a sequential forward feature selection procedure using the RF as follows. First, the importance of each feature was calculated by RF using all the gaze patterns. Then, the root mean square error (RMSE) was calculated by RF using the highest importance feature. RMSE is the error from the actual value and is defined as

$$\mathrm{RMSE} = \sqrt{\frac{1}{n}\sum_{k=1}^{n}(y_k - \hat{y}_k)^2}\,, \qquad (2)$$

where n is the number of pages, y_k is the specified d-prime of the kth page, and $\hat{y}_k$ is the d-prime predicted by the model. Second, RF was executed by adding the feature with the next highest importance, and the RMSE was similarly calculated. Third, the above process was repeated until the RMSE was the smallest, and the features effective for the review quality were extracted.

As a result, we obtained the 15 most important features extracted by RF, which are listed in Table 2. The blink rate was observed to be the most important. This indicates that the blink rate was the feature that was the most predictive of the d-prime.

Table 2: Features and their importance as extracted by RF

Rank	Features	Importance
1	blink rate	2.23
2	kurtosis of sccade duration	2.09
3	fixation duration / saccade duration ratio	1.93
4	number of blinks	1.93
5	max of saccade duration	1.88
6	range of saccade duration	1.80
7	kurtosis of pupil diameter	1.77
8	min of fixation duration	1.56
9	proportion of time spent blinking	1.50
10	mean of saccade duration	1.31
11	standard deviation of saccade duration	1.30
12	skew of saccade duration	1.27
13	proportion of horizontal saccade	1.14
14	median of saccade distance	1.08
15	median of fixation duration	1.01

Review quality prediction model Using the selected 15 features in Table 2, decision tree (DT), support vector regression (SVR), and multiple linear regression (MLR) models were constructed to predict the d-prime.

For validating these regression models, we performed a 10-fold cross validation (random split all trials) using their mean square errors (MAEs) and RMSEs. The MAE is defined as

$$\text{MAE} = \frac{1}{n}\sum_{k=1}^{n}|y_k - \hat{y}_k|. \qquad (3)$$

The results calculated for each algorithm by constructing the review quality prediction model are listed in Table 3. SVM exhibited the lowest MAE and RMSE, whereas the RF exhibited the second lowest ones. To determine how effectively the model predicts the d-prime, we present the scatter plot of the d-prime of the data and the one predicted by SVM in Figure 5 and the corresponding correlation coefficient in Table 4.

To summarize the above results, 15 out of the 47 gaze features are significantly important for predicting the review quality measured by the d-prime. Among these significant features, the blink rate was observed to be the most important. This result of the model-based analysis is consistent with the observation in Analysis 1: The blink rate has a higher predictability than the other types of gaze features; thus, it is unlikely that the relationship between the blink rate and the review quality is the result of a spurious correlation.

Table 3: Review quality prediction model

		RF	DT	SVR	MLR
d-prime	MAE	0.224	0.323	**0.214**	0.283
	RMSE	0.304	0.451	**0.289**	0.361

Table 4: Correlation coefficient between actual and predicted d-prime

		d-prime (actual)
d-prime (predicted)	Pearson correlation	.750
	p-value	.000

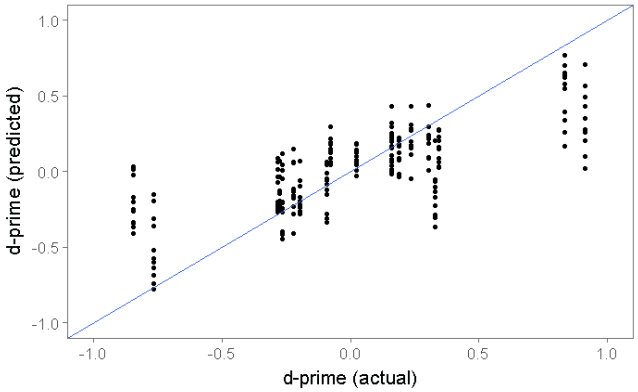

Figure 5: Scatter plot of actual d-prime and predicted d-prime

d-prime positive/negative classification model It is also intriguing whether we can classify the type of defects, which may be reflected as the positivity of the d-primes. Therefore, we next construct a classifier of the positivity of the d-prime by using the selected 15 gaze features. The algorithms adopted in this study were RF and support vector machine (SVM), which had exhibited a high prediction performance of d-prime in the experiment described in the previous section. Unlike the previous model-based analysis, we used the positivity of the d-prime as a class label rather than the d-prime value.

The classification accuracy is the coincidence rate between the predicted class and the specified class defined by

$$\text{Accuracy} = \frac{TP + TN}{TP + FP + TN + FN}, \qquad (4)$$

where TP, TN, FP, and FN are the elements in the confusion matrix presented in Table 5.

Table 5: Confusion matrix

		Actual values	
		positive	negative
Predict values	positive	*TP*	*FP*
	negative	*FN*	*TN*

The classification accuracy for each algorithm is presented in Table 6. This result indicates that a classifier constructed upon the gaze features can predict the two potential types of defect detection with reasonably high accuracy 84%.

Table 6: Accuracy of d-prime positive/negative classification model

	RF	SVM
Accuracy	83.83%	**84.38%**

General Discussion

Blink rate and review quality

In prior study of SE, the gaze data has been used to elucidate cognitive process, however, the fixation and the saccade are often focused on and the blink rate is hardly taken consideration (Sharafi, Shaffer, et al., 2015). And it is also same trend in the study on reading and understanding of narratives (Augereau et al., 2016; Campbell & Maglio, 2001; Okoso et al., 2015). In this study, we focused the blink rate associated with each sub-process in the review and analyzed the relationship between the blink rate and the review quality.

In Analysis 1, we determined a nonlinear relationship between the blink rate and d-prime and that the blink rate was a U-shaped function of the d-prime estimated in each trial. This result is consistent with our hypothesis that the review quality (measured by d-prime) is related to the internal attention (measured by the blink rate). In Analysis 2, we tested the potential possibility that the relationship between the blink rate and d-prime is a spurious correlation owing to other confounding gaze features. We performed the regression analysis on the blink rate as well as the 46 other gaze patterns extracted from fixation, saccade, blink, and pupil. This analysis revealed that the blink rate was the most predictive of the d-prime; moreover, it indicated the blink rate to be a major gaze feature of the degree of review quality.

Limitations

It should be remarked that the result of Analysis 1, both positive and negative d-primes determined, was an indication of the likely presence of two potential groups of subjects detecting different types of defects owing to the ambiguity of the instruction for the review session. Considering this limitation of the experiment, it is feasible to have a few remarkable reviewers who detect both types of defects (the type defined and the other types not adequately defined in this study); such a reviewer may be evaluated near zero d-prime because he/she would detect both "signal" and "noise" according to our definition. Thus, in future works, an improved experimental design should have a list of defects covering most types of defects in the RDD material in order to prevent the problem of multiple types of defects.

Although we could not exhaustively classify all the types of defects using only the blink rate, Analysis 2 revealed that the positivity of the d-prime, indicating whether the detected defect was pre-defined or not, is classifiable with the blink rate and the other gaze features. There were numerous features on saccade duration in the 15 features. In general, these saccadic features capture gaze trajectory, and the saccade duration reveals the time of this trajectory. Thus, this result is likely to indicate the reading style such as reading order; moreover, the speed depends on the type of defects detected.

The set of RDDs used in this study was used for our customer's system development; its quality was supposed to be at least a specified level. However, it was likely that an immature RDD exhibited certain different types of potential defects than the defects introduced in this study. We cannot exclude the possibility that a reviewer's gaze pattern is affected by these mixed types of defects. This fact also necessitates a reconsideration of the experimental design that regulates the types of defects and investigates the relationship between the detection accuracy and the gaze patterns for each targeted defects.

Abstract

This article used an empirical experiment and a computational model to test the hypothesis that humans rely on the visual system to solve the traveling salesperson problem (TSP). We tested two consequences of this hypothesis: (1) humans should perform better on Euclidean TSP than not–Euclidean TSP; (2) a model of the visual system should account for performance in Euclidean TSP. Participants were asked to solve Euclidean or not–Euclidean TSP, and a pyramid model of the visual system was used to solve the same tours as the humans. The results show that deviations from the optimal tour were smaller in Euclidean problems than in not–Euclidean problems, and the fit of the pyramid model to human performance was worse on not–Euclidean problems then on Euclidean problems. These results suggest that participants solve Euclidean problems with the visual system, but that other mechanisms are needed to succesfully solve non–visual problems.

Keywords:

Problem Solving; Visual Processing; Traveling Salesperson Problem; Pyramid Model

Introduction

A problem is a situation in which an agent seeks to attain a given goal without knowing how to achieve it. Humans solve problems every day. Example problems include winning at tic–tac–toe or winning a battle, air traffic control, control of an uninhabited vehicle, getting to checkmate in chess, visually–guided navigation, proving a logic theorem, solving math and physics problems, cracking the enigma code, or formulating a new scientific theory. Some problems are more visual, such as planning a tour around a grocery store, while others are more abstract, such as proving a theorem using predicate logic. In this conference article, we focus on the Traveling Salesperson Problem (TSP), a well–known optimization problem. In the TSP, a set of points is presented to participants. Each point represents a city, and the goal is to find the shortest possible route that visits all the cities exactly once, and returning to the starting city. We refer to this route as a TSP tour. The TSP has high relevance since it (1) has an important visual component (i.e., cities or points are spatially laid out on a map) and (2) it has important real–life application in many areas such as logistics, transportation, and shipping.

TSP has been studied extensively by cognitive scientists to reveal the underlying processes in human problem solving (van Rooij et al., 2006; Chronicle et al., 2008; Dry et al., 2006; MacGregor, 2013). One reason that makes the TSP an interesting problem for cognitive scientists is that the problem space of the TSP is very large. Even for solving a 16 city TSP, there are 6×10^{11} possible solutions, which is more than the number of neurons in the human brain (Azevedo et al., 2009). Also, the TSP is proven to be computationally NP–hard, meaning that there is no algorithm that can find an exact optimal solution for the TSP in polynomial time (Pizlo & Stefanov, 2013).

Human working memory can only store and manipulate a few items at a time and cannot make more than a few comparisons at a time (Pizlo & Stefanov, 2013). Yet, even with these severe limitations in memory and processing power, humans are able to solve the TSP near optimally in approximately linear time (MacGregor & Chu, 2011; Pizlo et al., 2006). How can humans with these limitations be able to solve the TSP fast and near optimally? What cognitive systems and processes have evolved to solve the TSP in the human brain?

Goals and Hypotheses

Pizlo and colleagues have argued that the TSP is solved by parallel processes in a pyramid–like hierarchical architecture of the visual system (Graham et al., 2000; Pizlo et al., 2006; Pizlo & Stefanov, 2013). The assumption that humans solve the TSP visually has important implications on the types of problems that can be solved. The human visual system has evolved in Euclidean space, so the visual system likely assumes a Euclidean cost function when solving optimization problems. As a result, performance in optimization problems with not–Euclidean or non–metric cost functions might be impaired.

To test this hypothesis, we designed a TSP experiment where participants solved either a regular (Euclidean) or not–Euclidean TSP. The participant's data was then compared with tours produced by a well–known computational model of the visual system, namely the pyramid model (Adelson et al., 1984; Pizlo et al., 1995). According to our hypothesis,

human participants should perform well in the Euclidean version of the TSP but not in the not–Euclidean version of the TSP. Further, the pyramid model should provide a good account of participant TSP tours in the Euclidean TSP but not in the not–Euclidean TSP. These results would support the hypothesis that participants are solving the regular TSP using the visual system, but not the not–Euclidean TSP. Further, the compensatory mechanisms used to solve the not–Eucliean TSP are not as efficient as the visual system at solving optimization problems.

Method

The first aim of this study was to explore how humans perform in different conditions of the TSP (i.e., Euclidean and not–Euclidean). The second aim was to explore how human performance is compatible with the visual pyramid model. The experiment and model are described in turns.

Participants

Ninety–one Purdue undergraduate students participated in the experiment for course credit. Participants were randomly assigned to one of three conditions: Single–color ($n = 36$), Colored–with–no–switch–cost ($n = 28$), and Colored–with–switch–cost ($n = 27$).

Apparatus and Stimuli

The stimuli were 30 maps each generated by putting 50 randomly scattered cities (points) in a $900px \times 900px$ display. The minimum distance between two cities was set to $50px$ to prevent overlapping points. The resulting set of 30 maps was used to create two different stimulus sets. In the first stimulus set, all cities were colored red. This stimulus set is referred as containing *single–color maps* (See Figure 1a). In the second stimulus set, half of the cities (points) were randomly selected and colored red. The remaining cities (points) were colored blue. This stimulus set is referred as containing *colored maps* (See Figure 1b).

The experiment was run on a regular PC. Stimuli were displayed in a 21–inch monitor (1,920 × 1,080 resolution). Participants responded by clicking on the city (point) that they wanted to visit next using a regular computer mouse. After each mouse click, a dark blue edge was drawn between the last visited city and the city that was clicked in the current trial. The order of the city visited was recorded.

Procedure

Each participant solved all 30 maps in one of three conditions. (1) *Single–color (Euclidean)*: This was a typical TSP experiment. The first stimulus set was used (i.e., single–color maps). Participants were asked to find the shortest TSP tour on each map, one map at a time. The cost between cities was Euclidean (i.e., the distance on the screen). No feedback was provided. (2) *Colored–with–switch–cost (not–Euclidean)*: The second set of stimuli was used (i.e., colored maps). In this condition, the cost between two points was not always Euclidean. Specifically, when travelling from a blue city to a red city (or vice–versa), the calculated distance (cost) was twice the distance on the screen. Otherwise, when travelling between two cities of the same color, the distance was as seen on the screen. Note that this arrangement can break the triangle inequality and make the cost non–metric. (3) *Colored–with–no–switch–cost (control)*: Similar to (2), this condition used the second set of stimuli (i.e., colored maps). However, the distance between two points was always the distance on the screen, so the colors could be ignored. This condition was designed to control for possible grouping effects that could be created by having cities of two different colors. In all conditions the experimenter explained the cost structure to the participants (as described above) and instructed them to find the tour with the smallest cost for each map.

Pyramid Model

A pyramidal architecture refers to multiple representations of the input data, with different representations having different scales and resolutions. In vision, the input data is the retinal image and the first layer is represented by the retinal ganglion cells. Each ganglion cell receives information from a particular region of the retina called the cell's receptive field. Receptive fields of different cells partially overlap. In the second layer of the pyramid, each "parent" cell receives input from several "child" cells. In the third layer, each "grandparent" cell receives input from several of its children. This process continues until a single cell on the top of the pyramid can "see" the entire image. Cells at lower layers can see small parts of the retinal image but they can process the information with high spatial resolution. Cells in higher layers can see larger parts of the retinal image but with lower resolution. More generally, cells in higher layers can handle only some statistical information about their receptive fields. The mean value of some property, like intensity, speed, contrast and so on, is the simplest example.

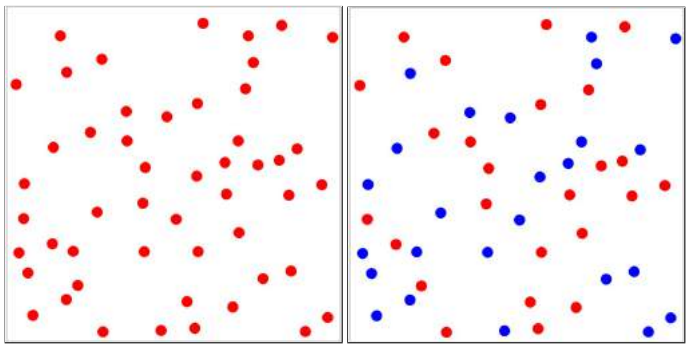
We implemented a Pyramid model adapted from Pizlo et al. (2006). The algorithm is presented in Figure 2. We used Python for our implementation. Inputs to the model were the maps that the participants in the experiment had solved. Because we hypothesized that the visual system evolved in a Euclidean world, the distances between the cities were considered Euclidean in all three conditions. This corresponds to the visual system not being able to process not–Euclidean distances.

Finding Optimal Tours

We used NEOS server of Concorde TSP solver to find the optimal TSP tours for each map. Concorde is one of the best exact TSP solvers currently available. It is available freely for academic use: https://neos-server.org/neos/solvers/co:concorde/TSP.html.

Results

One participant in the Single–color condition had tours that were three standard deviations longer then the condition



(a) Single–color map (b) Colored map

Figure 1: Example maps used in the experiment.

mean. All tours produced by this participants were not included in the following analyses.

Human Performance

Figure 3 shows typical example solutions produced by participants in each condition. As can be seen, the colored–with–switch–cost tour was qualitatively different from those obtained with the single–color and with colored–with–no–switch–cost conditions. Specifically, the not–Euclidean condition included a number of path crossings, which would be suboptimal in Euclidean space (but could be optimal in not–Euclidean space). These crossings were not observed when colors were present without a switch cost.

To quantify the participant performances, the error (i.e., deviation from optimal) was calculated for each map:

$$error_{ji} = \frac{(S_{ji} - O_i)}{O_i} \quad (1)$$

where $error_{ji}$ is the error or participant j on map i, S_{ji} is the length of the tour produced by participant j on map i, and O_i represents the length of the optimal tour for map i .

Table 1 presents the mean error in each condition. As can be seen, the single–color error was 12.6% and the colored–with–no–switch–cost (Euclidean) error was 12.7%, which is almost half of the error observed in the colored–with–switch–cost (not–Euclidean) TSP condition. This shows that participants perform well in Euclidean space but struggle in not–Euclidean space. Also, participants were able to ignore the irrelevant color and the longer tours obtained in the not–Euclidean condition were not caused by a perceptual effect of the city colors. Hence, larger errors for the not–Euclidean condition were not the result of unwanted color grouping effects.

To investigate if the observed differences were statistically significant, we performed Holm–corrected pairwise comparisons t–tests for all three conditions. Error in the not–Euclidean condition significantly differed from error in the single–color $(t(60) = 6.10, p < .0001)$ and error in the color–with–no–switch–cost $(t(53) = 5.63, p < .0001)$ conditions. The two Euclidean conditions did not differ from each other $(t(61) < 1, n.s.)$.

Table 1: Mean participant error in each condition

Condition	Error
Single–color	12.6%
Colored–with–no–switch–cost	12.7%
Colored–with–switch–cost	20.7%

The results show that the errors for the single–color and control conditions were not statistically different. However, the colored–with–switch–cost condition differed from the other two conditions. These statistical differences clearly show that participants' performances were highly dependent on the problem being Euclidean or not–Euclidean, and support the hypothesis that the visual system may assume a Euclidean cost function in solving the TSP.

The performance of the Pyramid model

In Table 2, we compared the Pyramid model generated tours with optimal tours. As can be seen, the error is 14.2% for both Euclidean conditions (single and color), and it increased to 34.5% for the not–Euclidean condition. As expected, the model error was similar to humans in the Euclidean conditions. The RMSD was 4.6% in the single–color condition and 4.5% in the color–with–no–switch–cost condition. However, the model provided a poor fit of human performance in the not–Euclidean condition (RMSD = 15.0%). Assuming that the Pyramid model is an adequate model of human vision, this result suggest that participants solving the Euclidean TSP used the visual system (good model fit), but not the not–Euclidean TSP (poor model fit). Since the participants were doing better than the model in the not–Euclidean condition, this result also suggest that participants may have access to a separate (compensatory) mechanism to attempt to solve not–Euclidean TSP. The pyramid model, in contrast, was purely a model of the visual system and could only deal with Euclidean spaces.

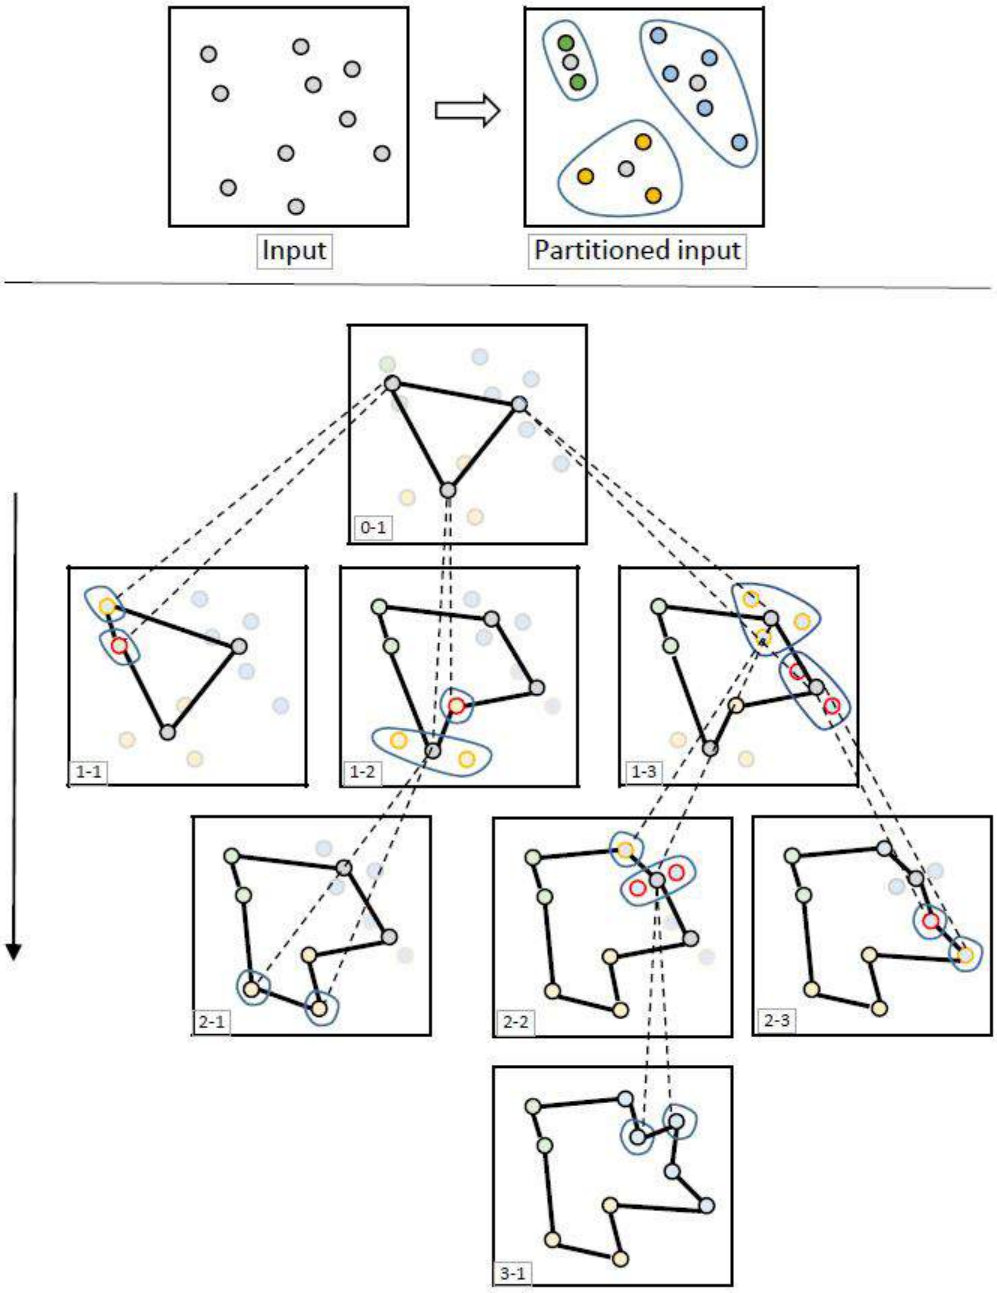


Figure 2: A representation of the Pyramid model. The top row shows the input as it gets partitioned into k clusters (by using a clustering algorithm, such as k–means). In this example, $k = 3$. Next, the pyramid is built. The root of the Pyramid (0–1) is the TSP solution for the centers of the clusters for the partitioned input. The solution for this TSP at the root is trivial because there are only three points and all three points are connected to each other. In the next level of the pyramid (level 1), each cluster is considered separately and recursively repeats the clustering until there is only one point (or city) in each cluster. For example, (1–1) shows the partition of the top–left cluster into k clusters (if the number of points is smaller than k, then $k-1$ is used, here $k = 2$), and a TSP solution for this cluster is found. Since, there were only two points, the solution is trivial, and the two points were connected to each other. Then by brute–force (considering all possibilities), the incoming and outgoing edges are connected to this cluster to obtain the shortest edges. The model then moves to the next cluster (1–2) and repeats the same procedure, until there is no non–visited cluster.

Colored–with–no–switch–cost	14.2%
Colored–with–switch–cost	34.5%

Discussion

This article used an empirical experiment and a computational model to test the hypothesis that humans solve the TSP by assuming an Euclidean cost function. This assumption follows from the TSP being solved visually, and the visual system having evolved in an Euclidean world. We specifically tested two consequences of this hypothesis, namely that humans would perform better on Euclidean TSP than not–Euclidean TSP and that a model of the visual system could account for performance in Euclidean TSP. Participants were asked to solve the TSP in three conditions, two Euclidean and one not–Euclidean. A pyramid model of the visual system was used to solve the same tours as humans. The results show that the deviations from the optimnal tours were almost twice as small in Euclidean problems than in not–Euclidean problems, and the fit of the pyramid model to human performance was three times worse on not–Euclidean problems than on Euclidean problems.

Relevance for Problem Solving Research

Some problems are visual, like TSP on a Euclidean plane or visual navigation, but other problems may not have an obvious visual representation. Algebra problems, first order logic, and chess are examples. Logic is not visual, but set theory, with Venn diagrams, provides a visual version for at least some logical problems. However, not all problems are amenable to a useful visual representation. In these cases, the massively parallel nature of the visual system is no longer sufficient: problems need to be solved sequentially. One possibility is to use reinforcement learning (Sutton & Barto, 1998). In this framework, the agent is a sequential decision–making system and the environment is another system evaluating the distance between the current problem state and the goal state (Dandurand et al., 2012). In visual cases, the environment could be the visual system with geodesic estimates. In more abstract cases, the environment could be a meta–cognitive system used to evaluate states and rewards. Regardless of how the environment is implemented, actions are selected in each state by using a policy. The policy numerically describes the desirability of each action in each state. The goal of reinforcement learning is to find a policy that maximizes the return, which is the sum of all future rewards, until the problem is solved. However, any sequential system attempting to solve a NP–hard problem, such as the TSP, will quickly be overwhelmed by complexity. This could explain why human participants did better than the pyramid model in not–Euclidean TSP but did not do as well as in the Euclidean problems.

Future Work and Limitations

Future work can be directed in two ways. First, we can further test the theory of the engagement of the visual system in solving the TSP. It can be done by studying whether human performance is compatible with other characteristics of the visual system such as its limited ability to learn. The second direction is proposing a more complete model of human problem solving. Implementing a dual–system model of problem solving, including both a parallel visual module and a sequential decision–making module can be a promising direction. Tentatively, using a reinforcement learning agent for sequential decision–making would allow for learning in problems that cannot be solved visually. This possible dissociation in learning ability for visual and non–visual problems may allow for optimizing the way we represent and solve problems. Future work should be devoted to implementing and testing such a model.

Abstract

While there is substantial evidence showing that assistance provided to students during problem-solving activities influences learning outcomes, it is not yet clear how to best design educational technologies to maximize learning through various types of assistance. One common type of assistance corresponds to hints delivered by an educational technology. To date, however, there is little research on the impact of different types of hints, including high-level hints vs. specific bottom-out hints. Our research takes a step in filling this gap, through an experimental study with an intelligent tutoring system we implemented in the domain of algebra (N = 50). We did not find evidence that the type of hint, high level vs. bottom out, influenced learning, with both types of hints producing similar outcomes. We did, however, find support for the conclusion that the number of hints accessed interacted with the type of hint to influence learning, and specifically, that accessing more hints was correlated with learning but only in the high-level hint condition.

Keywords: Intelligent Tutoring Systems; high-level and bottom-out hints

Introduction

There is established evidence that instructional feedback and assistance, such as hints and explanations during instructional activities, influence student learning (Shute, 2008). An open question, however, is how explicit should this assistance be to facilitate learning?

Prior research suggests that students learn best when they engage in constructive behaviors as compared to ones that are merely active or passive. This is a key prediction made and confirmed by Chi's (2009) ICAP framework that distinguishes levels of student engagement during instructional activities. To illustrate in the context of human tutoring, when a tutor prompts their student with general suggestions and/or questions, this encourages the student to generate substantive contributions, namely domain-related utterances that are positively associated with learning (Chi, Roy, & Hausmann, 2008). As another example, Ferreira, Moore, and Mellish (2007) compared two common strategies human tutors used to respond to student errors and misconceptions, namely *giving-answer assistance* and *prompting-answer* assistance. They found that *giving-answer* type of assistance occurred more often, but *prompting-answer* type of assistance was more effective for learning. Thus, in the context of human tutoring, tutors don't encourage constructive student processing because they provide the answer instead of eliciting it from the student. When students are working on their own without a tutor, they also default to passive strategies. For instance, VanLehn (1991, 1998) showed that when students were given access to worked-out examples during paper and pencil problem-solving activities, they commonly missed learning opportunities because they copied from the examples rather than trying to generate the problem solution without the help of the example.

The findings on learning from human tutoring and related activities have influenced the design of educational technologies, including that of *tutoring systems*. These technologies rely on artificial intelligence techniques to personalize instruction, in some cases approaching the effectiveness of human tutors (Vanlehn, 2011). Based on research that students benefit from active processing and that reduced assistance may promote it, some work has examined the effects of manipulating assistance in computer tutors. For instance, in separate experiments, Borracci, Gauthier, Jennings, Sale, and Muldner (2019) and Lee, Betts, and Anderson (2015) found that students learn better from tutoring systems that provide reduced assistance as compared to high assistance. In these studies, assistance was operationalized through examples that aided problem solving, with the level of similarity between an example and its corresponding problem determining how much assistance the example provided (high similarity resulted in high assistance, low similarity in reduced assistance). We next review tutoring systems that provide assistance through hints.

A common way to integrate hints into tutoring systems is to use a specific progression of assistance, one that starts off general with hints that provide high-level suggestions, but that become more specific as students ask for more help (Arroyo, Mehranian, & Woolf, 2010; Roll, Aleven, McLaren, Ryu, Baker, & Koedinger 2006; Vanlehn, Lynch, Schulze, Shapiro, Shelby, Taylor, Treacy, Weinstein, &

Level 1: *Check your trigonometry* **Level 2:** *If you are trying to calculate the component of a vector along an axis, here is a general formula that will always work: Let qV be the angle as you move counterclockwise from the horizontal to the vector. Then: V_x = V*cos(qV-qx) and V_y = V*sin(qV-qx).* **Level 3: (bottom-out hint)** *Replace cos(20°) with sin(20°)*	**Level 1:** *Enter the value of the radius of circle A* **Level 2**: *How can you calculate the value of the radius of circle A given the value of the diameter of circle A*? **Level 3**: *The radius of a circle is half of the diameter* **Level 4: (bottom out hint):** *The radius of circle A 1⁄4 46.5*

Figure 1. The hint progression sequence in two established tutoring systems: Andes (left) and the Cognitive Geometry tutor (right)

Wintersgill, 2005). The final hint in the progression is commonly referred to as a *bottom-out* hint, and this type of hint essentially provides the answer (e.g., the solution step the student needs to produce to make progress in solving the problem). To illustrate, Figure 1 shows an example of such a hint progression from two established tutoring systems: (1) the *Andes* tutor in the domain of physics (Vanlehn et al., 2005) and (2) the *Cognitive Geometry* tutor (Aleven, McLaren, Roll, & Koedinger, 2006).

The rationale behind using a hint progression that starts with high-level hints is to encourage students to be constructive and so generate the answer with minimal assistance from the high-level hint; if students continue asking for help, they are given more specific assistance. While this type of design mirrors what *expert* human tutors do (i.e., start off more general in their assistance and only provide the answer if students are truly stuck), in the context of tutoring systems students often abuse help functionalities (Aleven et al., 2006; Muldner, Burleson, Van de Sande, & VanLehn, 2011; Peters, Arroyo, Burleson, Woolf, & Muldner, 2018), a behavior referred to as *gaming* (Baker, Corbett, Koedinger, & Wagner, 2004). In the context of systems that make hints available, students who "game" tend to quickly and repeatedly ask the tutoring system for a hint, without reading the high-level hints, until they reach the bottom-out hint in the hint progression, at which point they copy the answer the hint provides into the problem they are working on.

Skipping high-level hints in tutoring systems is a well-documented event (e.g., Arroyo et al., 2010, Muldner et al., 2011). How does this behavior impact learning? Some argue that students still learn because they use the bottom-out hints as worked examples, which may promote learning in ways that abstract hints do not (Shih, Koedinger & Scheines, 2011). This conclusion was reached through a data mining analysis. Others have found more mixed findings on the utility of either type of hint. To illustrate, Muldner et al. (2011) used exploratory methods corresponding to Bayesian parameter machine learning to investigate the utility of high-level and bottom-out hints. Specifically, to model learning from hints, a knowledge-tracing Bayesian network was used that included nodes representing student actions, knowledge of domain principles (rules), and hints. The network encoded the probability that students will learn a rule given that they saw a certain type of hint (high-level vs. bottom-out). To obtain those probabilities, machine learning was applied to learn the parameters from data corresponding to students interacting with the Andes tutoring system. The findings showed that neither type of hint was very effective at promoting learning and there was little difference between the two types of hints. Specifically, the probability of a rule being learned was only at about 25% when a hint was used and this value was similar for both bottom-out and high-level hints.

The work cited above used exploratory methods to investigate the utility of different types of hints. The motivation for the present study is that to date there is very little experimental work comparing the effect of different types of hints on student learning. One exception is the study by Chi et al. (2001), albeit this work involves human rather than artificial tutors. Specifically, Chi et al. (2001) manipulated the type of hint human tutors were allowed to give: high-level prompts only vs. detailed hints. The results indicated a lack of a difference in learning between the two conditions, with similar posttest scores. In contrast to this study, our work investigates the effect of different types of hints provided by a computer tutor, as we now describe.

The Present Study

To test how different types of hints influence learning from a tutoring system, we created a computer tutor using the Cognitive Tutor Authoring Tools (CTAT) framework (Aleven, McLaren, Sewall, & Koedinger, 2006). CTAT facilitates the construction of tutoring systems by providing tools that a human author uses to create the tutor interface and specify the tutor's behavior. For the latter, a human author creates a *behavior graph* for each problem that specifies the tutor's behavior for that problem (e.g., what kinds of hints to show, what feedback to provide on solution entries, what to do if a student wants to move on to the next problem).

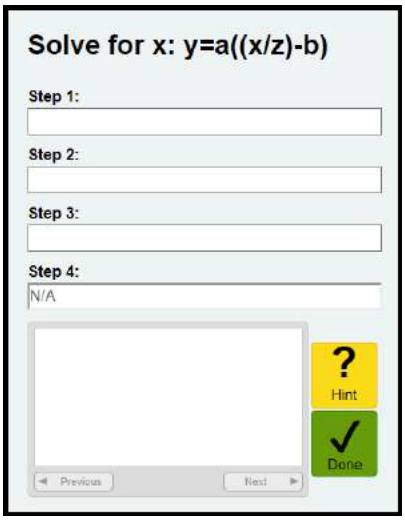

Figure 2. A problem in the algebra tutor

The algebra hint tutor

Our tutor provided students with problems to solve in the target domain of algebra (see Figure 2). The problem format was adopted from prior work and used variables instead of numeric constants (e.g., similar to the approach used by Cooper and Sweller, 1987).

All problems in the tutor required three to four solution steps for the final solution; each step was produced by applying algebraic manipulations (i.e., rules) to the prior step (or specification if the current step was the first one). A single algebraic manipulation corresponded to moving a variable from one side of the equation to the other. For example, given the equation $y = (a+x)b$, a manipulation required to solve the problem for the variable x involves moving the b variable to the other side of the equation, resulting in the equation $y/b = a+x$. Each solution step had its own input box in the tutor's interface that the student could type into. The tutor provided two forms of support: (1) feedback for correctness and (2) on-demand hints.

Feedback for correctness was realized by having the tutor color a student's entry as red (incorrect entry) or green (correct entry) directly after students indicated they were done with the entry by hitting the *return* key. The tutor was flexible in terms of accepting various forms of solutions, e.g., recognized $x = yab$ as equivalent to $x = a *y(b)$. This flexibility was accomplished through functionality we added to the tutor following the algorithm proposed by Shapiro (2005). This algorithm involves using mathematical calculations to check for equivalence without pre-storing all possible versions of a solution, thus saving significant development effort as well as computational cost of evaluating student solutions. To further scaffold the solution entry process, the solution steps had to be entered in the order required by the algebraic process and steps could not be skipped. Once a problem was done (all steps were correctly generated), students clicked the *Done* button (see Figure 1) to move on to the next problem.

Table 1
Examples of hints used in the algebra tutor

Hint Type	Example
Bottom-out Hint	Enter $ya=(x/z)+b$ into the highlighted field.
High-Level Hint (Level 1)	x isn't isolated (alone on one side of the equal sign). So we must reverse the operations acting on the variable(s), starting with the outermost ones (i.e. a in $y=xa$)
High-Level Hint (Level 2)	For this step, you need to move b to the opposite side of the question using addition.

As they were solving problems, students could ask for a hint, done by clicking on the *Hint* button in the interface (see Figure 1). We created two different versions of the tutor: one version provided only *bottom-out* hints and the other provided only *high-level* hints. To design the wording of the hints, we consulted existing tutoring systems as well as online educational sites specific to algebra. To check the wording of the hints was appropriate, we conducted several rounds of pilots.

Bottom out hints Bottom-out hints told students the exact equation they had to enter (see row 1, Table 1), and thus provided high assistance to problem solving. These hints were context specific, meaning that if the student entered a part of the solution and then asked for a hint, the hint would correspond to the next step they had to enter.

High-level hints High-level hints provided reduced assistance because they only prompted the student without giving the answer away. There were two levels of this type of hint: level 1 prompted the student about the next goal they needed to fulfill, but in contrast to a bottom-out hint did not specify exactly how to do that (see row 2, Table 1). If the student wanted further help, they could click the hint button again to access a level 2 hint. This type of hint specified the required operation and the variable that would be moved as a result (see row 3, Table 1).

Like the bottom-out hints, the high-level hints were context specific, and tailored to the student's problem-solving progress. For example, if the next step that had to be entered corresponded to the equation $y-a = (x+b)/c$, the hint would tell the student to move the variable c over to the other side of the equation using multiplication. In instances where two different manipulations were possible, the tutor would pick one at random (students could enter the steps in whichever order they wished). To avoid the hints sounding repetitive, we created several variations of each and the tutor cycled randomly through these variations. We chose to have the high level hints include prompts for both the variable and the operation because both were integral to the solving the problem.

We did not include bottom-out hints in the high-level hint tutor version because we wanted to investigate whether general prompts alone would be sufficient to foster learning.

Each of the two versions of the algebra tutor were populated with the same 12 algebra problems (all required 3-4 steps for their solutions, of the type shown in Figure 2). Both tutor versions logged all student actions in the tutor. We used a basic python script to extract the salient information from the log files (e.g., number of hints, number of errors).

Participants

The participants (N = 50) were undergraduate students at a Canadian University recruited via Sona and compensated with course credit. To be eligible for the study, participants could not have taken or be currently enrolled in any university-level math courses.

Materials

To assess algebra knowledge, we used a paper and pencil algebra pretest and posttest from our prior research that included 11 questions (Borracci et al., 2019). The tests were equivalent (only variable names were changed between them). The tests were scored out of 40, with the points for a given question corresponding to the number of rule applications needed for the question's canonical solution. For instance, if a question required three rule applications for its solution, its point value was three. This scoring method is more sensitive than marking a question as correct or incorrect, given that each question required multiple rule applications.

Several other questionnaires were used in the study to measure personality traits but we do not describe them as we do not include analysis from their data here.

Design

We used a between-subjects design with two conditions: *high-level hints* (participants used the version of the alebra tutor that included only high-level hints) and *bottom-out hints* (participants used the version of the tutor that included only bottom-out hints). As noted above, the problems solved in both conditions were identical, and the only difference between the two conditions was the type of hint available in the tutor.

Procedure

Each session was conducted individually and lasted approximately 90 minutes (the duration varied slightly based upon the amount of time participants spent on the various components). The procedure for the two conditions was the same.

Participants first completed the algebra pretest (they had up to 20 minutes to do so). They then filled in a demographics questionnaire and were assigned to their condition. Participants initially were assigned to a given condition in a round robin fashion; after about 10 participants, we began using a matching procedure based on pretest score with the goal of equalizing pretest scores between the two conditions, while maintaining similar sample size between the two conditions[1]. The experimenter then introduced participants to the algebra tutor, and explained its various features (e.g., that feedback for correctness was provided, and that all solution steps had to be correctly generated for a given problem before moving on to the next problem). Participants were told to treat this part of the study as if it were a homework situation: they had some problems to solve and were doing so to prepare for an upcoming test. Once participants confirmed they understand how to use the tutor, they were given 40 minutes to complete the 12 problems in their respective tutor version. Participants then completed the algebra posttest (20 minutes), and the personality questionnaire (10 minutes).

Results

The analysis is based on 47 participants. We excluded from the analysis three participants who were at ceiling on pretest, i.e., 95% or higher.

Does type of hint influence learning?

The descriptives for the pretest and posttest are in Table 1. Before checking if the type of hints influenced how much students learned from pretest to posttest, we verified there was no significant difference in pretest scores between the two conditions – this was the case (p = .24).

A between-subjects ANCOVA with *pretest* as the covariate, *posttest* as the dependent variable, and *condition* (high-level hints, bottom-out hints) as the independent variable did not find a significant effect of condition, $F(1, 44) = .1$, $p = .75$ and the effect size was very small, $\eta_p^2 < .01$. As shown in Figure 3, the mean posttest scores adjusted by the pretest through the ANCOVA were very similar in the two conditions. There was also no significant effect of condition on performance as measured by the number of errors made during problem solving (we extracted this information from the log files). Specifically, as expected on average participants made more errors with high-level hints, M = 29.2, SD = 20.1, as compared to with bottom-out hints, M = 23.0, SD = 15.7, but this difference was not significant, $t(45) = 1.2$, $p = .25$.

Thus, we did not find evidence that the type of hint provided influenced either learning from the algebra tutor or overall performance. However, it may be the case that that the number of hints participants accessed influenced learning differently depending on the condition. The next analysis investigates this possibility.

[1] The pretests were graded during the experimental session but in a separate room to avoid making participants uncomfortable. To save time, we used a coarser grading scheme than for the present analysis (where each question was assigned one point it was fully correct and zero points otherwise).

Table 1
Descriptive statistics for each condition

	Bottom-out hints (n = 24)		High-level hints (n = 23)	
	M	*SD*	*M*	*SD*
Pretest (/40)	10.8	14.2	15.7	14.3
Posttest (/40)	26.2	11.3	28.1	9.5

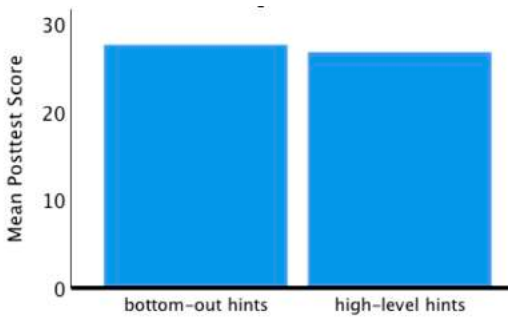

Figure 3. Posttest scores in the two conditions (adjusted by the pretest covariate); posttest was out of 40

What is the relationship between number of hints accessed and learning in each condition?

On average, participants requested more hints in the bottom-out hint condition (M = 15.6, SD = 17.5) than in the high-level condition (M = 13.4, SD = 15.1). This finding is not surprising given that the bottom-out hints facilitated problem solving by telling the students precisely what to do. To get a preliminary view of how the number of hints accessed influenced learning in each condition (operationalized as posttest score – pretest score), we plotted the relationship between these two variables for each condition. As shown in Figure 4, the relationship between the number of hints accessed and learning in the high-level hint condition is positive: the more participants accessed the high-level hints, the more they learned. In contrast, the slope of the line characterizing this relationship in the bottom-out hint condition is almost flat, suggesting there is little association between learning and number of bottom-out hints accessed.

We formalized this analysis by conducting a regression. In preparation, we dummy coded the condition variable so that the bottom-out hint condition was assigned the value 0 and the high-level hint condition the value 1 (the choice of which variable to assign the value 1 is arbitrary and does not impact the results). We proceeded with the regression by entering *posttest* as the outcome variable, and the following four predictors: *pretest*, *condition*, *number-of-hints requested*, and *number-of-hints requested x condition*.

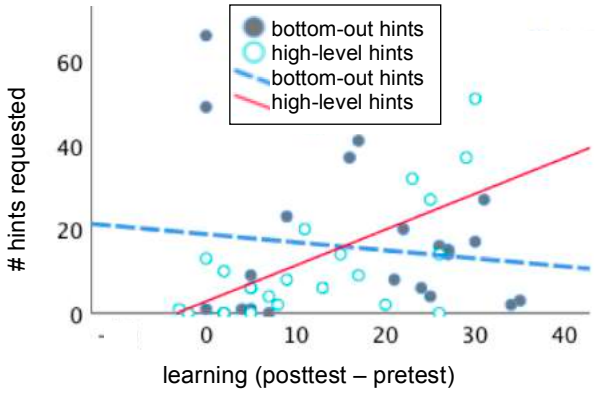

Figure 4. Relationship between number of hints accessed and learning for each condition

The overall model we obtained, shown in Table 2, was significant, $F(4, 42) = 11.3$, $p < .001$, $R^2 = .52$. Of primary interest is the interaction term (i.e., *number-of-hints x condition*), which informs on whether condition influenced the impact of number of hints requested on posttest score. Since the interpretation of the other coefficients is affected by the interaction term (Braumoeller, 2004), which essentially renders them "baseline" slopes (Grace-Martin, 2000), they are not discussed here. The interaction is modest but significant and indicates that overall, the number of hints accessed had a stronger positive relationship with posttest for high-level hints, as compared bottom-out hints. This conclusion is based on the fact that the coefficient for the interaction term is positive, indicating that when students were given high-level hints (recall this was dummy-coded as 1), their posttest score increased by the corresponding amount, controlling for the influence of the other predictors.

Table 2
Linear regression coefficients

Predictors	*B*	*β*	*t*	*p*
# hints x condition	**.34**	**.4**	**2.3**	**.022**
# hints	-.37	-.57	3.6	.001
condition	-5.4	-.26	1.7	.091
pretest	.32	.43	3.2	.003

B = Unstandardized Coefficients
β = Standardized Coefficients

Do high-level hints promote more active processing than bottom-out hints?

High-level hints offer reduced assistance because they don't tell the student the answer directly. Thus, these types of hints should promote more constructive processing on the part of the student. One way to check this is to analyze the amount of time students spent on a solution entry after they saw a high-level hint and compare that to the other

condition in which students only saw bottom-out hints. Students spent longer generating a solution entry after seeing a hint in the high-level hint condition (M = 18.0 sec, SD = 6.1) than after seeing a hint in the bottom-out hint condition (M = 21.2 sec, SD = 7.1). This trend did not reach significance but approached it after controlling for pretest score, $F(2, 34) = 2.8$, $p = .1$, $\eta_p^2 = .08$. While this result is somewhat expected as the high-level hints provided less information, it does open up the possibility that students in the bottom-out condition were not actively processing the contents of the hint before asking the tutor to check their answer (i.e., by pressing the enter button as soon as they finished entering the solution step).

Another way to check if hints are influencing student processing is to analyze how long students waited after entering a solution step (and receiving feedback on it) before pressing the hint button. If there are differences between conditions, this may suggest different levels of processing taking place for each group. Note that the alternative action after entering a solution step is to enter another solution step – here we focus on the subset of actions after a solution entry pertaining to hints only because are interested in conditional effects of hints. When students requested a hint after generating a solution entry, they waited significantly longer to do so in the high-level condition (M = 17.6 sec, SD = 23.9) as compared to the bottom-out condition (M = 6.3 sec, SD = 3.5), F (2, 37) = 5.2, p = .029, η_p^2 = .12 (controlling for pretest does not affect this result). The large standard deviation in the high-level condition implies there is a lot of variability in this condition. To ensure extreme values were not affecting the result, we removed 3 outliers flagged by SPSS and re-ran the analysis. The results remained significant and so the outliers were not influential.

Discussion

The present study investigated the utility of two types of hints in the context of a tutoring system: bottom-out hints that told students exactly what step was needed to proceed with problem solving, versus high-level abstract hints that merely suggested at what was needed to generate the corresponding problem solution step. Thus, the two types of hints provided high vs. reduced assistance to problem solving, respectively. We did not find evidence that either type of hint had a differential impact on learning and in fact the learning outcomes were very similar between the two conditions. While we recognize that conclusions can not be drawn from non-significant results, these findings echo prior experimental results (e.g., Chi et al., 2011). Our findings also echo exploratory studies using machine learning to investigate student learning from different types of hints (Muldner et al., 2011) - this latter work also did not find a difference in learning from the two types of hints.

If high-level hints are not more effective for learning, are they a less *efficient* instructional tool because they take longer to process and thus increase time on task? When we checked total time spent in each condition, we did find a trend that students overall took longer in the high-level hint condition (while this did not reach significance, that may be due to lack of power given the high variability). If high-level hints do not produce more learning than bottom out-hints but are less efficient, then that is an argument for not using them. Our subsequent analysis, however, suggested a more nuanced view of each type of hint's impact, where the number of hints students accessed interacted with the type of hint available to influence learning. It may be that students benefited from both types of hints, but that if they accessed too many bottom-out hints, they failed to learn effectively because they could not resist passively copying from the hints. Prior research in example-based learning found this type of pattern, with students copying indiscriminately from examples (VanLehn, 1998). In contrast to bottom-out hints that promote more passive cognitive processing, high-level hints in general may encourage learning because they promote active processing of the hint content, needed to infer the additional information not provided by the hint. While we did not find strong evidence in this regard, we found some indications: (1) the number of hints accessed was positively associated with learning in the high-level hint condition, and (2) students waited longer in the high-level condition to request a hint, suggesting they were less reliant on assistance provided by the tutoring system and thus more constructive. Promoting constructive processing is generally important, but may be especially challenging to realize when students are interacting with tutoring systems rather than human tutors due to accountability (i.e., students may feel less accountable with technologies than humans), although this conjecture awaits validation through future studies.

A limitation of our study is that we only measured short-term learning. High-level hints require students to process the material, possibly using common-sense or overly general reasoning to infer new rules (Vanlehn, 1991). The benefit of these types of hints may not show up until some time has passed, and so a delayed post-test would be beneficial to include in future studies to measure retention in each condition. Another limitation is the modest sample size, highlighting the need for replication. In general, given the relatively little research on what types of hints best promote learning in tutoring systems, more work is needed to validate and extend our findings.

Are Cross-Linguistically Frequent Semantic Systems Easier to Learn? The Case of Evidentiality

Abstract

It is often assumed that cross-linguistically more prevalent distinctions are easier to learn (*Typological Prevalence Hypothesis* - TPH). Prior work supports this hypothesis in phonology, morphology and syntax but has not addressed semantics. Using an Artificial Language Learning paradigm, we explore the learnability of semantic distinctions within the domain of evidentiality (i.e. the linguistic encoding of information sources). Our results support the TPH, since the most prevalent evidential system was learned best while the most rare evidentiality system yielded the worst learnability results. Furthermore, our results indicate that, cross-linguistically, indirect information sources seem to be marked preferentially (and acquired more easily) compared to direct sources. We explain this pattern in terms of the pragmatic need to mark indirect, potentially more unreliable sources over direct sources of information.

Keywords: evidentiality; artificial language learning; learnability; semantics; information sources

Learnability and the Typological Prevalence Hypothesis (TPH)

It is often assumed in the literature that linguistic distinctions that are encountered more frequently across different languages share some characteristics that make them easier to learn than others (Jacobson, 1971; Rosch, 1972; Clark, 1976; Pinker, 1984). This idea has been captured effectively by Gentner and Bowerman's (2009, p.467) *Typological Prevalence Hypothesis* (TPH): "All else being equal, within a given domain, the more frequently a given way of categorizing is found in the languages of the world, the more natural it is for human cognizers, hence the easier it will be for children to learn". Gentner and Bowerman (2009) tested this hypothesis within the spatial domain, comparing how English-speaking and Dutch-speaking children acquire their native language's support prepositions. English and Dutch differ in the number of prepositions they use to express spatial support: Dutch utilizes three different prepositions (*op, aan, om*) to express the same meanings that English encodes with the single preposition *on*. Importantly, these two support systems differ in their typological prevalence, with the English preposition system being more typologically common. The TPH therefore predicts that the English preposition system should be more easily learned than the Dutch system. Gentner and Bowerman's results support this prediction. One issue with this conclusion, however, is that the slower acquisition rate could be due to the increased number of subcategories found in Dutch compared to English as opposed to an inherent learnability asymmetry of semantic categories per se. This language asymmetry complicates the interpretation of Gentner and Bowerman's results and hence the evidence in favor of TPH.

In this paper, we offer a new test of TPH using an Artificial Language Learning Paradigm. This type of experimental design often requires participants to learn different versions of a target language that differ minimally from each other in terms of a grammatical or lexical feature (see Folia, Uddén, de Vries, Forkstam, & Petersson, 2010 for a review). Typically, this design includes an initial learning phase in which learners are exposed to the grammar/lexicon of the artificial language, usually with the help of visual stimuli. The learning phase is followed by a test phase in which the extent to which participants learned the linguistic target is assessed. This paradigm offers a unique opportunity to explore the participants' learning process in relation to a specific linguistic feature of interest (Fedzechkina, Newport & Jaeger, 2016). By having participants learn minimally different versions of the same artificial language, one can bypass the role of frequency in the learnability of attested systems in individual languages, such that any learnability pattern that surfaces can be more directly tied to the inherent characteristics of the cross-linguistic distinction that is being explored. Moreover, it is possible to have adults learn the target artificial language which in turn eliminates the possibility that any learnability patterns observed could be due to cognitive-developmental limitations in the learners themselves.

Previous studies using an Artificial Language Learning paradigm have confirmed that cross-linguistically common distinctions are learned more easily than less common ones in the domains of syntax, phonology and morphology

(Newport & Aslin, 2004; Wonnacott, Newport, & Tanenhaus 2008; Merkx, Rastle, & Davis, 2011; Culbertson, 2012; Tabullo, Arismendi, Wainselboim, Primero, Vernis, Segura, Zanutto & Yorio., 2012; Culbertson & Newport, 2015;). Nevertheless, within the domain of semantics (which was the main focus of TPH), this hypothesis remains to be tested systematically. Here we address this open issue. We focus on a semantic domain that is not grammaticalized in English and can be taught to adults within an Artificial Language Learning paradigm without native language interference: the domain of evidentiality, i.e., the linguistic encoding of information source.

Evidentiality and TPH

Languages differ in the way they encode evidentiality: some languages like English make use of lexical means such as verbs (e.g., *see, hear, infer*) or adverbs (e.g., *allegedly, reportedly*) to mark information sources. Other languages use a set of grammatical morphemes to indicate information sources in an utterance. There are three common types of evidential morphemes depending on which information source is marked: Visual (firsthand/perceptual evidence), Inferential (inference based on evidence), and Reportative (hearsay) (Willett, 1988; Papafragou, Li, Choi & Han, 2007; deHaan, 2013b; Aikhenvald, 2018). In the Wanka Quechua examples below, *-mi* in (1) marks the speaker's direct visual experience of the event, *-chr-* in (2) marks an inference drawn by the speaker and *–shi* in (3) marks another person's report about what happened (Aikhenvald, 2004):

(1) Chay-chruu-mi achka wamla-pis walashr-pis alma-ku-lkaa-ña.
this-LOC-DIR.EV many girl-TOO boy-TOO bathe-REEL-IMPF.PL-NARR.PAST.
'Many girls and boys were swimming' (I saw them).

(2) Daañu pawa-shra-si ka-ya-n-chr-ari.
Field finish-PART-EVEN be-IMPF-3-INFR-EMPH.
'It (the field) might be completely destroyed' (I infer).

(3) Ancha-p-shi wa'a-chi-nki wamla-a-ta.
too.much-GEN-REP cry-CAUS-2 girl-1P-ACC.
'You make my daughter cry too much' (they tell me).

Across languages that grammatically mark only one type of information, evidential systems that involve only Reportative morphemes are the most widespread ones; systems that use an indirect morpheme to mark inference or reports are less frequent (Papafragou et al., 2007; deHaan, 2013a; Aikhenvald, 2004, 2018; Ünal & Papafragou, 2018;). Evidential systems that only have Visual morphemes are rare (Aikhenvald, 2018). The reasons for this asymmetry have not been discussed extensively but might be connected to the pragmatic need to mark indirect, probably unreliable sources but not direct/perceptual, and hence more reliable, experience (Dancy, 1985; and discussion below).

Here we used an Artificial Language Learning paradigm to compare the learnability of three evidential systems (see Table 1): 1) a system in which a grammatical morpheme is used only when the speaker has full direct visual access to what happened (*Visual* System), 2) a system where a grammatical morpheme is used only when the speaker infers what happened based on some visual cues (*Inferential* System), and 3) a system in which a grammatical morpheme is used only when the speaker obtains information by another person (*Reportative* System). Based on the typological frequency patterns for evidential systems reviewed earlier, the TPH predicts that the Reportative system should be the most learnable and the Visual system the least learnable (with the Inferential system falling somewhere in-between). The experiment that follows tested these predictions.

Table 1: Evidential Systems.

Evidential System	Speaker's Information Access		
	Visual Perception	Inference	Report
Visual	morpheme		
Inferential		morpheme	
Reportative			morpheme

Experiment

Our experiment consisted of two phases following the general Artificial Language Learning experimental design: a Training Phase and a Testing Phase. In the Training Phase, participants were exposed to one of the three evidentiality systems in Table 1 and had to figure out when the evidential marker was used. In the Testing Phase participants were evaluated on how well they had learned the target evidentiality system through a Production and a Comprehension Task.

Participants. We recruited 101 participants between the ages of 18 and 22. All participants were undergraduate students at the University of Delaware and were enrolled in an Introductory Psychology course that awarded credit for their participation.

Stimuli and Procedure. For the Training Phase, we filmed 21 videos in three versions each, with each version corresponding to a type of information access (Visual Perception, Inference, Report). In each video there were three characters; across videos, they were played by the same three female undergraduate research assistants. The roles of these characters were consistent across the videos: one of the characters (henceforth the "Agent") performed an event using some materials and then put these materials away. The second character accessed the event in one of several ways and would later describe the event (henceforth the "Speaker"). A third character manipulated the Speaker's access to the event (e.g., either allowed the Speaker to watch

Figure 1: Sample screenshots from one Training Phase video shown in 3 versions corresponding to Access types: (A) Visual Perception, (B) Inference, (C) Report. Across Access types the video ended with the Speaker producing a sentence (Panel 5) that either included or omitted an evidential (e.g., "She drawing copiedga", "She drawing copied").

the event or blocked her visual access for the complete duration or part of the event). The setting was identical for all the videos: the Agent and the Speaker were sitting on different sides of a table while the third character stood behind them in full view of the table. Each video was approximately 15 seconds long. At the end, the Speaker turned to the camera and described what happened. At that point, the video stopped and a speech bubble appeared with an artificial language sentence, and stayed there for 7 seconds before the next video began.

Figure 1 shows a sample event in which the Agent copied a drawing (the Speaker is pictured in a blue shirt). In the Visual Perception version (series A), the Speaker had continuous direct visual access to the event (A1 began with occluded access to ensure that the hands-over-eyes would not be an easy-to-detect difference among access types, but the hands are removed from the Speaker's face immediately). In the Inference version (series B), the Speaker had visual access only for the beginning and the end of the event (panels 1 and 4), but her access was blocked for the middle portion (panels 2 and 3); therefore, she could infer what happened from the last stage of the event. In the Report version (series C), the Speaker's visual access was blocked throughout the event (panels 1-3); later (panel 4), the Speaker got a report about what had happened from the third character. All videos ended by displaying the Speaker's artificial-language description of what happened within a speech bubble (panel 5). The artificial language shared the same vocabulary with English (for simplicity's sake) but had a different syntactic structure (Subject-Object-Verb) and lacked function words. A novel verb-final morpheme, *ga*, appeared when appropriate as a marker for evidentiality.

We designed 3 evidential systems to be acquired (Visual, Inferential, Reportative) by having the Speaker describe only one type of Access with an evidentially marked sentence (e,g, *She drawing copiedga*, as in Figure 1) and include no marker for the other two Access types. For instance, for the Visual System, only the sentences in the Visual access versions included *-ga*. Then for each evidential system, we created 3 basic lists for the Training Phase (for a total of 9 lists): each basic list contained 21 videos, with 7 videos per Access type. Across lists, the videos rotated through each Access type. For instance, if the video in Figure 1 was shown in the Visual Perception version for list 1, then the same video was shown in the Inference version for list 2 and the Report version for list 3. The presentation order of the videos was randomized across lists.

We randomly assigned participants to one of 3 conditions depending on the System they were exposed to (n = 34 for the Inferential and Reportative System, and n=33 for the Visual System). Each participant was given one of the 9 stimulus lists. We tested participants in small groups, in a dimly lit, quiet room. Participants were told that they would watch some videos and one character would describe the videos in an "alien language". This language would share some words with English but would be different in several ways and would contain a special marker, *ga*. Their task was to pay attention to when *ga* appeared in order to try and figure out what it meant.

When the Training Phase was over, the Testing Phase began. Participants had to complete both a Production and a Comprehension task. For these tasks, we filmed new videos that were similar to those for the Training Phase (except for some features of the language in the event descriptions – see below).

For the Production task, we used 12 new videos, each filmed in 3 different versions corresponding to the 3 Access types. We arranged these stimuli into 3 basic lists, with each list containing 12 videos, 4 per Access type. As in the Training Phase, the lists were created by rotating each video through the three different Access types. For each basic list, three randomized presentation orders were created, resulting in 9 presentation lists in total. Within each condition, participants were assigned to one of these lists. As mentioned already, the structure of the videos in the Production task was identical to the Training Phase but when the speech bubble appeared at the end, the evidential marker was replaced by a gap next to the verb. Using an answer sheet, participants had

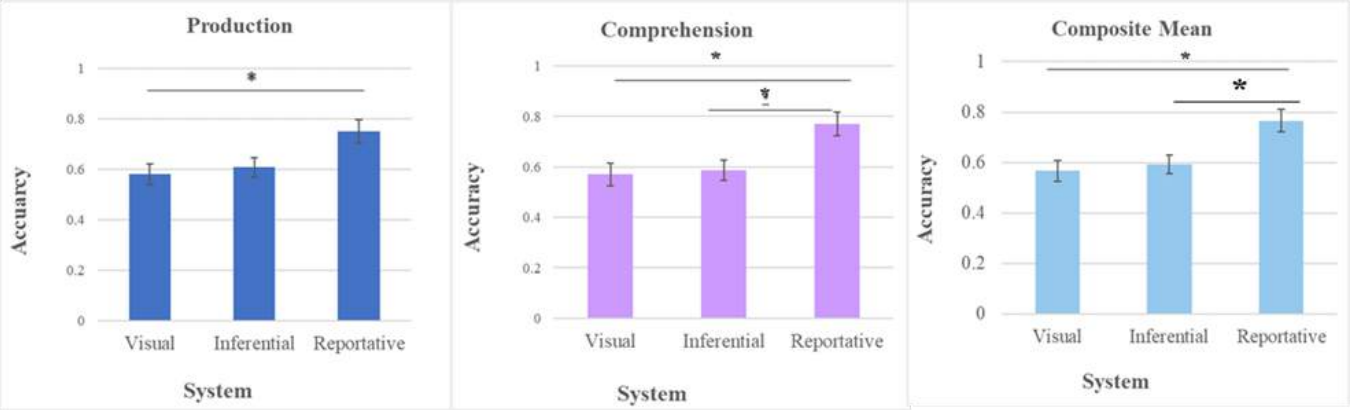

Figure 2. Accuracy Means Across Systems. The composite score represents a combined Production/Comprehension score. Error bars represent ± 1 S.E.

to write down the verb either with or without *ga* depending on whether they thought it was needed to correctly complete the character's phrase.

For the Comprehension task, we used 36 new videos, each filmed in 3 different versions corresponding to the 3 Access types. We arranged these stimuli into 3 basic lists, with each list containing 36 videos (12 per Access type) using the rotation method described above. Similarly to the Production task, for each of these basic lists, 3 lists with a unique randomized presentation order were created (9 lists in total). In half of the videos within each list (and within each Access type), the Speaker erroneously used the marker *ga*: she either failed to use the marker when she should have or used it for the wrong types of Access. In the remaining videos, the use of the marker was correct. Within each condition, participants were assigned to one of the presentation lists. The participants' task was to write 'yes' or 'no' in their response sheet to indicate whether or not they thought the character was using the marker correctly. At the end of the experiment, we asked participants to write down what they thought that the marker *ga* meant and when it was/was not used.

Results

Participants' responses were coded for accuracy. We calculated the accuracy means for each System. In addition, we averaged each participant's Production and Comprehension score yielding a Composite accuracy mean across tasks. We subsequently calculated a Composite Mean per System. The results can be seen in Figure 2.

For the Production task, a one-way ANOVA with System as a factor revealed a main effect of System ($F(2,98)= 4.771$, $p<0.05$). Pairwise comparisons using Bonferroni corrections revealed a significant advantage of the Reportative over the Visual System ($p=.014$) but no significant difference between either the Inferential and the Visual System ($p=1.0$), or the Inferential and the Reported System ($p=.058$).

For the Comprehension task, the same ANOVA revealed a main effect of System ($F(2,98)=6.509$, $p<0.01$). Pairwise comparisons (Bonferroni corrections) showed an advantage of the Reportative System over both the Inferential ($p=0.01$) and the Visual System ($p=.005$). However, there was no statistically significant difference between the Visual and Inferential System ($p=1.0$).

Lastly, a one-way ANOVA conducted on composite Production and Comprehension means revealed an effect of System ($F(2,98)=6.535$, $p<0.01$). Pairwise comparisons (Bonferroni corrections) revealed again a significant advantage of the Reportative System over both the Visual ($p=.004$) and the Inferential System ($p=0.01$).

Participants' answers about the meaning of the marker reflect the results' pattern: out of the 34 participants exposed to the Reportative System, 21 correctly associated the marker with reportative access, specifically alluding to the *speaker's* mental state by mentioning that she "was told" about the event. Of the 33 participants of the Visual system, only 12 associated the marker with speaker's direct visual experience of the event. only Similarly, only 9 out of the 34 participants exposed to the Inferential System correctly associated the marker with the character inferring the action. Across systems, participants that did not identify the correct marker meaning, associated the marker with some type of grammatical distinction (e.g., singular/plural forms, past or completed actions, articles such as *the*/*a*) or associated it with the incorrect type of access. Overall, these responses show that participants associated evidential meanings with the marker, but they did so much more consistently for the Reportative System.

Discussion

Our goal was to test the assumption that the frequency of cross-linguistic semantic patterns is related to the inherent learnability of these patterns, an assumption captured in Gentner and Bowerman's (2009) TPH. Using an Artificial Language Learning paradigm, we set out to compare the learnability of evidential semantic systems, focusing on those that encode a single type of information source (Table 1). The most typologically common evidential system within this group (and also the single most prevalent type of evidential system in general; Aikhenvald, 2018) is the Reportative system in which a marker is used only for the least direct type

of access to information – namely, the cases when the speaker conveys information reported by another person. The least common system is the Visual system in which only direct visual access to an event is marked morphologically. In our study, as predicted by TPH, the Reportative system was learned more easily by our participants compared to the Visual system. Our experiment offers strong evidence for the conclusion that highly frequent semantic distinctions are more learnable than less frequent ones. Furthermore, it adds to previous studies that have studied learnability with the same methodological paradigm within the domains of syntax, phonology and morphology.

Not all aspects of our data are compatible with the predictions of TPH. Specifically, even though exclusive encoding of visual evidentials is rare, and there is a broad preference to mark non-visual/indirect over visual/direct sources cross-linguistically (Aikhenvald, 2018), the Inferential and Visual systems were equally learnable in our data. A possible explanation for this outcome lies with the fact that our Inference videos contained strong visual clues to what happened, bringing this type of information access closer to a direct perceptual experience than to an indirect inference on the speaker's part. This explanation is in line with several findings from a recent study by Ünal, Pinto, Bunger and Papafragou (2016). In that study, when English speakers had to state how they had found out about an event, they stated having seen events that they had experienced in their entirety. However, when they had only seen the beginning and aftermath of an event and had to "fill in" the event from these visual cues, their statements varied. Closer inspection suggested that, when the visual cues were indeterminate, participants consistently stated that they had inferred the event; but when the visual cues were more determinate and highly constrained the inference, participants were equally likely to say that they had seen vs. inferred the event. The authors proposed that there are several varieties of inference, and that stronger, more constrained (and thus more secure) inferences from visual cues might be difficult to distinguish from purely perceptual experience. These varieties of inference had implications for evidential language: Ünal et al. (2016) found that these different types of inference impacted the use of evidential morphology by speakers of Turkish, a language that grammaticalizes evidentiality. Furthermore, inference types had effects on memory: building on classic studies showing that people often have a false memory of having actually experienced events that they have only inferred (Johnson, Hashtroudi, & Lindsay, 1993; Hannigan & Reinitz, 2001; cf. Strickland & Keil, 2011), Ünal et al. (2016) found that, across English and Turkish speakers, such misattributions to perception were more common when inferences were strongly constrained by visual cues and thus harder to distinguish from pure perception. This line of reasoning leads to the prediction that replacing Inference scenarios in our paradigm with less direct cases of inference from visual cues (e.g., footsteps on snow) should allow the learnability difference between the Visual and Inferential systems to emerge.

On a broader level, our results raise questions about the origins of the typological generalizations in the domain of evidentiality. According to the basic observation motivating the present work, across languages, the least formally marked source of information is visual, or direct access (Aikhenvald, 2018, a.o.). Why should this be so? One possibility is that "the tendency to mark direct, or visual, or sensory evidentials less than others may reflect the primacy of vision as an information source" (Aikhenvald, 2018, p.16). Direct perceptual experience of an event is regarded as a very reliable source because it is assumed to correspond to reality (Dancy, 1985). Additionally, developmental research suggests that children draw the connection between seeing and knowing from early on (Pillow, 1989; Pratt & Bryant, 1990; Ozturk & Papafragou, 2016), which highlights the the primacy of visual perception as an information source. Relatedly, indirect sources of information such as inference or reports are deemed more peripheral and less reliable in the sense that the former may be based on incomplete premises while the latter depends on the informant's reliability (Dancy, 1985; Koring & De Mulder, 2014; Papafragou et al., 2007; Matsui & Fitneva, 2009; McCready, 2015; Aikhenvald, 2018; Wiemer, 2018;). This has been found to be true even for languages that do express information access through *perception verbs* and not through obligatory grammatical morphemes (Lesage, Ramlakhan, Toivonen & Wildman, 2015). According to some researchers (Sperber, Clement, Heintz, Mascaro, Mercier, Origgi & Wilson, 2010), human cognition uses epistemic vigilance as a mechanism to avoid unreliable sources and the risk of being misinformed. However, exercising epistemic vigilance could entail an additional processing cost: listeners would have to give up the assumption that the communicative exchange they are engaged in offers truthful, informative contributions and would need to evaluate not only the actual information they receive but also their interlocutor's reliability and intentions. Thus, pragmatic pressures to mark sources of information would affect indirect and probably unreliable sources more than direct/perceptual, and hence more reliable, experience.

If this perspective is on the right track, our results would support a more nuanced version of TPH. Recall that, on Gentner and Bowerman's original proposal, the roots of TPH lie in the cognitive naturalness of the semantic classes that the learner acquires. Here we have proposed a broadened notion of naturalness that also includes pragmatic (and not only conceptual) factors. In our studies, adult learners acquired semantic systems of varying cross-linguistic frequency but both the frequency patterns and the learnability outcomes were pragmatically (not conceptually) motivated.

If the frequency patterns for linguistic evidentiality systems reflect the pragmatic need for information source marking, as we have suggested, a further prediction follows: it might be possible to obtain similar learnability patterns even if we used a non-linguistic marker to encode information source (e.g., a pictorial symbol). We are currently pursuing this possibility in ongoing work.

Not All Exceptions Are the Same: Different Memory Demands for Differentiation, Isolation and Odd-ball Exceptions

Abstract

There is an influential body of research arguing that category exceptions have a special status in memory compared to regular category members. However, the memory advantage for category exceptions has typically been demonstrated using one very specific category structure (Differentiation). Here we present a study examining whether the reported memory advantage is specific to this particular structure or whether it can be generalized to other kinds of exceptions (Isolation and Odd-ball). We compare three different types of category exceptions that have varying memory demands due to different levels of feature binding required for accurate categorization. The results suggest that only those exceptions that require binding together multiple features are remembered better than regular, rule-following items. The present work clarifies that the memory advantage for exceptions characterizes certain kinds of exceptions rather than exceptions in general.

Keywords: category exceptions; rule-plus-exception; binding requirement

Introduction

Whales are mammals. Penguins are birds. Tomatoes are fruit. Many categories include items that look different, behave differently, or lack important qualities that define the majority of members of the category. We refer to these items as *exceptions,* because they violate our expectations about the category.

Since the goal of categorization is to encode key aspects about the members of the category, it is reasonable to ask: How are exceptions, items that violate those key aspects, learned and represented?

Memory Advantage for Exceptions

There is an influential body of research arguing that category exceptions have a special status in memory. Palmeri and Nosofsky (1995) demonstrated that exceptions to a category rule are remembered better than the items that follow that rule. This initial finding of a memory advantage for category exceptions is supported by a number of subsequent category learning studies (Sakamoto & Love, 2004, 2006; Davis, Love & Preston, 2012) and found to be in accordance with the predictions of several influential models of category learning: RULEX (Nosofsky, Palmeri & McKinley, 1994) and SUSTAIN (Love, Medin, & Gureckis, 2004).

Work on this topic in the categorization literature was preceded by studies in memory (Von Restorff, 1933) and schema research (e.g. Rojahn & Pettigrew, 1992; Stangor & McMillan, 1992), where an advantage in memory for exception items has long been established. Although the approach (both in terms of methodology and primary research questions) differed between the memory and categorization literatures, the fact that these findings paralleled each other further strengthen the view that there is a general advantage in memory for information that does not fit in with salient knowledge structures.

What Makes (Some) Category Exceptions Memorable?

Although a memory advantage for category exceptions seems to be well established, the nature of the effect is not well understood. One obstacle to understanding what makes category exceptions more memorable is that previous studies focused on one very specific type of category structure. We refer here to this structure as the Differentiation case (see Figure 1).

Although exceptions are not limited to the Differentiation case, the vast majority of influential work on this topic (Palmeri & Nosofsky, 1995; Sakamoto & Love, 2004; Davis, et al., 2012) has studied this kind of exception. One reason the Differentiation structure has received so much attention is that it presented an interesting challenge for models of category learning to explain. And so, researchers often selected structures with the purpose of evaluating or comparing models of categorization, and were not necessarily concerned with representing all types of exceptions.

Thus, it remains unclear whether the reported memory advantage for category exceptions is specific to this particular structure or whether it can be generalized to other kinds of structures. In what follows, we describe how the difference in category structures may affect memory demands.

Different Memory Demands for Differentiation, Isolation and Odd-ball Exceptions

Figure 1 illustrates three different structures of exception items: Differentiation, Isolation and Odd-ball exceptions. All three types of exceptions (a) violate the category rule and (b) are dissimilar to other items in their own category. However, they differ in how much they share with the contrasting category members.

Differentiation exceptions, the most commonly used structure, are highly similar to items of the contrasting category. Not only do they follow the contrasting category rule, but they also share other features with items of the contrasting category. Due to its specific structure, this kind of exception cannot be categorized correctly on the basis of any one individual feature.

Since it is not enough to remember one or even multiple isolated features, Differentiation exception features have to be bound together and committed to memory. This is because each feature of the exception (in our case, the color, the size and the shape) has a competitor in the contrasting

category, thus making only the whole configuration (but not individual features) sufficient. For example, the past tense of the irregular verb teach (taught) is very different from that of similar sounding regular verbs (reach, breach, or preach), but is similar to that of a phonetically different verb (e.g., think).

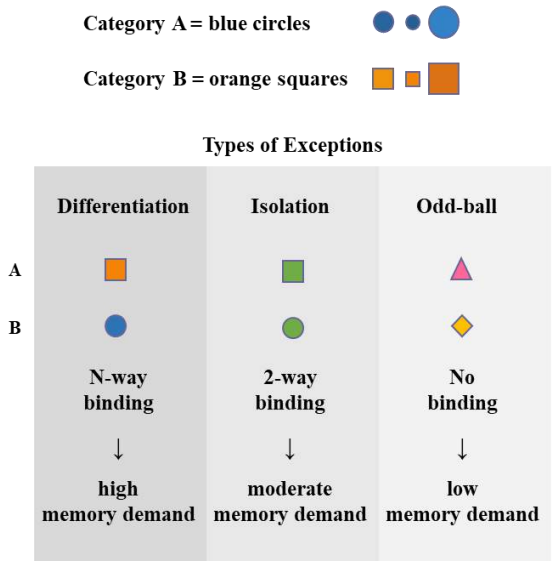

Figure 1: Three different types of exception items for categories of blue circles and orange squares. Exceptions vary in how similar they are to the contrasting category and therefore in the amount of feature binding and memory demands required for accurate categorization.

Although the Differentiation structure is commonly used in experimental studies, this kind of exception is likely quite rare in the real world. Most exceptions found outside of the lab, even the most commonly cited examples (e.g. bats as exceptions to category of mammals), in addition to shared features also have some distinctive features. Figure 1 illustrates two types of such exceptions: Isolation and Odd-ball.

Isolation exceptions follow the contrasting category rule, just like Differentiation exceptions, but, crucially, they also have distinctive features. The distinctive features make Isolation exceptions less similar to items of the contrasting category. As fewer features are shared, less complex binding is required, which reduces memory demands. In the example shown in Figure 1, the green square has the same shape (rule dimension) as members of the contrasting category. However, its unique color (different from both its own and the contrasting category) allows for the categorization problem to be solved based on binding of only two dimensions: color and shape. Analogous to this example, bats are flying creatures (characteristic of the contrasting category of birds) with membranous wings (a distinctive feature), and therefore could be represented as exceptional mammals by binding these two features: flying and membrane wings.

The third kind of exceptions shown in Figure 1 is the Oddball exception. Odd-ball exceptions do not share any features with members of contrasting category. Since all of their features are distinctive, no binding is required, and categorization can be made on the basis of any single feature. Critically, in case of the Odd-ball structure, representation of exceptions can be as simple as representation of regular items. The pink triangle in Figure 1 violates both shape and color of the category of blue circles. However, since there is no overlap on these dimensions with any items in category B, accurate categorization can be based on either its pink color or triangular shape alone. One example of such an oddball is an hourglass as an exceptional member of the category of time-keeping devices.

Present Experiments

Although all three of the different structures presented in Figure 1 represent rule-violating exceptions, they have different memory demands. Since the categorization literature has focused almost exclusively on the Differentiation case, it remains unclear whether in previous studies exceptions were remembered better (a) because they violated a salient knowledge structure (von Restorff, 1933; Hunt & Lamb, 2001; Busey & Tunnicliff, 1999; Nairne, 2006), or (b) because of the additional binding requirement resulting from the high overlap with the contrasting category (Sakamoto & Love, 2006).

In support for the latter possibility, Sakamoto and Love (2006) demonstrated that exceptions that are more similar to the contrasting category (i.e., Differentiation) are remembered better than exceptions that are more distinctive (i.e., Isolation). The stimuli in Sakamoto and Love (2006) were lines that varied in color and size and the focus of this study was on comparing different exceptions to each other. Thus, memory advantage for both kinds of exceptions over regular items was assumed although not directly tested due to the limitations of the stimuli design.

The present experiments were designed to tease apart the roles of (a) violation of a salient knowledge structure (i.e. similarity of an exception to its own category) and (b) differences in binding requirement (i.e. similarity of an exception to the contrasting category).

Three experiments were conducted. Experiment 1 was set as a replication of previous studies that examined recognition memory for Differentiation structure. The category structure completely follows the one reported by Davis, Love, & Preston (2012) and uses the same experimental tasks and procedures. Experiment 2 and Experiment 3 build on Experiment 1 by employing the same experimental design, procedures and materials to examine memory for Isolation (Experiment 2) and Odd-ball (Experiment 3) exceptions.

If the memory advantage for category exceptions results from violation of a salient knowledge structure, exceptions should be remembered better than regular items across the three experiments. However, if the advantage for exceptions

is dependent on differences in binding requirements, Differentiation (and potentially Isolation exceptions) should be remembered better, while there should be no advantage for Odd-ball exceptions.

Experiment 1: Differentiation

Methods

Participants Participants were 38 undergraduate students from a Midwestern university who received course credit for their participation. Two additional participants were excluded due to the failure to finish the experiment.

Materials The stimuli were schematic clown-like faces that varied along four (feature) dimensions. Items were accompanied by two novel category labels: Zuzu and Tati. As it can be seen in Figure 2, the four feature dimensions were hair, eyes, mouth and side whiskers. Side whiskers were selected as a rule dimension and the three other features varied between the two categories.

The category structure Table 1 shows an abstract representation of the category structure used in Experiment 1 (as well as ones used in Experiments 2 and 3). Each of the two categories had three Regular, rule-following items and one Exception.

Rule-following items could be categorized accurately based on the value of a single rule-dimension (side whiskers). The rule dimension was held constant across participants. The other three dimension varied between the categories, with exactly the same combinations of the three features used for constructing items of category A and category B (see Table 1). The Exceptions appeared to belong to the opposing category based on their value on the rule-relevant dimension. Additionally, the two exceptions had the same values on the three other dimensions, and thus could be categorized accurately only based on the representation that captures the combination of the rule and (at least) 2 other features.

Based on the items presented in Table 1 that were used during training, we constructed foils for memory test. The foils had the same feature values as training items, but in novel combinations. There was a total of 8 foils constructed for memory test in Experiment 1.

Table 1: The category structure used in Experiments 1-3

	Category A	Category B
Regular items		
same set across the three experiments	**1** 334 **1** 343 **1** 433	**2** 334 **2** 343 **2** 433
Exceptions		
Exp 1: Differentiation	**2** 444	**1** 444
Exp 2: Isolation	**2** 555	**1** 555
Exp 3: Odd-ball	**8** 888	**9** 999

Note. 1 = rule of category A; 2 = rule of category B; 3 = probabilistic; 4 = probabilistic; 5 = novel non-diagnostic; 8 = unique for exception A; 9 = unique for exception B.

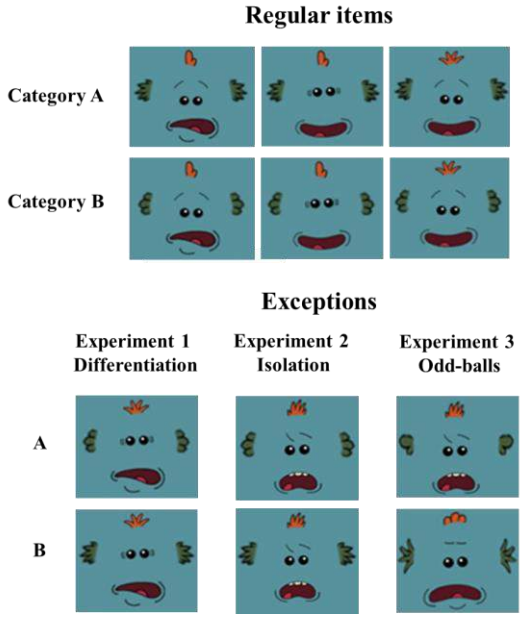

Figure 2: Complete set of stimuli used in the training (Experiments 1–3). Regular items were the same across the experiments.

Procedure

The experiments consisted of three phases: training, memory test and categorization test.

Training During training participants were presented with the exemplars of the two categories and were asked to classify each exemplar.

Following the procedure of previous studies, participants were given explicit instructions indicating the rule feature. They were encouraged to use this feature during categorization and to memorize items that violate this rule (Davis, Love, & Preston, 2012).

Items were presented individually, and corrective feedback was provided after each response. There was a total of 64 trials presented during training, 48 rule-following items and 16 exceptions (i.e. each of the 6 Regular and 2 Exception items presented 8 times in random order).

Memory test Following training, participants were introduced to the memory test. In the memory test, participants saw two items at a time: one training item and one foil (item that had the same features as the training items, but in a novel combination). Their task was to say which of the two items was old (presented during the training). There was no feedback given during memory test. The test had 48 trials presented in a random order.

Categorization test In the categorization test participants were presented with Regular and Exception items they saw during the training. The procedure was exactly the same as in the training session with the only difference being that during the categorization test, participants were not provided with feedback. There were 16 categorization test trials, 8 Regular items and 8 Exceptions.

Results

Figure 3 shows participants' recognition memory and categorization accuracy (panel a).

Participants were less accurate at categorizing Exceptions (M = 0.49, SD = 0.37) than Regular items (M = 0.82, SD = 0.24), $t(37) = 5.06$, $p < 0.001$, $d = 0.82$. However, they had better recognition memory for Exception items (M = 0.63, SD = 0.19) than for Regular, rule-following items (M = 0.47, SD = 0.12), $t(37) = 3.77$, $p < 0.01$, $d = 0.61$.

Both of these results, memory advantage for Exceptions and better categorization accuracy for Regulars, are in accordance with previously reported findings (Palmeri & Nosofsky 1995; Sakamoto & Love, 2004, 2006).

It is important to note that here, as in the previously reported studies, the advantage in memory for rule-violating exceptions results from optimization in memory for Regular items. Since participants categorized Regular items relying on the category rule, the rule feature is the only feature they needed to represent and thus they had no need to remember individual exemplars representing the category. On the other hand, in order to learn Exceptions, they had to bind in memory information about a minimum of three features (the rule and two other features).

Experiment 2: Isolation

The goal of Experiment 2 was to test the robustness of the memory advantage for Exceptions, when rule-violating items are Isolation Exceptions. Isolation Exceptions have lower memory demands than Differentiation Exceptions, but they still require binding of information about the rule and (at least) one more feature.

Methods were identical to Experiment 1, except for the type of Exception participants needed to learn (See Table 1). Foil items for the memory test were designed accordingly to include features of Isolation Exceptions, which resulted in 19 foil items in total. Twenty-three undergraduates from a Midwestern university participated for course credit.

Results

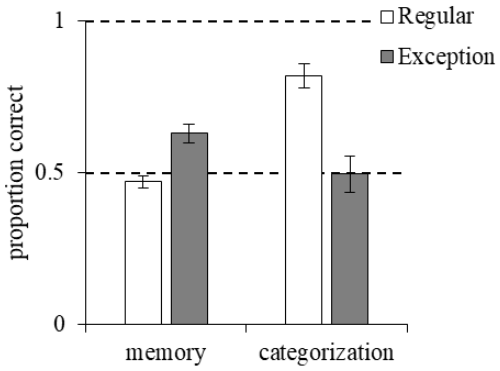
The pattern of results in Experiment 2 closely replicated the one observed in Experiment 1 (Figure 3).

Although participants were more accurate when categorizing Regular (M = 0.85, SD = 0.18) than Exception items (M = 0.65, SD = 0.36), $t(22) = 2.41$, $p < 0.05$, d = 0.50, they remembered Exception items (M = 0.67, SD = 0.26) more accurately than Regular, rule-following items (M = 0.51, SD = 0.09) , $t(22) = 2.91$, $p < 0.01$, $d = 0.61$.

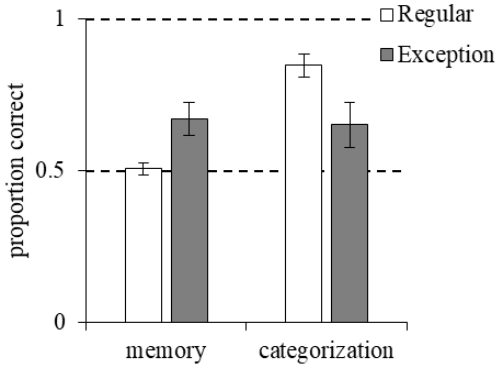
Experiment 3: Odd-ball

The critical difference between Experiment 3 and Experiments 1-2, was that learning of rule-violating items in Experiment 3 did not require forming of a complex binding structure. Both Regular and Exception items could be categorized based on a single, individual feature. Thus, any differences in recognition memory between Regular items and Odd-ball Exceptions could be solely due to effects of rule violation.

a. Experiment 1: Differentiation



b. Experiment 2: Isolation



c. Experiment 3: Odd-ball

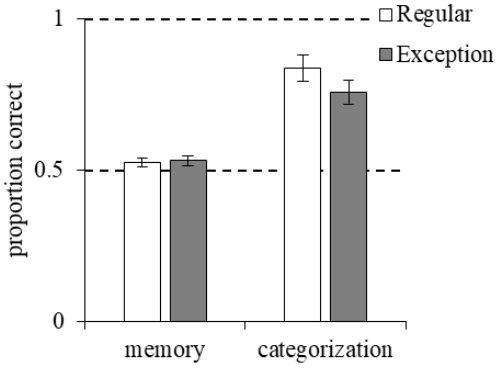


Figure 3: Recognition memory and categorization accuracy across the three experiments. Error bars represent standard errors of mean.

Methods were identical to the ones used in Experiment 1-2, except that Experiment 3 used Odd-ball Exceptions as the rule-violating items (See Table 1). Foil items for the memory test were constructed following the logic of Experiment 1 and 2. There was a total of 21 foil items used for the memory test. Forty undergraduate students from a Midwestern university participated for course credit.

Results

In Experiment 3, participants were equally accurate when categorizing Exceptions (M = 0.76, SD = 0.25) and Regular items (M = 0.84, SD = 0.28), $t(39) = -1.30$, p = .203, d = 0.20.

Critically, we observed no difference in recognition memory between the two item types, $t(39) = 0.18$, p = .858, d = 0.03. Participant had no memory for exemplars of either Regular (M = 0.53, SD = 0.10), or Exception items (M = 0.53, SD = 0.11). One sample t-tests against chance were approaching significance for both Regulars ($t(39) = 1.79$, p = .081) and Exceptions ($t(39) = 1.78$, p = .084).

Discussion

The presented work aimed to clarify whether category exceptions merit a special memory representation because they violate a salient knowledge structure, as it has been previously assumed (e.g., von Restorff, 1933; Hunt & Lamb, 2001; Busey & Tunnicliff, 1999; Nairne, 2006), or is it only those exceptions that have high binding requirements that have the special memory status. This is a critical question, as in the latter case, the special memory status characterizes certain kinds of exceptions rather than exceptions in general. Consequently, the generalizations often present in the categorization literature when discussing exceptions would be unjustified.

The recognition memory comparisons across the three experiments revealed that participants had better recognition memory for exceptions that required binding of two or more features to be accurately categorized. However, when memory demands for regular and exception items were equal, there was no memory advantage for exceptions. In other words, when category structure does not require feature binding for successful categorization and both item types can be classified based on the individual features, exception items are treated as any other regular item. Participants may optimize their memory when learning exceptions in the same manner as they do when they learn regular items, and thus have poor exemplar memory for both regulars and exceptions.

Model Predictions

The results of previous studies on recognition memory for categories with exceptions were found to generally conform to the predictions of RULEX and SUSTAIN (Palmeri & Nosofsky, 1995; Sakamoto & Love, 2004, 2006). Pure exemplar storage models, such as the context model (Medin & Schaffer, 1978), have also been considered and found to be inadequate at simultaneously predicting categorization accuracy and recognition memory for categories with exceptions (Palmeri & Nosofsky, 1995). Our results replicate this failure of exemplar models. Exemplar models have difficultly predicting good categorization, but bad memory, for regulars since categorization relies directly on memory storage. Similarly, they struggle with good memory, but poor categorization, of exceptions. In general, exemplar models would tend to predict that both categorization and memory would be better (or possibly both worse) for exceptions than regulars, but they would not predict opposite patterns for categorization and memory.

RULEX provides good predictions for the patterns that were found in the Differentiation and Isolation structures, correctly predicting better categorization of rule-following items, but poorer memory for those items since they are not represented independently in memory. Memory is predicted to be better for exceptions since they need to be stored individually in memory. It is unclear, though, what RULEX would predict for the Oddball structure.

Versions of RULEX have been formulated for binary-valued discrete dimensions, and continuous-valued dimensions (Nosofsky & Palmeri, 1998), but (to our knowledge) not for discrete dimensions with more than two possible values. While there are straightforward ways in which to extend RULEX to accommodate this type of stimulus structure, there are several alternative formulations that would provide opposite predictions.

Existing versions of RULEX first try simple unidimensional rules. If perfect rules fail, it then attempts unidimensional rules with exceptions stored in memory. If those representations are inadequate, it moves to considering more complex rules. Our Oddball category structure could theoretically be solved with a disjunctive rule on a single dimension (i.e. value 1 *or* 8 on dimension one is Category A, 2 *or* 9 is category B; see Table 1). It is unclear whether RULEX would attempt to use this type of rule prior to or after it attempts to store exceptions in memory (considering that the rule is technically unidimensional but also somewhat complex). If it tries storing exemplars first, it would predict similar behavior as in the Isolation structure (and therefore, fail to predict our results). If it tries the disjunctive rule first, then it would not need to store any exemplars in memory, and could match participants' data well. So, RULEX could predict all of our results in theory, but it depends on exactly how it is formulated to handle this type of stimulus representation.

SUSTAIN (Love, Medin, & Gureckis, 2004), on the other hand, can naturally process the stimulus structures used in our study without needing modification, but its predictions are somewhat less intuitive. Like RULEX, the predictions depend on whether it stores exceptions separately (by creating additional clusters) or together with regulars. In theory it can do either depending on the exact parameter settings and the order in which it encounters the exemplars. To test whether SUSTAIN would create different numbers of clusters for the three different stimulus structure, we

performed simulations of the model. We first fit the model to each participants' training data using maximum-likelihood estimation in order to obtain reasonable parameter estimates. Then we simulated the model using each parameter combination on all three stimulus structures (1000 simulations per parameter combination, per structure).

Results of the simulations generally match the behavioral results: better categorization for regulars than exceptions in all structures, but better memory for exceptions than regulars—except in the Oddball structure where memory performance was roughly equivalent between regulars and exceptions. Additionally, the number of clusters formed was found to be highest for the Differentiation structure (median: 6 clusters; mode: 4 clusters), slightly lower for the Isolation structure (median: 4 clusters; mode: 4 clusters) and lowest for the Oddball structure (median: 3 clusters; mode: 3 clusters). Importantly, that there were typically fewer than 4 clusters in the Oddball structure indicates that exceptions were not represented completely independently of the regulars, which is consistent with worse memory for exceptions compared to the other two structures.

In summary, both RULEX and SUSTAIN can potentially account for our results by representing exceptions separately from regulars in the Differentiation and Isolation structures, but not in the Oddball condition. SUSTAIN produces this pattern as a normal result of its category learning process, while RULEX produces this result under one of several possible instantiations of its decision process. In both models the separate representations of exceptions are consistent with increased feature binding for those items compared to regulars, though they may not have been described in terms of feature binding in previous work.

Conclusions

Taken together, our findings suggest that the previously reported advantage for memory exceptions reflects elevated memory demands of specific kind of exception which does not generalize to other kinds of exceptions.

This work further adds to our understanding of what makes *some* category exceptions more memorable, by focusing on the critical role of competition between the exception and contrasting category members.

Acknowledgments

This information will be added to the final version of this manuscript (in order not to violate double-blind review process).

Rapid Semantic Integration of Novel Words Following Exposure to Distributional Regularities

Abstract

Our knowledge of words consists of a lexico-semantic network in which different words and their meanings are connected by relations, such as similarity in meaning. This research investigated the integration of new words into lexico-semantic networks. Specifically, we investigated whether new words can rapidly become linked with familiar words given exposure to distributional regularities that are ubiquitous in real-world language input, in which familiar and new words either: (1) directly co-occur in sentences, or (2) never co-occur, but instead share each other's patterns of co-occurrence with another word. We observed that, immediately after sentence reading, familiar words came to be primed not only by new words with which they co-occurred in sentences, but also by new words with which they shared co-occurrence. This finding represents a novel demonstration that new words can be rapidly integrated into lexico-semantic networks from exposure to distributional regularities.

Keywords: word learning; semantic priming; distributional semantics; semantic integration

Introduction

Starting early in development and continuing through adulthood, we amass sizable vocabularies commonly estimated to contain tens of thousands of words (Schmitt & McCarthy, 1997). Beyond the size of the resulting vocabulary, word learning is remarkable both because much of it unfolds merely by encountering words in linguistic contexts without explicit instruction, and because it leads to the formation of an organized lexico-semantic network in which different words and their meanings are linked by relations. For example, our lexico-semantic networks contain links both between words that can be combined to form meaningful utterances (e.g., *eat* and *apple*), and words similar in meaning (e.g., *apple* and *grape*) (Jones, Willits, Dennis, & Jones, 2015). These links are a fundamental facet of our lexico-semantic knowledge that influence behavior even without awareness, reasoning, or recall of relevant information from episodic memory (as is evident from phenomena such as priming). How do the new words we encounter become integrated into our lexico-semantic networks?

The purpose of the present research is to investigate the rapid integration of new words into existing lexico-semantic networks purely on the basis of regularities with they are distributed with other words in linguistic input. As demonstrated by the seminal work of Landauer and Dumais (1997) and many subsequent modeling efforts (Frermann & Lapata, 2015; Huebner & Willits, 2018; Jones & Mewhort, 2007; Rohde, Gonnerman, & Plaut, 2004), sensitivity to distributional regularities may represent a powerful mechanism for building lexico-semantic networks. First, links between words that can be combined to form meaningful utterances such as *eat* and *apple* can be formed from the regularity with which they co-occur in language. Critically, although words similar in meaning such as *apple* and *grape* may not reliably co-occur, links between them can also be formed from the regularity with which they *share* each other's patterns of co-occurrence (e.g., *apple* and *grape* may not reliably co-occur, but do share each other's co-occurrence with *eat*, *juicy*, etc.). These distributional regularities are sufficiently abundant in language that mechanistic models that form representations of words purely on the basis of these regularities capture the majority of links present in human lexico-semantic networks (Jones et al., 2015).

In spite of the extensive evidence from modeling research supporting the potential contributions of sensitivity to distributional regularities, we know little about whether exposure to these regularities actually drives the integration of new words into lexico-semantic networks in human learners. Accordingly, the present research was designed to assess whether adults semantically integrate novel words with familiar words after reading sentences rich in distributional regularities. Specifically, we investigated whether familiar words came to be semantically primed not only by novel words with which they co-occurred, but also by novel words with which they never co-occurred, and instead shared patterns of co-occurrence with another word.

In what follows, we first review existing evidence about human learner's sensitivity to distributional regularities. In this review, we highlight the paucity of prior research that is informative about the role of distributional regularities abundant in language in building human lexico-semantic networks. We then present an experiment designed to illuminate this role.

Human Sensitivity to Distributional Regularities in Language

Extensive evidence from statistical learning research suggests that humans are sensitive to some forms of distributional regularities in some modalities. Specifically, numerous studies have revealed that we are sensitive to the regularity with which items such as speech sounds or shapes co-occur, either simultaneously, sequentially, or separated by some number of other items (Conway & Christiansen, 2005; Fiser & Aslin, 2002; Gomez, 2002; Saffran, Johnson, Aslin, & Newport, 1999).

However, this evidence cannot directly illuminate whether distributional regularities of words in language can drive lexico-semantic integration for two reasons. First, very little statistical learning research conducted to date has investigated whether we form links between items that never occur together, and instead share each other's patterns of co-occurrence with other items (to our knowledge, only one study visual domain, Schapiro, Rogers, Cordova, Turk-Browne, & Botvinick, 2013, is suggestive of this form of learning). However, this process is a critical facet of the potential importance of sensitivity to distributional regularities for building lexico-semantic networks, because many words similar in meaning do not reliably co-occur, and can instead only be linked based on their shared patterns of co-occurrence (Jones et al., 2015). Second, statistical learning research has focused on learning links between items in domains that intentionally do not carry meaning, such as speech sounds, acoustic sounds, and shapes, and tactile stimuli. Because statistical learning phenomena vary even across these studied domains (Conway & Christiansen, 2005), it is unclear whether they generalize to the formation of semantic links between novel and familiar words in language.

To our knowledge, the only evidence relevant to the role of distributional regularities in semantic integration comes from a handful of studies conducted by McNeill (McNeill, 1963, 1966). In these studies, novel words were organized into triads, in which one novel word A co-occurred in sentences with either of two other novel words, B and C. Accordingly, the distributional regularities consisted of both the direct co-occurrence of A- B and A-C, and the shared co-occurrence of B-C (which never actually co-occurred, but both co-occurred with A). By administering a free association task at multiple points during sentence reading in which participants were asked to produce the first novel word that came to mind when prompted with another, McNeill observed that participants first formed links between novel words that directly co-occurred (i.e., A-B and A-C), and then between those that shared co-occurrence (i.e., B-C). This finding provides evidence that people can learn the distributional regularities of words in sentences online, as they are experienced. These regularities therefore represent a viable candidate for drivers of semantic integration. However, these studies were not designed to investigate the semantic integration of novel words into existing lexico-semantic networks, because novel words only ever shared distributional regularities with each other, and not with familiar words. Moreover, the use of a free association task to assess learning leaves open the possibility that these links participants apparently formed were based on retrieving the episodic experiences of reading the sentences from memory, rather than on the formation of automatically-activated semantic links. The role of distributional regularities in lexico-semantic integration therefore formed the focus of the present experiments.

Present Experiments

The present experiments were designed to investigate whether distributional regularities can drive the rapid integration of new words into existing lexico-semantic networks. Specifically, participants read sentences in which were embedded triads of words that consisted of a novel pseudoword (e.g., foobly) that regularly preceded a familiar word (e.g., apple) in some sentences, and another novel pseudoword (e.g., mipp) in other sentences. Accordingly, the sentences contained distributional regularities with which a familiar word (e.g., apple) both directly co-occurred with one novel psuedoword (foobly), and shared this pattern of co-occurrence with another (mipp) (Fig. 1). The sentences otherwise contained no information from which the meanings of the novel pseudowords could be derived. For example, participants might read "My sister loves to see a foobly apple" and "I saw a foobly mipp on vacation".

Immediately following a short session of sentence reading, we then assessed lexico-semantic integration by testing whether the familiar word came to be primed by both the novel pseudoword with which it co-occurred, and the novel pseudoword with which it shared this pattern of co-occurrence. To show both patterns of priming, participants must: (1) Learn the novel word forms, (2) Form links between novel and familiar words that directly co-occur, and (3) Derive links between novel and familiar words that never co-occur, but instead share each other's patterns of co-occurrence.

Method

Participants

Participants were 45 undergraduate students from a Midwestern university who received course credit. An additional five participants were excluded due to failure to complete the experiment.

Stimuli and Design

Training. The training stimuli were two triads of words (1: foobly-apple-mipp; 2: dodish-horse-geck) that each consisted of a pseudoadjective (e.g., foobly) that consistently preceded one familiar noun (e.g., apple) and one pseudonoun (e.g., mipp) in different sentences. Each word pair from these triads (foobly-apple, foobly-mipp, dodish-horse, dodish-geck) was embedded in 10 unique sentence frames, for a total of 40 training sentences. These sentences therefore conveyed both direct co-occurrences between words in the same pair from the same triad, and shared co-occurrences between familiar and pseudonouns from the same triad. The sentences did not convey any other cues to pseudoword meaning (Figure 1).

Test. For testing purposes, we added two new pseudowords (nuppical; boff) and 2 pictures: One of an apple and one of a horse.

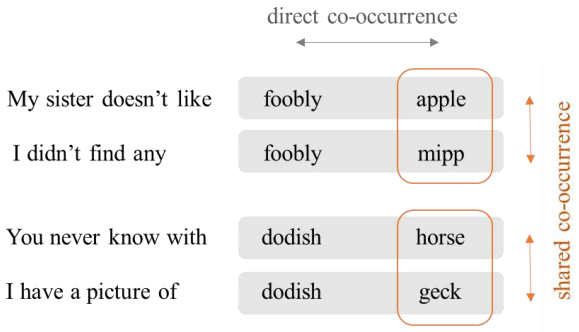

Figure 1: Illustration of training sentence structure.

Using these stimuli, we generated five types of Prime-Target word pairs. Primes were always novel pseudowords, and Targets were always one of the two familiar nouns used during training (apple or horse). First, we generated two types of Related pairs that were consistent with the training triads: Related Direct, in which a pseudoadjective preceded the familiar noun that it had preceded during training (e.g., foobly-apple), and Related Shared, in which a pseudonoun preceded the familiar noun with which it had shared co-occurrence during training (e.g., mipp-apple). Second, we generated corresponding Unrelated Direct and Unrelated Shared pairs in which the Primes from Related pairs were switched, such that they violated the regularities present during training (e.g., foobly-horse). Finally, we generated Neutral pairs, in which the new pseudowords that were only present during Test (nuppical; boff) preceded each familiar noun.

Procedure

The experiment had 2 phases: Training and Test.

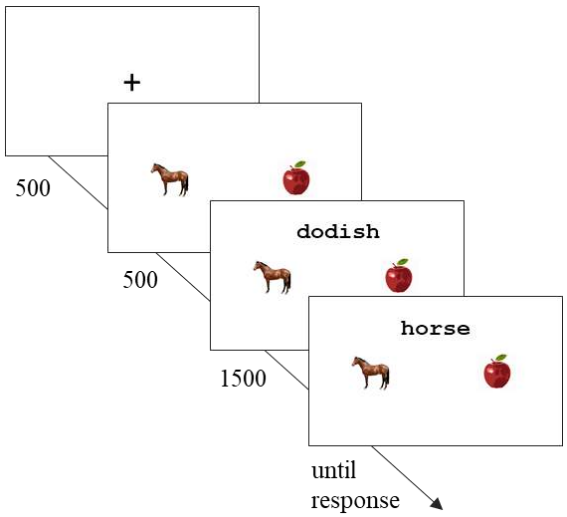

Figure 2: Timing of events during the primed visual search task used in the Test phase.

Training. The Training consisted of three blocks. In each block, participants first read all of the 40 training sentences in a random order at their own pace. To check whether participants were attending to the sentences, three control questions appeared following random sentences in which participants were prompted to type the novel words from the last sentence they had read. The reading component of each block was followed by a free association task in which participants were asked to respond with the first novel (pseudo) word they could think of when prompted with each of the pseudowords from the training sentences. Each of the pseudowords (foobly, dodish, mipp, geck) was presented 3 times in a randomized order.

Test. For the test phase, participants performed a primed visual search task (see Figure 2 for timing of events in trials). At the start of each trial, participants saw a fixation cross followed by two images, one on either side of the screen: A horse, and an apple. Two words (a Prime and Target) were then consecutively presented as text on the top of the screen. Participants' task was to read both words, but choose the image labeled by the second (i.e., Target) word using the mouse. During a practice phase consisting of 8 trials, the two words consisted of Neutral word pairs (i.e., a new pseudoword followed by apple or horse). During the actual task consisting of 144 trials, the two words consisted of Related Direct, Related Shared, Unrelated Direct, Unrelated Shared, and Neutral pairs.

Participants were given an unlimited time to make their responses, but were prompted to respond quickly and were shown a message saying that they were too slow if their response time on a trial was > 800ms.

Results and Discussion

Preliminary analyses: Free association

To test whether participants were attending to the sentences, we analyzed participants' responses on the free association task. Participants responded as instructed by responding with one of the training pseudowords on an average 90.6% of all free association trials. Participants tended to respond with training pseudowords that had directly co-occurred with the prompt pseudoword: 88% of all responses to pseudoadjective prompts were with the noun that followed the pseudoadjective during training, and 77% of responses to pseudonoun prompts were the pseudoadjective that preceded it during training. Only 2.5% of all responses to pseudonouns were based on shared co-occurrence. This confirmed that participants read the sentences and learned the word forms.

Main analyses: Priming[1]

The purpose of the main analyses was to investigate whether the novel pseudowords were semantically

[1] The full pattern of effects on reaction time have also been replicated with two samples (*N*s= 25 and 28) of participants recruited from Amazon Mechanical Turk: Once as an exact replication, and once as a conceptual replication in which

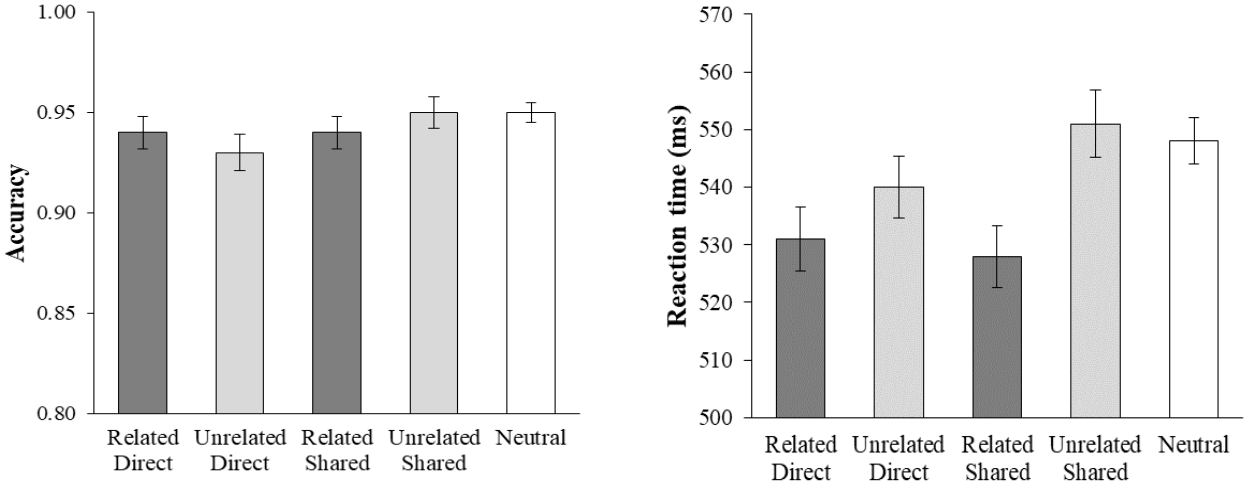

Figure 3: Mean accuracy (left) and reaction times (right) across five conditions. Dark gray bars represent Related (Direct and Shared) conditions, and light gray bars represent Unrelated (Direct and Shared) conditions. The Neutral condition (new pseudoword) is presented in white. Error bars indicate the standard errors of the means.

integrated with familiar words with which they shared distributional regularities (i.e., direct or shared co-occurrence) in training sentences. We accomplished this investigation by measuring whether the novel pseudowords affected the speed and accuracy of processing familiar words in the priming task used during the Test phase. Specifically, we compared the speed and accuracy with which participants identified whether the Target word was apple or horse when it was preceded by a novel pseudoword in the Related Direct, Related Shared, Unrelated Direct, Unrelated Shared, and Neutral conditions. Related pseudowords were expected to facilitate Target word identification, whereas Unrelated pseudowords were expected to inhibit identification. Moreover, these facilitation and inhibition effects may be greater for Direct versus Shared co-occurrences.

Prior to conducting this analysis, we first eliminated data from 8 participants with extremely short reaction times (more than 2/3rds of RTs < 100ms), leaving a sample size of 38 participants. Accuracies and Reaction Times are presented in Figure 3.

Accuracy. We analyzed effects on accuracy using a linear mixed effects regression model in which Relatedness (Related vs Unrelated) and Type (Direct vs Shared) were fixed effects, and Participant was a random effect. This model revealed no effect of either Relatedness or Type on accuracy (Relatedness: B = - 0.004, SE = 0.008, t = - 0.55, p = .59, d = 0.004, Type: B = - 0.012, SE = 0.008, t = - 1.48, p = .15, d = 0.012).

Reaction Time. For analyses of reaction time, we removed data from incorrect trials, and trials with extremely short (<100 ms) and extremely long response latencies (>1500 ms), resulting in removal of 8.1 % of trials.

We then generated a linear mixed-effects model with Relatedness (related; unrelated) and Type (direct; shared) as fixed effect factors and Participants as a random effect. This model revealed no significant effect of Type (neither as a main effect nor in interaction with Relatedness). Thus, Type was excluded from the final model. A log-likelihood ratio test indicated that the best fitting random effects structure included only a random intercept for participants. Thus, the final model included Relatedness as a fixed effect factor and a random intercept for participants. This model revealed a significant effect of Relatedness on reaction times, B = 14.82, SE = 5.10, t = 2.91, p < .01, d = 0.096 (see Brysbaert & Stevens, 2018 for effect size estimate approach). Participants were 14.9 ms faster in related than in unrelated conditions (Figure 3, right panel). The model explained 16% of total variance (R-squared based on Nakagawa & Schielzeth, 2013).

The follow-up analyses compared Related and Unrelated conditions to the Neutral condition. A linear mixed-effects model with Condition (Neutral; Related Direct, Related Shared, Unrelated Direct, Unrelated Shared) as a fixed effect factor and a random intercept for Participants revealed that only Related conditions were significantly different than the Neutral (Related Direct: B = - 16.11, SE = 6.30, t = - 2.56, p = .01, d = .104; Related Shared: B = -16.56, SE = 6.32, t = - 2.62, p < .01, d = .104). There was no significant difference in RT between the Neutral condition and Unrelated conditions. In other words, participants were faster to respond when the Target was preceded by a pseudoword that either directly co-occurred with the Target (Related Direct) or shared the pattern of co-

the pseudoadjectives were changed from foobly/dodish to foobing/doding.

occurrence (Related Shared) than when it was preceded by a new pseudoword that only appeared in the Test and not the Training phase. Primes that were incongruent with the regularities presented during the training (Unrelated Direct, Unrelated Shared) did not affect speed.

General Discussion

The present experiment provides a novel demonstration that new words can be rapidly integrated into existing lexico-semantic networks based on the distributional regularities of words in sentences. Specifically, immediately following a short session of sentence reading, familiar words came to be primed by both novel words with which they co-occurred in sentences, and novel words with which they never co-occurred, but instead shared a pattern of co-occurrence with another novel word. Given that these distributional co-occurrence regularities are ubiquitous in language (Jones et al., 2015), the present results provide evidence that sensitivity to these regularities may represent a critical way in which new words are rapidly integrated into lexico-semantic knowledge.

Implications for Lexico-Semantic Integration

The present findings build upon prior research in two key ways. First, prior evidence about the potentially powerful contributions of distributional regularities to building lexico-semantic networks comes primarily from modeling research. The present findings therefore substantially underline this potential by demonstrating that new words can be added to actual human lexico-semantic networks through mere exposure to distributional regularities.

Second, this evidence also adds to our understanding of how rapidly new words can be integrated into our existing lexico-semantic networks. Specifically, extensive prior research has investigated the lexico-semantic integration of novel words through different kinds of input, such as studying definitions of novel words, or repeatedly observing words co-occurring with images of specific familiar objects (Breitenstein, Zwitserlood, de Vries et al., 2007; Clay, Bowers, Davis, & Hanley, 2007; Dagenbach, Horst, & Carr, 1990; Dobel, Junghöfer, Breitenstein et al., 2010; Tamminen & Gaskell, 2013). Much of this research has suggested that newly learned words are only gradually integrated into existing lexico-semantic networks, following at least one day and up to several weeks of consolidation. In contrast, a handful of recent findings (Borovsky, Elman, & Kutas, 2012; Mestres-Missé, Rodriguez-Fornells, & Münte, 2006; Zhang, Ding, Li, & Yang, 2019) have suggested that lexico-semantic integration of novel words can occur more rapidly when learning is driven by reading sentences in which novel words appear in a position typically occupied by a specific, familiar word (e.g., "It was a windy day, so Peter went to the park to fly his *dax*"). The present findings add to this evidence that novel words can be integrated into existing lexico-semantic networks very rapidly, immediately following an initial learning experience.

Future Directions

The evidence provided by the present experiment highlights a new avenue for future research to investigate *how* distributional regularities foster semantic integration. For example, do direct co-occurrences foster integration more rapidly than shared co-occurrences, or do these processes unfold in parallel? This question could be addressed by measuring integration (e.g., using the priming approach taken in the present experiment) at multiple points throughout training. Moreover, addressing this and related questions could help to generate and arbitrate between different potential mechanistic accounts of distributional regularity-driven semantic integration.

Summary

Throughout our lives, we amass a sizable and interconnected body of knowledge of words and their meanings. The present research highlights how the formation of these lexico-semantic networks may be critically facilitated by the rapid integration of new words via sensitivity to the regularities with which words occur with other words in linguistic input.

Abstract

The aim of this study is to refine a cognitive model for the takeover in highly automated driving. The focus lies on the impact of objective complexity on the takeover and resulting outcomes. Complexity consists of various aspects. In this study, objective complexities are divided into the complexity of the non-driving-related task (no-task, listening, playing, reading, searching) and the traffic complexity (relevant vehicles in the driving environment). The impact of a non-driving related tasks' complexity on the takeover is evaluated in empirical data. Following, the cognitive model is run through situations of different traffic complexities and compared to empirical results. The model can account for empirical data in most of the objective complexities. Additionally, model predictions are tested on significant variations in different complexities until the action decision is made. In more complex traffic conditions, the model predicts longer times on different processing steps. Altogether, the model can be used to explain cognitive mechanisms in differently complex traffic situations.

Keywords: highly automated driving; HAD; cognitive modeling; ACT-R; takeover; conditional automation; NDRT; non-driving related tasks; real vehicle study; Objective complexity; traffic complexity; Complexity of NDRT; cognitive model predictions;

Introduction

In the field of Highly Automated Driving, the development of technological innovations is growing rapidly. It is not only necessary to develop working technology, but to understand human cognition, enhance the human-machine interaction (HMI) and improve safety and comfort (Sun et al., 2017). Approaching the next SAE Level of automation (Level 3, conditional automation), where the driver still has to take over the driving task if requested (SAE, 2014), the state of the driver plays an important role. Here, the state is determined as the awareness of the surrounding traffic and necessary action decisions. It depends highly on the situation and its complexity in which the driver has to take over. Different approaches of defining situation complexity exist (Baumann and Krems, 2007; Haerem and Rau, 2007; Schlindwein and Ison, 2004). A key factor concerning the driver is the expectation about the future development of a situation, that is activated when a type of situation occurs (Baumann & Krems, 2007). These types of situations can be distinguished in various ways. They could for example be a traffic situation (congestion, construction zone, intense or low traffic etc.), a type of traffic environment (city, highway etc.), a weather condition or further differentiations.

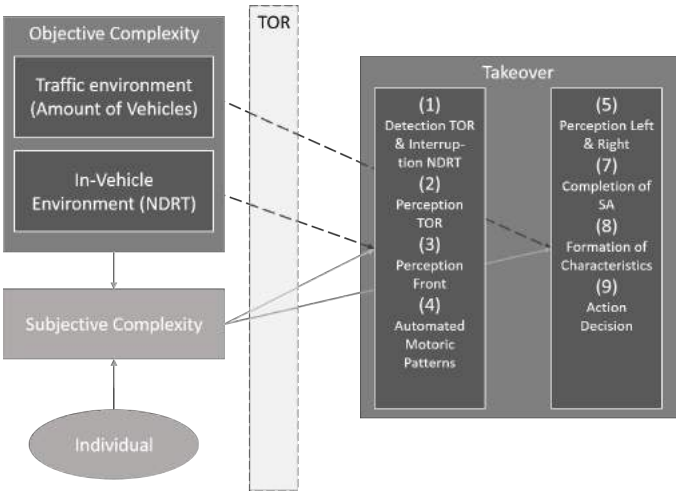

Figure 1: Outline of the Assumed Dependencies, leading to the Approached Hypotheses concerning the Impacts of Objective- and Subjective Complexity on the Takeover Performance. Dark Grey Variables and Interactions are Focus in this Study (Source: own figure).

Due to Schlindwein and Ison, 2004, complexity can be understood as a result of a particular perception of a situation of complexity or resulting from a distinction between expectation and situation development. As we live embedded in situations of complexity, it is important to distinguish between descriptive (objective) and perceived complexity. The perception, that is made by an observer and individually variable, can be determined as perceived complexity (Schlindwein & Ison, 2004). Objective complexity on the other hand describes the complexity a certain traffic situation has. For the first modeling approach presented in this paper, the objective complexity will be the focus of the cognitive model. The impact of the objective complexity on the takeover is analyzed and displayed in the model. According to Paxion, Galy,

and Berthelon (2015), the objective complexity of a situation in driving can vary with road geometry (rectilinear vs. curvilinear), the roadside environments (quantity and variability of traffic signs, variability of scenery) and traffic density (low vs. high). Thus, the role played by objective characteristics is very important (Haerem & Rau, 2007) for the takeover task and will be addressed here. The focus is set on understanding the impact of objective complexity on cognitive mechanisms during a takeover on a highway with varying traffic density in the relevant areas of interest. Thus, an explanation of how the visual perception and the resulting cognitive processing is provided and differences that occur due to different complexities can be displayed. To provide a safe and cognitive adequate takeover, it is necessary to understand which cognitive mechanisms influence different behavior of the driver. Based on such a comprehension of the situation the development of a useful HMI in highly automated driving is possible. It can thus incorporate the current situation and adapt and support the driver accordingly to enable a safe and comfortable takeover.

In this study links between objective complexity and the impact on the takeover are assumed and visualized in (Figure 1). Objective complexity is based on the amount of relevant vehicles in the traffic environment as well as the complexity of the non-driving related task (NDRT) in the in-vehicle environment. The subjective complexity on the other hand is assumed to be influenced by the objective complexity as well as by the individual perception of the objective complexity and management abilities. Both complexity versions should have an impact on cognitive mechanisms and the processing stages during the takeover and the resulting action decision. Nevertheless, as mentioned earlier, in the current context, the focus is set on understanding the impact of objective complexity before approaching subjective complexity. This is important, as the subjective complexity can only be measured, if an understanding about the impact of the objective complexity on the takeover already exists.

In order to perceive different stimuli in a complex environment, awareness of the situation has to be reached and sensory information understood (Plavsic, 2010). In driving, the most important human sense is the visual perception, involving several sub-processes. These are seeing, detection and recognition (Plavsic, 2010). To comprehend the impact of complexity on the takeover in highly automated driving, cognitive processes during a takeover and the influence of objective complexity have to be understood. This can be captured and simulated by a cognitive model. Further resulting behavior can be predicted based on the model.

Cognitive modeling is used to understand more precisely, how complexity emerges and subsequently affects the takeover. Thus, the exploitation of the resources in different complexity combinations can be revealed. For the implementation of the cognitive model, the ACT-R (Adaptive Control of Thought-Rational) cognitive architecture (Anderson et al., 2004) was used. It provides a more accurate representation of human abilities than standard programming languages (Salvucci, Boer, & Liu, 2001). Several cognitive patterns can be modeled and clearly distinguished between the different resources. The architecture provides different modules for each resource that can act simultaneously and interact with each other. Especially the visual module is able to illustrate precisely the above mentioned sub-processes of the visual perception. In conclusion, cognitive modeling is used, as it is a valid and useful method to depict human cognition very detailed with respect to the different resources (visual, haptic, auditory). The ACT-R cognitive architecture is chosen, as it is an architecture that incorporates all relevant mechanisms for the takeover task and enables the modeling of the whole task with respect to the different resources and their interactions. To understand underlying cognitive mechanisms as a function of the objective complexity, the cognitive model is established based on empirical data of a previous study (project KoHAF) and run through different levels of objective complexity. As task performance is reliant on the availability of resources (Kahneman, 1973) and auditory perception uses different resources than visual perception does (multiple resource theory; Wickens, 2008), traffic density has a strong influence on the takeover quality in highly automated driving Radlmayr, Gold, Lorenz, Farid, and Bengler (2014). The developed cognitive model gives an understanding about the underlying cognitive mechanisms. This is necessary for future development of the HMI in highly automated driving. In order to test, whether the model correctly depicts the cognitive processes, the following questions are addressed in the examination of this paper:

- Is the cognitive model able to validly display differences in objective complexity that are found in empirical data?
- Is the cognitive model able to generate predictions that significantly vary with different objective complexities in the traffic environment?

Methods

In this paper, the impact of the complexity of a NDRT and the traffic environment is addressed. As non-driving related tasks (NDRT) play an important role when it comes to taking over the driving task (Radlmayr et al., 2014), the impact of tasks with different complexities is investigated. To validate the cognitive model, data of a previous study (KoHAF) was used. In a first step (Step 1) the influence of NDRT-Complexity on takeover stages in empirical data is evaluated. Further, an ACT-R cognitive model for the takeover task per se, that displays

underlying cognitive mechanisms during a takeover is developed. The model is run through scenarios of different objective complexities and resulting predictions are compared to empirical data (Step 2). The predictions of the model in environments of different complexities are then tested significant differences in prediction times.

Data Acquisition

The data that is evaluated in this paper comes from a previous study in the project KoHAF. As it includes all the relevant information, necessary for the model, it supports the assumptions, that are addressed in this paper. For the realization of a takeover in a real scenario rather than an simulator, a Wizard of Oz vehicle is used. It allows the passenger to drive the vehicle covertly via a hidden control. Thus, a takeover in a real driving environment is possible, simulating a Level 3 automation. Due to that, participants feel like driving an automated vehicle in real traffic (Ko-HAF, 2017) and can engage into secondary tasks during the mock-automation.

The study was held in 2017 in the area of Stuttgart. Overall data of $N = 14$ participants is evaluated. Takeover requests (TOR) after five different NDRTs are covered. A first evaluation of empirical data shows, that NDRTs have a significant influence on the takeover. Due to this, the complexity of the different NDRTs is rated on a ten point likert-scale by three experts based on resource capacities that are needed to solve the tasks. Conditions without NDRT are rated as lowest complex with one point (1P.). A bit more complex, listening to an audiobook (3P.) is valued as it occupies the auditory channel. This is followed by playing Tetris (6P.). Reading a newspaper (7P.) as well as searching something in the back of the vehicle (7P.) is assessed as most complex, each with seven points. Tetris was rated as less complex than reading a newspaper or searching something in the back, as the tablet was mounted to the center console and participants did not need to hold it. Thus, it is assumed as less resource-demanding with regard to the task of taking over. The data was evaluated by two independent raters concerning the different steps of the takeover and the objective complexity of the scenery (amount of visible vehicles on the road and their position). The overall objective complexity thus consists of the scenery and the traffic conditions and of the driving situation. The scenery has a high influence on the objective complexity of a situation (Rommerskirchen, Helmbrecht, & Bengler, 2013), including possible distraction sources from the in-vehicle driver's point of view (e.g. NDRT's).

Cognitive Model

As the most important factor in driving is the visual perception, the focus of the cognitive model to update situation awareness (SA) during the takeover task lies on modeling the perception behavior. Overall longer takeover times are found in a more complex scenery (Radlmayr et al., 2014). This is realized in the model with the focus on visual perception mechanisms of the relevant objects in the traffic environment. The model interacts with a graphical user interface in Lisp. It represents the ego-vehicle on the center lane of a three lane highway. The surrounding traffic is inserted at random, varying between zero and five vehicles in the environment.

Besides visual perception patterns, the cognitive model for the takeover task incorporates motoric and cognitive retrieval patterns. In the following, the steps, that are undertaken until control is regained during a takeover are defined as well as the realization in the cognitive model (Figure 2). While engaging into a secondary task, the driver is alert on whether a takeover request (TOR) appears. This is due to the drivers awareness of situation and task. As soon, as a TOR is detected (0), the NDRT is interrupted (2) and the gaze oriented to the TOR message (1). The model reacts to a stimulus in the visual or aural module, that fits the condition of a TOR message. The meaning of the TOR message is retrieved from the declarative memory and the TOR visually attended, fixated and processed. Then, the visual resource is oriented to the road center and the front lane (near and far area; Salvucci, 2006) is perceived (4). First sensory-motoric patterns (hands to steering wheel, feet to pedals) are automatically applied (3), resting on automated reactions rather than intentionally directed movements. The visual resource further attends and processes the left and right lane (5), storing the status (car or no car) of the attended areas in chunks. In the data, this is followed by the deactivation of automation (6). This is not implemented in the model though, as deactivation modalities vary and there is no common mechanism yet. The model thus completes the perception phase (7), and forms characteristics of current status. The current status of the environment is compared to the task ((8) status-task-mapping) and a decision made based on that (9). Finally, the motoric module performs the selected action ((10) sensory-motoric intervention patterns) that are either to follow, change the lane to the left or right. The vehicle is then stabilized (11). This final step is not explicitly included in the model though.

The cognitive model incorporates these steps and displays the cognitive processes that occur during each one (Figure 2).

Results

Statistical analysis is used, to show, that the cognitive model is able to depict differences that occur due to objective complexity. The two objective complexity measurements (complexity of NDRT and amount of objects in traffic environment) are evaluated separately. The impact of complexity of the NDRT is evaluated in empirical data. NDRT complexities are then scaled and compared

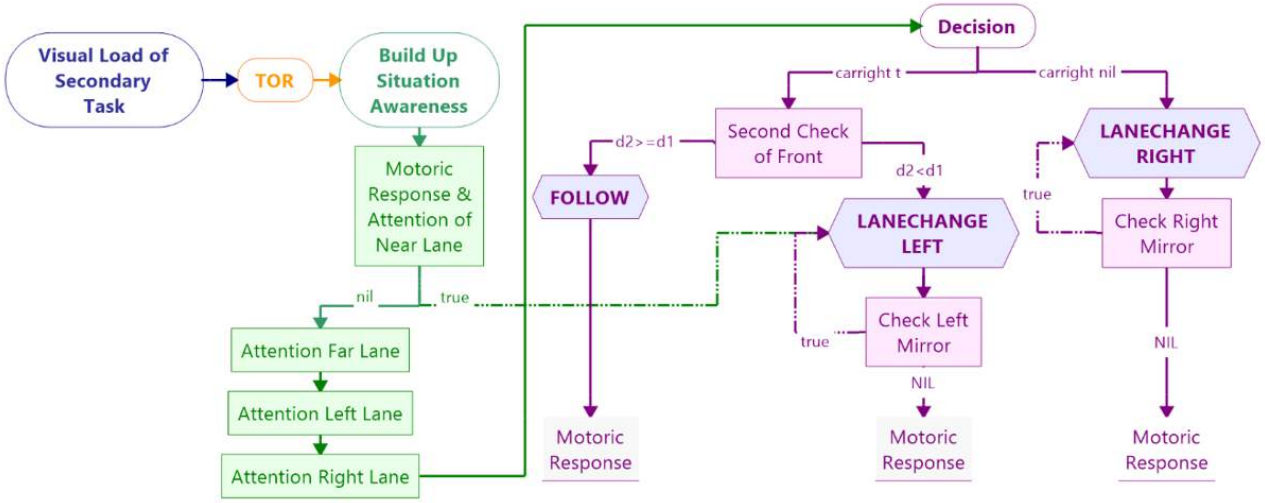

Figure 2: Representation of Main Productions, the Cognitive Model Resolves to Display Cognitive Processes During the Takeover in Highlay Automated Driving (Source: own figure).

to the cognitive model to show, that cognitive model predictions are able to account for empirical data. Based on these results, the model itself is further run through conditions of different traffic complexities and tested on significant variations between those conditions.

The influence of the NDRTs on takeover patterns is tested first using ANOVA for statistical evaluation. Based on that, regression analysis is used to measure the impact of the complexity of the NDRT on the performance of the takeover in empirical data (Step 1). Further, it is examined, whether predictions of the model correlate with the results found in empirical data (Step 2). Finally, model predictions of action decisions are tested on the influence of objective complexity variations (Step 3).

Step 1: Influence of NDRT-Complexity on Takeover Times in Empirical Data

ANOVAs show significant results for the takeover patterns one to four ((1) visual re-orientation and fixation of takeover request (TOR) message, (2) interruption of NDRT, (3) first sensory-motoric patterns, (4) visual orientation to road center). The time until the gaze gaze is directed to the TOR differed statistically significant for the different NDRTs ($F(4,65) = 3.088, p < .05$). The same applies for the time until the NDRT is stopped ($F(4,65) = 4.221, p < .01$), the time until the hands are moved to the steering wheel ($F(4,65) = 12, p < .001$) and the time until the gaze is directed to the road ($F(4,65) = 5.808, p < .001$). Due to this, the impact of complexity on takeover patterns is evaluated, using regression analysis. Based on the regression equation $y = x\beta + \epsilon$, the impact of the Complexity of the NDRT ($CNDRT$) is tested on significance to reject the null hypothesis. Further, the amount of variance that can be explained by the regression (multiple determination coefficient R^2) is evaluated. Regression analysis is tested on normal distribution of residuals, heteroscedasticity, non-linearity and multi-collinearity by plots (Liborius, 2015; Ligges, 2007). Analysis of empirical data ($N = 14$) on $CNDRT$ on the takeover shows significant effects for all takeover processes (Figure 3).

The time until the Gaze is directed to the TOR significantly rises with higher $CNDRT$ ($\beta = .004, p < .01$). The complexity of the NDRT explains 11.3% percent of variance ($R^2 = .113, t(68) = 2.943, p < .01$).

The effect of $CNDRT$ on the time until the NDRT is stopped ($\beta = .0005, p < .001$), explains 16.4% of variance ($R^2 = .164, t(68) = 3.652, p < .001$). Variance in time until the hands are moved to the steering wheel can be explained with 29,07% ($R^2 = .2907, t(68) = 5.297, p < .001$). The time increases significantly ($\beta = 1.47\text{e}-06, p < .001$) with more complex NDRTs. $CNDRT$ also influences the time until the gaze is moved to the road ($\beta = 3.05\text{e}-05, p < .001$). 22.7% of variance can be resolved ($R^2 = .227, t(68) = 4.469, p < .001$). The results show, that the complexity of the NDRT has a significant impact on all four steps of the takeover that were measured empirically (Figure 3). The more complex the NDRT that is performed before the takeover, the longer do drivers need to perform the takeover steps. This shows, that more cognitive occupation during the NDRT occupies relevant resources that need to be freed in order to attend and process objects, that are relevant for the takeover. The more complex a non-driving related task

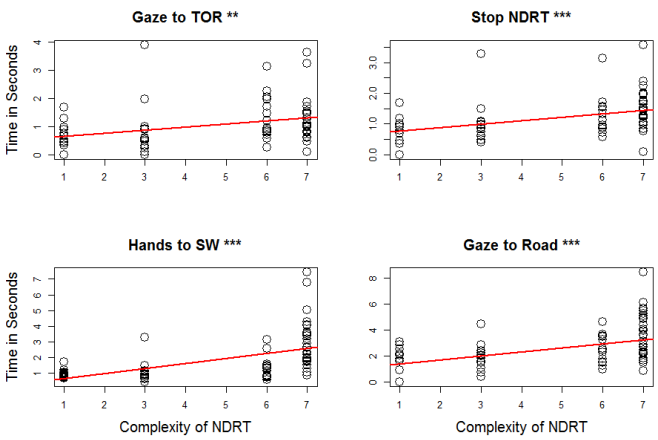

Figure 3: Regressions of the Influence the Complexity of the Non-Driving-Related Task (CNDRT) has on Times of Takeover Patterns (Significance codes: 0 '***' .001 '**' .01 '*' .05 '.' .1; Source: own figure).

is, the longer do drivers need to complete the outlined steps for taking over the driving.

Step 2: Correlation between Model Predictions and Empirical Results of Different Objective Complexities

Further, model predictions under different complex traffic conditions are tested against the results found in empirical data ($N = 14$), that are described above. The comparison of empirical takeover times with different surrounding traffic conditions and model predictions shows, that model predictions correlate with the empirical data for almost all situations of objective complexity (amount of vehicles) significantly (Figure 4). Empirical data (gray) was evaluated for situations with zero to five vehicles in the surrounding traffic. Mean (pink) and median median (red) courses for empirical data are evaluated and median courses correlated with model predictions (green-dotted). For each traffic conditions, model predictions correlate with median values of empirical data. Especially with one, three and four vehicles in the environment, model predictions are in line with empirical data.

Step 3: Test whether Model Predictions of different Complex Traffic Environments show Significant Differences

Finally, predictions of the action decision (9, see section Cognitive Model) of the model are evaluated based on objective complexity measures. In the interaction of the model with different driving situations, it can be shown, that the time for an action decision increases with a more complex driving environment. Overall the model is run through 17 different complexity situations ($N = 17$), varying between zero to five vehicles in the driving environment. The time until an action decision is executed ranges from 1.37s to 4.86s ($M = 1.74$). Regression analysis results in significant regressions for the overall amount of vehicles in the environment ($\beta = 0.04, p < .05$). The parameter resolves 24.91% of variance ($R^2 = .25, t(15) = 2.23, p < .05$). Regarding the vehicle distributon in detail, it can be shown that the amount of vehicles on the right lane has a significant impact on the time until an action decision ($\beta = 0.04, p < .05$). 18.87% of variance ($adj.R^2 = .19, t(14) = 2.3, p < .05$) can be explained. Also the amount of vehicles on the left lane has a small impact on the time until an action decision is made ($\beta = 0.09, p < .1$), explaining 12.13% of variance ($adj.R^2 = .12, t(14) = 1.83, p < .1$). Neither for the vehicle in the front of the ego vehicle a significant impact can be shown. Nor the speed (faster/slower) in relation to the own position has an impact. This shows, that the perception of left and right lane (5), the completion of the perception phase (7) and the formation of characteristics and recognition of the current status (8) need more time in more complex driving environments and lead to a delay of the action decision (9).

Discussion

The results show, that the complexity of the NDRT has a significant impact on the time of takeover patterns in empirical data. It can thus be concluded, that more complex tasks that are done during the automated drive lead to longer takeover times. Portraying the processing patterns that are undergone during the takeover with a cognitive model, similar time trajectories can be shown. This is very important, as results show, that not only the overall time, but also processing steps can be identified and displayed in the model. Further, the model is run through situations with differently complex traffic situations (amount of relevant vehicles). Results show longer times for the processing patterns in more complex environments. The predicted time-lines of the cognitive model are compared to results in empirical data with respect to the traffic complexity. Model predictions correlate with empirically gathered trajectories in differently complex traffic environments. In addition, predictions of the cognitive model are tested on significance in differences between traffic complexities. It can be shown, that the traffic complexity (amount of relevant vehicles) has a significant impact on the time until an action decision is made. These results indicate, that the objective complexity of the NDRT as well as of the traffic situation play an important role concerning processing steps during a takeover in highly automated driving. The takeover behavior as well as the time until an action decision is made, show significant influences of complexity measures (NDRT and traffic environment). Still, the model is slightly faster in the overall performance (0.5 seconds). Since the difference already occurs at the first

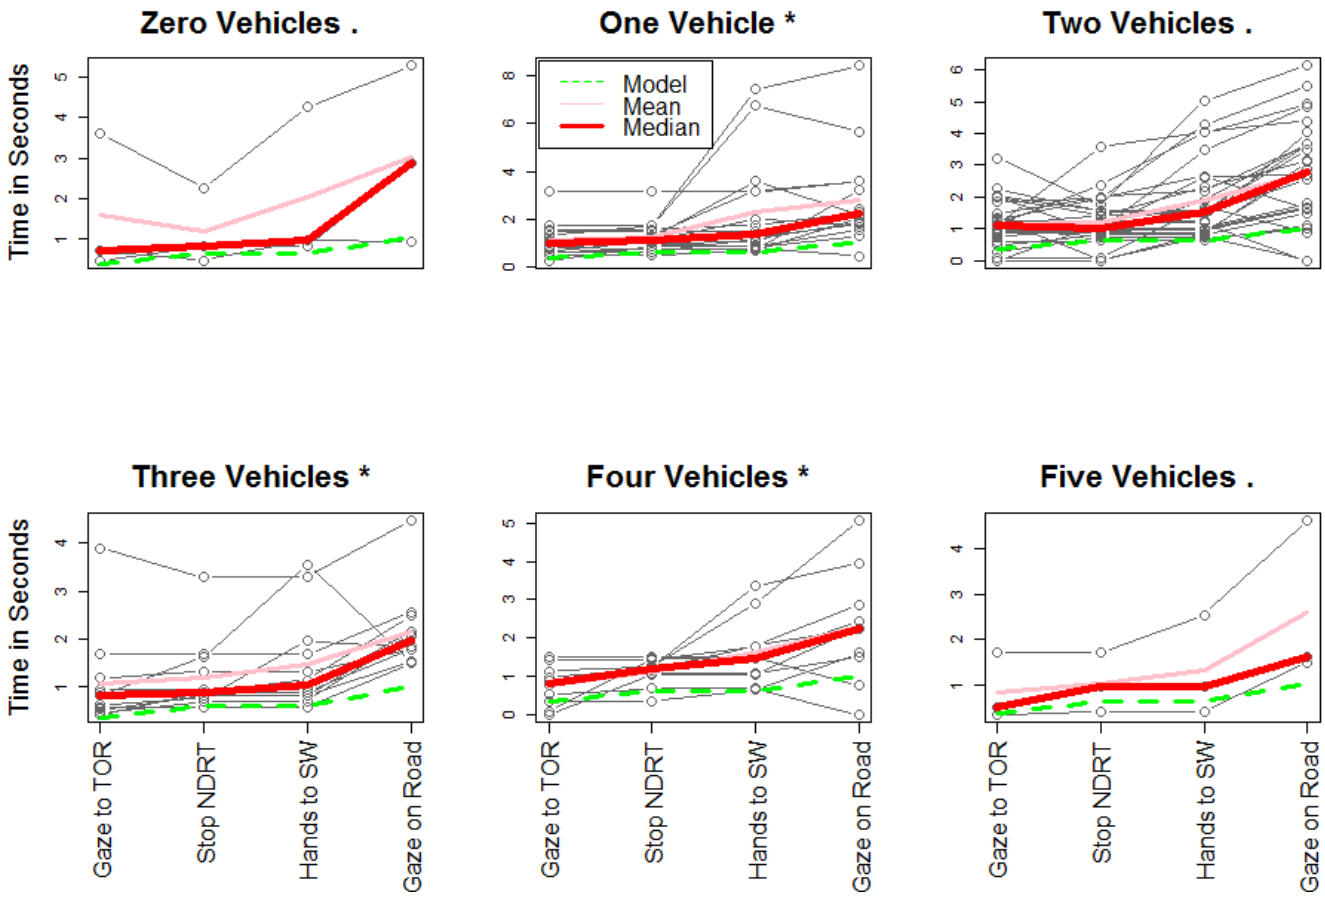

Figure 4: Correlations between Empirical Values and Model Predictions in Different Complex Traffic Situations (Significance codes: 0 '***' .001 '**' .01 '*' .05 '.' .1; Source: own figure).

processing step (Gaze to TOR), it is assumed, that cognitive processes before the gaze is directed to the TOR already have an influence. In the remaining sequence no noticeable time differences are observed. Thus, cognitive processes before the gaze is directed to the TOR have to be included into the model. Further, more aspects of the objective complexity have to be incorporated (e.g. notifications in the HMI, relevance of colors). It is though necessary to investigate on complexity measures concerning the takeover and incorporate further aspects of objective complexity. For an efficient development of interaction devices and estimates in highly automated driving cognitive models are important. They uncover underlying processes and should guide the development of highly automated driving. In this study, empirical data was collected in real traffic. The advantage of this is the creation of a more realistic scenario. However, traffic situations were not controllable and action decision patterns could hence not be evaluated. A simulator study in which the traffic conditions at the moment of the takeover request are controllable will thus be executed. This enables the collection of action decision parameters. The action decision is unequal to the action execution, as the decision may take place before the execution is possible due to the traffic environment. Thus, model predictions of the action decision in different complex situations can be validated by empirical data. In further investigations it will also be important to focus on subjective complexity in addition to objective complexity measures to include the individual into predictions. This is a very important factor, as only the consideration of individual differences enables a suitable, adaptable and safe development of the human machine interface. In order to focus on subjective complexity measures validly, it is though necessary to completely understand and control the objective complexity to separately carry out result analysis for subjective complexity measures.

Conclusion

Results of this study provide a first understanding of the impact of objective complexity on the takeover task. In a next step, action decision mechanisms in dependance of the objective complexity will be gathered. These will

be incorporated to further investigate in the subjective complexity of participants during a takeover. Additionally, steps that are undertaken during the takeover will be differentiated more detailed. Patterns like action decision, action execution and the quality of the takeover and of the action execution should be included. Later, subjective complexity measures will be addressed, to additionally select model predictions based on the individual.

Abstract

Cognitive enrichment for captive animals is the idea that cognitive stimulation can improve animal welfare. In zoos, cognitive enrichment not only helps the animals themselves but also contributes to zoo missions of educating the public, supporting research, and more. Technology-based cognitive enrichment tools are increasingly popular for a variety of reasons, though they also present unique challenges for design and deployment. In this paper, we present a short review of technology-based cognitive enrichment programs in zoo settings, and then describe the design and development process we used to create a new, touchscreen-based enrichment app for a group of orangutans at Zoo Atlanta. We discuss initial observations about the orangutans' use of this app, as well as lessons learned by our research team.

Keywords: animal-computer interaction (ACI); comparative cognition; interactive technology; user-centered design.

Figure 1: An orangutan uses the video activity in our app on a touchscreen at Zoo Atlanta.

Introduction

Zoos worldwide, which welcome nearly 200 million visitors annually, provide important scientific, economic, and educational benefits to the public through their captive animal care and management programs (*Zoo & Aquarium Statistics*, 2018). These programs are increasingly paying attention to the cognitive health of captive animals, in addition to their physical health, as a critical dimension of animal well-being.

In nature, animals experience many cognitive challenges requiring attention, search, memory, etc., often in situations directly related to their survival. Examples include foraging, reasoning about social dominance relationships, detecting predators/prey, and so on. Many animals in captivity do not experience the same kinds of challenges, since they are guaranteed food, water, territory, safety, and a social group.

Cognitive enrichment for captive animals is the idea that cognitive stimulation can improve animal welfare (Meehan & Mench, 2007), not just in zoos but in other settings as well, such as farm/livestock facilities (Manteuffel, Langbein, & Puppe, 2009). In zoos, cognitive enrichment programs can provide additional benefits beyond those for the animals themselves. Zoos generally have a mission of educating the public about animals, and cognitive enrichment can be both a point of connection with visitors as well as a topic for informal science education, for instance to engage the public around issues of cognitive health, the role of play and challenge in mental development, and more. In addition, zoos are often sites for important research in comparative psychology and anthropology, and cognitive enrichment both helps to maintain a healthy animal population for researchers and also provides platforms for conducting cognitive research.

Cognitive enrichment approaches that use technology are becoming increasingly popular in zoos, and have both advantages and disadvantages. Technology-based enrichment programs often require significant up-front investments in hardware acquisition and software development, especially when compared to non-technology-based enrichment tools like physical toys. However, if designed properly, these technologies can be reusable and extensible for continued enrichment activities, and furthermore, hardware costs for consumer-grade devices are continually decreasing. On the other hand, hardware can often be damaged by animals, technology-based activities may not be "realistic" to animals, and, just as with people, there may be harmful effects from animals spending too much time using screens.

Parallels can be drawn between studying technology usability for animals and for humans. The emerging field of animal-computer interaction (ACI), like human-computer interaction (HCI), emphasizes the development of systematic, user-centered design and evaluation practices for interactive technology applications (Mancini, 2011).

In this paper, we briefly review technology-based cognitive enrichment in zoos, and then describe the design process we used to create a new, touchscreen-based enrichment app for a group of orangutans at Zoo Atlanta. We discuss initial observations about the orangutans' use of this app, as well as lessons learned by our research team.

Cognitive Enrichment Using Touchscreens

In this section, we review and discuss a sampling of previous studies that used technology-based approaches for cognitive enrichment for captive zoo animals, with a focus on touchscreen-based applications.

Cognitive Enrichment Versus Cognitive Research

Many interactive technologies used with captive animals involve applications designed for research purposes. For example, many of the orangutans in our case study in Zoo Atlanta already have experience using touchscreens through cognitive psychology experiments that have studied capabilities like conspecific face recognition, working memory, etc. Often, the goal of a research application is to answer a specific cognitive science question, but the goal of cognitive enrichment is to provide enrichment. Secondarily, enrichment applications may, of course, also provide data that are interesting for cognitive research, but that is not the primary goal.

Thus, while the design of cognitive enrichment applications may be motivated by cognitive observations about a species, the applications themselves may be more open-ended or complex than those developed for research. Training animals to perform a task may also be less important in enrichment, as tasks are often designed to draw upon an animal's intrinsic curiosity and motivation. In this vein, cognitive enrichment applications do not always require the use of food rewards to motivate animals (though some do). Instead, enrichment can provide animals with entertainment, challenges, and a sense of control over their environment.

Research on the effectiveness of cognitive enrichment applications is critical (Weed & ONeill-Wagner, 2015), which brings up questions about how to measure the degree to which an animal is "enriched" by engaging in a set of activities. Usage or participation in the activity is one measure, but generally, the goal for enrichment is to provide benefits of a more holistic kind. Studies have used both qualitative and quantitative measures of observed animal behaviors to estimate different aspects of the overall "well-being" of an animal, such as, for example, reducing stereotypies or aggression, or increasing play behaviors, exploration, or social interaction (Alligood & Leighty, 2015).

Enrichment and Animal Welfare

Negative effects of typical zoo animal environments can stem from limitations in physical space, diversity of activities, lack of problem solving challenges, and even the withdrawal of rewards from previously entrenched reward-based activities. Minor mental challenges like puzzle-solving can therefore be positive for animal welfare, especially if the challenges are at an appropriate difficulty level. Benefits can include reduced anxiety, increased learning abilities, improved physical condition, more resistant immune systems, faster recovery from illness, and less fearfulness in new scenarios.

Although enrichment benefits animals the most when they are provided it from birth, it appears to have measurable benefits even if introduced later (Millar, 2013). Given the limited flexibility of many enrichment strategies, their utility is often limited by a lack of challenge or the inability to provide a lasting sense of control for animals, making them prone to habituation or frustration. Thus, what is needed is not just the introduction of one-off, ad hoc enrichment activities, but rather the development of flexible tools that support continually evolving, diverse enrichment programs.

Touchscreens and other technology-based applications have often been examined with respect to their effects on animal welfare outcomes. In some studies, technology-based enrichment approaches were found to have some aversive effects on animals (Ritvo & MacDonald, 2016; Tarou, Kuhar, Adcock, Bloomsmith, & Maple, 2004; Elder & Menzel, 2001). However, many other studies have found beneficial effects such as reduced negative behaviors like frustration, and more (see examples in Table 1).

Touchscreen applications have several practical advantages. Because digital enrichment can be dynamic and flexible, it can provide a breadth of activities and be customized to the needs of individual animals or groups of animals (Kim-McCormack, Smith, & Behie, 2016; Boostrom, 2013). This makes this technology more resistant to habituation when compared to traditional enrichment. This form of enrichment may also require little-to-no training for the animals. Touchscreen applications can also be useful in situations when animals are unable to be on exhibit because of inclement weather, injury, or group management.

Designing Applications for Non-Human Animals

When considering the design of an application for a different species, the consensus has been to begin with a user-centered approach (Wirman, 2013; Kim-McCormack et al., 2016; Wirman, 2014; Boostrom, 2013; Péron et al., 2012; Dolins, Schweller, & Milne, 2017). In the case of animal users who cannot directly provide input or feedback, zookeepers and other domain experts are critical resources for informing the design of new applications.

Studies have shown that applications with auditory and visual components along with frequent opportunities for touch interaction have been seen to have the highest interaction times overall, and in terms of content in the application, content displaying photorealistic images has been preferred over 2D graphics (Boostrom, 2013; Wirman, 2014). Having an application that provides immediate response to physical action can be rewarding because of the sense of control (Kim-McCormack et al., 2016). When creating graphics that encourage interaction from primates, designers of applications for primates have heavily focused on small details, such as thickness of borders around content, decisions about colors that will stand out against a background, the sizes of graphics, and more (Péron et al., 2012; Dolins et al., 2017; Wirman, 2013, 2014). One such program that focused on graphics presented to four chimpanzees a simple training regimen with thick, wide green borders along the four sides of a square against a black background (Dolins et al., 2017).

Designers have also considered the touchscreen itself, in-

Table 1: A sampling of the literature on technology-based cognitive enrichment for captive animals.

Reference	Species	# Individuals	Technology	Frequency/Duration	General Findings
Boostrom, 2013	Orangutans	16	iPad	5 min sessions at least twice per month per individual, over a span of 6 months.	There was varying interest in the iPad among the groups, with all groups showing a preference for brightly colored applications that also provided auditory stimulation.
Elder & Menzel, 2001	Orangutans	1	Computer with joystick	33 test days over a total study period of 90 days.	Extended periods of delay between trials induced signs of frustration, but stress was not induced by task performance.
Gray et al., 2018	Gorillas	7	Objects with IoT	Two 60-minute sessions.	Technology can help us learn about and tailor playful experiences for gorillas.
Martin & Shumaker, 2018	Orangutans	12	Touchscreen	Single 20 min session.	The versatility and programmability of computers tasks makes them an ideal platform for achieving functionally naturalistic outcomes for great apes.
Millar, 2013	Pigeons, dogs	16, 58	iPad	10-min sessions for 10 days (pigeons). Various number of 10-min sessions (dogs).	Both cognitive and physical enrichment were found to reduce agonistic behaviour and increase alertness.
Mueller-Paul et al., 2014	Tortoises	4	Touchscreen	Tested five days a week from 9 am to 5 pm.	Red-footed tortoises could operate a touchscreen and solve a spatial task.
Perdue et al., 2012	Orangutans	4	Touchscreen	Random 30-minute observation periods.	Touchscreen technology had no negative effects on the animals.
Péron et al., 2012	Parrots	3	Touchscreen	Always available; each piece of music lasted 90 seconds when played.	Music can be used as an environmental enrichment for captive parrots, and musical preferences seemed to be influenced by personality.
Ritvo & MacDonald, 2016	Orangutans	3	Touchscreen	30-60 min sessions, once per day for 3-4 days per week.	Musical stimuli were not reinforcing; use of music as enrichment may be more aversive than enriching for some species.
Scheel, 2018	Orangutans	11	Touchscreen	There were 10 random observations sessions.	Overall, the orangutans appeared to have enjoyed the touchscreen.
Schmitt, 2018	Gorillas, chimps, orangutans	5, 4, 4	Touchscreen	Available about 45 minutes per day, 3 to 5 times per week.	The ZACI system proved to be highly applicable for work with zoo-housed primates.
Tarou et al., 2004, Mallavarapu et al., 2013	Orangutans	8	Computer with joystick	1 hour sessions, for a total of 240 hours.	Behavioral changes associated with the computer included increases in aggressive behavior and more. The lack of habituation by frequent users indicates that computer-assisted tasks may be useful environmental enrichment for orangutans.
Wirman, 2012, 2013, 2014	Orangutans	2	Tablet-based touchscreen	Random, short durations of play with the touchscreen.	Digital play allows a form of communication that eliminates some obstacles and creates new ways for togetherness in play.

cluding viewing angle, software and hardware specs, and input mechanisms (Wirman, 2014), as well as expected physical usage. For example, orangutans often sit in an upright position to use a touchscreen, similar to human behavior.

Just as with the design of technologies for people, design for non-human animals requires significant creativity and imagination on the designers' part. Furthermore, non-human animals may interact with applications in unexpected ways, despite a designer's best-laid plans. Thus, early prototyping and "user testing" is key.

Our Case Study

We developed an enrichment application intended for use by the eleven orangutans (age 3-48 years) at Zoo Atlanta in Atlanta, GA, USA.

The zoo that our team worked with has an existing, somewhat unique technology installation in one of their open-air orangutan enclosures: an artificial "tree" (fiberglass, etc.) that has a touch-screen monitor built into one face, and houses a desktop computer inside (see Figure 2). The intent of this installation was to provide a platform for cognitive enrichment for the orangutans that could be used in a relatively unstructured way. The tree had previously been loaded with applications designed for comparative psychology research.

In conversations with our team, zookeepers stated their desire for a new "app" for the tree that would: 1) be easy enough for the orangutans to use without oversight from staff members; and 2) be engaging enough for the orangutans that they might choose to use it without extrinsic rewards (e.g., food).

In addition to these criteria, we added two more from the software development side: 3) be easily extensible by zookeepers to add/modify content to individual app activities; and 4) be modular and thus easily extensible by future developers to add/modify individual activities within the app.

Figure 2: "Learning Tree" touchscreen installation.

App Design and Development

Through many discussions with four zookeepers over a period of two and a half years, we designed a cognitive enrichment application that consisted of an "activity chooser" home screen, from which the orangutans would be able to select individual activities to engage in. Initially, we designed three modular activities to populate the system: 1) a video player activity, 2) a visual puzzle activity, and 3) a musical instruments activity.

A primary concern throughout the design process was aiming to ensure that the interface and individual activities would be simple enough for use by the orangutans. Often, such enrichment app designs overestimate the level of complexity that animals can understand in terms of interface and task design. In conversations with other zoos that attempted similar technology-based enrichment efforts with non-human primates, we learned that **simplicity** of the interface and **familiarity** of the elements presented to animals were both important design factors to keep in mind (McAuliffe, 2017).

Home screen. As illustrated in Figure 3 (left), the application's home screen holds an array of orangutan images, and a vertical green home button. Contrary to many common formats of reward-based applications, where the orangutans have to figure out where to press or what to do in order to get food, this design seeks to draw the animal's attention by showing them images they will recognize: familiar orangutans from their own social group. Research has shown that orangutans, while not among the most social of non-human primates, still do show fairly robust conspecific (e.g. within-species) visual recognition of familiar faces (Hanazuka et al., 2013; Talbot et al., 2015). Each cell with an orangutan image leads to one of three different activities.

The home button appears on all screens of the app and will always return the orangutan to the original home screen. The button appearance was not designed arbitrarily; the green gradient was featured in the home buttons of other reward-based applications that the orangutans had already been using. As a result, the familiar pattern attempts to give the orangutans visual clues about the button's function.

Video player activity. The first of the activities is illustrated in Figure 3 (right side, top row). Pressing any of four brightly colored boxes triggers a short video clip (15-30 seconds) of one of the zoo's orangutans, taken from the zoo's existing store of videos. The layout was designed to be simple and visually distinguishable from the other screens. Again, zookeepers thought that showing videos of individuals familiar to the orangutans would be engaging.

Visual puzzle activity. The second activity is the simple visual puzzle illustrated in Figure 3 (right side, middle row). We wanted to create an activity a bit more challenging than the passive-viewing video player activity, but also simple enough to be solvable by most of the orangutans fairly quickly, especially in their initial exposure to the app.

Thus, we created a design in which puzzle "pieces" of an image are shown around the perimeter of the screen, with a target grid in the middle. Pressing any of the puzzle pieces prompts the piece to move on its own to the correct grid location, greatly reducing the difficulty of the task while also providing some visual interest. Once all four pieces have been pressed and are in position, the completed image then plays as a video (puzzle images are taken from the first frames of video clips), providing a type of "visual reward" for completing the puzzle. As with the previous screens, images were chosen from the zoo's stock of photographs of their own orangutans, to facilitate interest through familiarity.

Musical instruments activity. Finally, as illustrated in Figure 3 (right side, bottom row), we created an activity that displays an array of eight different musical instruments which play an audio clip (1-30 sec) of their corresponding sound when pressed. While the recording is playing, the selected instrument icon also oscillates in place to emphasize the connection between the button and the sound.

Previously cited research suggests that musical stimuli is not reinforcing as orangutan enrichment, but we believed that research on musical enrichment is minimal enough to explore further. Additional cited research proposes that orangutans tend to be more interested in photorealistic images than graphics, but through conversations with zoo researchers, we concluded that this information is not as essential for images of instruments as it is for images and videos of orangutans contained in the other activities.

Modularity of design. Though our design choices primarily strive to achieve simplicity of use, it is also important to keep activities somewhat novel when designing for orangutans in order to prevent boredom and frustration (Wirman, 2013). Therefore, one important aspect of modular design in our app relates to the video content used for the video player activity and for the visual puzzle activity. Videos are drawn from a specific folder, and zookeepers can easily change the available videos by adding or removing video files from the library. In addition, the image/video used for

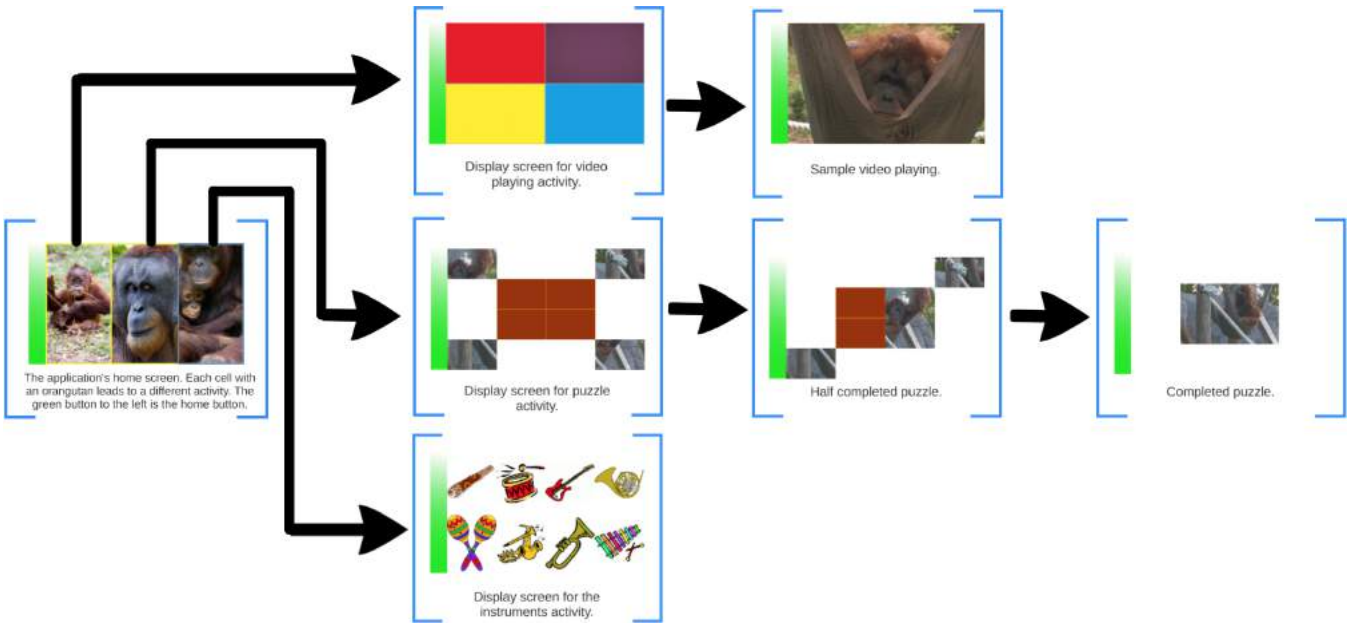

Figure 3: Flow diagram of the touchscreen-based application we designed to provide cognitive enrichment for orangutans.

the puzzle activity is randomly chosen from this store, to add some novelty to that activity over repeated sessions.

Because some orangutans become familiar with touchscreen activities faster than others, the goal was to design activities that were, on average, challenging, but not frustrating. Thus, an expectation was that some orangutans would learn activities more quickly than others, and that many orangutans would continue to perceive activities as novel for a substantial amount of time.

One other modular design choice is that each individual activity resides in its own "container." Thus, activities can be added or swapped in a relatively straightforward fashion. In conversations with zookeepers, one common issue with enrichment apps seems to be the lack of ease of extensibility, especially given that it is often difficult to access software developers to work on extensions or modifications.

Finally, log files are saved from each session and hold a timestamped record of every activity performed in the app. The information in these logs is valuable for understanding orangutan usage patterns, and perhaps inferring measures of orangutan amusement and satisfaction, as potentially important components of overall cognitive enrichment.

Ideally, additional data would be collected to establish a durable record of which individual orangutans were using the app at various times. For example, we discussed with zookeepers the potential value of having a webcam-like setup that would record video of the orangutan user every time the app was activated. Such a video would provide not only identifying information about users but potentially also information on the user's affect and engagement levels. However, due to logistical constraints, we were not able to deploy such a setup. As a result, our log files record usage but not which individual or individuals were using the app.

Observations and Lessons Learned

Initial deployment of the app with the group of orangutans at the zoo seems to show many positive signs. Based on our team's qualitative observations of the orangutans, they seemed curious and interested in what was happening on the touch screen, often rushing over in a group to see what was happening when zookeepers opened the app on the learning tree computer. Several individual orangutans were also observed at various times interacting with the app for moderately lengthy durations.

Figure 4 shows ten examples of orangutan interactions with the app, as recorded in the system logs. These ten sessions, shown on the y-axis in no particular order, were chosen from the full set of log data to show a sampling of interaction patterns that were observed. The x-axis shows time across a duration of about 24 minutes, measured from the first touch screen press that was recorded by the app during a given session.

Clearly, there is a lot of variability in usage. Sometimes (e.g., logs 2, 8, and 9), there is some initial activity that quickly tails off within a minute or two. Other sessions show much more sustained activity. The orangutans seem to have accessed each of the app's activities more than once, though the extent to which they are purposefully navigating through the app, versus just pushing various buttons, is an open question. More detailed analyses of such log files will be an important part of our future work.

In addition to the log data, we also discuss, in qualitative terms, two episodes of interaction that were particularly noteworthy. First, one of the most interesting moments occurred when Madu, a female orangutan in her 30s, was viewing videos through the video player activity. (The image in Fig-

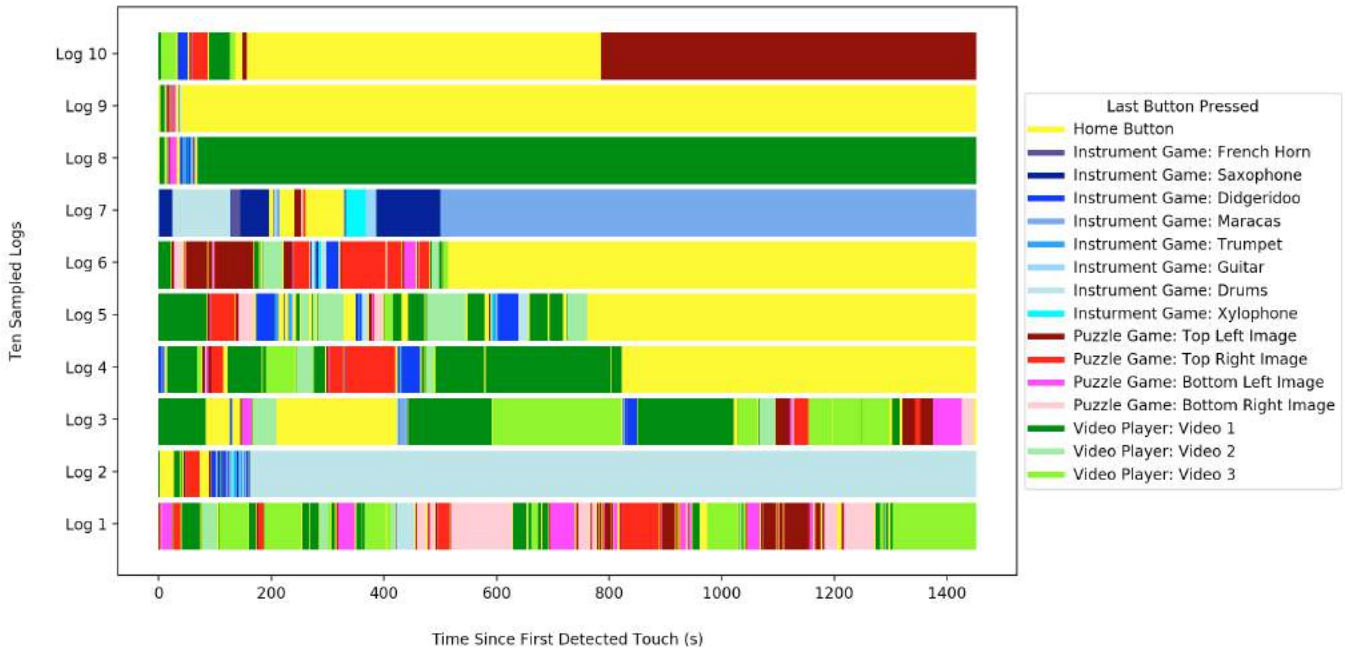

Figure 4: Sampling of app log data from 10 different interaction sessions (y-axis) across time, as measured from first touch screen press (x-axis).

ure 1 is a still from this episode.) She encounters a video of Alan, an older male orangutan who had passed away nearly four years earlier. Madu is visibly transfixed for 20 long seconds, and then tries to interact further by touching his figure in the video several times. Of course, we do not know for sure what was going on in Madu's mind at the time, but at least to the zookeepers who know her best, it seemed like she was remembering her old habitat neighbor. Note that we did not include videos of Alan on purpose; we were simply pulling from the zoo's stock of orangutan videos. However, this incident does seem to support the idea that familiar stimuli can be uniquely engaging to orangutans, even (or perhaps especially) in the case of dearly departed old friends.

Another time, one of the orangutans was interacting with the app and seemed to be searching for a food reward, looking up at the feeder mechanism on the tree (used in other, reward-based applications), tapping on the tree, and even banging on the touchscreen with a fist. The orangutan appeared to be quite frustrated at the absence of a food reward! Despite this episode, however, several of the orangutans at other times did find the app interesting enough to be worth engagement, even without food rewards. This raises interesting questions about the longer-term impacts on learning and motivation of using food rewards to stimulate certain behaviors.

We conclude with three takeaway lessons from our case study of cognitive enrichment for captive orangutans.

Familiarity of stimuli. The use of photos and videos of familiar orangutans did seem to support interest and engagement in the orangutans using our app. Further evaluations of this principle would be extremely valuable for cognitive enrichment programs in general, including at other zoos, with other species, and in a variety of enrichment activities.

Modularity in design. The modular design that we implemented, especially in terms of enabling zookeepers to easily swap out image/video content without requiring any programming skills, seems to be a promising approach to enable technology-based enrichment activities to be modifiable. Studies of orangutan engagement over time will be informative, and we expect that the ability to regularly change app content will keep the novelty factor up.

Engagement with the public. There is continued debate on the pros and cons of adding technology to the daily experiences of zoo animals, not only with respect to the animals themselves but also with respect to the public education missions that most zoos have. Is it really teaching the public the right ideas about wildlife to show orangutans playing "video games?" There is no easy answer to this question, but Zoo Atlanta has aimed to strike a balance by establishing a "naturalistic" setting for their technology-based enrichment—the learning tree shown in Figure 2.

These applications can also serve to teach the public about the cognitive health of captive animals, and to showcase joint efforts by zookeepers and researchers to ensure that animals have a stimulating cognitive environment. The "coolness" factor of technology-based interventions may provide positive benefits for engaging the public (Perdue et al., 2012); for example, the video of the Madu-Alan episode described above was viewed on the zoo's social media page over 15 thousand times. In addition to media influence, zoo visitors can participate in weekly zookeeper-led showcases of

the orangutans using the touchscreen in their exhibit, through which they have the opportunity to ask questions about orangutan behavior with the touchscreen and view real-time touchscreen interactions on an additional screen display that is located just outside the enclosure.

In summary, while non-technological cognitive enrichment activities also have their place, we expect that technology-based interventions will continue to provide valuable contributions for the study and care of captive zoo animals, as well as for basic research in cognitive science.

Acknowledgment

This research study was approved by the Zoo Atlanta Scientific Review Committee. Many thanks to Laura Mayo for her original suggestions on creating this enrichment application, and also to Liam Kelly, Avery Twitchell-Heyne, Jodi Carrigan, Marieke Gartner, and others at Zoo Atlanta for their contributions to this work.

Thanks also to the following individuals who worked on initial app design and implementation at the Georgia Institute of Technology in 2014-2015: Benjamin Seco, Katie Delisle, Brett Garcia, Samantha Kassem, Brandon Levester, Shannon Nguyen, Jee Kong, Andrew Scheinbach, George Zheng, and Weng Ling Chen.

Abstract

We investigated the application of non-linear analysis techniques for capturing stability of neural oscillatory activity within and across brains. Recurrence Quantification Analysis (RQA), a technique that has been applied to detect stability and flexibility of motor performance, was extended to observe and quantify changes in patterns of non-linear neural activity. Participants synchronized their finger-tapping with a confederate partner who tapped at two different rhythms while neural activity was recorded from both partners using electroencephalography (EEG). Auto-recurrence (intra-brain) and cross-recurrence (inter-brain) of EEG activity were able to distinguish differences across tapping rhythms in stability of neural oscillatory activity. We also demonstrated the efficacy of RQA to capture how both period and phase changes in neural dynamics evolve over time.

Keywords: joint action; neural dynamics; electroencephalography; recurrence quantification analysis

Introduction

Researchers have become increasingly interested in capturing complex oscillatory signals common to human behaviors, and which often show non-linearities that evolve over time. This can be seen in individual motor behaviors like postural sway and finger-tapping (Schmit, Regis & Riley, 2005; Schmit, Riley, Dalvi, Sahay, Shear, Shockley, & Pun, 2006; Scheurich, Zamm, & Palmer, 2018), and in joint motor behaviors like conversational speech and music performance (Dale & Spivey, 2006; Demos, Chaffin, & Kant, 2014). One way in which these complex signals can be represented is through Recurrence Plots (RPs), which display the points in time at which an individual returns to previous behavioral states (i.e., self-similarity), or the points in time at which two individuals visit the same behavioral state (i.e., similarity between individuals; Eckmann, Kamphorst, & Ruelle, 1987). RPs are useful tools for observing transitions between states in a system and can be further quantified using Recurrence Quantification Analysis (RQA). These quantifications give insights into the behavioral dynamics of one or more systems over time through measures such as recurrence rate: how often a system returns to previous states or two systems visit the same state; and mean diagonal line length: the time over which one or more systems are stable (Marwan, Romano, Thiel, & Kurths, 2007; Marwan & Webber, 2015). One advantage of RQA is that it can be applied both within individuals during solo tasks (i.e., auto-recurrence) and between individuals during joint tasks (i.e., cross-recurrence; Marwan, Romano, Thiel, & Kurths, 2007; Marwan & Webber, 2015). Thus, these tools have been useful for characterizing dynamics of motor behaviors over time both within and across individuals during a variety of solo and joint behaviors (e.g., Schmit, Regis, & Riley, 2005; Schmit, Riley, Dalvi, Sahay, Shear, Shockley, & Pun, 2006; Romero, Fitzpatrick, Schmidt, & Richardson, 2016; Demos & Chaffin, 2017; Scheurich, Zamm, & Palmer, 2018).

Complex oscillatory signals are not unique to behavior, but are also observed in human brain activity. This can be seen, for example, in the oscillatory neural activity that underlies rhythmic auditory-motor behaviors (e.g., Nozaradan, Zerouali, Peretz, & Mouraux, 2013; Nozaradan, 2014; Morillon & Baillet, 2017; Zamm, Debener, Bauer, Bleichner, Demos, & Palmer, 2018). However, common methods for examining oscillatory neural activity supporting these kinds of behaviors often do not measure dynamics over time, but instead assume stationarity of the signal. RQA has been applied to oscillatory neural activity, as measured through electroencephalography (EEG), in a limited scope. This has been primarily in clinical settings, in which outcomes such as recurrence rate and mean diagonal line length, which provide information about the stability of neural activity, have been used successfully to classify periods of epileptics' EEG activity as normal, pre-ictal, and

ictal activity (Acharya, Sree, Chattopadhyay, Yu, & Ang, 2011). Furthermore, RQA outcomes have been applied for monitoring consciousness of patients undergoing anesthesia (Becker, Schneider, Eder, Ranft, Kochs, Zieglgänsberger, & Dodt, 2010). In addition to its clinical applications, researchers have proposed RQA as a method for studying event-related potentials (ERPs). Although traditional methods of studying ERPs require averaging over many trials to obtain a clear waveform, RQA allows for the use of single trials to identify changes in ERP components, as demonstrated in an auditory perception experiment using the auditory oddball paradigm (Marwan & Meinke, 2004). No research, to our knowledge, has yet applied RQA to capture oscillatory neural activity that distinguishes different rhythmic auditory-motor behaviors.

The current study applies RQA to capture the dynamics of oscillatory neural activity during a 2-person rhythmic tapping task. Participants tapped at two different rhythms with a confederate partner while EEG was recorded from each partner. In one rhythm condition, the confederate tapped at twice the frequency of the participant. In the second rhythm condition, the confederate tapped at half the frequency of the participant. The neural activity at the participant's (constant) tapping frequency was compared across rhythm conditions. Only activity at the constant frequency was examined to identify changes in oscillatory neural activity related to changes in tapping ratios between partners as opposed to changes in absolute frequency. Auto- (intra-brain) and cross-recurrence (inter-brain) analyses of EEG activity were expected to reveal greater stability of oscillatory neural activity when the participants' tapping frequency was the dominant frequency (i.e., more auditory feedback at that frequency).

Methods

Participants

Data from eight adult musicians aged 18-30 years old with at least 6 years of private music instruction on an instrument other than percussion were taken from a larger study. Their duet tapping trials met a performance cut-off of at least 75% error-free trials (i.e., no missed taps) for each condition in which partners performed live together. Other conditions included in the larger study in which participants performed with pre-recordings of their partner were not examined in the current paper. A single confederate experimenter (more than 6 years of piano instruction) tapped with each participant to maintain consistent timing properties of live and pre-recorded conditions as well as social presence across participants. All participants and the confederate were right-handed and had normal hearing (< 30 dB HL threshold, 125 – 750 Hz) as determined by an audiometry screening. Participants and the confederate reported no current psychiatric or neurological conditions and were not taking medication affecting the central nervous system at the time of testing.

Equipment and Materials

Participants' hearing was assessed with a Maico MA40 audiometer. Participants tapped on a Roland A500s MIDI keyboard and the confederate tapped on a Yamaha PSR 500m MIDI keyboard. Auditory feedback was delivered in a sine tone timbre generated by a Roland Sound Canvas, amplified to a comfortable listening level using a Behringer Headphone Amplifier, through EEG-compatible earphones (Etymotic ER-1, Etymotic Research Inc.). Participants' auditory feedback was presented at pitch G4 (392.00 Hz), and the confederate's auditory feedback at pitch E5 (659.25 Hz). MIDI data were collected using FTAP software (Finney, 2001). FTAP was modified to integrate Lab Streaming Layer (LSL; Kothe, 2014) similar to Zamm, Palmer, Bauer, Bleichner, Demos, & Debener, 2017. This modification allowed for keystroke, metronome, and time triggers from FTAP on a Dell computer running Linux to be sent over the local area network and received by a second Dell computer running Windows 7, where LSL synchronized the keystroke and EEG data collection from both partners (Zamm et al., 2017).

EEG Data Recording

EEG data were recorded from each partner at a 512 Hz sampling rate via two separate but synchronized 64-channel BioSemi Active-Two systems (BioSemi, Inc.). Electrodes were positioned according to the 10-20 system. Data were recorded using a common mode sense (CMS) active electrode and driven right leg (DRL) passive electrode which formed the reference (http://www.biosemi.com/faq/cms&drl.htm). External electrodes were placed above and below the right eye to detect eyeblinks, on the outer corner of each eye to detect lateral eye movements, and on the mastoids to detect muscle artefacts.

Stimulus Materials and Design

Each stimulus was constructed of an approximately 40-second series of taps generated by the Participant and Confederate. Each pair (Participant and Confederate) completed the joint tapping tasks in a within-subjects design with 2 rhythm conditions: 1-2 (Confederate-Participant) and 4-2 (Confederate-Participant). In the 1-2 condition, the confederate tapped at half the rate (~0.95 Hz) of the Participant (~1.89 Hz). In the 4-2 condition, the Confederate tapped at twice the rate (~3.78 Hz) of the Participant (~1.89 Hz). Thus, the Participants' tapping frequency was constant across conditions. Each pair completed one practice trial and 12 experimental trials in each rhythm condition. Rhythm was blocked within pair, and blocks were counterbalanced across pairs. The dependent variables were auto- (intra-brain) and cross-recurrence (inter-brain) outcomes of Recurrence Rate, describing how much of the RP is occupied by recurrent points (how often a single system returns to previous states in auto-recurrence, or two systems visit similar states in cross-recurrence), and Meanline,

describing the average diagonal line length (the mathematical stability of the system(s); see **RQA Application to EEG**).

Procedure

After giving informed consent upon arrival to the lab, participants completed an audiometry screening. Then both the participant and the confederate were outfitted with EEG caps and electrodes. The participant and confederate were taken to the testing room where the confederate was introduced to participants as an experimenter who served as the partner in each pair to maintain consistency of interactions across pairs. The participant and the confederate were seated at two separate keyboards across from one another with a barrier placed between the keyboards such that the partners could only see one another above the shoulder.

The participant and confederate then completed the two tapping tasks together at the two different rhythmic ratios. They were instructed to tap with the index finger of their right hands on a single key of the keyboard while minimizing eyeblinks and eye movements. The participant and confederate were first presented with separate recorded examples of each tapping part in isolation, and then they were presented with a recorded example of how the two parts sounded together. After listening to the examples, the participant and confederate were instructed that they would hear a four-beat metronome cue sounded at the participant's prescribed rate at the beginning of each trial, and they were presented with a recorded example of how their parts sounded together with the metronome cue. The participants were instructed that they should synchronize with the confederate's tapping while maintaining the rate cued by the metronome, and the confederate was instructed to maintain a steady pulse. After completing a practice trial, pairs completed 12 experimental trials. This procedure was repeated for each rhythm condition. After completion of the tasks, participants were debriefed and received a small compensation. The whole experiment lasted approximately three hours.

EEG Preprocessing

EEG data were preprocessed in EEGLAB (Delorme & Makeig, 2004). Data were first prepared for artefact correction with Independent Component Analysis (ICA), using a procedure adapted from Zamm et al. (2017). Data were concatenated across all trials in all experimental tapping tasks, and re-referenced to the common average across electrodes. Electrodes reflecting poor signal quality were identified by visually inspecting electrode distributions of deviations from mean activity for each subject. Electrodes with very large deviations from mean activity were identified as noisy, and electrodes with no deviation from mean activity were identified as flat. These electrodes were removed, and data were subsequently filtered between 1 Hz and 40 Hz using a Hanning windowed sinc FIR filter (high and low pass filter order = 1000). Filtered data were then segmented into 1-second epochs, pruned for non-stereotypical artefacts, and submitted to extended infomax ICA. ICA components representing eyeblinks and lateral eye movements were visually identified and removed from the unfiltered data. After removing bad components, previously rejected electrodes with poor signal quality were spherically interpolated.

RQA Application to EEG

Power Spectral Density (PSD) estimates of ICA-corrected EEG activity were then computed similar to Zamm et al. (2017). PSD gives the amount of power present in the EEG signal at component frequencies. Preprocessed EEG data were high then low pass filtered using a Hanning windowed sinc FIR filter (high pass filter order = 1000, cutoff = 0.1 Hz; low pass filter order = 1000, cutoff = 20 Hz) and segmented into 3 10.56-second epochs (to control for tapping frequency drift). PSD was estimated for each electrode and epoch, and then was log-transformed before averaging across epochs and then trials. The electrode with maximal power on average across conditions, tapping frequencies, and participants was identified as electrode C1 (central and left-lateralized). This electrode is commonly identified as showing maximal activity in auditory-motor behaviors (e.g., Nozaradan, Zerouali, Peretz, & Mouraux, 2013; Nozaradan, 2014). Data from this electrode were used as input to auto- and cross-recurrence analyses.

ICA-corrected data from electrode C1 for participants and the confederate were then prepared for auto- and cross-recurrence analyses. First, the data were filtered at the participants' observed tapping frequencies. The filter frequency cutoffs were tailored per participant and confederate pair and rhythm condition to account for any deviations in expected tapping frequency. The data were high then low pass filtered using a Hanning windowed sinc FIR filter (high and low pass filter orders = 1000) with cutoff frequencies ± 2 standard deviations around the observed participant tapping frequency. Data were then segmented into 3 10.56-second epochs (for computational tractability) and *z*-scored per epoch.

Auto- and cross-recurrence analyses were run using the Cross Recurrence Plot Toolbox (Marwan, Romano, Thiel, & Kurths, 2007). Optimal auto- and cross-recurrence parameters were determined per epoch; final selected parameters were determined by examining the distribution of parameters across epochs. The optimal delay parameter was determined by computing Average Mutual Information (AMI). AMI gives the amount of information a time series shares with itself at different time delays, with the delays at which it shares least information with itself being optimal for RQA. The first delay at which shared information of the C1 time series with itself reached a minima was selected (selected delay = 68 samples, corresponding to 1/4 cycle of the participant tapping frequency). The optimal number of embedding dimensions was determined by computing False Nearest Neighbors (FNN). FNN gives the amount of false neighbors in phase space as a function of the number of

embedding dimensions (copies of the time series at the specified delay). The number of embedding dimensions at which number of false nearest neighbors was minimized and adding more dimensions no longer reduced number of false nearest neighbors was selected (selected embedding dimensions = 4). Finally, the maximum phase space diameter, corresponding to the standard deviation of the time series, was computed using the selected delay and embedding dimensions. The optimal threshold for which points in phase space are considered recurrent was determined by computing 10% of this value (selected threshold = 0.49; Schinkel, Dimigen, & Marwan, 2008). For auto-recurrence, the Thieler window, minimum diagonal line length, and minimum vertical line length were set to 34 samples (corresponding to 1/8 cycle of the participant tapping frequency). For cross-recurrence, the Thieler window was set to 0 samples and the minimum diagonal and vertical line lengths were set to 34 samples.

Results

Auto-recurrence Outcomes

We first investigated how auto-recurrence (intra-brain) outcomes changed with Rhythm, and whether these patterns held or changed across Partners within each pair. Separate two-way ANOVAs were run on Recurrence Rate and Meanline with Rhythm (1-2 and 4-2) and Partner (Participant and Confederate) as factors and pair as random variable. Results are summarized in Table 1 and sample RPs are shown in Figure 1. There was a significant main effect of Rhythm on Recurrence Rate: Recurrence Rate was higher for the 1-2 Rhythm (in which the participant tapped at twice the rate of the confederate) than for the 4-2 Rhythm. There was no significant main effect of Partner, $F(1, 7) = 0.012$, $p = 0.92$, or significant interaction between Rhythm and Partner, $F(1,7) = 0.415$, $p = 0.54$, on Recurrence Rate. There was also a significant main effect of Rhythm on Meanline: Meanline was higher for the 1-2 Rhythm than for the 4-2 Rhythm. Again, there was no significant main effect of Partner, $F(1,7) = 0.017$, $p = 0.90$, or significant interaction between Rhythm and Partner, $F(1, 7) = 0.582$, $p = 0.47$, on Meanline. These effects were replicated with mixed models in which random effects of Partner and Rhythm were allowed to vary as a function of the pair.

To ensure that the main effect of Rhythm on Meanline was not a function of differences in Recurrence Rate across Rhythms, we also examined the outcome of Meanline when Recurrence Rate was fixed to 10% across Rhythms during the process of computing the RQA. A two-way ANOVA was run on Meanline with Rhythm and Partner as factors and pair as random variable. The main effect of Meanline held when Recurrence Rate was fixed across Rhythms, $F(1, 7) = 17.577$, $p = 0.004$. Meanline was higher for the 1-2 Rhythm than for the 4-2 Rhythm. There was no significant main effect of Partner, $F(1, 7) = 0.001$, $p = 0.97$, or significant interaction between Rhythm and Partner, $F(1, 7) = 0.579$, $p = 0.47$.

Table 1: Auto-recurrence main effects of Rhythm.

Outcome	1-2	4-2	F	η^2	p
Recurrence Rate	3.06%	2.59%	23.03	0.79	0.002
Meanline	136.26	126.44	20.32	0.77	0.003

Figure 1 shows RPs for an example epoch from one participant for each Rhythm. As can be seen in these examples, there are more recurrent points and longer diagonal lines in the 1-2 RP (when the participant's tapping frequency is the dominant performance frequency) than the 4-2 RP. The white space between the diagonal lines on each plot corresponds approximately to the participant tapping frequency (1.89 Hz or approximately 271 samples).

Cross-recurrence Outcomes

Separate one-way ANOVAs were conducted on the same outcome measures (Recurrence Rate and Meanline) from cross-recurrence quantification analysis with Rhythm as factor and pair as random variable. Results are summarized in Table 2 and sample RPs are shown in Figure 2. There was a significant main effect of Rhythm on Recurrence Rate: Recurrence Rate was higher for the 1-2 Rhythm than for the 4-2 Rhythm. There was also a significant main effect of Rhythm on Meanline: Meanline was higher for the 1-2 Rhythm than for the 4-2 Rhythm. These effects were replicated with mixed models in which random effects of Rhythm were allowed to vary as a function of the pair.

To again ensure that the main effect of Rhythm on Meanline was not a function of differences in Recurrence Rate across Rhythms, we also examined the outcome of Meanline when Recurrence Rate was fixed to 10% across Rhythms during the process of computing the RQA. A one-way ANOVA was run on Meanline with Rhythm as factor and pair as random variable. The main effect of Meanline held when Recurrence Rate was fixed across Rhythms, $F(1, 7) = 14.264$, $p = 0.007$. Again, Meanline was higher for the 1-2 Rhythm than for the 4-2 Rhythm.

Table 2: Cross-recurrence main effects of Rhythm.

Outcome	1-2	4-2	F	η^2	p
Recurrence Rate	2.93%	2.53%	16.84	0.74	0.005
Meanline	131.22	122.78	16.81	0.74	0.005

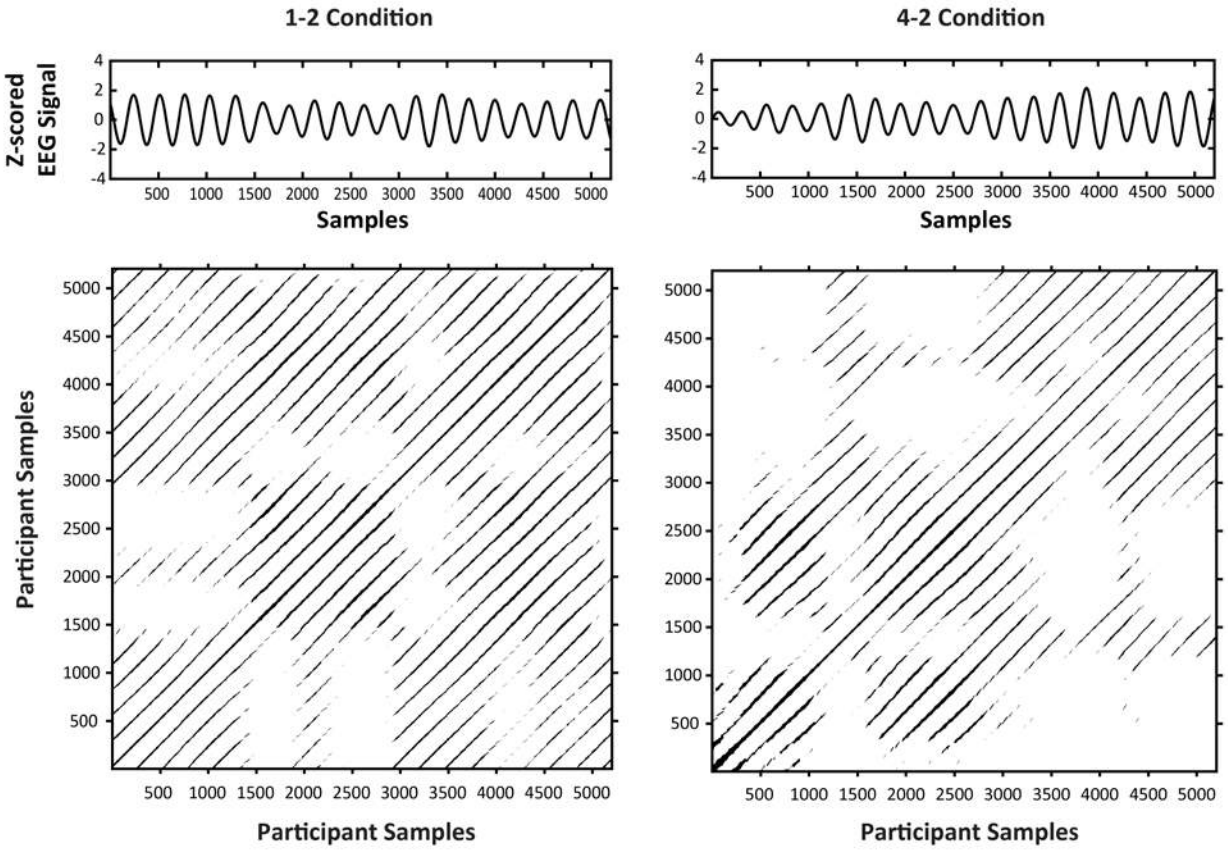

Figure 1: Time series and RPs with samples as a unit of time for one epoch from one participant for Rhythms 1-2 and 4-2. The time series shows the *z*-scored preprocessed signal from electrode C1.

Figure 2 shows example cross-recurrence plots (CRPs) for a single epoch from one pair for Rhythms 1-2 and 4-2 for the same trials shown in Figure 1. As can be seen in these examples, the 1-2 CRP is more densely occupied by recurrent points than the 4-2 CRP; these points also form longer diagonal lines than those in the 4-2 CRP. This indicates that the two signals overlap more often and for longer periods in phase space during the 1-2 Rhythm than the 4-2 Rhythm, indicating greater inter-brain stability. Furthermore, the white space between diagonal lines indicates the period at which the two neural signals recur with one another, and this period corresponds approximately to the participant tapping frequency (1.89 Hz or approximately 271 samples). Phase shifts between the two signals over time can also be observed by the degree of curvature in the diagonal lines in each CRP.

Discussion

The current experiment examined the application of RQA to neurophysiological data collected during a rhythmic tapping task between partners. Both auto- and cross-recurrence measures were sensitive to changes in stability of neural oscillations across tasks. Stability of neural oscillations at the participant tapping frequency was greater both within and across brains, as shown by larger recurrence rate and meanline outcomes from auto- and cross-recurrence, respectively, when there was more auditory feedback for both partners at the participants' tapping frequency.

We showed intra- and inter-brain recurrence that corresponded approximately to the participant tapping frequency. We also showed phase shifts in time as observed by the degree of curvature of the diagonal lines. Future work can further examine the time delay in recurrent points between two signals using quantifications such as the diagonal recurrence profile (e.g., Richardson & Dale, 2005; Dale, Kirkham, & Richardson, 2011), and subsequently relate this to behavioral performance. In contrast to other inter-brain metrics such as phase coherence, one advantage of cross-recurrence is the ability to show and subsequently quantify inter-brain dynamics when neural signals occupy the same phase space.

One limitation of the current experiment is that we only examined neural activity filtered at the participant tapping frequency. Future work can extend this technique to look at other stimulus frequencies to further examine the time evolution of neural dynamics in a joint motor task. We were also limited in our analyses by a small sample size. With more pairs, it could be possible to apply more sophisticated analysis methods to RQA outcomes such as an Actor-Partner Interdependence Model to examine how partners influence one another (Kenny, Kashy, & Cook, 2006). We also used PSD estimates for selecting a single electrode whose data were used for auto- and cross-recurrence

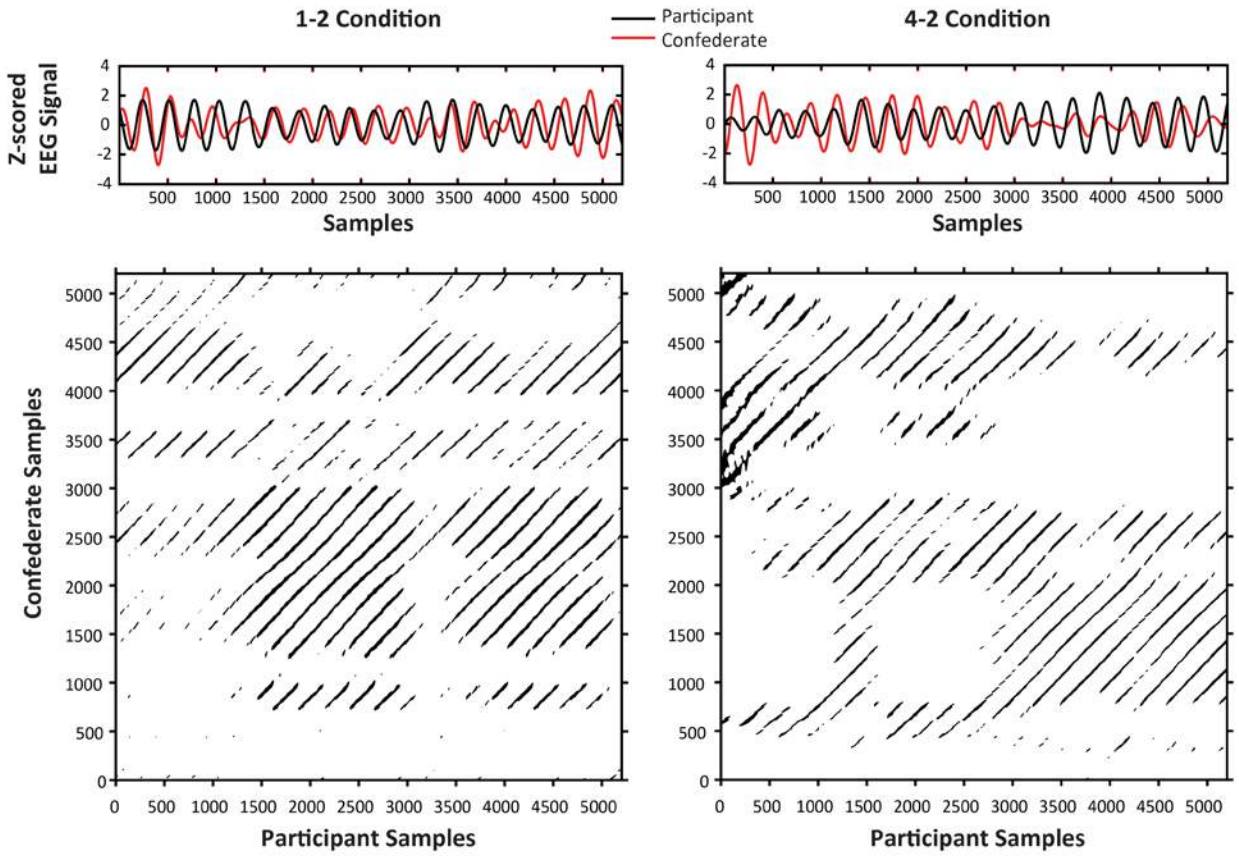

Figure 2: Time series and CRPs with samples as a unit of time for one epoch from one pair for Rhythms 1-2 and 4-2. Time series show the *z*-scored preprocessed signal from electrode C1 for the participant (in black) and the confederate (in red).

analyses. Future work can also extend this technique to identify regions of interest (i.e., multiple EEG electrodes) on which Multidimensional Recurrence Quantification Analysis (MdRQA) could potentially be applied (Wallot, Roepstorff, & Mønster, 2016).

In sum, recurrence quantification techniques were sensitive to changes in the dynamics of oscillatory neural activity that occurred during a joint rhythmic task. This is the first demonstration, to our knowledge, of RQA techniques to show consistent intra- and inter-brain differences in a joint auditory-motor task. These findings suggest that the sensitivity of RQA to stability of oscillatory neural activity might lend the technique to more fine-grained characterization of non-linearities in neural dynamics in a variety of behaviors and participant populations.

Abstract

Despite constantly using energy and having extensive interactions with household appliances, people consistently mis-estimate the amount of energy that is used by home appliances. This poses major problems for conservation efforts, while also presenting an interesting case study in human perception. Since many forms of energy used are not directly perceptible, and since the *amount* of energy that is being used by an appliance is often difficult to infer from appearances alone, people often rely on cues. Some of these cues are more reliable than others and previous literature has investigated which of these cues people rely on. However, past literature has always studied these proximal cues in isolation—despite the fact that, during real-world perception, people are always integrating a variety of cues. Here, we investigate how people rely on a variety of cues, and how individual differences in the reliance on those cues predicts the ability to estimate home energy use.

Keywords: energy; perception; estimation; home appliances; multi-dimensional scaling

Introduction

Despite its importance in the face of catastrophic climate change, energy and energy use are not well or widely understood by the public. For many home appliances, we have only indirect access to the appliances' energy use and energy units are difficult to understand. However, people frequently make choices as energy consumers: When should I turn off the lights? For how long should I take a hot shower? To what temperature should I set the thermostat? These daily decisions all depend on a perception of energy use. Given people's poor understanding of energy use and the difficulty of perceiving energy use, how do people make these daily decisions about using energy?

In some contexts, people have access to explicit information about appliances' energy use. For instance, some smart meters are digital devices that indicate, in real time, how much energy is being used by an appliance; other appliances may have labels indicating their average energy use (e.g., "Energy Star" labels on efficient appliances). However, explicit information about energy use is the exception, not the rule.

In the absence of direct, explicit information about energy use, people must rely on indirect indices of energy use. (For reference on similar work done in the HCI community see He, Greenberg, and Huang, 2010 and Heller, Konstantinos, Borchers, 2013.) Vacuums are noisy. Lightbulbs are luminous and sometimes hot. It is these observable features that are typically available to individuals when they are making decisions about their energy use. Some of these cues, however, are more reliable than others. For instance, generating and extracting heat requires a lot of energy; mechanical movement, while perhaps more perceptually salient, can be accomplished with far less energy. Good judgements and decisions about energy use, therefore, requires a good sense of which proximal cues to rely on, and which to ignore. Understanding and improving these judgments can translate to energy conservation, as illustrated by the conservation benefits of in-home smart devices that give real-time feedback on energy-use (Darby, 2006; Delmas, Fischlein, & Asensio, 2013), although these energy technologies may be years away from becoming mainstream.

Past work on situated perception and decision making has advocated for similar approaches to understanding how people make judgments about entities that cannot be perceived directly. For instance, Brunswick (1956) proposed a "lens model" of perception, in which people must integrate across proximal cues in order to decide whether some target entity or property exists in the world; on this account, learning to perceive correctly involves learning how best to weight these different cues, so that more reliable cues (i.e., those that most often co-occur with the target phenomenon) are weighted more. A similar perspective has been advocated by researchers in the Judgement and Decision Making world, who have argued that, for many difficult decisions, people deploy 'replacement heuristics' — relying on some simpler or more easily perceived property or feature to make decisions about some target phenomenon that is more complex or difficult to perceive (Kahneman & Frederick, 2002). On all these approaches, understanding how people make complex perceptual judgments about 'invisible' entities, such as energy use, requires understanding the proximal cues or features they are relying on.

A number of past studies have tried to do exactly that. Previously, in the energy literature, different replacement heuristics have been studied. Past work has suggested that novices base their estimates of home energy use on perceptions of appliances' size (Cowen & Gatersleben, 2017), frequency of use (Schley & DeKay, 2015), effect on temperature (heating or cooling) (Attari, DeKay, Davidson, & de Bruin, 2010), and type of appliance (Lesic, Bruin, Davis, Krishnamurti, & Azevedo, 2018). But these past studies have focused on a single dimension

of experience (e.g., size), in isolation from the many other features which that dimension may be correlated (e.g., frequency of use). As a result, we still do not know how people weight the range of features to which they have access, or whether there is one or a subset of features that are driving most of people's energy estimates.

Moreover, all these approaches share the prediction that *better* judgements will involve better weighting of proximal cues. How do individual differences in weighting these features relate to individual differences in estimation ability?

Here, we attempt to answer these three outstanding questions: Which features are people relying on to make energy estimates? How do individual differences in cue-weighting relate to estimation skill? And how can we capture people's feature representation of appliances in a way that accounts for correlations among features?

In the following studies, we first surveyed participants for the most important or relevant features of energy in home appliances. We then took the most frequently cited features and used them to create feature rating scales for participants to rate multiple home appliances along. A multiple regression was performed on a few theoretically-driven features to determine how they competed with one another. Multi-dimensional scaling (MDS) was performed on all the features to capture the structure in how people perceive appliances and their energy use.

By performing these analyses on multiple features at once, we can establish which features matter *most* in the larger context of available appliance features. We also hope to paint a more clear and nuanced — and thus complete — picture of how these features are combined with one another. MDS affords us a look at categories of appliances that emerge and have implications for why some categories matter. These targeted analyses in concert with the larger picture of appliance feature perception, will hopefully inform future projects on how to help people better understand and use energy (Marghetis, Attari, and Landy, under review).

Methods

Participants

We recruited adults (N = 299) from the United States through Amazon Mechanical Turk, an online labor market that has been used previously for online studies. Each subject participated in return for $5. Only the data from those participants who completed the entire study were analyzed ($N = 261$). We also removed participants who repeated the exact same response for their estimates of all appliances (n = 1), giving us a final sample of N = 260.

Feature Selection

Participants rated features that were selected based on a previous study with different participants ($N = 17$) in which people were asked to list all features that they would use to estimate an appliance's energy use. On the basis of these free response features, we compiled a list of features that were most frequently cited and most widely applicable to our list of home appliances ($N = 13$, see Appendix).

Procedure

Participants first completed a feature rating task, in which they were presented with typical home appliances ($N = 36$) and asked to judge each appliance in terms of a set of perceptual or experiential features (e.g., brightness, loudness). They were first instructed "For each question, [to] please imagine a typical version of that appliance *while it is in use* and answer accordingly." The survey was organized by feature. For each feature, e.g. "How loud is each appliance?", participants were given a Likert scale from 1-10 as well as a Not Applicable box for each appliance. Both appliances and features were presented in a random order. Participants supplied ratings for the following features: how frequently the appliance is used, how big the appliance is, how long the appliance is used, how much light the appliance produces, how much the appliance heats itself/its environment, how much sound it makes, how much water it uses, how much it cools itself/its environment, how big its motor is, how much it heats water, how complex its software is, how complex its internal electronic components are, how complex its internal mechanical components are, how much movement it generates in itself/environment. Each participant rated each appliance along each feature dimension, totaling 36 x 13 ratings for each participant.

After the feature rating task, participants were asked to make energy estimates for each appliance. They were given a point of reference: "A 100-watt incandescent light bulb uses 100 units of energy in one hour." Then they were asked to make an estimate for each appliance, "How many units of energy do you think each of the following devices typically uses in one hour?" Appliances were presented in a random order. This task has been used in prior studies to investigate and elicit accuracy in energy perceptions (e.g., Attari et al., 2010).

Analysis

A multiple regressions analysis was run on features that have been identified in past research as important for energy estimation use (Cowen & Gatersleben, 2017; Schley & DeKay, 2015; Marghetis, Attari, and Landy, under review), namely: size, how "electronic" the appliance is, frequency of use, and how much the appliance changes the temperature (i.e., the maximum of the heating and cooling ratings). Feature ratings were z-scored across participants. In a mixed effects model, there were fixed slopes for the interaction of features and feature ratings of every participant, random intercepts on every appliance, and random slopes on feature ratings by participant. The random slopes for every participant's ratings were extracted and used to investigate individual differences in energy estimating accuracy.

Results

What proximal cues do people use to estimate appliances' energy use?

We first zoomed in on those features that have been identified, in past literature, as playing a role in novice's judgements of home energy use. These included how frequently the appliance is used, how "electronic" the appliance is, how much the appliance changes the temperature (the max of the 'heat' and 'cool' ratings), and how large the appliance is. Using a linear mixed effects model, we predicted participants' energy estimates (log transformed) using these four features, with random intercepts and slopes for participants, and random intercepts for appliances. Feature ratings were z-scored within each participant. See Figure 1 for coefficient estimates of reliance on these proximal cues.

Participants' estimates of appliances' energy use were driven almost entirely by how large they judged the appliance to be (b = 0.10 ± 0.01 SEM, p<.001). Most variance in estimates is accounted for by differences in *size*. By contrast, people's judgments of how much the appliance changed the temperature and of how "electronic" an appliance was also had much smaller relations to their energy estimates (b = 0.04 ± 0.01 SEM, p<.001, b = 0.05 ± 0.01 SEM, p<.001). Critically, we found no relation between judgments of how often an appliance is used and estimates of how much energy it uses — despite past work that has argued that frequency-of-use is used as a 'replacement heuristic' for energy estimation (Schley & DeKay, 2015). Note that people's estimates of energy use were explained primarily by judgments of the appliance's size rather than by how much the appliance changed the temperature, even though heat is a more reliable cue to energy use, because heating and cooling use a lot of energy.

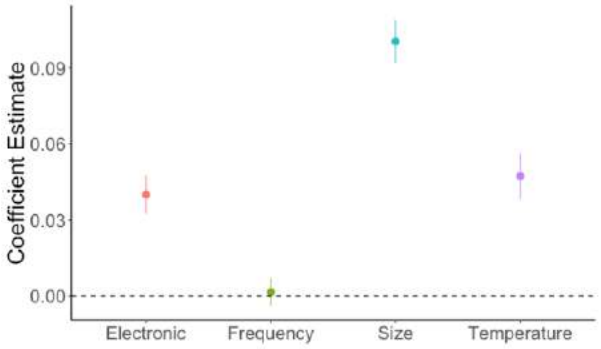
Individual differences in the use of proximal cues to estimate home energy use

We next investigated individual differences in the features that were associated with energy estimates — that is, we asked whether some people relied more on some proximal cues (e.g., size) than on others (e.g., temperature change).

	Size	Electronic	Frequency **of use**	Tempe**rature** Change
Size	1.00	0.183	0.066	0.215
Elect.		1.00	0.103	-0.131
Freq.			1.00	0.023
Temp.				1.00

Table 1: Correlation matrix of key features

Figure 1: Reliance on proximal cues to estimate energy use. Points indicate coefficient estimates from a mixed-effects model of energy estimates. Error lines indicate standard errors.

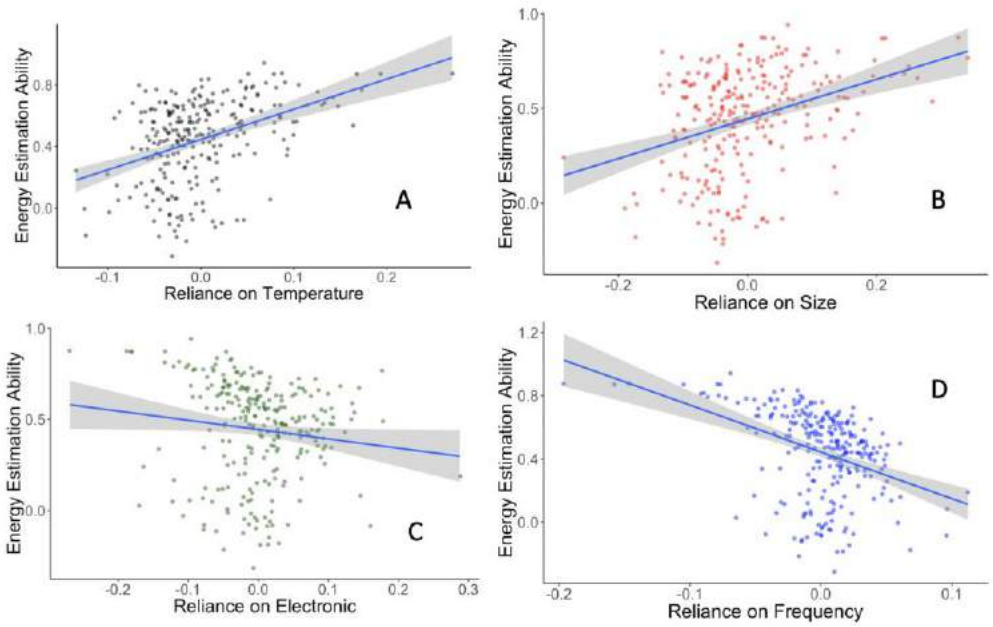


To capture these individual differences, we used the random by-participant slopes from our mixed effects model of energy estimates; for each participant, therefore, we had four random slopes, one for each feature (size, frequency-of-use, temperature change, and electronic-ness). Positive values of these random slopes indicate that a participant relies on that feature more than the group average; negative values indicate that they rely on that feature less than average.

In general, there was considerable variability in how strongly these features were associated with individuals' energy estimates (Fig. 2, panels A, B, C, and D). Some individuals' energy estimates were explained primarily by their judgments of the frequency of an appliance's use, despite the fact that frequency of use is a poor proxy for energy use. Others, however, appeared to ignore frequency and instead relied on temperature change, a reliable cue to energy use. Indeed, participants who relied more on temperature change tended to rely less on frequency of use (R = -0.60). Size and temperature change, both fairly good proxies for energy use, were highly correlated (R = 0.95), suggesting that people who use one feature to evaluate appliances' energy use are also likely to use the other.

All this together suggests that individual difference in the reliance on proximal cues might be associated with variability in how *good* people were at estimate home energy use. To quantify individual differences in estimation ability, we calculated, for each individual, the correlation between their estimates and the true energy used by each appliance. As predicted, participants who relied more on how much an appliance changed the temperature were also, overall, significantly better at estimating home energy use (b = 1.97 ± 0.27 SEM, p<.001); the same held for participants who relied more on the appliance's size, though to a lesser degree. Indeed, past work has found that lay people reliably underestimate the energy used by large appliances that heat or cool (Attari et al, 2010); here, our results suggest that there may be important variability in people's sensitivity to appliances' size and temperature change (Fig. 2A, 2B). By contrast, participants

Figure 2: Energy estimation ability as predicted by reliance on select features



who relied more on electronic-ness and frequency-of-use were overall worse at estimating home energy use (b = -0.51 ± 0.24 SEM, p<.05, b = -2.96 ± 0.43 SEM, p<.001). We also ran a correlation on the participants' reliance on each of these four features (Table 1). We found reliance on frequency of use and electronic-ness to be positively correlated, while frequency of use and temperature change were negatively correlated.

Characterizing the complex structure of the full appliance space

Finally, we combined ratings of all thirteen features (e.g., size, brightness, movement, etc.) to characterize lay perception of home appliances. To do so, we used multi-dimensional scaling (MDS). This technique takes the similarity between paired appliances and uses that to generate a reduced dimensional representation that captures how similar or different appliances are to each other. This approach gets at the rich structure that exists in how people perceive appliances as varying along multiple dimensions, many of which covary with each other. This approach is also necessary, because when dimensions are treated as independent, classic approaches like multiple regression do not account for collinearity of dimensions.

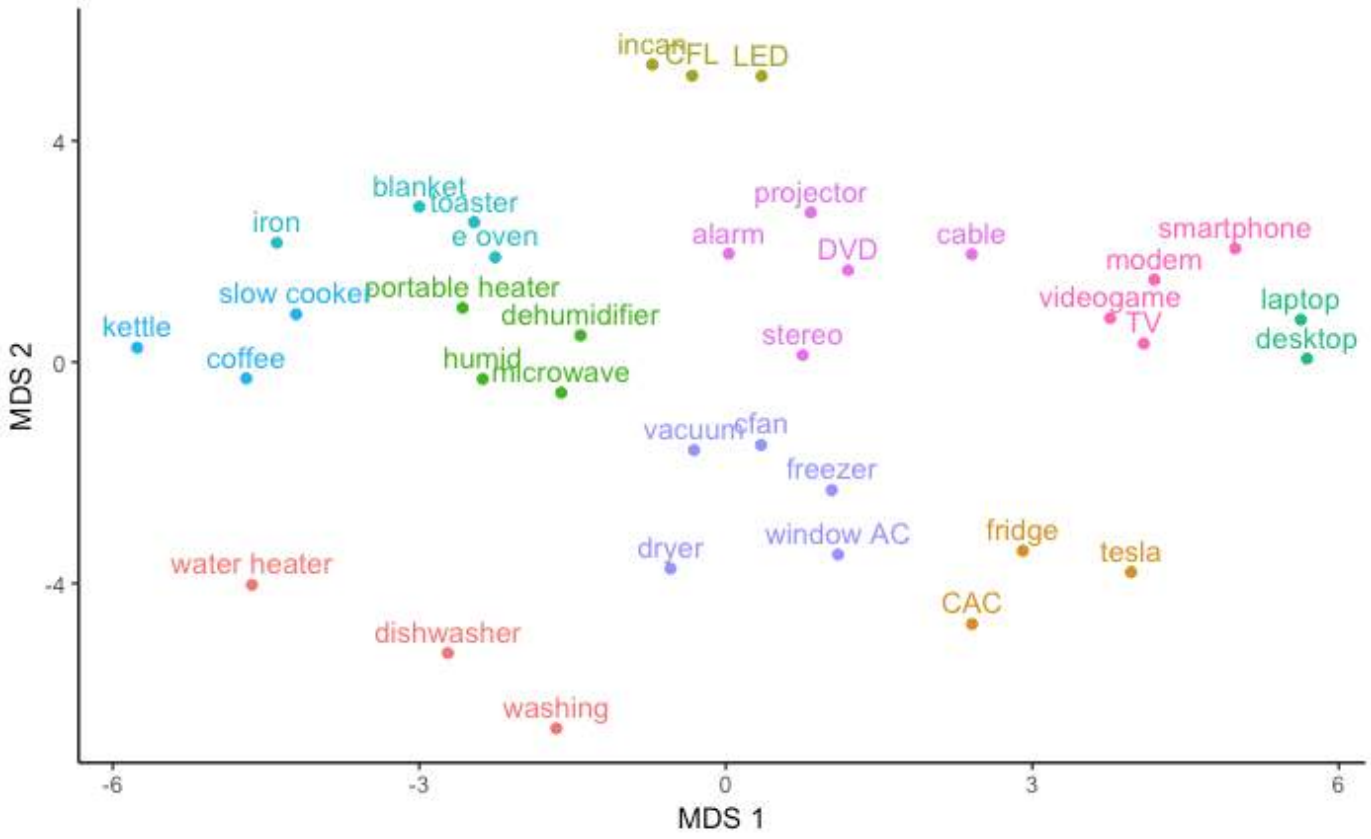
The two-dimensional MDS solution is illustrated in Figure 3. Note the rich structure that emerges bottom-up from this approach, with some appliances clumping together into meaningful groups, with related appliances clustering together into meaningful categories. We used k-means clustering (k=8) to capture these categories (Fig. 2). For example, all the light-bulb appliances (i.e. incandescent lightbulbs, Compact Fluorescent Light bulb, and LED bulb) group together because people rated those appliances very similarly.

While this MDS solution can characterize people's mental representations of appliances, it is blind to people's estimates of the appliances' energy use. However, when we regressed the MDS dimensions onto estimation ability, we found both MDS axes were related significantly to energy estimates increase (dimension 1: b = 146.88 ± 67.5 SEM, p<.05; dimension 2: b = -254.68 ± 104.0 SEM, p<.05). This was true despite the fact that these MDS dimensions combine multiple experiential features in complex, non-linear ways. Thus, lay people have structured perceptions of appliances, and these perceptions seem to relate systematically to their perceptions — and misperceptions — of their energy use. Future work should try to leverage this to improve energy decisions and behaviors.

Discussion

We began by asking how it is that people are able to estimate the energy used by appliances, when that energy use is often hidden. We found that estimates of appliances' size accounted for most of the variance in people's energy estimates. People relied, to a lesser extent on temperature change and how "electronic" an appliance, but they did not rely on frequency of use as a cue. Previous literature has claimed that all these features matter. Our results put those findings in a new light because we found that size is the primary driver of energy estimates. Since these replacement cues correlate, previous findings such as 'people use frequency of use as a replacement

Figure 3: Two-dimensional MDS solution for home appliance space



heuristic' might indicate that people tend to use bigger appliances more often. Interestingly, people relied more on size than heat, despite heat being a better indication of energy use. Heating (and cooling) both take a lot of energy but are perhaps not as obvious to people because the energy used to heat (and cool) are often used to achieve homeostasis. Your heating bill is high in the winter because so much energy has to be exerted to maintain your home at a constant temperature.

When we examined individual differences in the reliance on these cues, we found that the degree to which people relied on certain features predicted how good their energy estimates were. People who relied more on temperature change had better energy estimates than people who relied more on size, or any of the other theory-driven features used in our model. The more participants relied on how "electronic" an appliance was or on frequency of use, the worse their energy estimation ability was. When we ran a correlation on individual differences of reliance, we found that reliance on frequency is negatively correlated with reliance on temperature change. We also found that reliance on frequency is positively correlated with reliance on electronic-ness. This suggests that teaching people to use these more reliable cues may have benefits for energy judgments and decisions (Marghetis et al., under review).

Using multi-dimensional scaling, we also sought to characterize the public's mental representation of home appliances. This bottom-up approach found significant structure in people's perceptions of appliances; moreover, this two-dimensional representation was related systematically to people's energy estimates. In Fig. 3, the upper-left quadrant of the graph seems to include all the appliances that heat water, while the lower-left quadrant includes the appliances that heat without water. This suggests that this two-dimensional MDS solution has picked out *heat* as a notable component of one of its major axes. The appliances near the top of Fig. 3 are quite small and increase in size as you go down the MDS 2 axis, suggesting that this MDS solution has picked out size as a major component of its other axis. It is quite notable that even just a two-dimensional solution has, in a bottom-up way, picked out the two most useful and frequently used replacement heuristics. The clustering as shown in Fig. 3, also created through the bottom-up k-means algorithm, is quite remarkable as well. Kitchen appliances that heat water have clustered together on the left (blue); devices that are electronic or involved in entertainment have clustered together on the right (pink and green); appliances that heat or cool and move air around have also clustered together in the middle of the figure (purple). These clusters suggest that this MDS solution is a fruitful way to access the internal structure of people's complex perceptions.

Conclusion

We set out to answer three main questions. The first was 'Which features are people relying on to make energy estimates?' The answer to this is not simple. Our MDS solution shows that people rely on a complex and correlated set of proximal features. However, when comparing a smaller set of theoretically important features, size far outstrips any of them. Among the features we examined, people seem to rely most on size, even though it is not the best indicator of energy use. The best indicator of energy use was heat or temperature change.

We also set out to answer how individual differences in cue-weighting relate to estimation skill. Fig. 2A shows that as people rely on heat as a cue, their estimation skill improves. This is true to a lesser extent of size as well (Fig. 2B). As people rely on how electronic an appliance is, or how frequently it is used, their estimation skill decreases (Figs. 2C, 2D).

Finally, we set out to capture people's feature representation of appliances in a way that accounts for correlations among features. With an MDS solution, we found that meaningful clusters of appliances emerge, even from bottom-up clustering methods, and that the dimensions of this representation were related systematically to estimates of energy use.

This study speaks to previous energy literature that has attempted to identify the most predictive cue of people's energy estimates. By looking at several cues at once while accounting for correlations, we can say with confidence that despite the many, many features to choose from, the size of an appliance matters to people.

People do rely on the superficial cues about energy that they have access to. It is important to understand which of these people most rely on, so that we can more deeply understand how people understand and choose to use energy. Good energy choices can be encouraged in a variety of way, including but not limited to top-down policies, market-based incentives, extensive educational programs, home energy audits, and new home technologies. For example, in-home smart devices that give real-time feedback on energy-use can encourage energy conservation (Darby, 2006; Delmas et al., 2013). But implementing effective climate policies is politically difficult (Dietz, Ostrom, & Stern, 2003), home audits require time and resources that make scaling up nearly impossible, and new in-home energy technologies may be years away from mainstream use.

By understanding, and eventually changing either the cues people have access to, or their perceptions, we hope to encourage better ways of communicating energy information and making possible good and widely usable energy consumption habits.

Abstract

What drives people's exploration in complex scenarios where they have to actively acquire information? How do people adapt their selection of queries to the environment? We explore these questions using Entropy Mastermind, a novel variant of the Mastermind code-breaking game, in which participants have to guess a secret code by making useful queries. Participants solved games more efficiently if the entropy of the game environment was low; moreover, people adapted their initial queries to the scenario they were in. We also investigated whether it would be possible to predict participants' queries within the generalized Sharma-Mittal information-theoretic framework. Although predicting individual queries was difficult, the modeling framework offered important insights on human behavior. Entropy Mastermind opens up rich possibilities for modeling and behavioral research.

Introduction

Humans are curious animals. From learning how to speak to launching rockets into space, exploration drives mankind's progress small and large. Human exploration has been studied in self-directed learning paradigms in adults and children, in domains including causal learning (Bramley, Dayan, Griffiths, & Lagnado, 2017), categorization (Meder & Nelson, 2012), control (Osman & Speekenbrink, 2012), and explore-exploit tasks (Wu, Schulz, Speekenbrink, Nelson, & Meder, 2018). Some experiments have used games including Battleship (Gureckis & Markant, 2009) and 20 questions (Nelson, Divjak, Gudmundsdottir, Martignon, & Meder, 2014). Self-directed learning can lead to improved performance (Gureckis & Markant, 2012; Markant, Ruggeri, Gureckis, & Xu, 2016). For instance, participants actively intervening on a causal system made better inferences about the underlying causal structure than subjects who received identical information passively (Lagnado & Sloman, 2004).

Recent conceptual work (Coenen, Nelson, & Gureckis, 2018; Gureckis & Markant, 2012; Schulz & Gershman, 2019) is underpinned by the assumption that behavior is goal-directed and that people select observations based on a metric of usefulness (Settles, 2009). What metric best predicts how people evaluate the usefulness of possible queries? Past work has focused on the expected reduction of uncertainty, the extent of predictions' improvement, or the maximization of future rewards (Nelson, 2005). One study optimized experimental materials to maximally distinguish between different measures in an experience-based probabilistic classification task (Nelson, McKenzie, Cottrell, & Sejnowski, 2010). Results showed that participants were better described by probability gain than by information gain or other measures.

Markant and Gureckis (2012) tested whether participants maximize payoffs or information gain in a game of "battleships" (Gureckis & Markant, 2009), where each query cost money and an attempt to maximize utility would lead to different queries than information-gain based strategies. Surprisingly, participants' sampling behavior was nonetheless best matched by information gain. The authors argued that using information gain would lead to more knowledge about the underlying structure and therefore can be an effective strategy, no matter what the final task will be. Similar results have been obtained in an active causal learning task (Bramley, Lagnado, & Speekenbrink, 2015).

Exploiting the characteristics of the Entropy Mastermind game, we investigate people's sensitivity to the information structure of their environment (mathematical entropy or psychological uncertainty) and adaptive strategy selection when facing different levels of probabilistic uncertainty. In particular, we focus on what information metrics best predict how people evaluate the usefulness of possible queries, and on what initial-guess strategies people use.

A quintessential game of exploration

In the Mastermind code-breaking game, both information search and exploitation are essential for breaking the code. Thus, Mastermind offers a potential platform for bringing together pure information models (like expected information gain) and reinforcement learning models. In the classic two-player version of the game one player generates a secret colour code (e.g. blue, red, green) and the other player has to guess the secret code by repeatedly testing codes (making queries) and receiving feedback about the correctness of items in the guessed code. Although Mastermind has been extensively studied in computer science (for references see Berghman, Goossens, & Leus, 2009; Knuth, 1976), comparatively less work has been done in cognitive science (but see Laughlin, Lange, & Adamopoulos, 1982; Zhao, van de Pol, Raijmakers, & Szymanik, 2018).

We introduce the game "Entropy Mastermind" for studying exploration-driven problem solving and uncertainty reduction (Fig. 1). Key attributes of Entropy Mastermind, which distinguishes it from the classic game, are that Entropy Mastermind is a single-player app-based game in which hidden codes are drawn from known, and typically nonuniform, probability distributions. The probability distribution from which the hidden fruit code is drawn is depicted as a "fruit bowl" icon

array. The player is informed that the items are mixed before each draw, and drawn with replacement to form the hidden fruit code. Thus, Entropy Mastermind makes it possible to research how the level of entropy affects people's strategies and efficiency in game play.

As a first step toward modeling behavior in a probabilistic framework, we use a model that values both maximizing the probability of a correct query and a curiosity bonus, similar to recent work on human reinforcement learning (Schulz, Konstantinidis, & Speekenbrink, 2018; Wu et al., 2018). The curiosity bonus can be defined as information gain in the space of possible hypotheses (hidden codes). Whereas information gain has traditionally been thought of as reduction in Shannon entropy, any entropy metric could be used. We use the Sharma-Mittal space of entropy measures (Sharma & Mittal, 1977), which provides a framework within which many different kinds of entropy measures arise. According to the setting of two parameters, known as the *order* and *degree*, this entropy space can recover Shannon entropy, Bayes's error, and entropies from the Arimoto, Rényi and Tsallis families of entropy measures, among others (Crupi, Nelson, Meder, Cevolani, & Tentori, 2018). One of our research questions is whether Entropy Mastermind can help identify which model of uncertainty best predicts exploratory behavior.

In what follows, we formally define the Sharma-Mittal space as a unifying framework for information gain measures. We then report a preliminary study assessing and modeling human behavior in Fruit Salad Mastermind, a version of Entropy Mastermind in which the code jar is a fruit bowl and items are different kinds of fruits. First results show that participants adapted their queries to the level of entropy in the environment, solving games in less entropic environments more efficiently than in more entropic environments. Thus, basic assumptions for using Entropy Mastermind as a model of an information environment varying in entropy were met. Both the exploration and exploitation parts of the model were important to account for human behavior. However, distinguishing between different parts of the Sharma-Mittal space turned out to be difficult. Future research could work towards designing tasks that are optimized for the purpose of discriminating among specific entropy models.

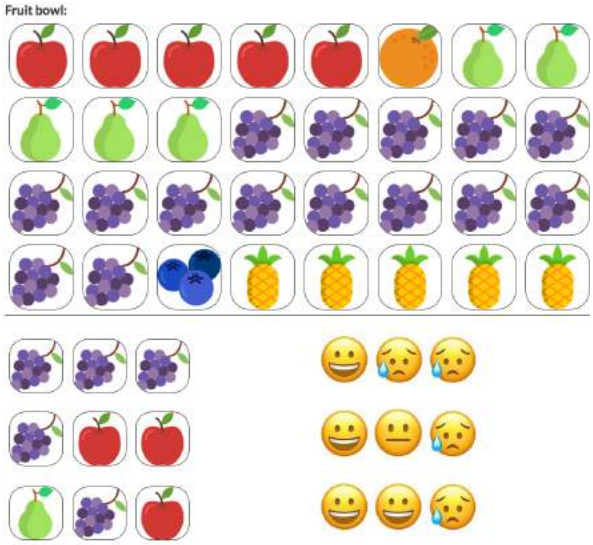

Figure 1: **Fruit Salad Mastermind: High Entropy Condition. Top:** Icon array presenting an example fruit bowl that generated the secret code. Probability distributions follow one of four entropy recipes, resulting in low, medium low, medium high and high entropy levels. Fruit types are apples, oranges, blueberries, grapes, pears, and pineapples for all possible versions of the fruit bowl. Codes are generated by randomly sampling fruits with replacement. Duplicates are allowed, so it is possible that the same fruit could appear in all positions of the hidden code. Players have to guess which fruit is in which position of the three slots of the secret code, by clicking on the position they want to change. Each position is initially blank; clicking cycles through the possible fruits. Once participants are satisfied with the proposed code, they can click on a "Check" button (not shown), and then receive feedback. **Bottom:** History of game play illustrating feedback. In the first guess, the player guessed 3 grape items. The feedback (one smiling face followed by two frowning faces) conveys that exactly one of the items is correct in type of fruit and in location. However, the player does not know which of their guesses is correct. There is no correspondence between the position of the guess and the position of the feedback: happy faces always come first, then neutral and lastly frowning faces. In the second guess, the player tested grape in the first position, and apple in each of the other two positions. The feedback (smiling face, neutral face, frowning face) indicates that one of the items is the correct type of fruit in the correct location, another item is in the code but needs to be moved to a new location, and another item is not in the code at all. As before, the guesser has to figure out which feedback face corresponds to which item in the code. The third guess of pear, grape, apple obtains two smiling faces and one frowning face. At this point the guesser can infer that the middle position is grape, and the final position is apple; the guesser must still figure out the first item.

Mapping the space of exploration

In Mastermind both *learning* about the true code and *guessing* the true code are important. To make this intuitive, suppose that there are two possible codes, given everything that has been learned to date, and that one of these codes has 90% probability of being the correct code. The same information, namely which code is correct, will be gleaned from testing either code; thus, the queries have equal value irrespective of which model of information gain is used. But clearly it is sensible to test the code that has 90% probability of being correct, thus having 90%, rather than 10%, probability of ending the game after the next query. We implement this idea via a softmax response rule on a value function which is based on the probability of each query being the correct code in the immediate time step, as well as a curiosity-driven exploration bonus[1]:

$$P(\text{action} = a_i) \propto P(\text{success}|a_i) + \beta \times \text{curiosity bonus}(a_i) \quad (1)$$

How promising a code seems is determined by its current probability of being correct $P(success|a_i)$. This probability is always the same given a specific history of queries and feedback. The curiosity bonus(a_i) is weighted by a free parameter

[1]Note that the parts of Eq. 1 are additive. Thus, even a query that has a probability of 0 of being the true code can still be chosen if it offers enough informational value.

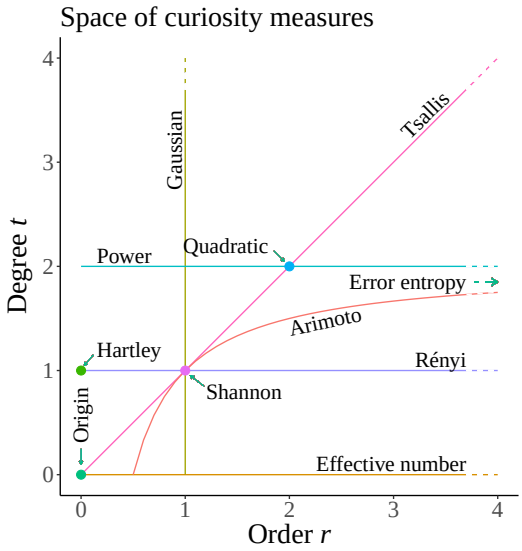

Figure 2: **Sharma-Mittal space.** The Sharma-Mittal family of entropy measures is represented in a Cartesian quadrant with values of the order parameter r and of the degree parameter t. The order parameter captures how much minor hypotheses are disregarded (e.g. that grapes may be contained in the code when the fruit bowl contains only a small proportion of grapes) and the degree parameter captures how prominent the goal of getting as close as possible to the state of certainty is (i.e. how much one strives to falsify existing hypotheses, e.g. that grapes are contained at all in the code). Each point in the quadrant corresponds to a specific entropy measure, each line corresponds to a distinct one-parameter generalized entropy function. Several special cases are highlighted.

β and can be defined as how much an action promises to reduce uncertainty over the space of possible hypotheses (i.e., how much it reduces uncertainty about possible codes).

The uncertainty in a discrete random variable $K = k_1, k_2, \ldots k_n$ can be measured by its entropy. We use the generalized Sharma-Mittal space of entropy measures, that unifies multiple past proposals (Crupi et al., 2018), and can be defined as:

$$\text{entropy}(K) = \frac{1}{t-1}\left[1 - \left(\sum_{i=1}^{n} P(k_i)^r\right)^{\frac{t-1}{r-1}}\right], \qquad (2)$$

where r is the *order* and t the *degree* of the entropy measure. Note that limits, which exist, are used for points where the above equation is undefined. Although the above equation may not be immediately intuitive, there are a number of ways to build understanding about this space. All of the Sharma-Mittal entropy measures can be thought of as quantifying the average surprise that would be experienced if the value of the random variable K was learned. In the case of Mastermind, this is the average surprise that would be experienced if one were to immediately learn the true hidden code.

The degree parameter t governs which kind of surprise is averaged. If $t = 1$, then $surprise(k_i) = ln(1/P(k_i))$, as in Shannon and all of the Rényi entropies. If $t = 2$, then $surprise(k_i) = 1 - P(k_i)$, as in the cases of Quadratic entropy and Bayes's error. If $t > 1$, a test is more useful if it is conclusive than if it is not. If $t < 1$, a test is always less useful if it is conclusive than if it is not. The order parameter r determines what kind of averaging function is used. It can be thought of as an index of the imbalance of the entropy function, which indicates how much the entropy measure discounts minor (low probability) hypotheses. For example, when $r = 0$, entropy becomes an increasing function of the mere number of the possible options. When r goes to infinity, entropy becomes a decreasing function of the probability of a single most likely hypothesis. For further discussion and examples see (Crupi et al., 2018).

Several special cases exist within the Sharma-Mittal space, as Figure 2 illustrates. For example, Shannon entropy is the result of setting $r = t = 1$, and probability gain (also called error entropy) is the result of setting $t = 2$ and letting $r \to \infty$. One of the goals of the present research is to investigate whether people's striving for information (the curiosity goal) can be represented well as a generalized information gain metric, where information is defined as the expected reduction in one of the Sharma-Mittal entropy functions over the probability distribution of the possible codes.

Methods

Participants and Design Forty-seven first-year undergraduate students (38 female, M_{age}=19.04; SD=1.04; range: 18 to 23) at University of Surrey participated in our study as part of a cognitive psychology class. Participants gave informed consent in accordance with the University's procedures and the Helsinki Declaration. They were introduced to the rules and interface of the game and completed a pretest. Participants then played Fruit Salad Mastermind, spending an average of 10.5 minutes on the task.

Materials and Procedure Participants were required to correctly answer four comprehension questions before game play began. These questions tested participants' understanding of the goal of the game and the interpretation of feedback (i.e. making sure that they understood that the position of the faces did not correspond to the position of items in the entered code). Participants were instructed to figure out the secret code using as few guesses as possible. Since the experiment was self-paced, the number of rounds played varied between participants.

Entropy conditions In each game, one of the four entropy conditions was chosen at random and the six fruits were randomly assigned to the six proportions of that condition. The resulting generating "fruit bowl" was presented to participants as an icon array above the current game. A "hidden fruit code" was generated from that distribution. In the *very high entropy* condition, the secret code was sampled based on the proportions $(5,5,5,5,6,6)$. This means, for example, that there could be 5 pineapples, 5 apples, 5 pears, 5 blueberries, 6 grapes, and 6 oranges, out of a total of 32 items, from which three fruits were sampled with replacement to generate the secret code. In the *high entropy* condition, the secret code

was sampled based on the proportions $(1,1,5,5,5,15)$. In the *low entropy* condition, the secret code was sampled based on the proportions $(1,1,1,4,4,21)$. Finally, in the *very low entropy* condition, the secret code was sampled based on the proportions $(1,1,1,1,1,27)$.

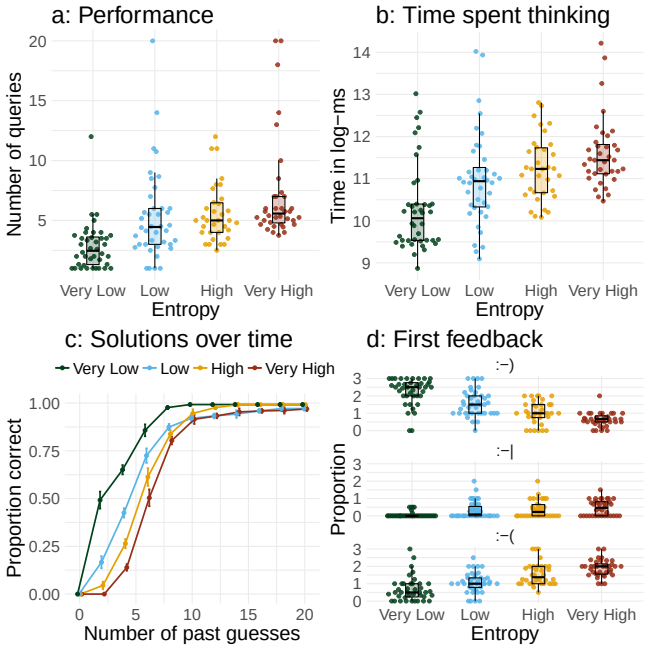

Figure 3: **Behavioral results. a:** Number of queries required to solve a game by entropy condition (ordered from lowest to highest). **b:** Time spent thinking (measured in log-ms per guess) by entropy condition (ordered from lowest to highest). **c:** Proportion of correct guesses in dependency of number of past guesses by entropy condition. **d:** Mean proportional feedback after first guess by entropy condition. Points represent mean per participant. Error bars indicate the standard error of the mean.

Behavioral results

We analyzed behavioral results using both frequentist and Bayesian statistics. For testing hypotheses regarding the behavioral data and the model comparison, we used the default two-sided Bayesian t-test for independent samples with a Jeffreys-Zellner-Siow prior with its scale set to $\sqrt{2}/2$ (Rouder, Speckman, Sun, Morey, & Iverson, 2009).

We first analyzed the number of required guesses to solve a game as a function of the entropy condition (Fig. 3a). This revealed a positive average rank correlation between how much entropy a condition contained and the number of queries participants required to solve a game (Kendall's $\tau = 0.48$, $t(46) = 12.44$, $d = 1.81$, $BF > 100$). More specifically, participants required fewer queries on average for the very low entropy games as compared to low entropy games ($t(46) = -5.69$, $p < .001$, $d = 0.83$, $BF > 100$). They also required fewer queries for the low entropy games than for the high entropy games ($t(46) = -3.16$, $p = .002$, $d = 0.46$, $BF = 11.8$). Finally, participants needed fewer queries for the high entropy games than for the very high entropy games ($t(46) = -3.96$, $p < .001$, $d = 0.58$, $BF = 97.2$).

Next, we analyzed how much time participants spent thinking to enter a guess by entropy condition (Fig. 3b). Thus, we assessed their mean time to submit a query measured in log-milliseconds. There was a positive average rank-correlation between a game's entropy and participants' average time spent thinking, Kendall's $\tau = 0.48$, $t(46) = 12.44$, $d = 1.68$, $BF > 100$. More specifically, participants spent less time thinking during the very low entropy games than during the low entropy games ($t(46) = -4.07$, $p < .001$, $d = 0.59$, $BF = 97.2$). They also spent less time thinking in the low entropy than in the high entropy games ($t(46) = -3.68$, $p < .001$, $d = 0.54$, $BF = 45.5$). Finally, they spent less time in the high entropy than in the very high entropy games ($t(46) = -4.05$, $p < .001$, $d = 0.59$, $B > 100$).

We also analyzed the proportion of solved games as a function of the number of past guesses, again comparing the different entropy conditions (Fig. 3c). We thus estimated a Bayesian logistic regression of number of past guesses onto the proportion of correct guesses for each of the entropy conditions, using Metropolis-Hastings Markov chain Monte Carlo sampling (implemented in `MCMCpack`, Martin, Quinn, Park, & Park, 2018). The resulting posterior estimate for the effect of number of past guesses onto the probability of guessing correctly was smallest for the very high entropy condition ($\hat{\beta} = 0.15$, 95%HDI=[0.14, 0.16]). The same estimate was higher for the high entropy condition ($\hat{\beta} = 0.19$, 95%HDI=[0.18, 0.20]), which did not differ meaningfully from the low entropy condition ($\hat{\beta} = 0.18$, 95%HDI=[0.17, 0.20]). The very low entropy condition showed the highest estimated effect ($\hat{\beta} = 0.30$, 95%HDI=[0.28, 0.33]). Thus, participants' solution rates differed meaningfully between entropy conditions, with lower entropy leading to faster rates.

In our last behavioral analysis, we looked at the very first query participants submitted as well as the feedback they received for that query (Fig. 3d). The number of smiling faces received on the very first guess was negatively rank-correlated with entropy condition, $\tau = -0.51$, $t(41) = -9.80$, $p < .001$, $d = 1.51$, $BF > 100$, whereas the number of frowning faces showed a positive rank-correlation, $\tau = 0.30$, $t(30) = 6.00$, $p < .001$, $d = 1.06$, $BF > 100$. Interestingly, participants adapted their first queries to the entropy condition, leading to a positive rank correlation between the set size of their first query (the number of unique kinds of fruit contained in the query) and the entropy of the generating distribution, $\tau = 0.40$, $t(46) = 9.00$, $p < .001$, $d = 1.31$, $BF > 100$. Put differently, if the generating distribution was higher in entropy, then participants tested a larger number of different fruits as part of their first query.

Computational modeling

We now turn to a model-based analysis of participants' exploration strategies. For this, we first need a formal account of intelligent Mastermind play. Logically, all combinations that are still consistent in round i based on the feedback received so far are part of a feasible set $\mathcal{F}_i$. Note that in Entropy Mastermind, not only the feasible codes but also their prob-

abilities (which are not in general equal) are relevant. Code combinations ruled out by prior feedback have zero probability. The remaining items' probability mass is proportional to the probability of obtaining the item via sampling from the code jar. The effective size of the feasible set is the total number of all non-zero probability codes left in the set. Let the probability that c_i is the hidden code given the current feasible set be denoted $P(c_i)$. The feasible set is guaranteed to shrink after each round unless a guess c_i is repeated. A general playing strategy consists of (i) identifying the set of feasible combinations $\mathcal{F}_i$ (with $\mathcal{F}_0 = \mathcal{E}$), where prior feedback is used to determine which combinations are still viable; and (ii) picking a combination c_i for the next guess. Let us denote the informational usefulness of playing combination c in the current round with $u(c)$, with

$$u(c) = \text{entropy}(\mathcal{F}_i) - \sum_{r}^{\mathcal{R}} P(f) \cdot \text{entropy}(\hat{\mathcal{F}}_{c,f}), \qquad (3)$$

i.e. the difference in entropy (under a particular Sharma Mittal entropy measure with specified order and degree) between the current feasible set and the expected entropy when playing code c. To compute expected entropy, for each possible feedback $f \in \mathcal{R}$, we compute the product of the probability of receiving that feedback $P(f)$ times the entropy of the updated feasible set $\hat{\mathcal{F}}_{c,r}$ when playing combination c and receiving feedback r. To compute $P(f)$ for a given c, we look at all the combinations $c_j \in \mathcal{F}_i$, that lead to feedback f. To this end, we define a feedback function $h(c,c_j) = f$ that returns the feedback f obtained from checking code c against code c_j. The probability of feedback f for code c can then be calculated as follows:

$$P(f) = \frac{\sum_{c_j}^{\mathcal{F}} P(c_j) \cdot \mathbb{1}_{h(c,c_j)=f}}{\sum_{c_j}^{\mathcal{F}} \sum_{c_k}^{\mathcal{F}} P(c_k) \cdot \mathbb{1}_{h(c_j,c_k)=f}}.$$

The indicator function $\mathbb{1}_{h(c,c_j)=f}$ ensures that we only sum over codes c_j that generate the required feedback f. The probability of any combination of fruits $c = m_1 m_2 ... m_n$ can be computed as

$$P(c = m_1 m_2 ... m_n) = P(m_1) \cdot P(m_2) \cdot ... \cdot P(m_n) \qquad (4)$$

where each $P(m)$ represents the probability of sampling the corresponding fruit item from the fruit jar. The other term of Equation 3, entropy$(\hat{\mathcal{F}}_{c,f})$, requires us to compute hypothetical feasible sets $\hat{\mathcal{F}}_{c,r}$. Given the current feasible set $\mathcal{F}_i$, a combination c we want to evaluate, and hypothetical feedback f, we need to exclude all combinations $c_j \in \mathcal{F}_i$ for which $h(c,c_j) \neq f$; that is, all combinations c_j that are not consistent with obtaining feedback f.

Lastly, one has to assign a utility to a feasible set $\mathcal{F}$. For this, we use the Sharma-Mittal entropy framework to compute the entropy of a probability distribution defined over set $\mathcal{F}$, $P_{\mathcal{F}}(c)$. For each combination $c \in \mathcal{F}$

$$P_{\mathcal{F}}(c) = \frac{P(c)}{\sum_{c_j}^{\mathcal{F}} P(c_j)},$$

where the nominator $P(c)$ is computed according to Equation 4 and the denominator is a normalization term.

We assess how well the combination of an entropy-based exploration bonus and the probability of making a correct guess describes players' guesses over time. For this, we analyzed the last five games of the 34 participants who played at least five games in total. We restricted our analysis to the last five games as our goal was to study strategies used rather than early learning. Next, we calculated the expected information gain for all of the $6 \times 6 \times 6$ possible fruit combinations that a participant could enter on every trial for each participant, given the participant-specific history of queries in a game. We calculated this information gain for every combination of order $r = [1/16, 1/8, 1/4, 1/2, 1, 2, 4, 8, 16, 32, 64]$ and degree $t = [1/16, 1/8, 1/4, 1/2, 1, 2, 4, 8, 16, 32, 64]$, i.e. 121 models per participant in total. We then combined the probability of a guess being correct with the information gain assessed by the specific entropy measure following Equation 2 to arrive at a value of an action's usefulness $V(a_t)$, which we put in a softmax function to calculate choice probabilities:

$$P(x) = \frac{\exp(V(a_t(\mathbf{x}))/\tau)}{\sum_{j=1}^{N} \exp(V(a_t(\mathbf{x}))/\tau)} \qquad (5)$$

where τ is a free temperature parameter. We followed previous work (Wu et al., 2018; Parpart, Schulz, Speekenbrink, & Love, 2017) and calculated each model's AIC$(\mathcal{M}) = -2\log(L(\mathcal{M})) + 2k$ and standardized it using a pseudo-R^2 measure as an indicator for goodness of fit, comparing each model $\mathcal{M}_k$ to a random model: $\mathcal{M}_{\text{rand}}$, $R^2 = 1 - \text{AIC}(\mathcal{M}_k)/\text{AIC}(\mathcal{M}_{\text{rand}})$.

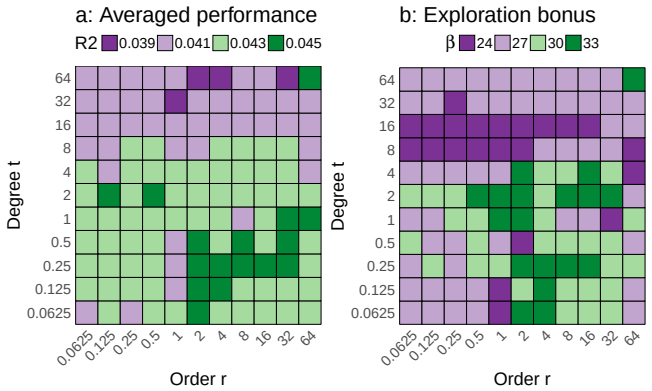

Figure 4: **Modeling results. a:** Averaged r^2 for different Sharma-Mittal parameters. **b:** Estimated exploration bonus β for different Sharma-Mittal parameters.

The results of this analysis revealed a mean pseudo-R^2 of 0.041 over all orders and degrees, which was low but significantly better than chance ($t(33) = 20.52$, $p < 0.001$ $d = 1.86$, $BF > 100$). Moreover, the estimated median temperature parameter was $\tau = 1.02$, indicating a relatively wide spread of

predictions. There was a significant negative rank-correlation between the degree parameter and model fit, $\tau = -0.37$, $z = -5.84$, $p < .001$, $BF > 100$, whereas this correlation was not significant for the order parameter, $\tau = 0.04$, $z = 0.60$, $p = .54$, $BF = 0.3$. Thus, even though entropies with smaller degree parameters seemed to generally work better at modeling participants' queries, there was no meaningful effect of the different order parameters.

The range of pseudo-R^2 values, $0.038 - 0.045$, also shows that most of the entropy measures led to similar performance. We also assessed the magnitude of the estimated exploration bonus β (Fig. 4b), which had a mean of $\hat{\beta} = 27.81$, and therefore differed significantly from 0, $t(33) = 115.47$, $p < .001$, $d = 10.9$, $BF > 100$. This means that the final model of participants' game play had to incorporate both a code's probability of being correct as well as its potential information gain. Interestingly, areas of the Sharma-Mittal space with higher r^2 also tended to have higher β estimates.

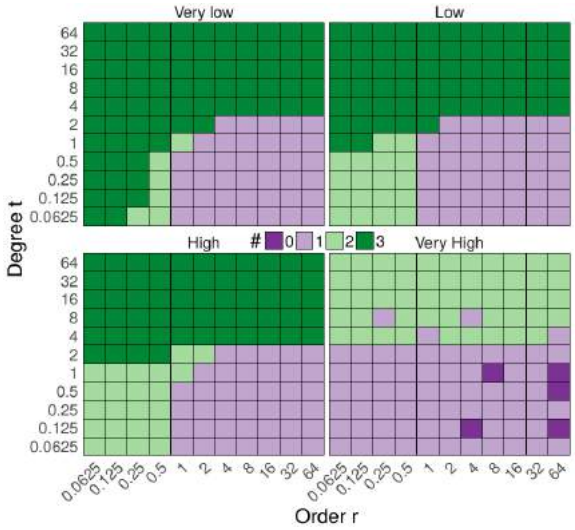

Figure 5: **Number of times the most likely fruit was chosen in the first query by simulated entropy models across entropy conditions.**

Finally, we compared how often participants put the most likely fruit into their first query with how often simulated models of different order and degree parameters chose the same fruit in their first query, for each entropy condition (see Fig. 5). The higher degree models chose the most likely fruit more often than people did. Specifically, participants put on average 2.14 of the most likely fruit in their first query in the very low entropy condition, 1.60 in the low entropy condition, 1.26 in the high entropy condition and 0.48 in the very high entropy condition. This analysis therefore corroborated our previous finding that the lower degree entropies better matched participants' queries. In relation to previous work modeling behavior with the Sharma-Mittal framework, Entropy Mastermind appears to be more similar to experience-based than to description-based probabilistic classification tasks (see Crupi et al., 2018, Fig. 7).

Discussion and conclusion

We introduced Entropy Mastermind as a game for researching human curiosity and exploration in complex environments. More specifically, we suggest this game as a paradigm for the study of how people select queries to reduce uncertainty under different levels of initial entropy. The complexity of the game resembles aspects of scientific inference (Strom & Barolo, 2011) and life. For instance, in life and in science, it can be a challenge to fully assimilate feedback that we get when we make queries. Entropy Mastermind thus complements existing games, such as Battleship (Gureckis & Markant, 2009), 20-questions (Nelson et al., 2014), or explore-exploit (Wu et al., 2018) tasks.

We found that participants required fewer queries, spent less time thinking about queries and showed faster learning rates if the distribution generating the secret code had lower entropy. They also adapted their queries to the code-generating distribution, and did so in sensible ways. In particular, many of the informational models (Figure 5) used greater proportions of the most-probable fruit in the first guess in lower-entropy conditions; participants also followed this pattern. Thus, one may conclude that people are generally sensitive to different levels of entropy, which is a prerequisite for a research agenda modeling human exploratory behavior within the Sharma-Mittal space.

Our modeling results paralleled earlier findings from other tasks (Crupi et al., 2018) suggesting that it is easier to identify the value of the degree parameter than of the order parameter in the Sharma-Mittal space. Interestingly, to identify the order parameter a different type of question could be asked, translating higher entropy into difficulty of game play in the sense of the number of queries required to guess the secret code (for the underlying mathematical result see Crupi et al., 2018). Participants could be directly asked which of two code jars would be harder to play Mastermind with (Figure 6).

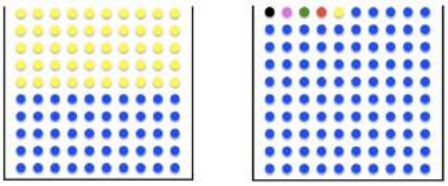

Figure 6: **Identifying the order parameter.** Which distribution is harder for playing Entropy Mastermind? Shannon entropy (order=1) deems the 50:50 distribution higher entropy, but lower-order entropies deem the 95:1:1:1:1:1 distribution higher entropy.

The general predictive performance of many models was relatively similar and rather low. This might be due to the overall complexity of choices, since there were 216 possible options on every trial, making it difficult to compare among candidate models (also see Parpart et al., 2017).

The difficulty of modeling could also be due to participants using cognitive shortcuts, as has been observed in other domains of active learning (Bramley et al., 2017). Furthermore, it is unlikely that participants evaluate the usefulness of all possible queries at each time point. Instead,

they might approximate a query's usefulness by sampling and reusing past hypotheses, as has been shown in other domains of human reasoning and hypothesis evaluation (Dasgupta, Schulz, & Gershman, 2017; Dasgupta, Schulz, Goodman, & Gershman, 2018; Lieder, Griffiths, & Hsu, 2018). Future studies should therefore investigate both heuristic strategies (Gigerenzer & Gaissmaier, 2011) and boundedly rational approaches (Griffiths, Lieder, & Goodman, 2015). Adaptive experimental designs (Cavagnaro, Myung, Pitt, & Kujala, 2010) could also be used to maximally discriminate among models.

Summing up, we propose Entropy Mastermind as a promising paradigm for investigating human exploration behavior in complex hypothesis testing scenarios. In related research we are assessing whether Entropy Mastermind can be used as an educational tool for primary or secondary school students, and for studying the effects of emotional states on strategies used and information search efficiency. Although our current modeling framework did not fully map out the space of exploration behavior, we believe that combining the Sharma-Mittal space of entropy measures with an enjoyable game rich in scientific history can further inform our theories of self-directed learning. We will keep exploring.

Speaker-specific adaptation to variable use of uncertainty expressions

Sebastian Schuster and **Judith Degen**
{sebschu, jdegen}@stanford.edu
Department of Linguistics, Stanford University
Stanford, CA 94305, USA

Abstract

Speakers exhibit variability in their choice between uncertainty expressions such as *might* and *probably*. Recent work has found that listeners cope with such variability by updating their expectations about how a specific speaker uses uncertainty expressions when interacting with a *single speaker*. However, it is still unclear to what extent listeners form speaker-specific expectations for *multiple speakers* and to what extent listeners are adapting to a situation independent of the speakers. Here, we take a first step towards answering these questions. In Experiment 1, listeners formed speaker-specific expectations after being exposed to two speakers whose use of uncertainty expressions differed. In Experiment 2, listeners who were exposed to two speakers with identical use of uncertainty expressions formed considerably stronger expectations than in Experiment 1. This suggests that listeners form both speaker-specific and situation-specific expectations. We discuss the implications of these results for theories of adaptation.

Keywords: psycholinguistics; semantics; pragmatics; adaptation; uncertainty expressions

Introduction

Speakers exhibit considerable production variability at all levels of linguistic representation (e.g., Liberman, Cooper, Shankweiler, & Studdert-Kennedy, 1967; Weiner & Labov, 1983; Finegan & Biber, 2001). This includes variation in lexical choice to describe a world state. For example, Yildirim, Degen, Tanenhaus, and Jaeger (2016) found that when asked to describe a scene with a candy bowl in which approximately half of the candies were green and half of the candies were blue, some participants judged "Some of the candies are green" to be the more appropriate utterance to describe the scene than "Many of the candies are green", while others displayed the opposite pattern.

Schuster and Degen (2018) found that participants exhibit similar production variability when describing an event with an objective event probability of 60%: Some participants judged the event to be best described with a sentence containing the uncertainty expression *might* ("You might get a blue gumball") whereas others judged a sentence with *probably* ("You'll probably get a blue gumball") more appropriate.

Such variability poses a challenge to a listener who aims to know what the world is like that the speaker is describing. When confronted with two speakers who use the same expression to convey different states of the world or who use different expressions to convey the same state of the world, listeners are doomed to draw the wrong inferences about the actual state of the world unless they track how individual speakers use language. Recent work suggests that listeners deal with this kind of variability by adapting to it (e.g., Norris, McQueen, & Cutler, 2003; Kraljic & Samuel, 2007; Bradlow & Bent, 2008; Kamide, 2012; Kleinschmidt & Jaeger, 2015; Fine & Jaeger, 2016; Roettger & Franke, submitted) and that in interaction, they learn how speakers choose among alternative utterances. In the domain of quantifiers, Yildirim et al. (2016) showed that listeners update their expectations about how a specific speaker uses the quantifiers *some* or *many* after being briefly exposed to a specific speaker. In line with their results, Schuster and Degen (2018) found that listeners update their expectations of how a specific speaker uses the uncertainty expressions *might* and *probably* to describe different event probabilities after a brief exposure phase. Participants who were exposed to a "*confident*" speaker, who used *probably* to describe the 60% probability event, expected the use of *probably* with a wider range of probabilities; participants who were exposed to a "*cautious*" speaker, who used *might* to describe the 60% probability event, expected the use of *might* with a wider range of probabilities.

The processes that lead listeners to update their expectations during semantic adaptation are poorly understood. In particular, it remains a largely open question to what extent listeners form speaker-specific expectations when interacting with multiple speakers. Some evidence for speaker-specific adaptation comes from the referring expressions literature. Metzing and Brennan (2003) found that participants exhibited a slowdown in resolving referring expressions when a confederate started referring to an object with a new expression after establishing a conceptual pact, but did not find such a slowdown when a new confederate was using a different referring expression than the original confederate.

Most closely related to our work, Yildirim et al. (2016) found that listeners form speaker-specific production expectations after being exposed to two speakers who used different quantifiers to describe a scene with a candy bowl in which half of the candies were green. While this suggests that listeners should also form speaker-specific expectations about the use of uncertainty expressions, there is evidence from other linguistic domains that speaker-specific adaptation is limited to specific items. For example, Kraljic and Samuel (2007) found that listeners adjust their phonemic representations for the fricatives /s/ and /sh/ to multiple speakers whereas lis-

teners adjusted their phonetic representations for stop consonants such as /d/ and /t/ only to the most recent conversational partner. It could therefore be that speaker-specific adaptation in other linguistic domains is also limited to specific items and that listeners do not form speaker-specific expectations for the use of uncertainty expressions.

Further, Yildirim et al. (2016) observed that the adaptation effect was considerably smaller when they exposed participants to two speakers with opposing biases as compared to only exposing participants to one speaker and comparing the adaptation effect between groups. There seem to be two likely explanations for this observation. First, it could be that due to memory limitations, listeners were unable to keep track of the exact statistics of each speaker's utterances. Since everything about the context except the speaker identity stayed constant throughout the experiment, it could be that listeners had difficulty separating their experiences with the two speakers in memory (see Horton and Gerrig (2005) for a similar account of memory limitations affecting audience design). Second, it could be that listeners were tracking the statistics of the individual speakers as well as the overall statistics in the experimental situation and their post-exposure expectations were a combination of their speaker-specific expectations as well as their expectations about the situation.

In this work, we build on the recent work by Schuster and Degen (2018) on adaptation to variable use of uncertainty expressions and take a first step towards investigating the nature of semantic adaptation in response to multiple speakers. In particular, we aim to answer the following two questions:

1. Do listeners form speaker-specific production expectations when they are exposed to speakers whose use of uncertainty expressions differ?

2. Do listeners form situation-specific production expectations independent of speaker identity?

In Experiment 1, we address question 1 by exposing listeners to two speakers whose use of uncertainty expressions differs. In Experiment 2, we expose listeners to two speakers whose use of uncertainty expressions is the same. We compare adaptation effect sizes across experiments to address question 2.

Experimental paradigm

In both of our experiments, we build upon the semantic adaptation paradigm used in Schuster and Degen (2018), which we briefly review here. This paradigm is a classic exposure-and-test paradigm which has been used to study adaptation across several linguistic domains (e.g., Norris et al., 2003; Kleinschmidt & Jaeger, 2015; Yildirim et al., 2016). As shown in Figure 1, each trial shows an adult sitting behind a table with a gumball machine on it. The gumball machine is filled with orange and blue gumballs. Next to the table, there is a child who is requesting a blue or an orange gumball with the utterance "I want a blue/an orange one". Participants are told that the gumball machine is too high up for the child to see and that only the adult can see the contents of the gumball machine.

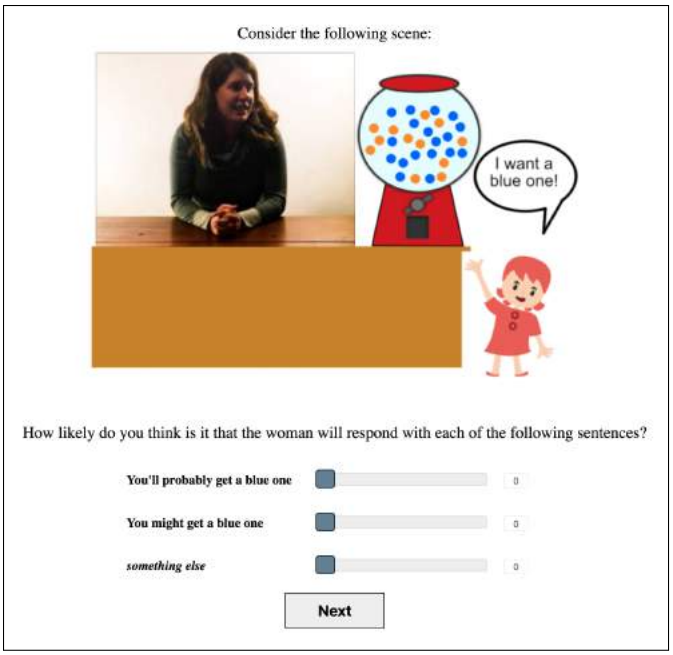

Figure 1: Example post-exposure test trial. On exposure trials the rating scales were absent, and the image of a speaker was replaced by a video of a speaker producing an utterance.

On each exposure trial, participants watch a short video clip in which the adult responds to the child with an utterance like "You might get a blue one". Across trials, the proportion of gumballs as well as the response by the adult vary.

On each test trial (Fig. 1), participants are shown a static scene in which they only see a picture of the speaker from the exposure trials. On these trials, participants are asked to provide ratings of how likely they think it is that the speaker would use the two provided utterances or some other utterance. Across trials, the proportion of blue and orange gumballs as well as the color of the gumball that the child is requesting (the target color) varies.

Experiment 1: Different speaker types

In Experiment 1, we exposed participants to two different speakers who use the uncertainty expressions *might* and *probably* differently. The primary purpose of this experiment was to test whether listeners form speaker-specific utterance choice expectations. Procedure, materials, analyses and exclusions were pre-registered on OSF (https://osf.io/qnspg).

Methods

Participants We recruited 104 participants on Amazon Mechanical Turk. Participants had to have a US-based IP address and a minimal approval rating of 95%, and they were paid $4.75 (approximately $12–$15/hr).

	MIGHT		PROBABLY		BARE	
	n	*p*	*n*	*p*	*n*	*p*
cautious	**10**	**60%**	5	90%	5	100%
confident	5	25%	**10**	**60%**	5	100%

Table 1: Number of exposure trials (n) per utterance (MIGHT, PROBABLY, BARE) and associated proportion of target gumballs (p) in the cautious vs. confident speaker block. Critical trials bolded.

Materials and procedure In the first part of the experiment, participants saw 40 exposure trials in two blocks. As mentioned above, each trial showed a child requesting a blue or orange gumball, a gumball machine with blue and orange gumballs, and a video of an adult male or female speaker. The speaker always produced one of the following six utterances:

- You'll get a blue/orange one (BARE)
- You might get a blue/orange one (MIGHT)
- You'll probably get a blue/orange one (PROBABLY)

The number of trials with each of these utterances as well as the gumball proportions varied across the two blocks (see Table 1 for an overview). Filler trials with the bare form were included to provide evidence that the speaker is generally cooperative. One of the blocks always showed a female speaker and the other block always showed a male speaker. Both speakers were from the East Coast and native speakers of American English. The order of blocks and the speaker assignment to blocks was counterbalanced across participants.

Participants were instructed to watch what the speaker had to say to the child. The video started automatically after a 400ms delay and participants had the option to replay the video as often as they wanted. To advance, participants had to press a button which was disabled until the video had ended.

After the two exposure blocks, participants went through two test blocks. In each of the blocks they saw a picture of one of the two speakers with a gumball machine next to it, and again, a child requesting a blue or an orange gumball. On each trial, participants were asked how likely they thought it was that the adult would respond with MIGHT, PROBABLY or a blanket *something else* option. Participants indicated their expectations by distributing 100 points across these three options using sliders. In each block, participants provided ratings for scenes with 9 different gumball machines ranging from 0% to 100% blue gumballs. For each machine, participants provided four ratings in total, resulting in 36 trials per block. The order of blocks was counterbalanced such that half of the participants saw them in the same order as the exposure blocks whereas the other half saw them in opposite order.

Attention checks To verify that participants were paying attention to the video and the scenes, we included 14 attention checks: after 14 of the exposure trials, participants were shown two different gumball machines and were asked to choose the one they saw on the previous trial.

Exclusions We excluded participants who provided correct responses to fewer than 11 attention checks. Based on this criterion, we excluded 31 participants. We further excluded participants whose utterance ratings for the different event probabilities strongly correlated ($R^2 > 0.75$) with their mean utterance ratings across all event probabilities. This suggests that they provided approximately the same ratings independent of the observed scenes and indicates that they did not pay attention. This led to one additional exclusion. None of the results discussed below depend on these exclusions.

Analysis and predictions Intuitively, a more confident speaker uses PROBABLY for a larger and MIGHT for a smaller range of gumball proportions than a more cautious speaker. Therefore, if participants track these different uses, we expect their ratings of what they think a specific speaker is likely to say to depend on how that speaker used uncertainty expressions during the exposure phase. Following Yildirim et al. (2016) and Schuster and Degen (2018), we quantify this prediction by fitting a spline with four knots for each expression and each participant and computing the area under the curve (AUC) for the splines corresponding to each expression, block and participant. The area under the curve is proportional to how highly and for how large of a range of gumball proportions participants rate an utterance, so if an utterance is rated highly for a larger range of gumball proportions, the AUC will also be larger. We therefore test whether listeners update their expectations by computing the difference between the AUC of the spline for MIGHT and of the spline for PROBABLY for each test block for each participant.

Based on the results of the adaptation experiment with multiple speakers by Yildirim et al. (2016), we expect speaker-specific adaptation effects. We thus predict that the mean AUC difference will be bigger for the *cautious* speaker test blocks than for the *confident* speaker test blocks.

As a secondary analysis, we also investigate whether the order of exposure blocks (*confident* or *cautious* first), the assignment of speaker to speaker type (whether the male speaker was the *cautious* speaker or vice versa), or the order of the test blocks (same as exposure or reverse) has an effect on adaptation. We do not expect any of these factors to have an effect on adaptation.

Results and discussion

Figure 2 shows the mean utterance ratings of participants grouped by the two post-exposure test blocks. As this plot shows, participants expected the *confident* speaker to be more likely to use *probably* for lower event probabilities than the *cautious* speaker. This is also reflected in the AUC differences between the splines for MIGHT and of the splines for PROBABLY: As predicted, this difference was greater for the *cautious* speaker ratings than for the *confident* speaker ratings ($t(142) = 2.92, p < 0.01$).

For our secondary analysis, we fit a linear regression model to predict the AUC difference with speaker type, exposure

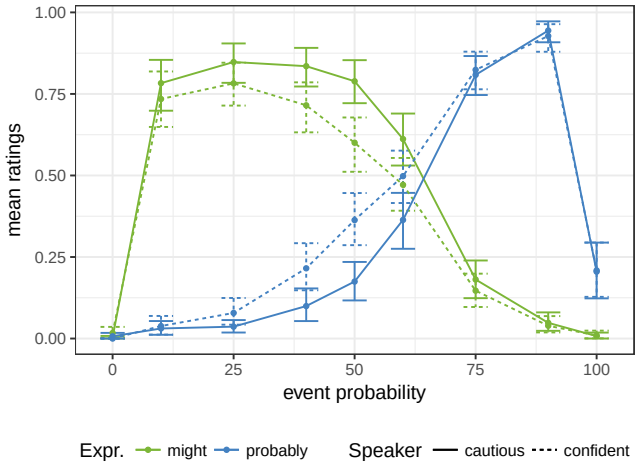

Figure 2: Mean utterance ratings for scenes with different event probabilities in Experiment 1. Error bars indicate bootstrapped 95% confidence intervals.

block order, speaker assignment, and test block order as predictors. Only speaker type is a significant predictor in this model (exposure block order: $\beta = 5.72$, $t(139) = 1.30$, *n.s.*; speaker assignment: $\beta = 1.21$, $t(139) = 0.28$, *n.s.*; test block order: $\beta = 2.28$, $t(139) = 0.52$, *n.s.*). Further, a model that includes these four predictors does not explain significantly more variance than a model that only includes speaker type as a predictor ($F(3,139) = 0.67$, *n.s.*).

The results of this experiment suggest that listeners form speaker-specific expectations of how different speakers use uncertainty expressions after brief exposure. At the same time, the results provide concrete evidence against two other accounts. First, they provide evidence against an account according to which participants only adapt to the experimental situation: If participants had only updated their expectations of what a generic speaker would say in the scenes presented in the experiment, we would not have expected to see differences in ratings between speakers. Second, they also provide evidence against a pure priming account according to which listeners update their expectations to the most recent exposure. Note that the adaptation effect was independent of the order of presentation and the order of test blocks. If participants had been primed by the most recent exposure speaker, we would have expected that participants' post-exposure ratings were primarily influenced by the behavior of the second exposure speaker.

The results of this experiment also replicate the finding by Yildirim et al. (2016) of differing effect sizes between the single-speaker and two-speaker experiments: The adaptation effect was considerably smaller in this two-speaker experiment (Cohen's d: 0.486) than in the single-speaker adaptation experiment by Schuster and Degen (2018) (Cohen's d: 1.263).

As suggested by a reviewer, one reason for the smaller effect size in the two-speaker experiment could be some form of self-priming and that participants' responses in the first test block influenced their responses in the second block. We evaluated this hypothesis in a post-hoc analysis of the responses from the first test block. We compared the responses of participants who were first tested on the *cautious* speaker to the responses of participants who were first tested on the *confident* speaker. If responses in the first test block influenced responses in the second test block, we would expect a larger effect size if we only consider the data from the first block. We did indeed find a larger effect size in the first block (Cohen's d: 0.723), which suggests that participants exhibited some form of self-priming.

However, even if we only consider the first block of responses, the adaptation effect remains smaller in the two-speaker experiment (Cohen's d: 0.723) than in the one-speaker experiment (Cohen's d: 1.263). This could be either a result of memory limitations or a result of listeners jointly tracking the statistics of each speaker as well as of the overall experimental situation (situation-specific statistics). We further investigate these possibilities in the next experiment.

Experiment 2: Identical speaker types

In Exp. 1, we found that the adaptation effect was smaller than it was in the single-speaker version of the experiment, which could have either been a result of memory limitations or joint speaker-specific and situation-specific adaptation. In this experiment, we investigate whether there is evidence for one of these two accounts. We exposed listeners to two speakers of the same type.[1] If the smaller effect in Exp. 1 was caused by listeners' inability to separate their experiences with the two speakers in memory, i.e, some experiences might have been attributed to the incorrect speaker, we would expect the adaptation effect in this experiment to be on average the same as in the one-speaker experiment. This is because even if listeners cannot perfectly separate their experiences with each speaker, they would on average still have the same number of experiences with each of the two speakers as listeners had with the one speaker in the single-speaker experiment. If, on the other hand, the smaller effect in the previous experiment was a result of listeners jointly tracking speaker-specific and situation-specific statistics, we would expect the adaptation effect to be larger here than in the single-speaker experiment. This is based on the assumption that more exposures lead to a larger adaptation effect and thus listeners' should adapt more to the situation if they are exposed to two

[1] In the spirit of open science, we note that the data from this experiment comes from a faulty version of Experiment 1. A scripting error led to participants always being exposed to the same speaker type instead of two different speaker types. Because of this error, the pre-registered analysis (https://osf.io/3cw79) deviates from the analysis that we report here. The reported analyses here are the only additional analyses we performed on the data. The reason for not discarding the data from this experiment but rather including it here is that it provides an informative data point for the question of whether listeners track situation-specific expectations.

speakers and hence also twice the number of interactions.

Methods

Participants We recruited 104 participants on Amazon Mechanical Turk. Participants had to have a US-based IP address and a minimal approval rating of 95%, and they were paid $5 (approximately $12–$15/hr).

Materials and procedure The materials and procedures were the same as in Exp. 1 except for the following two modifications. First, the speaker types for each participant were identical across the two exposure blocks: both speakers were either *confident* or *cautious* speakers. Second, the number of trials with PROBABLY and the number of trials with MIGHT were the same (10 trials per utterance and block) whereas in Experiment 1, the *confident* speaker produced only 5 instances of MIGHT and the *cautious* speaker produced only 5 instances of PROBABLY.[2] Assignment of speaker types was counterbalanced across participants, which means this experiment had a between-subjects manipulation.

As in Experiment 1, we excluded participants who provided correct responses to less than 11 of the attention checks as well as participants who seemed to provide random responses as defined above. In total, we excluded 11 participants because of the attention check criterion and 1 more participant because of random responses.

Analysis and predictions As the primary analysis, we compare the AUC differences between the splines for MIGHT and of the splines for PROBABLY between participants in the two conditions. Analogous to Experiment 1, we predict that the mean AUC difference will be bigger in the *cautious* speaker condition than in the *confident* speaker condition.

We again also investigate whether the assignment of speaker to speaker type or the order of the test blocks have an effect on the AUC difference. We do not expect either of these factors to affect adaptation.

Lastly, we compute the effect size measured by Cohen's d. As explained above, we expect the effect size either to be the same as in the single-speaker experiment or to be larger.

Results and discussion

Figure 3 shows the mean utterance ratings of participants for the two conditions. We again observe listener adaptation, resulting in a greater AUC difference in the *cautious* speaker condition than in the *confident* speaker condition ($t(89) = 8.01, p < 0.001$). Further, no factors other than speaker type are significant predictors of the AUC difference (speaker assignment: $\beta = -1.32$, $t(87) = -0.398$, *n.s.*; test block order: $\beta = 4.28$, $t(139) = 1.30$, *n.s.*).

Lastly, the effect size (Cohen's d: 1.68) was larger in this experiment than in Experiment 1 and the single-speaker experiment by Schuster and Degen (2018). While it would be premature to definitively conclude from these three experiments that listeners' expectations are jointly influenced by individual speaker's productions as well as all the productions in the experiment, our results point in this direction.

[2]The reason for the second modification is the above mentioned scripting error. See below for a discussion of potential implications.

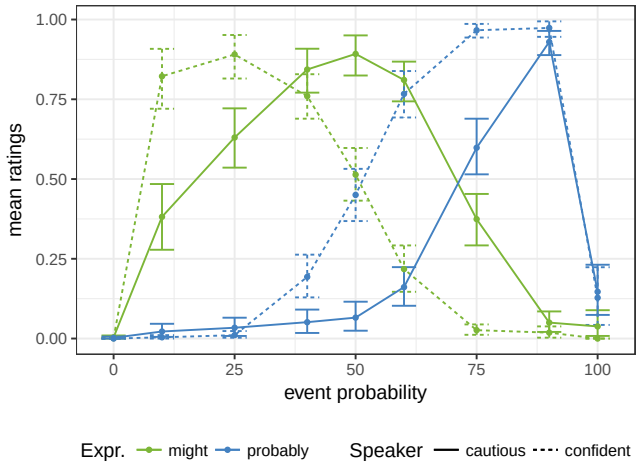

Figure 3: Mean utterance ratings for scenes with different event probabilities in Experiment 2. Error bars indicate bootstrapped 95% confidence intervals.

There is a potential confound in this experiment because participants saw 5 additional filler trials during each exposure block which could have led to the larger effect size as compared to the single-speaker experiment. However, this explanation seems unlikely considering previous work.[3]

General discussion and conclusion

In two experiments, we found that listeners form speaker-specific production expectations of uncertainty expressions after brief exposure to two speakers. This shows that the results by Yildirim et al. (2016) also extend to lexical items other than quantifiers.

At the same time, however, we found that the adaptation effect size varied depending on whether the two speakers had the same or divergent bias during the exposure phase. When listeners were exposed to two different speaker types, the adaptation effect was smaller and their expectations seemed to have been shaped by their experiences with the two speakers as well as all the experiences encountered in the experiment. When both speakers behaved the same, on the other hand, the adaptation effect was much more pronounced and even greater than in the single-speaker experiment from previous work.

[3]Yildirim et al. (2016) used a very similar paradigm to study semantic adaptation to the use of the quantifiers *some* and *many*. Analagous to our *confident* and *cautious* speakers, they had a *some-biased* and a *many-biased* speaker. They report two versions of their experiment: one in which there were no filler trials with the other quantifier and another version in which there was a balanced number of exposure trials with both quantifiers in both conditions. They found that the adaptation effect was smaller when there were more filler trials, so we would expect that if the additional fillers affected the size of the adaptation effect, the effect would be even larger had we not presented the extra fillers to participants.

One likely explanation for these observations is that apart from tracking speaker-specific statistics, listeners also track the situation-specific statistics of all interactions in the experiment and their expectations are guided by both of these factors. In the case of speakers with different uses of uncertainty expressions, speaker-specific adaptation is attenuated since the overall statistics guide listeners towards an "average" speaker whose use falls somewhere in between the *cautious* and the *confident* speaker. When listeners are exposed to two speakers of the same type, on the other hand, the situation-specific statistics reinforce the speaker-specific statistics and hence listeners adapt more to the two speakers.

An account based on "faulty" memory, according to which listeners have trouble keeping the speaker-specific experiences separate, does not predict the larger adaptation effect when listeners are exposed to two speakers of the same type. If every experience is encoded as an episode in memory but some with the incorrect speaker information, on average, the number of experiences with each speaker should still be the same as in the one-speaker condition and therefore it is unclear why listeners adapt more in the two-speaker experiment than in the one-speaker experiment.

Our findings also have implications for current models of semantic adaptation. Following the recent successes in modeling phonetic adaptation as an instance of Bayesian belief updating (Kleinschmidt & Jaeger, 2015), Schuster and Degen (2018) propose a computational model of semantic adaptation. According to this model, when interacting with a speaker Sp, listeners update their beliefs about a set of speaker-specific parameters Θ_{Sp}, which govern the speaker's lexicon and preferences.[4] Their model predicted the results of the single-speaker experiment well, but without modifications, it does not predict the differences in effect size.

We consider two promising extensions of this model. First, the model could be cast as a hierarchical model. Hierarchical models have been argued to explain many cognitive and perceptual phenomena (see e.g., Clark, 2013, for a review), including phonetic adaptation (Kleinschmidt, 2019), and also seem applicable here. In a hierarchical version of the adaptation model, we would assume that the speaker-specific parameters Θ_{Sp} are not only shaped by the listener's prior beliefs and the observed interactions by a speaker Sp but rather also depend on a distribution reflecting the situation-specific expectations. Figure 4 shows a sketch of a potential hierarchical model. Such a model would explain the differences in effect size: When listeners are exposed to different speaker types, the situation-specific parameter distribution would be influenced by two speaker types that essentially cancel each other out, which in turn would lead to less extreme speaker-specific distributions. On the other hand, when both of the speakers are of the same type, the situation-specific parameter distribution would be more strongly shifted towards the observed distributions which in turn would lead to more extreme speaker-specific distributions.

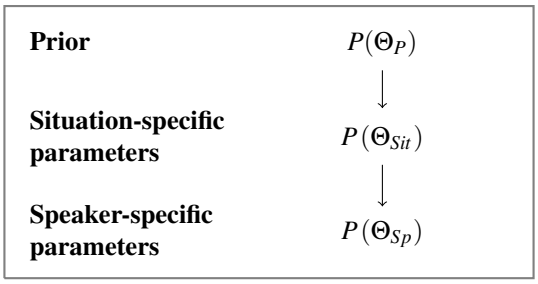

Figure 4: Hierarchical model of semantic adaptation. Situation-specific parameters $P(\Theta_{Sit})$ depend on prior beliefs $P(\Theta_P)$ and speaker-specific parameters $P(\Theta_{Sp})$ depend on the situation-specific parameters.

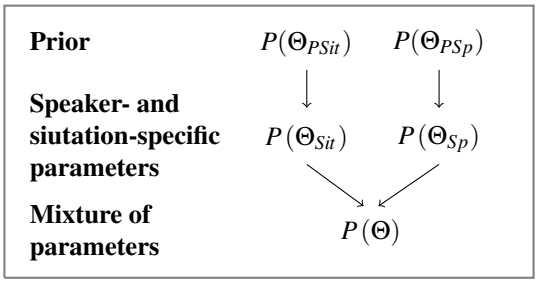

Figure 5: Mixture model of semantic adaptation. Overall production parameters $P(\Theta)$ are a weighted combination of situation-specific parameters $P(\Theta_{Sit})$ and speaker-specific parameters $P(\Theta_{Sp})$.

A second possibility would be to cast the model as a mixture model in which overall production parameters are a weighted combination of situation-specific and speaker-specific parameters (and potentially other factors). Figure 5 shows a sketch of a potential mixture model. According to such a model, listeners would form both situation-specific and speaker-specific expectations as a result of adaptation and then combine these expectations to their overall expectations. Such a model would also predict the smaller effect size in Experiment 1 since it would predict that the overall production expectations are influenced by the speaker-specific statistics as well as the situation-specific statistics and the latter drive the production expectations to be more similar to an "average" speaker. When listeners are exposed to two identical speakers, on the other hand, the situation-specific expectations (which are in line with the speaker type of both exposure speakers) would reinforce the speaker-specific expectations and therefore lead to a larger adaptation effect. Future experimental work should adjudicate between the hierarchical and the mixture model account.

In conclusion, we presented new experimental results from the domain of uncertainty expressions which suggest that speaker-specific semantic adaptation is a product of forming speaker-specific expectations and forming expectations about

[4] See also Hawkins, Frank, and Goodman (2017) for a similar model of the formation of conceptual pacts.

the situation independent of the speaker. These results raise a number of interesting questions, most pressingly regarding transfer effects to novel speakers, which have been observed in other linguistic domains (e.g., Bradlow & Bent, 2008; Xie, Earle, & Myers, 2018). In our experiments, the exposure and test speakers did not differ. This raises the question about whether and to what extent updated expectations transfer to novel speakers whose similarity to the exposure speaker(s) varies. Both models sketched above lend themselves well to capturing such transfer effects. In addition, participants saw very similar visual scenes on each trial. Another potential direction would be to study the extent of speaker-specific adaptation when listeners encounter more novel scenes during the test phase to investigate to what extent listeners form speaker-specific expectations independent of other contextual factors. Answering these questions will help disentangle the different adaptation processes and give us a better understanding of how listeners infer meanings in context.

Abstract

Mentalization is an important ability to acquire for children, as it allows humans to understand the mental state of others or oneself, that underlies overt behavior (Fonagy & Target, 1996). In the current study we examined the relationship between development of mentalization ability in children and their experience of playing with a doll by observing child-mother interaction and by using functional near-infrared spectroscopy (fNIRS). 44 dyads of children aged 2 to 3 and their mothers were divided into two groups (high and low) depending on the frequency of doll-play experience. We examined mother-speech interaction during the doll play. We also used fNIRS system to measure cerebral hemodynamic activation in the frontal and temporal regions during the observation of video clips showing hindering and helping behaviors. The results showed that a mother's proxy talk was related to a child's doll directed speech in the high group, but not in the low group. fNRIS data showed that cerebral activation in the helping condition was more increased in the low group than the high group. This suggests that doll-play experience facilitates the development of mentalization, which enables children to be aware of and understand other's psychological states.

Keywords: doll play; social understanding; mentalizing, young children; fNIRS.

This study investigated the relationship between children's experience in playing with dolls and the development of mentalization by using behavioral and neuroimaging measures. Mentalization refers to an ability to speculate and to understand other's psychological states (e.g., needs, desires, feelings, beliefs, goals, and reasons) based on their behavior (Fonagy, Gergely, & Target, 2007). Development of mentalization is important for children, as they need to interact with others by assuming other's mental sates in their socialization process. Fonagy and Target (1996) have suggested that play provides an intermediate area for the acquisition of symbolic thinking which is crucial for mentalization. Given this, it is important to see the relationship between play and the development of mentalization.

Children around age 1 begin to play by using an object as if it were something else or by pretending as if he or she was doing an actual action without the visible object. This kind of play is called "pretend play'. Pretend play is defined as a play expressing internal images by using actions, words, or objects, such as pretending to drink water by moving an empty cup to her mouth or feeding a doll by moving an empty toy fork to a doll's mouth (Lillard, Lerner, Hopkins, Dore, Smith, & Palmquist, 2013). Research has investigated pretend play because it indicates the emergence of mental representation in children in the sense that they enact an event or represent an invisible object by using their own body or different objects during play.
Pretend play normally peaks around preschool years when children start interacting with other children and gain access to more toys and resources for play (Lindsey & Colwell, 2013). Pretend play during preschool age is particularly important as it is related to the development of language (e.g., Orr & Geva, 2015), executive function (e.g., Carlson, White, & Davis-Unger, 2014), and social understanding including theory of mind (e.g., Lillard & Kavanaugh, 2014). Theory of mind refers to the ability to attribute mental states to others in order to understand and predict social behavior. The difference between mentalization and theory of mind is that mentalization mainly concerns the reflection of affective mental states, whereas, theory of mind focuses on epistemic states such as beliefs, intentions and persuasions (Wyle, 2014).
However few studies have shown the relationship between children's experience in pretend play and the development of mentalization. The current study addressed this issue.

Sachet and Mottweiler (2013) emphasized the distinction between two types of pretend play; Role-play and Object Substitution. *Role play* refers to pretend play that involves the mental representation of social or interpersonal content (e.g., pretending that a doll likes to eat sweets), whereas *object substitution* refers to pretend play that involves the mental representation of nonsocial content (e.g., pretending that a block is a chocolate). Both types of pretend play can provide opportunities for children to practice social skills or events happenings in the real world. Role-play has a special significance in the development of social understanding, because it provides opportunities for simulating social interaction (Harris, 2000). In fact, this was demonstrated by Wolf, Rygh, and Altshuler (1984). They visited children's houses from ages 1 to 7 and recorded their play with replica toys. They found that by the age of four, children can ascribe complicated psychological states including perceptions, sensations, emotions, and thinking to figures with which they are playing (Wolf et al., 1984). However there are three limitations in the previous studies on pretend play.

First, little research has been conducted to address how doll play affects social development such as mentalization, sympathy or prosocial behavior. Most studies have focused on object substitution and how it is related to social or cognitive development. Given that doll play provides opportunities for simulating social interaction (Harris, 2000), playing with a doll may foster children's social understanding. Brownell, Svetlova, Anderson, Nichols, and Drummond (2013) observed an interaction between toddlers and caregivers while reading a picture book in relation to toddlers' prosocial behavior. They found that children who helped and shared more tended to have parents who more often asked them to label and explain the emotions depicted in the books. This result suggests that caregiver's inputs that direct children's attention to inner thoughts or feelings of themselves or others assist the development of children's social understanding including mentalization.

Second, it is not clear how children's ability to ascribe the psychological states to dolls develops up until 4 years old. Lillard (2017) suggested that parent's input in pretend play is a crucial factor to develop children's social understanding because children need to learn how to pretend by properly interpreting social signals that parents send (e.g., strong eye contact or smile) as a cue of pretend play. Thus, it is worth investigating both children's and parent's behaviors during doll play to see how it affects the development of social understanding by the age of 4 years old.

Third, as Lillard (1993) pointed out, pretend play has been mostly analyzed by behavioral measures. There is no neuroimaging work on pretend play in children, although there are a few that have been done with adults (German et al., 2004; Whitehead et al., 2009). To see whether an experience in doll play affects the development of mentalization, the present study used functional near-infrared spectroscopy (fNIRS). Compared with other neuroimaging techniques, fNIRS imposes less physical constraints on the participant and it is relatively unaffected by motion artifact. Thus it can be applied in a natural setting even in young children (Nagamitsu, Yamashita, Tanaka, & Matsuishi, 2012). Previous studies have shown that medial prefrontal cortex (mPFC) and temporoparietal junction (TPJ) are involved in the mentalization process (Frith & Frith, 2006; Minagawa Xu, & Morimoto, 2018). Particularly mPFC is responsive when making social judgments about dissimilar others (Mitchell et al., 2005), whereas TPJ is activated more in response to theory of mind tasks (Mahy, Moses, & Pfeifer, 2014). Thus, if a doll-play experience facilitates the development of mentalization ability in children, these brain regions would be activated more in children having more experience in doll play than those who have less experience.

To address these three limitations, the current study aimed to reveal the relationship between doll-play experience and development of mentalization in children aged 2 to 3 by observing mother-child interaction and measuring fNIRS. We predicated that fNIRS data would show that brain areas involving the mentalizing process would be more activated in children having more doll-play than children having less experience when they see someone's helping/hindering behavior. We also predicted that mother-child interaction would be qualitatively different depending on children's doll-play experience.

Methods

Participants 44 female children aged 2 to 3 and their mothers participated in this study. They were divided into two groups in terms of frequency of doll play; high and low group. The playtime with a doll was taken via a questionnaire for mothers before the experiment. Each group included 22 children. Children in the High group play with a doll more than one hour per week, and children in the low group play with a doll fewer than 20 minutes per week. The mean age in months and the standard deviation for each group were as follows; Low group, M = 35.4, SD = 2.5, and High group M = 36.7, SD = 3.3. There was no significant difference in the average age between the two groups. All the participants were native monolingual Japanese speakers from middle-class families, and the children attended nursery schools in Tokyo, Japan.

Material and Apparatus The test consisted of two sessions; a doll play session and a fNIRS session. In the doll play session, the child-mother dyad participated in a 7-minute doll play session. We encouraged the child-mother dyad to play with a set of toys including a doll and replica of house items, as shown in the left panel in Figure 1. Experimenters recorded the child-mother interactions but did not participate in their play.

For fNIRS session, we created audiovisual video clips. Each video clip lasted 17sec (30 fps), presenting two girls making an event as shown in Figure 2. In total, we created nine clips (stories). After presenting a still picture for 0.5 second, each clip starts with the introduction phase (8.5sec) where one girl (girl A) is in need and the other girl (girl B) notices the trouble (e.g., girl A is looking for a pencil, and girl B notices it). Then each story ends with the ending phase (8sec), which has two types of endings; hindering vs. helping ending. In the hindering condition, girl B obstructs girl A's need (e.g., throwing the pencil away), whereas in the helping condition, girl B assists girl A's need (e.g., passing the pencil to girl A).

Figure 1. Toys used in doll play session (left panel) and a screenshot of data coding with ELAN (right panel).

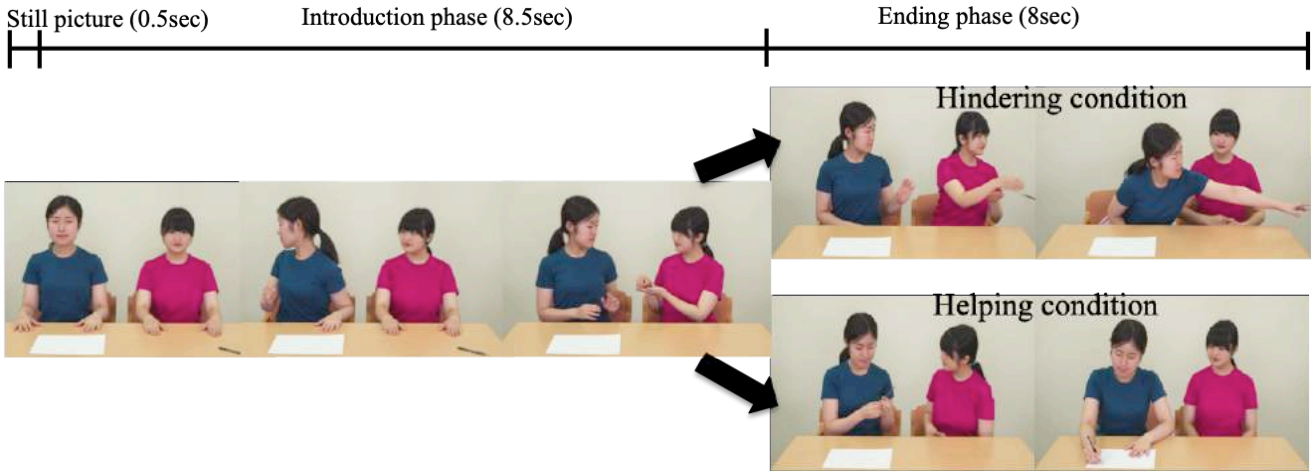

Figure 2. An example of video audio stimulus and the time line for fNIRS experiment. Each clip has two different endings; Hindering (top) and helping ending (bottom) in the Ending phase.

Procedure

The experiments were conducted in a test room with a sound-attenuated cabin for fNIRS in Keio University in Tokyo, Japan. First, each child-mother pair was instructed to play with a doll and some house items, shown in Figure 1, for seven minutes. They were encouraged to play in the same way as they do in their home. After the doll play session, they had a short break and moved to a booth with the fNIRS device. In the booth, mothers were instructed to hold their children on their laps and not interact with them during the fNIRS data collection. Children were instructed to watch the video clips on the monitor in front of them. The whole session was recorded using the mini-DV camcorder on a tripod. We counterbalanced the number of ending types that children were presented with, the locations of girl A and B, and the role of girls (e.g., one child watched the girl A helping in the pencil story, but other child watched the girl B helping in same story).

Analysis

Doll play data All narratives were verbatim transcribed. From the transcriptions, the mean number of utterances was then calculated. In this study an utterance was defined as a breath group. A breath group refers to a stretch of speech between two interword pauses, lasting 200ms or longer. We excluded an utterance from this study when it consisted of only fillers or meaningless exclamations such as "ah" or "um".

We counted the number of the following three speech types (*Desires, Emotion labels,* and *other internal state talk*) by using coding software ELAN (Lausberg & Sloetjes, 2009) (right panel in Figure 1). These categories were borrowed from a study by Brownell et al. (2013). *Desires* are references to wanting, or needing something concrete such as "he wants to eat an apple" or "she needs to go to bed". *Emotion labels* are defined as an utterance naming emotional feelings or behaviors without expansion or elaboration such as "the doll is happy" or "she likes vegetables". Other internal state talk is references to other internal states that are not affect- or mental state-related (e.g., physiological states) such as "she is thirsty" or "the doll is tired".

To see the psychological distance between participants and the doll, we also counted the number of instances of *proxy talk* and of *doll directed speech*. Proxy talk refers to an utterance when the speaker says something from doll's perspective, just like a ventriloquist, as if she or he is the doll (e.g., "oh I am so hungry, can you make a meal for me?"). In addition to the content of the utterance, if the pitch of the speaker's voice heightens higher than their usual pitch and/or he or she produced the utterance while operating the doll, it was counted as proxy talk. Doll directed speech refers to an utterance that directly addresses to the doll (e.g., "I will cook something for you").

fNIRS data We measured changes in concentrations of oxy-hemoglobin (oxy-Hb) and deoxy-hemoglobin (deoxy-Hb) in the frontal and temporal regions during the observation of video clips, using the NIRS system (ETG-7000, Hitachi). The NIRS system measures temporal changes in concentrations of oxy-Hb and deoxy-Hb in the cerebral cortex resulting from an increase in local cerebral blood flow by emitting and detecting two wavelengths of near-infrared light (780 nm and 830 nm). We used a 2 x 11 optode array, containing 27 measurement channels. The center optode in low row was placed on Fpz in the international 10-20 system to cover the frontal and temporal regions (Figure 5). The distance between each emitter and the corresponding detector was set at 2.5 cm.

Data was preprocessed using a platform for optical topography analysis tools (POTATo) developed by Research and Development Group, Hitachi, Ltd, within MATLAB2012 (Mathworks, Natwick, MA, USA). Pulse-related signal changes for head motion and overall trends were eliminated by high-pass (0.02 HZ) and low-pass (1 Hz) filtering. We defined 3.5 seconds before the onset of the ending phase as a baseline period and compared the relative change in oxy-Hb during a time analysis window (between 5 s and 8 s after the onset of the ending phrase) with the baseline period using a t-test. It is controversial which chromophore, namely oxy-Hb or deoxy-Hb best represents

BOLD (blood oxygen level dependent) signal. However, oxy-Hb has been dominantly used in previous fNIRS studies (Lloyd-Fox et al., 2010) and it has been pointed out that signal-to-noise ratio is higher for oxy-Hb rather than deoxy-Hb (Strangman et al. 2002). Thus, we decided to analyse only oxy-HB in this study.

Reliability

The first author coded the entire data set. To ensure the reliability of the gesture coding, about 50% of the data was re-analysed by a trained and independent native Japanese-speaking student. Ten children and mothers from each group (40 participants in total) were randomly selected and re-coded by the second coder. Point-to-point percentage agreement was calculated. The two coders agreed on the number of utterances 98% of the time for children, 97% of the time for mothers in the low group, and 98% of the time for children, 98% of the time for mothers in the high group. We calculated the percentage agreement for each speech category by collapsing groups. The two coders agreed on the number of doll directed speech 90% of the time in the low group and 93 % of the time in the high group, and on the number of proxy talk 93% of the time in the low group and 88% of the time in the high group. The Cohen's kappa statistic was used to assess inter-rater reliability for coding with more than two categories. Agreements between the two independent coders were overall high; for the low group, for desire speech kappa=.91; for emotion label kappa=.89; for other internal state talk kappa=.93, and for the high group, for desire speech kappa=.94; for emotion label kappa=.96; for other internal state talk kappa=.95. Any coding disagreements were resolved through discussion and subsequent consensus.

Results

1.1. Doll play analysis

The number of utterances We first calculated the number of utterances that children and mothers produced for each group. Children produced 46.3 (SD = 19.6) utterances in the low group, and 57.2 (SD= 26.9) in the high group. Mothers produced 121.3 utterances (SD = 26.3) in the low group, and 115.5 (SD = 26.8) in the high group. We conducted independent-sample t-tests and did not find a significant difference between the two groups, $t(42) = 1.53$, $p = 0.13$, for children, and $t(42) = 0.73$, $p = 0.47$, for mothers. This result showed that children and mothers in both groups produced same amount of utterances during the doll play.

Proxy talk and doll directed speech We first counted the number of instances of proxy talk and doll directed speech that were produced by children and mothers during the session. Then we divided them by the total number of utterances for each participant to calculate the proportion. The proportions of proxy talk were 0.00 (0.01) in children in the low group, 0.02 (0.02) in children in the high group, 0.13 (0.11) in mothers in the low group, and 0.37 (0.19) in mothers in the high group. To see whether there was a difference in the proportion of proxy talk between the low and high groups, after arcsine transformation of the proportion data, independent-sample t-tests were conducted for children and mothers. A significant difference was found in children, $t(42) = 3.39$, $p < .01$, $d = 1.02$, and in mothers, $t(42) = 5.00$, $p < 0.01$, $d = 1.51$. This result indicated that mothers and children in the high group produced proxy talk more frequently than those in the low group. The proportions of doll directed speech were 0.06 (0.09) in children in the low group, 0.23 (0.17) in children in the high group, 0.00 (0.00) in mothers in the low group, and 0.00 (0.01) in mothers in the high group. Independent-sample t-tests were conducted, and a significant difference was found only in children, $t(42) = 3.39$, $p < .01$, $d = 1.59$. This result indicated that children in the high group produced doll directed speech more frequently than children in the low group.

Correlation between proxy talk and doll directed speech

To see whether there was a relationship between mother's and children's statements, Pearson's correlation coefficient was calculated between the proportion of proxy talk and of doll directed speech made by mothers and children for each group. The result revealed that in the low group, there are no correlations between them, but in the high group, there is a significant correlation between mother's proxy talk and children's, $r = .69$, $p < .001$ (two-tailed). This indicated that when mothers produce proxy talk, their children produce doll directed speech during their play in the high group.

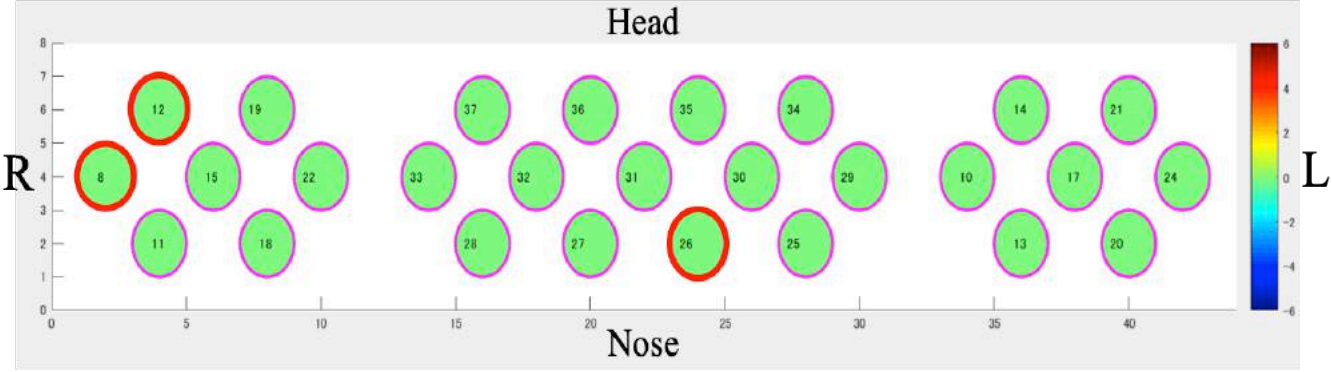

Figure 5. Arrangement of the near-infrared spectroscopy (NIRS) channels. The channels with a red circle indicate the channels showing the significant difference between the low and the high groups.

Proportion of speech type in children and mothers Proportions of each speech type were calculated by dividing the number of each speech type by the total number of utterances for children (Figure 3) and mothers (Figure 4). After arcsine transformation of the proportion data, paired t-tests were conducted for each speech type between two groups in children and mothers. A significant difference was found only in Emotion labels in adults, $t(42) = 2.43$, $p < .05$, $d = 0.73$. This indicates that mothers in the high group produced Emotion labels more frequently than those in low group.

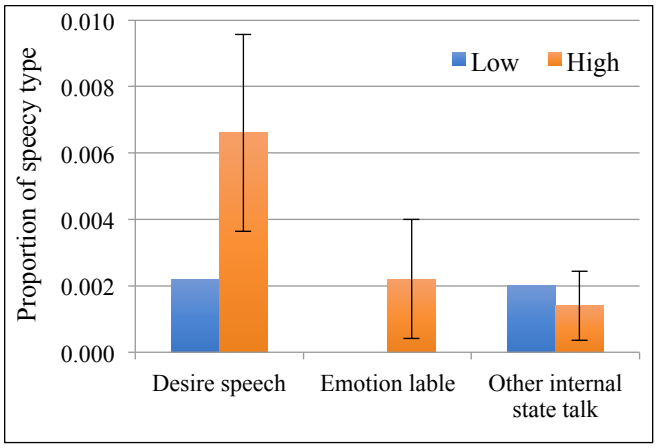

Figure 3. Proportion of each speech type in children

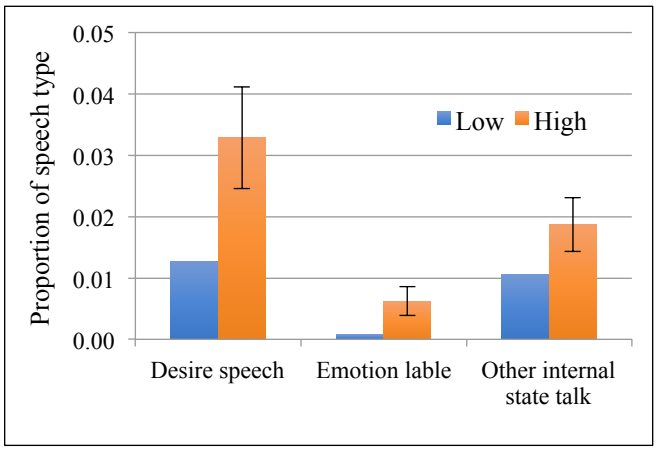

Figure 4. Proportion of each speech type in adults

2. 1. fNIRS analysis

We conducted paired t-tests on the difference in oxy-Hb change during the ending phase between two groups (the high vs. low group) for each channel, and for each condition (hindering and helping condition)

The result showed that there were no significant differences between two groups in the hindering condition, but the oxy-Hb concentration in the helping condition was significantly more increased in the low group than the high group for the measurement channel 8, $t(27) = 3.05$, $p < .01$,

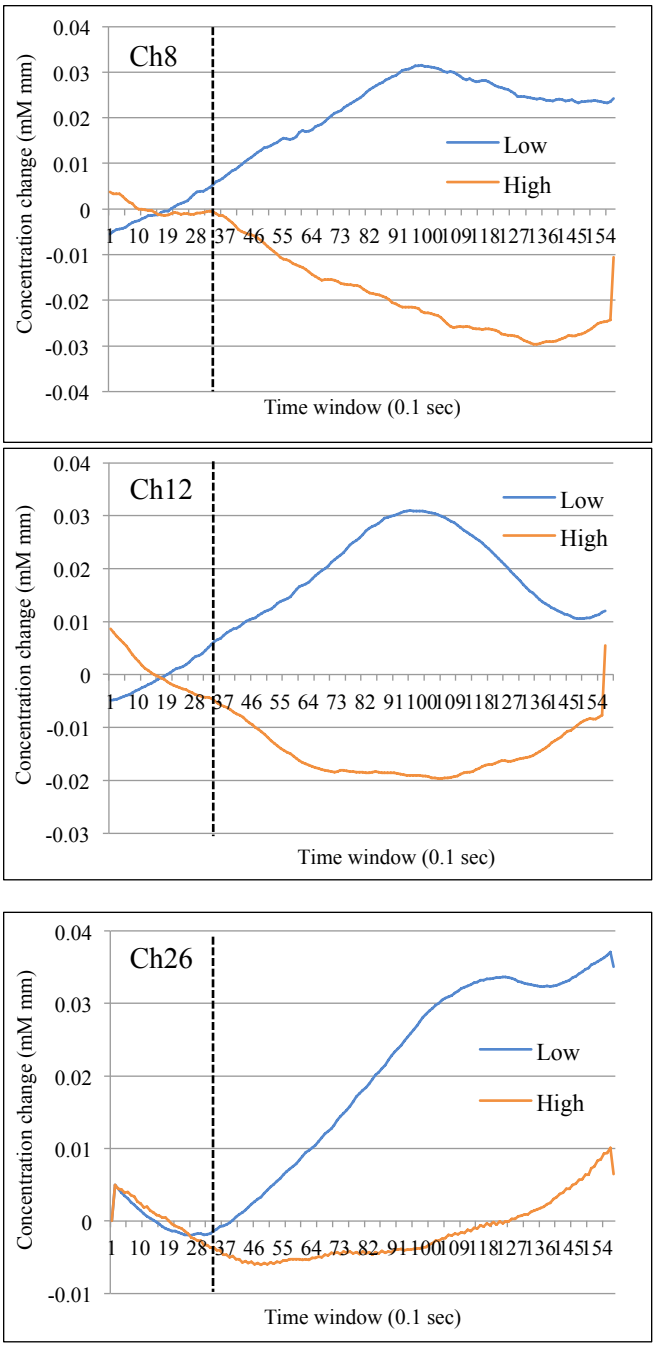

Figure 6. The time course of signal changes in oxy-Hb at TPJ (Ch8 and 12) and mPFC (Ch26) channels during the ending phase. The x-axis represents time units of 0.1 second. The dot line indicates the onset of the ending phase. We analysed the last 3 seconds of the ending phase, which is time windows from 85 to 115 on x-axis.

$d = 1.12$, the channel 12, $t(29)=3.58$, $p < .001$, $d = 1.29$, the channel 26, $t(30)= 3.28$, $p < .01$, $d = 1.16$. The channel 8 and 12 cover TPJ (temporoparietal junction) region, and the channel 26 covers mPFC (medial prefrontal cortex) region.

Taking TPJ's and mPFC's functional roles into account, these results suggested that children in the low group are more sensitive to other's helping behaviors and feelings than those in the high group. We conducted the correlation analysis between behavioral data (child/mother speech) and the three channels showing the significant differences between groups. However, any statically significant correlations between them were not found.

Discussion

The current study examined the relationship between doll-play experience and development of mentalization in children aged 2 to 3 by observing mother-child interaction and measuring brain activation by fNIRS. We found three main results. The first finding is that mother's talk differs depending on children's experience in playing with dolls. Mothers who have children with more experience in doll-play tended to produce more proxy talk and emotion labels during doll-play than mothers in the low doll-play experience group. The second finding is that children who have more experience in doll-play produced doll directed speech more frequently than children who have less experience in doll-play.

These findings indicate that mentioning a doll's internal feelings or talking to children by using the doll's voice direct children's attention to a doll's inner psychological states, which may lead children to the development of mentalization. In turn, children tend to talk to the doll as if the doll is an animate entity by using doll directed speech. This interpretation is consistent with previous research showing that mother's inputs are important to develop children's social understanding (e.g., Brownell et al., 2013; Lillard. 2017; Nakamachi, 2015). For example, Nakamachi (2015) found that mothers' pretend behaviors when toddlers were at 18 months predicted toddlers' understanding of a stranger's pretense 6 months later. Our data added new insight to this line of research. That is, as the result of correlation analysis shows, mother's proxy talk was significantly correlated to children's doll directed speech in the high doll-play experience group. Although it is difficult to determine the cause-effect relationship from our data set, we can speculate that mother's proxy talk makes children aware of a doll's inner feelings. In turn, children address their talk to the doll. This caregiver-child interaction through a doll may lead children to facilitate the development of mentalization.

The third finding is that in the measurement channel above TPJ (temporoparietal junction) and mPFC (medial prefrontal cortex) regions, the oxy-Hb concentration in the helping condition was more increased in the low group than the high group. This finding tells us that children in the low group are more sensitive to other's helping behaviors and feelings than the high group. It can be interpreted that children in the high group have seen a variety of helping scenes in doll-play. In contrast, children in the low group may not be as familiar. As the helping condition requires children in the low group to mentalize others feelings, the oxy-Hb concentration was more increased in TPJ and mPFC than children in the high group.

Contrary to our expectation, we did not find any difference in the oxy-Hb concentration in the hindering condition. This may be because it is too hard for children aged 2 to 3 to understand the situation in video clips as a hindering situation. Also, unlike the helping condition, the stories of the hindering condition do not have clear ending in the sense that the issue of the hindered person still remains. Thus, different time windows to measures brain activity may need for hindering and helping conditions respectively.

In conclusion, the current study showed that the experience in playing with a doll is related to the development of mentalization, and that maternal inputs toward her child and child's response toward a doll play important roles in the development of mentalization.

There are three directions of future studies. First, the current study used only audiovisual stimuli presenting helping/hindering behaviors to see the relationship between mentalization and doll play. But role-play is comprised of different elements such as verbal and nonverbal interaction, theory of mind, mentalization, sharing and reading intention, and object manipulation (Lillard, 2017). Thus, as a future task, it is important to examine whether and how doll play affects other social, linguistic, or cognitive process by using other stimuli that are sensitive to those domains. The second future task would be conducting longitudinal studies. Sachet and Mottweiler (2013) pointed out that it has remained unclear whether engaging in role-play enhances children's social understanding or the other way around. To make the cause-effect relationship between doll-play and social understanding clear, we need to longitudinally examine the developmental path of social understanding including mentalization and how caregiver's input and other environmental resources affect children's behaviors. Finally, given that play is a culturally constructed activity (Gaskins, 2013), it is important to examine whether findings in the current study holds true for populations with other demographics (e.g., different social-economic status, people with non-Japanese backgrounds, mother-son or father-child dyads).

Introducing quantitative cognitive analysis: ubiquitous reproduction, cognitive diversity and creativity

Abstract

The rise of ubiquitous computing has cemented ubiquitous reproduction (UR) as a defining feature of contemporary human environments. UR is most obvious on our televisions and smartphones but has homogenised most material aspects of our lives. Emerging technologies such as 3D printing and robotics will ensure that this trend intensifies. UR is an issue of global scale that is relatively intractable to qualitative treatment. This paper introduces a novel *quantitative* approach to cognitive science and to analysis of UR. The approach uses the finiteness of cognition to establish a minimal ontology with which to model cognitive diversity under UR. It demonstrates that, despite widespread valorisation of diversity, cognitive diversity must be declining at a global level. The implications of this for creativity are that the arc for creative impact is growing shorter as the need to be immediately intelligible promotes the formulaic at the expense of the interpretable.

Keywords: ubiquitous computing; ubiquitous reproduction; cognitive diversity; creativity; intelligibility

Introduction

Ubiquitous reproduction (UR), a feature of contemporary society accelerating under ubiquitous computing, has brought an unprecedented rise in the homogeneity of human environments. Our attention is increasingly occupied by images and sounds reproduced synchronously and asynchronously in millions of widely dispersed locations – on mega-screens that tower over us in cityscapes (as in Figure 1); on televisions and monitors in our homes; and on smart devices in our pockets and on our wrists. Within the cocoon of our digital habits we are now as likely to be glued to our favourite online resources and entertainments walking through a Bangkok market as a Finnish airport.

The material effects of UR are far from straightforward or short term. The digital reproduction of images and sounds has provided the scaffold for broader standardization of our physical world. Human environments are now measured, planned, designed, manufactured, distributed, and assessed with digital assistance. Our experience, derived from objects on computer screens in environments of computational origin, is becoming more and more homogenous. Everything from our first appearance *in utero* on ultrasound screens, to the digital curricula of the schools we attend, to the 3D printed artefacts we use, to the temperature and humidity of the air we breathe is melding into a common background.

Figure 1. Ubiquitous reproduction (UR) is occurring in many forms and on many scales in human environments.

The identical representations information technology makes possible are certainly a boon for productivity. They are also often touted as a godsend for creativity. Indeed, the ease with which digital amateurs can create and disseminate images and sounds has progressed to the level of "deep fakes" that threaten to undermine, as Baudrillard (1981/1994) foresaw, trust in reality itself. Thanks to UR there have appeared many new and popular activities to stock the digital repository. Entire new genres such as emoji, gifs and memes have emerged, and as technology progresses no doubt these will be joined by other technologically defined creative – if similarly pastiche-based – categories.

Alloyed to claims that UR promotes creativity is the promise (often promoted in marketing of new technology) that UR is a breakthrough for cognitive diversity. The argument is that UR allows us to learn about (or even virtually experience) other viewpoints, expand our cognitive degrees of freedom, and so overcome the ignorance that engenders bigotry. This meshes well with the conjointly valorised idea that creativity necessarily involves an increase in cognitive diversity. Afterall, if nothing new and hence expansive of diversity appears, how can creativity have taken place? In terms of cognition under UR, however, a worthy question is whether rising environmental homogeneity carries broader, unrecognized structural contractions actually inimical to *global* cognitive diversity. This paper introduces a quantitative view, based simply on the finiteness of cognition, that localized and anecdotal creative benefits of UR disguise a broader pattern of

reduced cognitive diversity and an inflection point in what is possible in, or even meant by, creativity.

Quantitative cognitive analysis

A common difficulty in cognitive science, and one perhaps retarding analysis of UR at present, is achieving ontological agreement. Cognitive science often ignores thorny philosophical dilemmas to concern itself almost entirely with *qualitative* aspects of cognition, which are typically treated as self-evident. It is, however, specious to claim that we know or can infer what a particular individual or group of individuals is thinking, or that any symbolic representation of cognition is meaningful outside symbolic systems, which rely themselves, after all, upon cognition. Well over sixty years ago, Quine (1951), as part of his critique of "modern empiricism", pointed out the circularity of assuming cognitive synonymy. Yet such assumptions continue to underpin psychology and cognitive science and are rarely challenged.

Historically, however, qualitative enquiry is not the sole – or even foundational – charter of either psychology or cognitive science. James (1890/2012, p. 9), for example, defined psychology as "the science of *finite* individual minds" [emphasis added]. This underexplored distinction has been examined recently by Shackell (2018, 2019, in press) in an attempt to bring clarity to information age challenges in semiotics. The bootstrapping move is to first treat questions of cognition *quantitatively* in order to derive a minimally committed and hence maximally surefooted ontology of cognition. For the present analysis, this "quantitative cognitive science" approach can be summarized in three axioms that can be confirmed from common experience:

1. Cognition is finite (i.e., we do not know everything; what we never think we never know)
2. Cognition can be similar or at least closely related (e.g., communication is possible)
3. Over time, common environments produce similarly structured cognition and behaviour in a population (e.g., many people in Paris speak French)

Most crucially, from the first of these axioms the construct of a global human cognitive field can be derived, which is simply a space-time concept of cognition occurring at a species level. This simple construct, shown in Figure 2, is the blank slate for quantitative analysis of cognition. Further explicit ontological commitments can be carefully introduced to examine various phenomena, among which the rise and role of UR is our present focus.

An attentional definition of environment

Environments that humans create and customise for themselves are more complicated than their appearance at any one moment in time suggests. Human environments are cognitive, defined just as much by habits of attention as possible targets of attention. Habits of attention, in turn, are shaped by perceptual processes over time – largely by what changes or modulates in an environment. Many people who live in sight of some remarkable wonder such as the Grand Canyon, for example, may nonetheless currently devote much of their time to Facebook or Twitter.

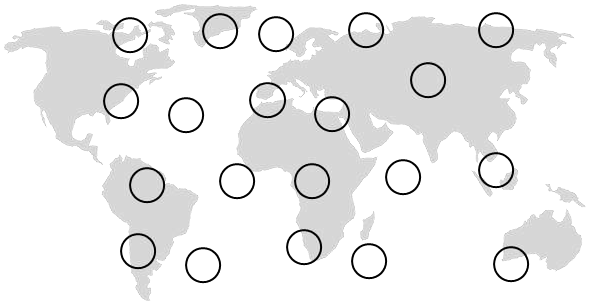

Figure 2. The cognitive field, a minimal construct facilitating careful *quantitative* analysis of cognition. Each circle represents a single agent's thought at a point in space and time. Adapted from Shackell (2018).

Our experience is a complex function of the attended and unattended stimuli we inhabit. UR brings determinative constraints to this function in ways that are difficult to perceive. An initial reaction to email in the 1990s, for example, may have been that it brings some incidental, standardising reproduction to our experience but ultimately is a source of extremely varied stimuli (e.g., words and images). However, if we examine the email of a large number of people today, will we find a rich and open-ended diversity of images, words, and most importantly, habits of interpretation? More likely we will find a quite clustered, reducible set of generic artefacts such as advertising, jokes, school news and so on. In fact, spam filters rely upon the very fact that email messages at a global level are not very diverse.

The issue of material homogeneity interacting with attentional proclivities to determine cognition is a complex one. For example, a hotel room containing a large television that is switched *off* has a very high level of material homogeneity relative to other hotel rooms but nonetheless allows many degrees of freedom for cognition. An agent sitting in that room may be thinking about a passing car, the colour of the carpet, a memory from childhood, rice salad recipes et cetera, each with a low degree of predictability. In contrast, the same hotel room with the large television switched *on* is less materially homogenous – the light and sound emitting from the television are dynamic and change the environment constantly. Cognitively, however, it is *less* diverse as a large proportion of people in such a situation will be on very similar trajectories promoted by the modulating television (e.g., experiencing an episode of *Seinfeld*). Such attentional and focus dynamics have a historical or formative component and are in a sense nested within one another (the homogenous, generic hotel room nests the seemingly diverse television output, which is itself derived from a restricted content set e.g., *Seinfeld* episodes). Cognition, therefore, can be homogenised by dynamic as

much as static stimuli according to prevailing attentional habits.

Pre-UR environments

Natural, pre-modern environments provide a baseline (or at least a point of comparison) for homogeneity. UR is limited in nature. No two mountains are the same. Nor any two rivers or places in them. Moreover, in nature there is little opportunity to view things habitually from the same perspective, or to view the same event repeatedly[1]. Importantly, there is a close linkage in pre-modern environments between stimulus and response. In pre-modern environments, if you saw a tiger you would think to run. Today you will likely just turn your head away and dismiss the vision as an advertisement for sneakers or a charity. Even in the nineteenth century, despite the rise of newspapers, museums and public libraries, it was relatively rare for large numbers of human beings to have encountered identical objects. Human cognition in the past likely exhibited a high level of idiosyncratic abstraction derived from variant stimuli. One person's concept of a mountain or a steam engine may have been much different than another's without ever causing economic or social friction. In other words, economic and social functions were performed despite quite a high degree of cognitive diversity.

Formalising cognitive diversity

To derive a formal model of cognitive diversity based on the axioms of finite cognition, we can begin by formalising the cognition of a population with *n* members over a chosen time period. Let *P* be the set of *n* contemporaneous thought sequences *s* in the population over the period:

$$P = \{s_1, s_2, s_3 \dots s_n\}$$

C can be defined as the set of distinct thoughts of *s*, a member of *P*, over the period.

The total cognitive diversity of *P* can therefore be expressed as the union of all *C*:

$$\bigcup_{1}^{n} C$$

Conversely, the total cognitive commonality of *P* can be written as the intersection of all *C*:

$$\bigcap_{1}^{n} C$$

A more meaningful measure of cognitive diversity for *P*, however, must include an awareness of the distribution of similar and different cognitive states among agents. A number of metrics are available in statistics for comparing set similarity. The Jaccard index, for example, is the size of the intersection of two sets divided by the size of the union. For *P*, a useful metric of similarity is the mean of the pairwise Jaccard indices of all *C*, which we can call that population's cognitive similarity *z*:

$$z = \frac{\sum_{i=1}^{n-1} \sum_{j=i+1}^{n} \frac{s_i \cap s_j}{s_i \cup s_j}}{\left| \binom{n}{2} \right|}$$

A *z* value of 1 would indicate a complete lack of cognitive diversity while a value of 0 would indicate complete cognitive diversity. While *z* can perhaps never be directly measured except in some future dystopia, it does give us a formal tool with which to reason about certain situations in which diversity is at issue, and more broadly the effects of phenomena such as UR.

Modelling cognition in increasingly homogenous environments

It would be difficult to sustain the argument that human beings living in environments that are increasing similar will not tend to think in increasingly similar or at least related ways. Even if thoughts do not circulate in an epidemiological manner, disparate reactions to common artefacts must lead to thoughts falling into finite patterns and hence concentrating within generic categories. For example, while everyone may not have positive emotions around the massively reproduced images of the last FIFA World Cup, large numbers of people will have some *species* of reaction such as disappointment, outrage, respect, indifference et cetera. Moreover, these reactions will be patterned in very broad ways, with people in the winning country, France, more likely to exhibit one of the more positive cognitive states. Such "made for television" events are often lauded, and indeed sought after, for bringing the world together and creating *connection*.

A connected world or a homogenous world?

In analyses of technological change, a common assertion is that cognition is changing because individuals are now highly "connected". This idea of connection, however, despite having the appearance of explanatory power and finality, bears some deconstruction. If we probe a little deeper into the material nature of increased connectivity, we find that UR is the enabling mechanism. Connection is possible because a message on a device at one location can be reproduced at another. More subtly still, reproduction of any image at different locations creates a connection *potential* between individuals by synchronising their experience to some extent – that is, by honing their ability to receive a related image later.

[1] This point is illustrated by the debate that raged for millennia as to whether, and at what point, all four of a horse's hooves leave the ground while galloping. The debate was resolved by Muybridge's 1878 *Sallie Gardner at a Gallop* photographs.

When we draw connections as an edge on a social network graph (as is routinely done – see, for example, Baronchelli, Ferrer-i-Cancho, Pastor-Satorras, Chater, and Christiansen, 2013), we are abstracting a very complex structure of UR into a simple metaphor. In specific *qualitative* analysis this reduction is often not afforded enough scrutiny: the complexity of a single connection is enormous and drags with it an implicit micro-mechanics that has never really been made clear. In *quantitative* analysis, however, such edges can be given a very precise meaning at the systemic level as environmental commonalities occasioning synchronisation of thought. Edges with such a meaning can be assigned probabilities based on environmental commonalities and attentional factors (as indeed marketing and advertising already do in some situations e.g., Allenby and Rossi, 1998).

Diversity in the cognitive field under rising UR

Using the construct of the cognitive field and edges introduced above we can model the effects of UR by assigning discrete *values of difference* to cognition – that is, by marking cognitive states as different or similar without claiming to know anything qualitative about them. In Figure 3, the colour of circles in the field indicates the difference or similarity of cognition. The edges are indicators of common experience produced by UR. As per the discussion above, the edges do not necessarily "spread" a cognitive state but rather increase the tendency of other agents to assume some complementary state.

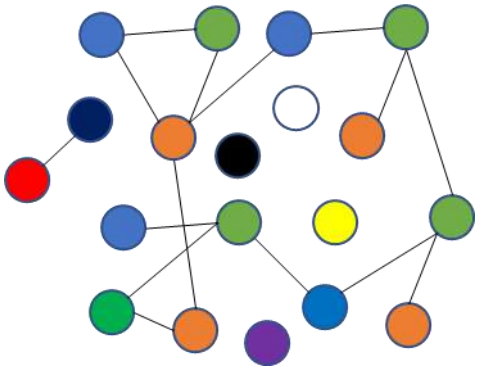

Figure 3. A cognitive field under low UR. Different colours represent different cognitive states. Edges represent common experiences facilitated by UR.

Figure 4 depicts a cognitive field under greater UR which facilitates more common cognition and hence less cognitive diversity. Notice that the "connections" between agents (the products of UR) are greater and hence the number of distinct states is lower than in Figure 3. The result is a move towards what is known as a "small world" graph.

Figures 3 and 4 show that if we stipulate that increasingly homogenous stimuli tend to produce less diverse cognition, then under global UR we can assume a falling cognitive diversity in human populations. The next question we may ask is why such a movement is underway?

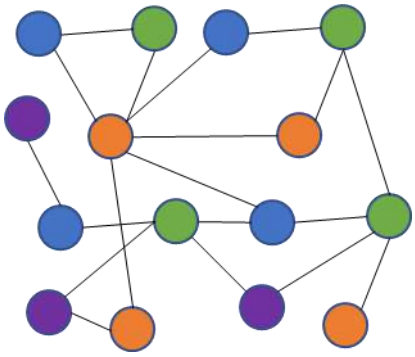

Figure 4. A cognitive field in an environment with a high level of UR. Greater "connection" leads to lower diversity.

The teleology of falling cognitive diversity

Falling cognitive diversity has one obvious cause: economics. As new methods for production and distribution of material goods and information evolve, these are quickly disseminated and adopted around the world. For example, producers will not continue to smelt iron in an inefficient and idiosyncratic way if a better method is obviously available. The adoption of the new smelting method, however, will require remote peoples to synchronise some of their cognition with others already using the method. This will also likely bring larger flow-on material changes: altered city locations and landscapes with smokestacks of a certain shape, new jobs with similar duty descriptions, and, most broadly, societal changes to do with increased availability of iron. The pace of economic change in regard to information technology is many times greater. Such changes are economically optimal but operate by decreasing cognitive diversity globally.

A counterintuitive view of diversity

With the current valorisation of diversity in race, gender, politics and religion, the conversation around cognitive diversity – which if one believes in the mediation of reality by cognition is the root of *all* diversity – turns quite counterintuitive. To anyone with a positive notion of truth or a commitment to democratic philosophy as espoused, for example, by Dewey (1916/2012), diversity is a fundamental value and a cornerstone of contemporary UR-dominated society. In fact, however, in terms of the analysis of diversity presented above, the rise of discourses about diversity – as for all *global* discourses – must be viewed as a symptom of *decreasing* cognitive diversity. Whereas a broad and idiosyncratic range of cognition around diversity once obtained, UR has brought global templates for cognition to every agent. Recently, for example, the #MeToo movement set the issue of gender into a certain polarised structure around the world. Whether this one phenomenon has reduced or increased cognitive diversity is

a moot, *qualitative* point. Taken as a whole, however, discourses that dominate globally via UR must have the *systemic* effect of reducing cognitive diversity overall.

Although it will not be traced here, it would seem possible to reconcile the teleology of declining cognitive diversity with the rise in global discourses *about* diversity. Put simply, the drive to economic and social optimality gives rise to discourses that efficiently allocate – or at least *consume* – cognition in support of it.

Intelligibility

The counterintuitive result above is that while technology is providing information in seeming abundance via UR, this leads to increased homogeneity of environments which must lead to a decrease in cognitive diversity. This decrease is disguised by a perceived increase in intelligibility whereby we expect, and have patience only for, stimuli that fit immediately into our cognition. The rise of the "random" as a term in popular culture might be regarded as a symptom of this increase in intelligibility: what is not immediately recognizable and intelligible is pushed from cognition as "random" as the mind seeks to navigate only those states on the homogenous, highly connected network. The term "stranger", for example, has largely been replaced by "random guy/girl" in many idiolects. In such a context we must re-examine what creativity – once capable of generational, revolutionary effect – now means.

Schematisation

In work that is easily related to the rising trend to fast intelligibility, Stiegler (1994/1998) has criticised the role of technology in "schematicising" cognition – that is, patterning thought into generalisable routines, or, as Quine, his forerunner, defined it: "positing sharp boundaries where none can be drawn" (Quine, 1990, p.12). Schematisation leads to shortcuts in thought for activities as diverse as recognizing villains in a movie by their smoking habits; interacting with checkout staff in ways learned from vending machines; or calling one's memory one's "hard drive".

Via schematisation, UR impacts social relations by the spread of common experience. To navigate the common environment, one must learn and acquiesce to routines of thought and action or be nudged[1] into line with other members by shared norms. The paradox of diversity applies: if one wishes to increase diversity in UR contexts one must commit acts of rebellion which will only be noticed if they in fact fit current schemas. As a rebel against UR one is in danger of creating a rebellious movement that can only thrive on the commonality supplied by technology, which under UR will quickly normalize it.

A relevant metaphor for cognition in homogenous environments is the (integrally related, embodying) adaptive development of our bodies. When living in natural environments full of uneven and undulating surfaces, we can attain almost any position. We will of course begin to wear pathways, but these evolve with our activities and are not fully determinative. Our physiology adapts so that our feet retain degrees of freedom, develop callous from certain movements over rocks or sand, and our awareness of terrain is of a certain fluid kind. Consider, in contrast, a human built environment in which surfaces are generally flat and even and any obstacles are essentially vertical (such as the side of a building or house). Our movement becomes limited in absolute ways. If we wish to go to a certain place there are hard restrictions on what paths are possible. Our feet will adapt to walk on flat surfaces; our awareness of terrain will be of a more binary kind; and we will inhabit an area having experienced only a small fraction of its terrain or viewpoints (not many of us have seen inside all the houses or apartments within 100 metres of our own). The effects of UR on cognition are of a similar, schematicising kind, which has profound ramifications for creativity.

Creativity under declining cognitive diversity

Under the axioms of finite cognition introduced at the start of this paper, a very straightforward quantitative definition of creativity is possible. Creativity is the mechanism by which one agent induces, or more romantically *inspires*, new cognitive states in another agent. UR under this definition has obviously increased the creative potential of each individual enormously. Each agent has the means to offer images and sounds via telecommunications to billions of others and to create new cognitive possibilities for them. This is in stark contrast to the world prior to UR, when it was difficult to affect large numbers of people even over long periods. It may, for example, have taken centuries for any significant number of people to have heard of, or formed a view about, an enormous public creative work such as Chartres cathedral.

We must pause to reflect, however, that, despite the new possibilities technology introduces, the total amount of cognition remains relatively constant. There are therefore two types of creativity that fit our quantitative definition. These roughly parallel Boden's (1990) psychological or "p-creativity", and historical or "h-creativity" but are worth reframing for the quantitative approach. Firstly, the new cognition need not necessarily be new in a global sense – only to one or more individuals. Creativity, therefore, involves, most minimally, a local increase in cognitive diversity that does not increase overall diversity. We might call this "zero gain" creativity and note that it tends to increase the *z* metric proposed above (makes cognition more similar). At the other extreme, creativity may involve provoking a completely new cognition never before attained by any agent (for example, Archimedes' eureka moment). We can call this "global increase" creativity and note that – at least initially – it tends to reduce *z* (makes cognition less similar). UR, by this distinction, overwhelmingly provokes a disproportionate amount of zero gain creativity.

[1] It is perhaps no coincidence that, in recent years, governments have formally embraced the notion of using UR to shape behaviour using techniques such as "nudging" (Thaler, 2009).

Diffusion and interpretation

A surfeit of zero gain creativity under UR has reduced the half-life of creative activity to very low levels. Anything new is quickly disseminated throughout the cognitive field. Novel thought is under pressure from (and likely to be displaced by) the next low gain stimulus. Moreover, the rapidity of dissemination discourages prolonged or novel interpretation of reproductions. Interpretation must be relatively shallow: the stimulus, as noted, must be immediately intelligible or will be simply ignored by the majority of receivers. It would seem absurd in the current context to spend years in careful interpretation of a single work of art to achieve something novel, but such activity was common and valorised in centuries past (as the long traditions of exegesis and hermeneutics attest).

In terms of the quantitative definition of creativity, under UR there is much creativity. Afterall, UR provokes new cognitive states in unprecedented numbers of individuals. The ubiquity and speed of that creative reception, however, is not growing the broader diversity of cognition as rapidly as the pre-UR age, which *ipso facto* lacked the apparatus of cognitive synchronisation.

Creativity, bending with the decrease in cognitive diversity, is becoming a short rather than long term possibility. Creative activity in homogenous environments is under pressure to be continuous and schematic or risk exclusion as "random". This leads to the increasing dominance of formulaic creativity. In Figure 5, for example, a piece of graffiti attributed to the artist Banksy combines simple images and colours. The placement of the graffiti in a drab urban context (not shown) draws viewers to its intelligibility and achieves – almost formulaically – a flash of creativity while also providing a ready-made meme for UR.

Should we limit environmental homogeneity?

Future historians may refer to our era not as The Information Age but as The Great Synchronisation. There exists a danger that the growing ubiquity of human interaction with technology and the homogenizing reproduction it enables may lead to restricted "closed" paradigms that we are not in control of – paradigms that are instead defined by the affordances and economics of the technology itself. The end result may be a counterintuitive and potentially pernicious reduction in cognitive diversity occasioning a new sterile aesthetics – an air-conditioned Dark Age in which there are no wrong clocks. Creativity expansive of human thought ("global gain") is at risk from creativity that is merely distributive ("zero gain"). We must beware that what is not instantly intelligible is not denied a place in the panoply of human cognition. A possible remedy that warrants further formalisation and research is the measurement and control of environmental homogeneity – something which must become a recognised parameter of our tolerance for ubiquitous computing.

Figure 5. Graffiti art attributed to Banksy known as *Girl with Balloon*. The image can be seen as an example of the trend to intelligible, formulaic, meme-friendly creativity.

Conclusion

This paper examined the paradox of cognitive diversity as a lauded societal value in the increasingly homogenous environments created by ubiquitous computing and the ubiquitous reproduction it allows. If we value diversity in any form, we must value cognitive diversity, for by definition all diverse reality springs from diverse cognition. The paradox is that ultimately our drive to communicate using reproductive digital means cannot be other than a force for reducing cognitive diversity to some optimally oscillating set.

The practical benefits of reduced cognitive diversity in the relation of humanity to its material needs – thriving in material terms with all resource exploitation and population itself optimized to maximum carrying rate – is unquestionable. Inefficient cognition leads to waste and error. We should question, however, whether we are ready to abandon some long-held commitments to our destiny as a species in order to embrace these benefits. For if creativity involves producing or inducing *new* types of cognition there can be only localized, short term creativity in a system that distributes stimuli and displaces existing diversity with superlative efficiency. We may in the process be condemning those who come after to lives of robotic absurdity, making them martyrs to our vainglorious and infinite conception of our very finite selves.

Abstract

We traced the development of sensitivity to symmetric relational patterns by creating a symmetry match-to-sample task. Children saw a symmetric standard made up of two shapes and choose between two novel alternatives: a symmetric pair and an asymmetric pair. We found that young children chose randomly between the two alternatives. Children were not reliably above chance until 8-to 9 years of age. In a second study, we found that young children could succeed in making symmetric relational matches if the triads were designed to invite informative comparisons. These findings show that relational insight of symmetry develops relatively late. However, as with other relations, comparison processes can promote sensitivity to the symmetry relation.

Keywords: symmetry; relational processing; comparison and contrast

Introduction

The acquisition and use of relational concepts are critical to higher-order cognition, and to learning in complex domains. Symmetry is arguably one of the most basic and ubiquitous relations in nature, evident in structures as small as molecules and as large as blue whales. Non-human animals are thought to show a preference for symmetrical over asymmetrical bodily features when choosing a mate, and there is evidence that humans rate symmetrical faces as more attractive than non-symmetrical ones (e.g., Grammer & Thornhill, 1994; Møller, & Thornhill, 1998). Based on these patterns, some researchers have suggested that sensitivity to symmetry may be biologically endowed (e.g. Grammer & Thornhill, 1994).

Evidence in favor of this claim comes from three lines of research. First, symmetry is easily processed by the human visual system (e.g., Wagemans, 1997). Researchers have suggested that symmetry detection is an automatic process that is rapid and robust to noise (Carmody, Nodine, & Locher, 1977; Royer, 1981). Symmetry processing is also thought to be a fundamental component of perceptual organization, playing a crucial role in object representation (e.g., Driver, Baylis, & Rafal, 1992; Marshall & Halligan, 1994).

Second, symmetry processing is widespread across species. Dolphins, pigeons, bamboo sharks, and bees are all capable of learning to discriminate between symmetric and asymmetric objects (Delius & Nowak, 1982, Giurfa, Eichmann, & Menzel, 1996, Schluessel et al., 2014, von Fersen et al., 1992).

A third point is that sensitivity to symmetry is early to emerge in human infants. Human children are sensitive to symmetry from infancy, although vertical symmetry is typically more readily perceived than horizontal symmetry. For example, using a habituation-dishabituation paradigm, Fisher, Ferdinandsen, and Bornstein (1981) found that 4-month-olds discriminated vertically symmetric single objects from those that were horizontally symmetric or asymmetric, but did not discriminate between horizontally symmetric and asymmetric objects. Other researchers have found converging results with older children (Bornstein and Stiles-Davis, 1984; Chipman & Mendelson, 1979).

The findings reported above have all focused on within-object symmetry. Taken together, they suggest that within-object symmetry may be a low-level visual feature that is universally detected. However, symmetry is not confined to single objects—many scientific discoveries emerge from detecting symmetrical patterns between objects or events (e.g., Gross, 1996). We want to raise the possibility that discriminating within-object symmetry is quite different from detecting symmetry between two or more distinct objects; the latter requires symmetry to be construed as a relation while the former does not. Although previous research on symmetry processing has revealed much on how humans and non-human animals perceive symmetry within a single object (see Cattaneo, 2017; Giannouli, 2013; Treder, 2010; Wagemans, 1997 for reviews), comparatively little is known about the development of the ability to recognize and match symmetry between objects. This paper aims to shed light on the development of children's insight of the between-object symmetry relation.

Is Symmetry the Basis for *Same/Different* Detection?

A secondary motivation for examining children's ability to detect and match symmetry relations is to explore how symmetry pertains to other fundamental relational concepts, such as *same* and *different*.

If between-object symmetry is fluently processed, as a low-level visual feature, even by very young children, it is possible that symmetry detection may inflate children's performance on *same*/*different* relational tasks. In an insightful analysis, Hochmann and colleagues (2017) discussed this possibility. They pointed out that in many *same*/*different* relational tasks, *same* pairs are also symmetrical (e.g., [O,O]), whereas *different* pairs are asymmetrical (e.g., [O,X]). Thus, participants could potentially pass such tasks by responding to symmetry.

Walker and Gopnik (2017) reported evidence that runs against this contention. Using a relational causal paradigm (the "Blicket Detector"), they found that 18-to 30-month-olds

could learn to discriminate between *different* pairs (e.g., [A, B]) and *same* pairs (e.g., [Ↄ, C]). Note that, as discussed above, the *different* pair is asymmetrical and the *same* pair is symmetrical, leaving open the question of whether the children were relying on symmetry rather than sameness. However, when the objects were fused together to form either a single symmetrical object (made from two identical objects) or a single asymmetrical object (made from two different objects), the toddlers failed to learn the discrimination. These findings suggest that within-object symmetry is not the basis for the children's performance on this *same/different* relational task. However, it does not address whether between-object symmetry detection influences *same*/*different* detection.

Can Children Detect Symmetry Between Objects?

One study that explicitly examined whether children can detect symmetry between objects was done by Kotovsky and Gentner (1996). They presented 4-, 6-, and 8-year-olds with a relational matching task in which children were given a standard composed of three figures and had to choose which of two alternatives was more like the standard. One of the alternatives matched the standard's relation and the other had the same objects in a nonmatching configuration (see Figure 1). Within each trial, the two alternatives included the same objects. Children were given a random mixture of four trial types that differed across dimension and polarity.

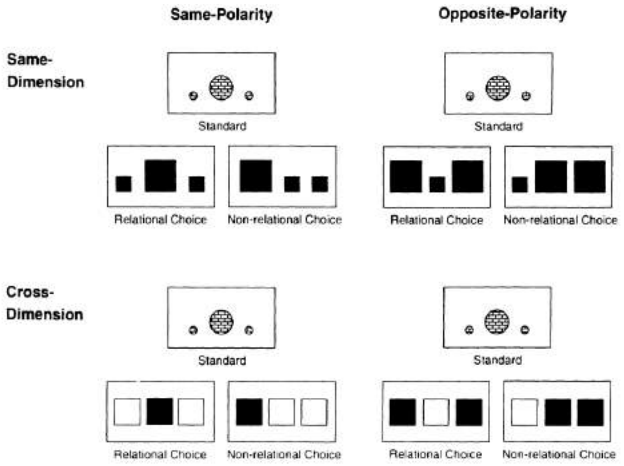

Figure 1: Schematics of stimuli used in Kotovsky and Gentner (1996).

The 6-and 8-year-olds performed well on this task. In contrast, 4-year-olds performed above chance only on trials where the correct alternative and the standard shared a concrete relation—same dimension and same polarity (Figure 1 top left panel). In these trials, the standard and the correct relational alternative share an overall shape (a low-high-low or an inverted V pattern), so it is not clear whether the 4-year-olds were attending to the relational pattern that defines symmetry or were instead simply responding to the common low-high-low shape.

The Kotovsky and Gentner (1996) study provides evidence that, at least by 6 years of age, children can perceive symmetry as a relation between objects, as well as make relational matches based on symmetry. Previous research has shown that children can make abstract *same/different* relational matches by 4 years of age without practice (e.g. Christie & Gentner, 2014), whereas the 4-year-olds in Kotovsky and Gentner's study were only able to make concrete symmetry matches. Further, we cannot confidently extrapolate from Kotovsky and Gentner's findings with 6- and 8-year-olds to the case of symmetric pairs like [Ↄ, C], because the figures in Kotovsky and Gentner's study (1996) all involved three objects. Although these are more complex than two-object figures, it could be that the larger patterns are easier to perceive.

In the current work, we trace the trajectory of children's ability to perceive and match symmetry in a task analogous to a classic *same/different* relational matching task in order to facilitate comparison of the developmental trajectories of these two relations. If we find that between-object symmetry matching is mastered earlier than same-different matching, this will leave open the possibility that same-different judgments could be drawing on symmetry perception.

Current Studies

The current work aims to (1) trace the development of human children's ability to detect and use the symmetry relation; and (2) investigate the learning processes by which children gain insight into the symmetry relation.

To do so, we created a Symmetry-Match-to-Sample task (SMTS) by analogy with the Relational-Match-to-Sample (RMTS) task (Christie & Gentner, 2014; Hochmann et al., 2017; Premack, 1983, Thompson, Oden, & Boysen, 1997). The RMTS task assesses understanding of *same* and *different* relations. For example, to assess the ability to match the *same* relation, the RMTS triad is AA (standard), BB & CD (alternatives). It is designed so that there is only one viable similarity match—the relational match based on the *same* relation. Analogously, in the SMTS task, children are shown a symmetric standard and asked to choose which is more similar: another symmetric pair, or an asymmetric pair. The standard and alternatives did not share any common objects, so there was only one viable choice (See Figure 2a).

Experiment 1

Methods

Participants One hundred 3-to 9-year-olds participated in this study: 19 3-year-olds (M = 42.8 months, SD = 2.3 months, 11 females), 21 4-year-olds (M = 53.6 months, SD = 3.4 months, 11 females), 20 5-year-olds (M = 68.4 months, SD = 1.6 months, 10 females), 20 6-year-olds (M = 80.4 months, SD = 1.8 months, 11 females), and 20 8- to 9-year-olds (M = 105.8 months, SD = 7.5 months, 9 females). An additional 11 children were tested but excluded from the final analysis, one child due to experimental error and ten children

due to failing to pass the catch trials described below (one 4-year-old and nine 3-year-olds). The racial and economic composition of the sample reflected those of the local population (majority European-American, middle- and upper-middle-class). All children were recruited from the greater Chicago area and received a small gift for their participation.

Materials and Procedure Children completed a Symmetry-Match-to-Sample (SMTS) task. The SMTS included eight test trials and three catch trials. Each trial was composed of a standard card and two alternative match cards (see Figure 2). The child was asked to choose the alternative that was most like the standard. In all test trials, the standard and correct match both depicted two identical shapes that were symmetric around the vertical axis; the incorrect match card showed two shapes that were in an asymmetric configuration (Figure 2a). Within a triad, each card was made up of unique shapes and colors.

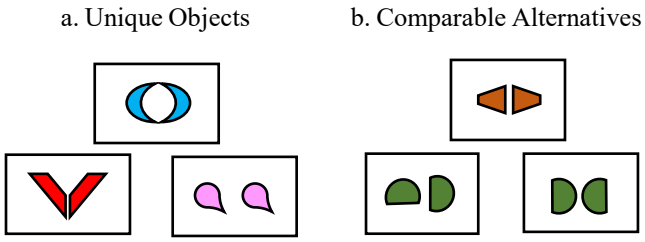

Figure 2: a. Sample test trial from Exp. 1: SMTS; b. Sample test trial from Exp. 2: SMTS with Comparable Alternatives.

After the test trials, there were three catch trials to determine whether the participants understood the task. These catch trials were literal similarity matches that did not require the child to judge relational similarity. For example, on one of the catch trials, children saw a red fish as the standard and had to choose between a blue fish (correct match) and a yellow cup. Children who failed any of the catch trials were not included in the analysis (n = 10).

Children were tested individually by an experimenter in a quiet room in the child's school or in a research laboratory. On each trial, the experimenter first presented the standard card and asked, "Do you see this one?" Then she placed the two alternative cards below the standard (as in Figure 1) and asked "Do you see these two? Which one of these two is more like this one?" Left/right placement of the alternatives was counterbalanced and no more than two subsequent trials had the correct match on the same side. Children were not given corrective feedback; only general encouragement (e.g., "You were so fast!", "Alright!") was provided.

Results

We measured the mean proportion of relational matches participants made in the eight test trials of the SMTS task. A one-way ANOVA revealed no difference in performance across the age groups, $F(4,95) = 1.16$, $p = .33$, $\eta 2 = 0.05$. When we compared the means of each age group to chance (50%), we found that only the 8- to 9-year-olds ($M = 0.69$, $SD = 0.27$) selected relational matches significantly more than chance, $t(19) = 3.17$, $p = .005$. The younger groups scored at chance (6-year-olds [$M = 0.57$, $SD = 0.29$]; 5-year-olds [$M = 0.59$, $SD = 0.28$]; 4-year-olds [$M = 0.61$, $SD = 0.26$]; 3-year- olds [$M = 0.53$, $SD = 0.15$]; all ps > .05]. Figure 3 shows the mean percentage of correct responses in each age group.

To assess whether learning occurred across trials despite the absence of feedback, we compared the proportion of correct matches that children made in the first three trials with that of the last three. There were no differences between the

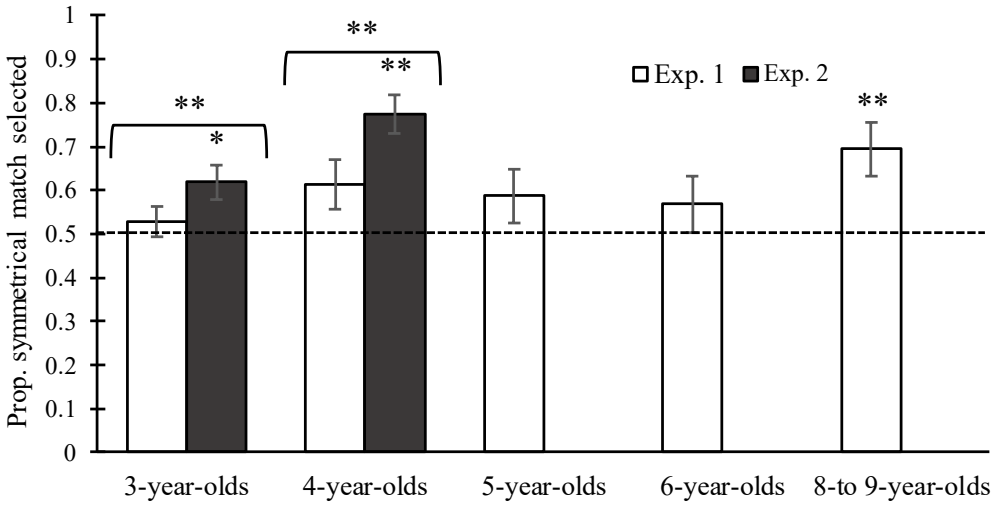

Figure 3: Mean proportion of symmetrical matches selected by children in Experiment 1: SMTS and Experiment 2: SMTS with Comparable Alternatives. Error bars depict standard error. * p < .05; ** p < .01

two in any age group, all *p*s > .13. Thus, performance did not improve across the eight test trials.

Discussion

The SMTS task was surprisingly challenging for children. Children who were six years of age or younger performed at chance rates. Even the 8- to 9-year-olds, who chose the relational match at significantly above chance rates, were only correct 69% of the time. It is unlikely that the younger age groups' poor performance was due to a failure to understand the task, since all participants were correct on the catch trials.

Why did children perform so poorly on the SMTS task compared to the findings in Kotovsky and Gentner? Kotovsky and Gentner (1996) found that 6-and 8-year-olds, and even 4-year-olds to a lesser extent, were able to make relational matches based on between-object symmetry. We propose that a crucial difference between our Experiment 1 and the Kotovsky and Gentner study was how much the experimental design scaffolded children's detection of the target relation.

Research has shown that an effective way to promote relational reasoning is by decreasing the salience of individual objects (Gentner & Rattermann, 1991; Goldstone & Son, 2005; Kaminski, Sloutsky, & Heckler, 2008). In similarity tasks, young children and novices tend to focus on objects rather than relations, and this can impede their relational processing (Gentner, 1988; Gentner & Toupin, 1986; Richland, Morrison, & Holyoak, 2006). In many studies, object salience has been reduced by using simple and uniform objects (Gentner & Rattermann, 1981; Mix, 2008). Kotovsky and Gentner (1996) further reduced object salience by presenting children with triads in which the two alternatives shared the same objects and differed only in the relation between the objects.

We hypothesize that using comparable alternatives promoted children's symmetry matching for two reasons: (1) using the same objects in both alternatives invites spontaneous comparison between them, and this may call attention to the key relational difference—that one is symmetric and the other is not; and (2) using the same objects in the two alternative pairs allows the child to discount object matches in making their choice and focus instead on any relations they may have perceived. In Experiment 2, we test this hypothesis by presenting children with a version of the SMTS that utilized comparable alternatives. We focused on the two younger age groups—the 3-and 4-year-olds.

Experiment 2: Comparable Alternatives

Methods

Participants Twenty 3-year-olds (M = 44.7 months, SD = 1.8 months, 9 females) and twenty 4-year-olds (M = 53.1 months, SD = 3.2 months, 11 females) were recruited for this experiment using the same methods as Experiment 1. Six additional children (four 3-year-olds) participated in the study but were excluded from analysis due to failing at least one of the catch trials.

Materials and Procedure As in Experiment 1, we created a relational matching task based on the symmetry relation. However, we modified the alternatives so that the two alternatives in a given trial consisted of the same objects, one in a symmetric configuration and the other in a non-symmetric configuration (see Figure 2b). The catch trials and procedure were as in Experiment 1.

Results

The mean proportions of relational matches are shown in Figure 3. Two-tailed one sample t-tests revealed that both 3-year-olds (M = 0.62, SD = 0.18) and 4-year-olds (M = 0.78, SD = 0.20) performed significantly better than chance, $t(19) = 2.97$, $p = .008$, and $t(19) = 6.24$, $p < .001$, respectively. However, the 4-year-olds made a significantly higher proportion of relational matches than the 3-year-olds, $t(38) = 2.63$, $p = .01$. Children in both age groups performed equally well on the first three and last three trials (all *p*s > .05).

We next compared the performances of the 3-and 4-year-olds in the current experiment (Comparable Alternatives condition) and those in Experiment 1. A two-way ANOVA revealed a significant main effect of age (3-year-olds vs. 4-year-olds, $F(1,76) = 7.19$, $p = .009$) and a significant main effect of condition (Experiment 1 vs. Experiment 2, $F(1,76) = 7.88$, $p = .006$). The interaction between age and condition was not significant. In both experiments, 4-year-olds performed better than 3-year-olds. Both age groups performed better in Experiment 2 than Experiment 1.

Discussion

Consistent with our hypothesis, 3-and 4-year-olds performed well on the SMTS when presented with alternatives that were composed of the same objects, but in different relational configurations. Both age groups performed significantly better in Experiment 2 than in Experiment 1. In addition, both 3-and 4-year-olds chose the symmetric match at above chance rates, whereas only the 8-and 9-year-olds in Experiment 1 were able to do so.

The two alternatives in Experiment 2 were extremely similar— the same object was used to form the object pairs on both alternative cards, with the only difference being the symmetric or asymmetric configuration between the objects. As noted above, we hypothesized that this would have two advantages: first, common objects can invite comparison between the alternatives, and this may lead to noticing that the relational patterns differ; and, second, when the same objects are used in both alternatives, children should be less likely to rely on object matches to discriminate between them, thus inviting attention to the previously less salient relational information (e.g., Mix 2008).

Consistent with this prediction, children performed markedly better in Experiment 2 than in Experiment 1. When the relation depicted by each alternative card was more salient, the process of detecting and matching these relations

(comparison and contrast) seemed to be more fluent. Thus, 3- and 4-year-olds who previously were not able to pass the SMTS were able to do so when presented with comparable alternatives.

General Discussion

Across two experiments, we explored children's ability to perceive and match symmetry between two objects using a Symmetry-Match-to-Sample (SMTS) task. In Experiment 1, we found a long developmental course for between-object symmetry matching: children did not pass the task until after 6 years of age.

In Experiment 2, we explored the method of Comparable Alternatives in facilitating children's relational insight. We presented children with a matching task in which the two alternatives were composed of the same objects. With Comparable Alternatives, even 3-and 4-year-olds chose the symmetric match at significantly above chance rates. We propose that there were two reasons for this improvement. First, the common objects promoted online comparison between the two alternatives, setting the stage for children to discover the crucial difference between them—whether or not the two objects in each alternative were symmetrical to each other. Second, using common objects in the two alternatives signaled to the children that object similarity could not be the basis for matching, thus allowing them to shift their attention to relations.

Symmetry does not inform *Same/Different* Detection

The present findings provide evidence against the claim that symmetry detection informs *same/different* detection. Researchers have consistently found that 4-and 5-year-olds can pass the standard Relational-Match-to-Sample (RMTS; with unique objects) task without any prior training, corrective feedback, or linguistic assistance (Christie & Gentner, 2014; Hochmann et al., 2017, Hoyos, Shao, & Gentner, 2016). However, children do not pass a similar Symmetry-Match-to-Sample (SMTS) task (Experiment 1) until after 6 years of age. Taken together, these findings suggest that children are not passing the RMTS by responding to symmetry. In fact, between-object symmetry matching appears to emerge later than *same*/*different* matching.

Bootstrapping relational insight

Because of the importance of comparison in acquiring relational insight, a number of techniques have been explored for promoting relational comparison. One such technique is Progressive Alignment—the phenomenon whereby carrying out relatively concrete and easy-to-align matches promotes subsequent ability to match less surface-similar, more challenging pairs that instantiate the same relation (e.g., Gentner, Loewenstein, & Hung, 2007; Haryu, Imai & Okada, Kotovsky & Gentner, 1996; Loewenstein & Gentner, 2001).

In Kotovsky and Gentner's (1996) initial study, 4-year-olds only succeeded on trials that involved concrete matches, suggesting that they did not have an abstract representation of the symmetry relation. In a follow-up study, Kotovsky and Gentner (1996) presented a new group of 4-year-olds with the same trials as before, but in an order designed to promote progressive alignment. Children were first shown a block of concrete (within-dimension) trials and then progressed on to more abstract (across-dimension) trials. The 4-year-olds showed a gain in performance on the abstract trials.

The technique used in Experiment 2—Comparable Alternatives—is another way to scaffold children's relational insight. Here, the two alternatives share the same objects but instantiate different relations, only one of which matches the standard. This design not only promotes comparison between the two alternatives, potentially highlighting the relational difference, but also de-emphasizes the role of objects, signaling that objects are not the basis for matching.

To our knowledge, the current study is the first to explicitly investigate whether the use of comparable alternatives is a way to promote relational insight. Prior studies have used alternatives that share common objects in relational matching tasks, but have not investigated whether this procedure promotes relational insight than using standard dissimilar alternatives (e.g., Kotovsky & Gentner, 1996; Mix, 2008). We are currently investigating whether presenting children with relatively easy comparable alternatives trials could serve to bootstrap later performance on the more abstract SMTS—analogous to progressive alignment.

Within-Object Versus Between-Object Symmetry

In this paper, we focused on a relatively overlooked aspect of children's symmetry development—the ability to detect and match between-object symmetry. Our findings contrast with a large body of research on within-object symmetry detection that has viewed symmetry as a low-level visual feature. We found evidence suggesting that between-object symmetry—at least for 3- and 4-year-olds—can be perceived and processed as a relation. As with other relations, children's initial relational representations may be quite concrete (Gentner, 2010); but further experience—notably experience in comparing examples (and nonexamples) of the relation—can lead to more abstract, portable representations.

This leads to the question of whether the representations and mechanisms that support processing within-object symmetry are the same as those that support processing between-object symmetry. For example as noted above, there is evidence that many animals can detect within-object symmetry. Can the same species detect between-object symmetry, and can they construe symmetry as an abstract relation?

Although we do not have the answers to these questions, we propose that researchers may take inspiration from the existing rich literature on *same/different* processing. Premack (1983), among others, has proposed species graded differences in relational reasoning ability (see also Gentner, 2003; 2010; and Penn, Povinelli & Holyoak, 2008). A substantial body of empirical findings supports this proposal. For example, there are more species that can learn to

discriminate between *same* and *different* pairs (e.g., rhesus macaques [Katz, Wright, & Bachevalier, 1984] than species that can learn to make relational matches based on *same*/*different* pairs, hence passing the Relational-Match-to-Sample task (e.g., chimpanzees [Premack, 1983; Thompson, Oden, & Boysen, 1997]; and hooded crows [Smirnova, Zorina, Obozova, & Wasserman, 2015]). Does a similar distinction hold for symmetry? If so, we would expect to see a gradient between species that can detect symmetry and those that can pass a Symmetry-Match-to-Sample task, as investigated here.

Conclusions

The present work provides an initial exploration of the development of insight into the symmetry relation. Using a Symmetry-Match-to Sample task, we found that the ability to process relational matches based on symmetry emerges relatively late in development. However, as with other relations, insight into the symmetry relation can be scaffolded through comparison processes. The present work also explores a novel way of promoting relational insight—using comparable alternatives that share objects but not relations. These findings underline the importance of comparison in supporting children's understanding of symmetry and other relations.

Is an over-polite compliment worse than an impolite insult?: Pragmatic effects of non-normative politeness in Korean

Abstract

Honorifics in Korean appear as verbal inflections and have been considered as markers of politeness. This study investigates the pragmatic effects of honorifics, and suggests that honorifics can contribute to the semantic interpretation of verb phrases in complex ways. Native Korean speakers reported different inferred meanings of "did very well" and "did very poorly" based on the normative or non-normative honorific forms. We found significant effects of non-normative honorifics in positive assessments: over-polite honorifics brought negative interpretations. This suggests that pragmatic listeners interpret utterances based on the interaction between literal meanings, honorifics, and the normativity of the honorifics within a relationship context, to obtain an estimate of the speaker's intended meaning. This is inconsistent with the previous explanations of honorific usage as discernment or volitional politeness. We suggest that non-literal meaning inferences reflect listeners treating the honorifics as signals to potential communicative goals.

Keywords: pragmatics; semantics; politeness; honorifics; pragmatic inference; Korean

Introduction

Languages have many ways of expressing politeness. Some languages explicitly mark politeness with *honorifics*: grammaticalized or lexicalized forms for politeness. Honorifics are prevalent in languages such as Japanese, Javanese, Hindi, and the subject of this investigation: Korean. Because appropriate honorifics depend on the speaker-listener relationship, they primarily function as a reflection of social norms (*discernment politeness*). However, speakers may strategically deviate from the normative form in certain contexts, such as when making requests (*volitional politeness*, Hill et al., 1986).

In this paper, we investigate whether such deviations integrate more generally into the pragmatic inference process that listeners undertake when interpreting a message. Specifically, we look at whether a speaker's choice of honorific forms influences how a listener assesses the speaker's true opinion. We carry out judgment experiments to compile data on Korean listeners' interpretations. Our result shows that the inferred meaning of the message changes with honorifics in a complex manner that cannot be adequately explained by either strictly normative or strictly strategic use of honorifics. Instead, honorifics could be used as pragmatic signals to the meaning depending on the context.

Overall, this suggests that despite grammaticalized forms seeming to be low in semantic content, they can still significantly influence the inferred meaning of the message. We argue that a full understanding of honorific use will require their incorporation into frameworks of pragmatic inference, such as the Rational Speech Act framework (RSA, Frank & Goodman, 2012; Goodman & Stuhlmüller, 2013).

Table 1: Honorific inflections of the past tense of "do" (*ha-*) in Korean. Honorification decreases from top to bottom and left to right. *-ess* is past tense suffix.

Speech Level	Honorific Suffix *-sy*	
	Present	Absent
DEF (deferential)	ha-**sy**-ess-*supnita*	ha-ess-*supnita*
POL (polite)	ha-**sy**-ess-e-*yo*	ha-ess-e-*yo*
INT (intimate)	ha-**sy**-ess-*e*	ha-ess-*e*
PLN (plain)	ha-**sy**-ess-*ta*	ha-ess-*ta*

Honorifics in Korean

Honorifics in Korean have two main realizations: honorific lexical items and honorific inflections. This study focuses on verbal honorific inflections, specifically speech levels and the *-sy* suffix. Table 1 demonstrates some of the honorific inflections that are available for the verb "do" (*ha-*). The speech level appears at the end of the verb phrase, and reflects the relationship between the speaker and the addressee. Four levels presented in Table 1 are tested in this study, and their perceived honorification decreases from top to bottom. The presence of honorific suffix *-sy* increases the honorification toward a subject of a sentence or a referent of the verb. This study examines cases where the subject of the sentence is the addressee, thus both the suffix and the speech level refer toward the listener. Honorific inflections, therefore, can be generally defined as stylistic features reflecting the speaker and listener's position within a social hierarchy, not the truth-conditional meanings (Sohn, 1999).

In colloquial Korean, speakers must choose some level of honorific inflection to form valid verb phrases; there is no default form or level. In most cases, the appropriate honorifics can be determined by the speaker-listener relationship, as honorifics were mentioned as relationship-acknowledging devices (Matsumoto, 1988). Honorifics are grammaticalized and conventionalized in relation to the speaker-listener relationship. Speakers using appropriate honorific forms assigned by the relationship context will therefore stay aligned with the normative use of honorifics. This type of honorific use can be summarized as *discernment politeness* (Hill et al., 1986; Ide, 1989; Koo, 1995).

Besides the normative use of honorifics, they can also be used more strategically. Politeness Theory (Brown & Levinson, 1987) has explained strategic honorific use through *negative politeness*, a politeness strategy for minimizing threats to the listener's *negative face*—the desire not to be imposed

upon.[1] This form of politeness is distinguished from *positive politeness*, a strategy used to minimize threats to *positive face*—the desire to be liked or approved. In the Politeness Theory perspective, speakers use honorifics largely to mitigate the potential face threats existing in the utterance. This type of honorific use can be summarized as *volitional politeness* (Hill et al., 1986; Ide, 1989; Koo, 1995)

These explanations for honorifics' uses are well-supported, but such general politeness strategies may represent only a subset of how honorifics are actually used. We argue that deviations from normative politeness levels can function as a pragmatic signal to the listener about the intended meaning of an utterance. We suggest that honorific use ties to a more general pragmatic behavior than previously described, providing pragmatic information beyond mitigating face-threats and potentially signaling a speaker's communicative goals.

Hypotheses

Based on the above discussion, we consider three hypotheses for the potential effects of honorifics on pragmatic inference. These span from a null pragmatic effect (if honorifics mainly express the speaker-listener relationship) to a monotonic relationship between inferred meaning and levels of honorifics (if honorifics mainly manage face-threat) to a complex relationship between honorifics and inferred meaning (if honorifics provide cues about the speaker's communicative goals).

To test this, we examined listeners' inferences of values for scalars: speakers' statements that a listener had done "well" or "poorly" on a test. We first described the speaker-listener relationship, then provided assessment sentences with eight honorific inflections from Table 1, and asked participants to estimate the exam score based on the assessment. More details are in the next section, but our hypotheses and the predictions they make follow.

> **Hypothesis 1:** Honorifics are primarily about *discernment politeness*. **Changes in levels of honorifics will have no significant effects on pragmatic interpretation of scalars.**

Under this hypothesis, the speaker-listener relationship determines the appropriate honorifics, and forms that deviate from the normative standard would be similar to errors of subject-verb agreement—they could affect the perceived acceptability of a sentence, but not the meaning. If Hypothesis 1 is correct, we should not see differences in the listener's interpretations depending on the honorific forms used within the relationship context. This hypothesis is consistent with traditional analyses of the Korean honorifics, as in Sohn (1999).

> **Hypothesis 2:** Honorifics primarily serve to mitigate face threat through *volitional politeness*. **As the utterance becomes more honorific, inferred values of scalars will be monotonically decreased**.

Under this hypothesis, speakers would use higher levels of honorifics to offset the negativity of an honest assessment. Therefore, we can expect to see a monotonic decrease in listeners' inferred values of scalars as the honorific level increases, with the "poorly" condition possibly showing a larger effect due to the more explicit face-threatening assessment. Being over-polite or being under-polite (relative to normative forms) should show opposite effects on the inferred meaning. This hypothesis is similar to the threat-management account of Politeness Theory (Brown & Levinson, 1987), or the social utility addition (Yoon et al., 2016) to the RSA framework explaining listeners' discounting of compliments when they thought the speaker was being polite.

> **Hypothesis 3:** Honorifics, in addition to their discernment or volitional use, also can signal cues that influence the listener's interpretations in complex ways. **Effects of honorific levels will differ by the relationship context and the literal meanings of the utterance.**

Under this hypothesis, there will be a significant but non-monotonic effect of honorific levels. Unlike Hypothesis 2, here we do not necessarily expect under- versus over-polite messages (again, relative to normative forms) to have different effects on the listener's inference. Instead, deviations from normative honorifics could signal that the speaker is indicating different meanings or goals, for example, being hyperbolic or sarcastic. This hypothesis is similar to the QUD (Question Under Discussion) addition (Kao & Goodman, 2015) to the RSA explaining ironic interpretations.[2]

Experiment 1: Literal interpretations

Method

Design The purpose of Experiment 1 was to establish the literal baseline interpretations of the phrases "did very well" and "did very poorly". Each question in the experiment started with a vignette describing a conversation and a relationship context: a speaker is asked to tell a listener how the listener did on an exam, when the listener does not know of his own exam score. The speaker's assessments of the listener's exam score were then presented. Each participant rated 8 assessment sentences: 2 valences (positive, negative) in 4 relationship settings. Participants were asked to guess the listener's exam score in a number between 0 and 100.

Relationship settings were explicitly stated. In the Friend-Friend setting, the speaker and the listener were defined as friends who were in the same year at college. In the Upperclass-Underclass setting, the speaker was a student senior than the listener. In the Professor-Student setting, the speaker was a professor and the listener a student. In the Underclass-Upperclass setting, the speaker was a student junior than the listener. These four settings were chosen to have normative honorifics that allowed for a range of under-

[1] Despite the term, *negative politeness* is still a way of being polite; it is the "do no harm" counterpart to the "do good" sense of *positive politeness*.

[2] More details on the hypotheses can be found in the Open Science Foundation preregistration page: `http://osf.io/s8nfu/register/5771ca429ad5a1020de2872e`.

and over-polite forms by varying the honorific forms. In all settings, both the speaker and the listener had male Korean names to keep gender differences from influencing the result.

Stimuli Participants saw the speaker's description of the listener's score presented as indirect quotes (i.e., [Speaker] said [Listener] did very well/poorly on the exam), so that participants would not see what honorific inflections the speaker used and thus would respond with their baseline inference in the absence of honorifics.

Participants Experiment 1 was posted on the online crowdsourcing website Dooit Survey (`http://www.dooit.co.kr`) based in South Korea. A total of 67 adult native Korean speakers completed the experiment for a small cash-value reward.

Result

Baseline scores In Experiment 1, literal interpretations of positive and negative phrases "did very well" and "did very poorly" were measured within each relationship setting. The mean of the scores in each condition were then treated as baseline scores representing literal interpretations in further analyses, since they represented the participants' estimates in the absence of honorifics. Baseline scores in each setting and condition are presented by horizontal dashed line in Figure 1. Participants reported mean baseline scores of 85.60 for the positive and 47.92 for the negative phrases. There was no significant differences according to t-tests between the relationship settings within the positive or negative valence, suggesting that participants viewed all four relationship settings having similar expected literal meanings.

Experiment 2: Inferences from honorific use

Design Experiment 2 followed the same basic idea of Experiment 1, but participants were asked to infer scores based on direct quotes, with honorific inflections. Deviations between the literal baselines from Experiment 1 and the inferences in Experiment 2 should therefore reflect pragmatic interpretations guided by the honorifics. Each participant rated a total of 16 sentences: 2 valences (positive, negative), each with 8 honorific inflections (4 speech levels $\times$ *-sy* present/ absent), in one of the 4 relationship settings (Friend-Friend, Upperclass-Underclass, Professor-Student, Underclass-Upperclass). After presenting the relationship context and the speaker's assessment, participants were again asked to infer the listeners exam score with a number between 0 and 100.

Stimuli Each assessment sentence was presented as a direct quote (i.e., [Speaker] said the following sentence: "[Address of the listener] did very well."). The presence of a direct quote meant that the sentence included one of the eight honorific inflections from Table 1, and therefore could influence participants' inferences accordingly. A sample vocative address of the listener by the speaker was included in these sentences to reinforce the normative honorifics for each relationship. In the Friend-Friend and Upperclass-Underclass setting, where the speaker was in an equal or higher position to the listener, the speaker addressed the listener with a plain "you". In the Underclass-Upperclass setting, the honorific addressee term *senbay-nim* was used. In the Professor-Student setting, no addressee term was presented, because the speaker is on a much higher social rank than the listener and could in principle use any of the honorific inflections. Below shows the assessment sentences given in the Friend-Friend setting, with *-sy* and the deferential speech level[3].

neo	*cham*	*cal*	*ha-sy-ess-supnita*
You	very	well	do.AH.PST.DEF

Positive: "You did very well."

neo	*cham*	*mos*	*ha-sy-ess-supnita*
You	very	poorly	do.AH.PST.DEF

Negative: "You did very poorly."

Participants Experiment 2 was also posted on Dooit survey. Unlike Experiment 1, we asked each participant to answer for only one relationship type, to avoid any confusion about the speaker-listener relationships. 81 adult Korean participants were collected in total, with 20 participants in three settings and 21 participants in the Underclass-Upperclass setting. The participants in Experiment 1 and 2 were recruited separately.

Results

Baseline scores vs. Normative scores The baseline scores from Experiment 1 were then compared against the "normative" scores from Experiment 2. These normative scores are the mean of the inferred scores in each setting obtained from sentences with normative honorific forms established for that setting. Normative scores are presented by black points in Figure 1. For example, in the Friend-Friend setting, normative scores were calculated from the scores reported on sentences with intimate or plain speech level without an honorific suffix *-sy* (INT, PLN, black triangles in Figure 1). The Professor-Student setting did not include a specific addressee term to establish normative forms, because of the high social position the speaker was in. To calculate the baseline scores, we considered deferential and polite speech levels used as teacher's classroom register (Sohn, 1999). In Figure 1, normative forms (black points) aligned closely to the baseline scores (dashed line), showing that participants treated utterances with normative honorific forms similarly to the literal interpretations. This is confirmed by the regression below.

Baseline scores vs. Non-normative scores Scores reported on non-normative honorific forms are presented by the red points in Figure 1. In the Friend-Friend setting, participants reported the baseline score of 82.74 for the positive condition and 46.68 for the negative. When positive assessments appeared with non-normative *-sy* (red circles), regardless of the following speech levels, participants reported scores far lower than the baseline score (*sy*+DEF: 54.25, -28.49 score difference from the baseline score; *sy*+POL: 50.10, -32.64; *sy*+INT: 46.00, -36.74; *sy*+PLN: 56.25, -26.49)[4]. This is

[3] AH: Addressee honorification, PST: Past tense suffix, DEF: Deferential speech level

[4] We test for significance on these values in the following regression model.

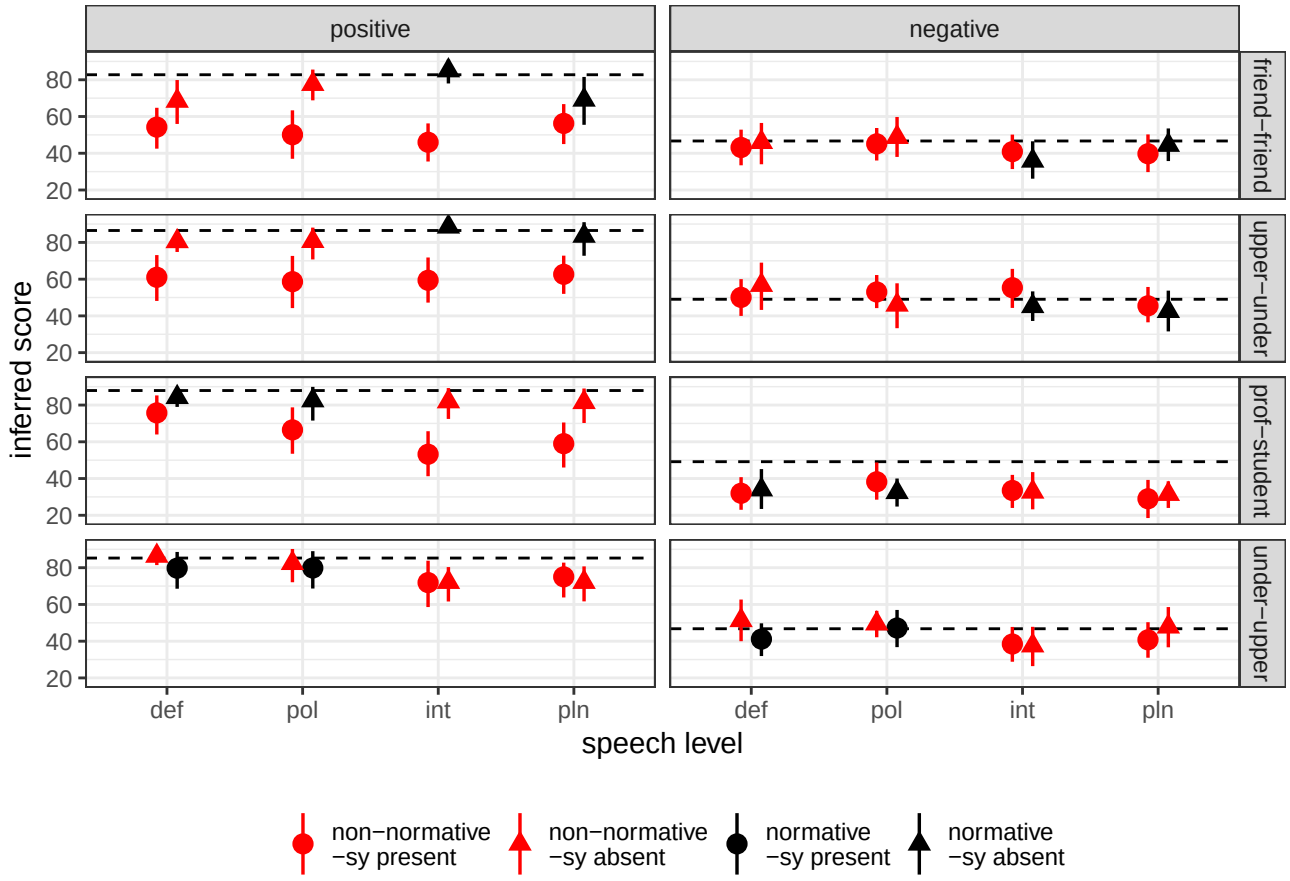

Figure 1: Participants inferred exam scores under valence (positive, negative), honorific suffix *-sy* (*-sy* present, *-sy* absent), and speech level (DEF, POL, INT, PLN) conditions in each relationship settings (friend-friend, upper-under, prof-student, under-upper). Circles and triangles indicate the *-sy* suffix being present or absent. The colors show the normativity of the forms, red being non-normative and black being normative. The dashed line in each condition shows baseline scores (from Expt 1). Vertical lines in each score point show 95% confidence interval calculated from 5000 bootstrap samples.

our first piece of evidence that over-polite forms can induce large pragmatic effects that substantially reduce the estimates of the test scores.

In the Upperclass-Underclass setting (Upperclass speaker), participants reported the baseline score of 86.49 for the positive condition and 49.05 for the negative. Normative forms were defined as intimate or plaivel without the *-sy* suffix (INT, PLN, black triangles). When positive utterances appeared with the *-sy* suffix (red circles), participants reported scores below the baseline score across the speech levels (*sy*+DEF: 61.05, −25.44; sy+POL: 58.65, −27.84; *sy*+INT: 59.40, −27.09; *sy*+PLN: 62.65, −23.84). Again, over-polite forms caused participants' pragmatic inferences to substantially drop.

Professor-Student setting showed the similar result. The baseline score was 87.91 for the positive condition and 49.17 for the negative. Normative forms in this setting were the deferential or polite speech level without the *-sy* suffix (DEF, POL, black triangles). Participants reported lower scores when the professor's positive feedback were given with non-normative *-sy* (*sy*+DEF: 75.75, −12.60; *sy*+POL: 66.50, −21.41; *sy*+INT: 53.25, −34.66; *sy*+PLN: 59.00, −28.91). Under-polite forms (the intimate/plain speech levels) do not show any increase over the normative forms, as Hypothesis 2 would have predicted.

In the Underclass-Upperclass setting, the baseline score was 85.26 for the positive condition and 46.76 for the negative. The normative forms were defined as deferential or polite speech level with the *-sy* suffix (*sy*+DEF, *sy*+POL, black circles). This relationship setting showed the least amount of score variance among all settings. One explanation could be that non-normative forms in this setting produced outright socially unacceptable sentences. Not coincidentally, this is the one setting where the speaker is of a lower social standing than the listener. Since a lower-standing speaker speaking in under-polite forms violates social norms in a great degree, participants might have been confused with those sentences and have failed to properly reason on the meaning.

Table 2: Estimated effect sizes in the linear regression with random by-participant intercepts. Default values for Valence, Speech Level and Setting are negative, deferential and Underclass-Upperclass, respectively.

	β
(Intercept)	-0.29
Valence	
Positive	3.15
Speech Level	
Intimate	-4.40
Plain	-4.10
Polite	0.77
***-sy* suffix**	
Present	-0.63
Setting	
Friend-Friend	-1.14
Professor-Student	-13.39 ***
Upper-Under	3.12
Valence × Speech Level	
Positive × Intimate	0.27
Positive × Plain	0.12
Positive × Polite	-2.30
Valence × *-sy* suffix	
positive × *-sy* present	-15.88 ***
Valence × Setting	
Positive × Friend-Friend	-10.46 **
Positive × Professor-Student	6.67
Positive × Upper-Under	-9.62 **

$^{***}p < 0.001, ^{**}p < 0.01, ^{*}p < 0.05$

Overall, the presence of the over-polite and non-normative honorific *-sy* suffix when talking to an equal or lower-standing listener signaled participants that the positive feedback could not be taken literally, and participants substantially reduced their estimates of the test scores. This is strongly at odds with Hypothesis 1. At the same time, non-normative scores (red points) were mostly at or below the normative scores (black points) in the positive valence cases, regardless of the non-normative forms being over- or under-polite. This argues against both Hypothesis 1 and Hypothesis 2.

Linear mixed-effect model

We fit a linear mixed-effect model predicting the score differences (inferential score from Expt 2 minus the baseline score from Expt 1) with random by-participant intercepts. The fixed-effect variables were Valence × Speech level, Valence × *-sy* suffix, Valence × Setting. Regression coefficients (β) are reported in Table 2. The default values were set to the scores obtained in the Under-Upper setting, from negative sentences with no *-sy* suffix and the deferential speech level.

Starting from the top of Table 2, the intercept term confirmed that there were no significant differences between inferred scores and baseline scores in the default setting of the model. Among the main effects of the Setting, only the Professor-Student setting showed significantly lowered scores. This was because the default condition (no *-sy* suffix, deferential speech level) of the model was a normative form in the setting, thus brought literal (thus, more negative) meaning. Overall, the main effects were largely small and non-significant, with the exception of one setting. This confirmed our initial anticipation that honorifics' meanings should be considered relative to the context, including the literal meanings of the message and the speaker-listener relationship.

Moving onto the interaction terms, Valence × *-sy* suffix had a large effect, lowering the inferred scores by 15.88 points from the baseline ($p < 0.001$). This shows that positive sentences with the *-sy* suffix in the three settings where the speaker was at least equal in social standing to the listener (Friend-Friend, Professor-Student, Upperclass-Underclass) showed lower scores than in the one where the speaker was of higher social standing. Those three settings shared the normativity context that the *-sy* suffix was an over-polite form, and the inferred scores dropped as a result.

Valence × Setting term also reflected the result shown in Figure 1. Friend-Friend and Upperclass-Underclass showed lowered scores in positive sentences with deferential speech level (this was default setting of the model, which was a non-normative form in the relationship). The Professor-Student setting did not show significant differences from Underclass-Upperclass setting, again because the deferential speech level was the normative form in the relationship. This showed that the Friend-Friend and Upperclass-Underclass setting behaved similarly, as higher honorifics became non-normative and over-polite forms. We could see that Professor-Student and Underclass-Upperclass behaved similarly as well. These two settings shared deferential and polite speech levels (higher honorifics) as normative forms.

In both the numeric values in Figure 1 and the regression coefficients in Table 2, we see a few patterns. First, participants' inferred scores varied substantially based on the honorifics, contrary to Hypothesis 1, which considered the honorifics to primarily serve as an agreement to the relationship. This suggests that listeners assume that speakers have made volitional choices in their honorific inflections when they deviate from normativity. Second, looking at the regression model, we see strong evidence of an effect of the *-sy* suffix in non-normative context, generally lowering the score differences (inferred score − baseline score). But there is no consistent effect with the speech levels. This runs counter to the expectation of Hypothesis 2; there is no monotonic relationship between the honorific levels and the inferred scores. Instead, we see a complex pattern that is driven largely by the normativity of the forms, rather than their relative politeness. In the next section, we discuss the implications of these results and sketch a possible explanation for the phenomenon.

Discussion

The experiment results showed clear differences on listeners' interpretations, depending on the honorific inflections, the speaker-listener relationship, and the valence of the verb phrases. Contrary to Hypothesis 1, we saw significant effects of honorifics on the pragmatically-inferred values even within a given relationship setting. Contrary to Hypothesis 2, we did not see a monotonic effect of politeness levels; deviation from the normative form generally decreased (or maintained) the inferred value of positive verb phrases regardless of whether the non-normative form was more or less polite than expected. Furthermore, in the negative valence, normative and non-normative forms showed no significant difference in their interpretation. These results suggest that while there appears to be a volitional component to the speaker's choice of honorific forms, the choice extends beyond straightforward face-threat mitigation.

Hypothesis 3 therefore appears to be the best fit to our data, though in some sense it reflects a less specific explanation at present. How can we further expand our hypothesis to explain the observed variance in pragmatic inferences? A promising direction is to build on the Rational Speech Act (RSA, Frank & Goodman, 2012; Goodman & Stuhlmüller, 2013) framework. The core idea of the RSA is that speakers and listeners each know that the other is trying to communicate in an efficient, rather than a literal, manner. The listener considers the speaker's choice of utterance as a rational decision over the set of available alternatives. The speaker prefers utterances that maximize the expected conversational utility (such as maximizing the listener's probability of inferring the intended message). The listener then uses a recursive inference process to determine the most likely meaning.

Two particular extensions of RSA inference may be relevant for unravelling the inferences that result from honorifics. Yoon et al. (2016) proposed that the speaker not only has a desire to provide epistemic utility in their utterance (giving the listener an accurate representation of the world) but also social utility (such as minimizing listener's face-threats). Honorifics, especially in the Politeness Theory (Brown & Levinson, 1987) framework, can supply social utility alongside the epistemic utility of the message itself. This fits with, for instance, speakers' selective use of honorifics when making requests. In our data, however, we see that the same honorific forms lead to substantially different inferences based on the setting. Even if we view social utility relative to the speaker-listener relationship, with over-polite forms adding social utility and under-polite forms reducing it, this would still not be sufficient to explain the variation in Figure 1.

By combining the idea of social utility with a goal- or QUD-based approach (Kao & Goodman, 2015) in RSA, though, we may be able to capture the pragmatic effects of honorifics. A Goal/QUD framework says that when a speaker produces a message that seems to violate the listener's expectations, the listener may instead interpret the message with a different goal in mind. For example, if a speaker complains that they paid an unbelievably high cost for some object, the listener may infer that the speaker's epistemic utility is not coming from conveying the literal cost but rather an affective interpretation of the cost (i.e., hyperbole).

Building on these extensions to the RSA framework, we suggest that Korean honorifics may be modelled as an interaction between the relationship context r, shared knowledge of normative honorifics k, an intended meaning s, and a goal g. The speaker's choice of utterance can be broken down into the semantic content of the word stem c and the honorific inflections m:

$$P_{speaker}(c, m|s, r, k, g) \tag{1}$$

This expresses the idea that a speaker chooses c and m jointly to deliver their intended meaning s, conditioned on the relationship context r and normativity k for the honorifics, as well as their communicative goal or QUD g. If we assume that the listener has no uncertainty about the relationship r or normativity k, we can express the listener's inference process as Bayesian inference, marginalized over the potential goals of the speaker:[5]

$$P_{listener}(s|c, m, r, k) \propto \sum_{g} P_{speaker}(c, m|s, r, k, g)P(s)P(g) \tag{2}$$

This joint distribution over c and m gives the model the flexibility to capture the complex patterns in our results in a way that a basic social utility term alone cannot. Being overly polite may come from the speaker signalling their ironic intentions by violating normative expectations of the honorific inflections. When such a deviation from the norms is slight, or consistent with a goal of mitigating face-threat, the listener merely tweaks their interpretation. When the deviation from the honorific norms is large (as when a student is overly polite to their friend, or the professor talks to the student with the honorific *-sy* suffix), the listener assumes the speaker's goal has changed. In this way, honorifics signal cues to the meaning similar to the inferred product prices in Kao et al. (2014); a small deviation from expectations retains an approximately literal interpretation, while a large deviation triggers an ironic interpretation. This argument could be verified by a follow-up experiment measuring inferred goals.

Conclusion

We have examined honorific inflections and their effect on pragmatic inference. Contrary to discernment or volitional politeness accounts, we find complex interactions between honorifics and a listener's pragmatic interpretation. We propose that this result may be explained with an extended RSA framework with jointly-distributed content and honorifics that can both provide social utility and serve to signal a speaker's communicative goals.

[5] Of course, the listener may want to update their belief about their relationship with the speaker based on the speaker's choice of honorifics! If so, the listener could marginalize over r and k.

Abstract

Unscaffolded problem-solving before receiving instruction can give students opportunities to entertain their exploratory hypotheses at the expense of experiencing initial failures. Prior literature has argued for the efficacy of such Productive Failure (PF) activities in preparing students to "see" like an expert. Despite growing understanding of the socio-cognitive mechanisms that affect learning from PF, the necessity of success or failure in initial problem-solving attempts is still unclear. Consequently, we do not know yet whether some ways of succeeding or failing are more efficacious than others. Here, we report empirical evidence from a recently concluded classroom PF intervention (N=221), where we designed scaffolds to explicitly push student problem-solving towards success via structuring, but also radically, towards failure via problematizing. Our rationale for explicit failure scaffolding was rooted in facilitating problem-space exploration. We subsequently compared the differential preparatory effects of success-driven and failure-driven problem-solving on learning from subsequent instruction. Results suggested explicit failure scaffolding during initial problem-solving to have a higher impact on conceptual understanding, compared to explicit success scaffolding. This trend was more salient for the task topic with greater difficulty.

Keywords: Classroom Study; Productive Failure; Scaffolding

Introduction

Substantial research has demonstrated the efficacy of learning approaches where problem-solving as a preparatory activity precedes instruction (PS-I). PS-I includes (i) an initial problem-solving phase where students explore solutions to complex problems based on concepts they haven't formally learnt yet, and (ii) a subsequent explicit instruction phase where a coach introduces formalisms of the targeted concepts along with the canonical solution. Research suggests that PS-I is an effective learning design that improves student's conceptual understanding and positively impacts how well they transfer their knowledge to novel problem-solving contexts (Loibl, Roll, & Rummel, 2017).

A particular variant of the PS-I design that embodies learning from failure is Productive Failure (PF) (Kapur & Bielaczyc, 2012). PF comprises rich problem design that affords multiple representations and solution methods (RSMs), and follow-up instruction that compares and contrasts student-generated solutions with the canonical one. The positive benefits of approaches implemented based on the PS-I design (e.g., PF, Invent with Contrasting Cases (Schwartz & Martin, 2004)) have been attributed to different cognitive mechanisms. These include intentional activation of relevant prior knowledge, enhancement of students' awareness of the problem situation and own knowledge gaps, focused attention on search for deeper patterns rather than surface characteristics, and effortful retrieval to resolve incongruity. Some posited socio-emotional mechanisms include increased motivation to learn targeted concepts and elicitation of curiosity (Kapur & Bielaczyc, 2012; Loibl et al., 2017).

Research Gap

Despite PS-I designs often working better compared to traditional instructional approaches (usually direct instruction) on the acquisition of conceptual knowledge and/or transfer, there is a considerable variation in effect sizes (Cohen's d = 1.12$\pm$ 0.54) (Loibl et al., 2017). This has spurred lines of inquiry into systematically analyzing reasons for failure of PS-I approaches (Sinha & Kapur, 2019), and developing ways to improve overall effectiveness of the learning design. One prominent area of focus has been the initial problem-solving phase. Here, research has started to investigate the impact of scaffolding student solutions on fostering conceptually sound and transferable learning (Kapur, 2011; Loibl & Rummel, 2014). Despite growing research in the PS-I design space, we don't have conclusive evidence yet.

Templates of successful problem-solving usually aim at pro-active error elimination, and directing student's attention to the task by providing immediate feedback. Such instruction has the advantage of helping students perform the correct procedure. However, this may not always imply that students engage in optimal reasoning or acquire high depth of understanding of domain principles. Evidence favoring success-driven (SD) learning in PS-I suggests the presence of an association between successful problem-solving during the problem-solving phase and learning from instruction (e.g., Chin, Chi, and Schwartz (2016); Schwartz, Chase, Oppezzo, and Chin (2011); Loibl and Rummel (2014); Schalk, Schumacher, Barth, and Stern (2017); Chase and Klahr (2017)). However, attempts to scaffold such success, both cognitively (e.g., Kapur (2011); Loibl and Rummel (2014)) and metacognitively (e.g., Holmes, Day, Park, Bonn, and Roll (2014); Roll et al. (2018)), have been largely unsuccessful.

Templates of exploratory or unsuccessful problem-solving, on the other hand, hold the view that acquisition of solution schema is not the solitary goal of learning through problem-solving (Schwartz & Martin, 2004; Kapur & Bielaczyc, 2012). It is equally important to develop the cognitive and socio-emotional prerequisites to prepare novice students to see like an expert. Therefore, one should provide opportunities that help students develop awareness and appreciation for what is known and not known. Instructional attempts that increase chances of failure during problem-solving have the advantage of stimulating student's initiative in gaining knowledge. However, students may not spontaneously come back to the right track if an incorrect problem representation is invoked and they continue to work on it. Evidence disfavoring SD learning in PS-I suggests that a lack of success when the problem-solving phase is implicitly scaffolded (e.g. Aleven et al. (2017); Roelle and Berthold (2016); Mazziotti, Rummel, and Deiglmayr (2016)) or left unscaffolded (e.g., Kapur

and Bielaczyc (2012)) does not harm learning. Providing no explicit cognitive or metacognitive support is imperative in view of giving students complete agency in solution generation. A consequential side-effect is that the likelihood of experiencing failures increases.

However, there is no PS-I research that looks at explicitly scaffolding problem-solving phase towards failure. This sets up the guiding question of whether and to what extent is success or failure during initial problem-solving necessary for learning from PS-I. How does increasing likelihood of students experiencing success or failure differentially prepare them to learn from the instruction at a deeper conceptual level? Are some ways of succeeding or failing more efficacious than others? To answer these questions, we design SD or failure-driven (FD) scaffolds for the problem-solving phase, as inputs into a classroom PS-I intervention. Evidence for impact of these scaffolds on learning from PF is discussed.
