Turning now to the interactions, we found that ErrorRate and LastFix interact in both reading measures, which indicates that reading times and fixation rates increase in the high-error condition if the previous word has been fixated.

Only in fixation rate, there was also an interaction of Error and LastFix, indicating that fixation rate goes up for error words if the preceding word was fixated, presumably because of preview of the erroneous words, which is then more likely to be fixated in order to identify the error.

For fixation rate, WordLength interacts with LastFix: longer words are more likely to be fixated if the preceding word was fixated; again, this is likely an effect of preview. While Figure 1 seems to suggest an interaction of Error and Error Type, this was not significant in the mixed model.

Discussion

We have found four main results: (1) Erroneous words show longer reading times and are more likely to be fixated. (2) Higher error rates lead to increased reading times and more fixations, even on words that are correct. (3) Transpositions lead to an increased fixation rate compared to misspellings. (4) Whether the previous word is fixated or not modulates the effect of error and error rate.

However, it is conceivable that the effects of error and error rate are actually artifacts of word length. All else being equal, longer words take longer to read and are more likely to be fixated. So if error words and non-error words in our texts differ in mean length, then that would be an alternative explanation for the effects that we found.

For transposition errors, error words by definition have the same length as their non-error versions. For misspellings,

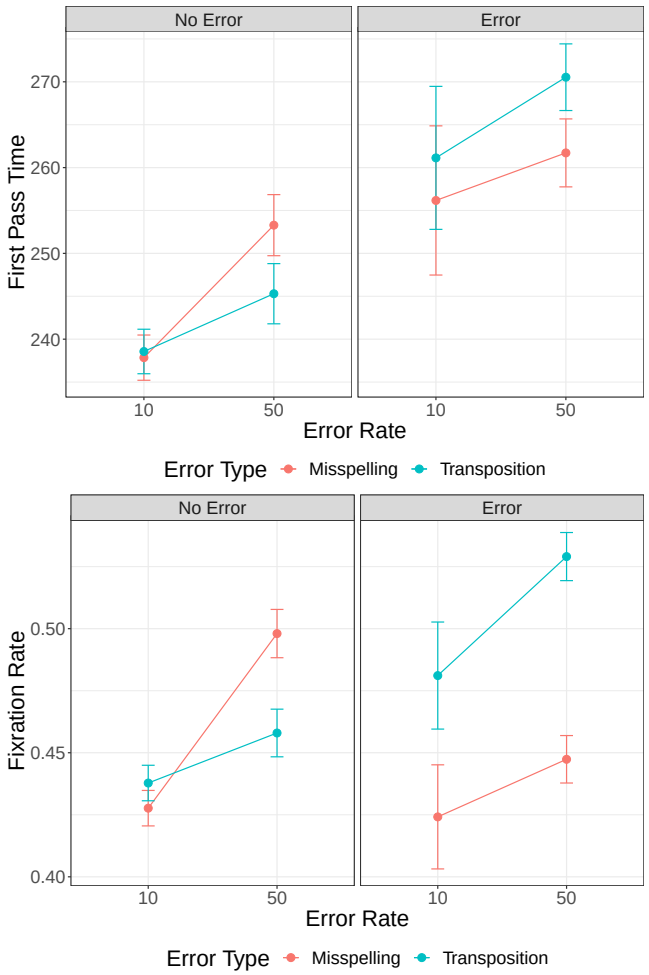

Figure 1: First pass time (top) and fixation rate (bottom) when reading texts with transposition errors or misspelling.

a mixed-effects analysis with word forms as random effects showed no significant difference in the lengths of error words and their correct versions (mean difference −0.011, SE 0.029, $t = -0.393$). Comparing the erroneous words of the two error types, we found that they differ in mean length (misspellings 5.44, transpositions 6.06 characters); however this difference was not significant in a mixed-effects analysis predicting word length of erroneous words from error types, with items as a random effect (mean difference 0.015, SE 0.010, $t = 1.449$).

Surprisal Model

Most models of human reading do not explicitly deal with reading in the face of errors. In fact, reading models that use a lexicon to look up word forms (e.g., to retrieve word frequencies) cannot deal with erroneous words without further assumptions. We can use the surprisal model of processing difficulty (Levy, 2008) to illustrate this: in its original, word-based formulation, surprisal is forced to treat all error words as out of vocabulary items; it therefore cannot distin-

guish between different types of errors or between different error rates.

Intuitively, a more fine-grained version of surprisal is required that computes expectations in terms of characters, not words. In such a setting, the word *inocent* would be more surprising than *innocent* in the same context, but not as surprising as a completely unfamiliar letter string. In other words, the surprisal of the same word with and without misspellings or letter transpositions would be similar but not the same. To achieve this, we can use character-based language models, which are standard tools in natural language processing for dealing with errors in the input (e.g., the work by Belinkov & Bisk, 2018, on errors in machine translation).

Crucially, once we have a character-based surprisal model, we can derive predictions regarding how errors should affect reading. We predict that transpositions should be more surprising than misspellings, as they involve character sequences that are unfamiliar to the model (e.g., *innocetn* contains the rare character sequence *tn*). Also, we predict that words that occur in texts with a high error rate are more difficult to read than words in texts with a low error rate: if the context of a word contains few errors, then we are able compute expectations for that word confidently (resulting in low surprisal). If the context contains lots of errors then expecations are difficult to compute and they become unreliable (resulting in high surprisal). We will now test these predictions regarding error type and error rate using a character-based version of surprisal.

Methods

We trained a character-based neural language model using LSTM cells (Hochreiter & Schmidhuber, 1997). Such models can assign probabilities to any sequence of characters, and thus are capable of computing surprisal even for words never seen in the training data, such as erroneous words. For training, we used the Daily Mail portion of the DeepMind corpus. We used a vocabulary consisting of the 70 most frequent characters, mapping others to an out-of-vocabulary token.

The hyperparameters of the language model were selected on an English corpus based on Wikipedia text.[5] We then used the resulting model to compute surprisal on the texts used in the eye-tracking experiment for each experimental condition.

The model estimates, for each element of a character sequence, the probability of seeing this character given the preceding context. We compute the surprisal of a word as the sum of the surprisals of the individual characters, as prescribed by the product rule of probability. For a word consisting of characters $x_t \dots x_{t+T}$ following a context $x_1 \dots x_{t-1}$, its surprisal is:

$$-\log P(x_t \dots x_{t+T} | x_1 \dots x_{t-1}) = \sum_{i=t}^{t+T} -\log P(x_i | x_1 \dots x_{i-1}) \quad (1)$$

In this computation, we take whitespace characters to belong to the preceding word.

To control for the impact of the random initialization of the neural network at the beginning of training, we trained seven models with identical settings but different random initializations.

The quality of character-based language models is conventionally measured in Bits Per Character (BPC), which is the average surprisal, to the base 2, of each character. On held-out data, our model achieves a mean BPC value of 1.28 (SD 0.025), competitive with BPC values achieved by state-of-the-art systems of similar datasets (e.g., Merity, Keskar, & Socher, 2018, report a BPC value of 1.23 on Wikipedia text).

In the introduction we predicted that word-based surprisal is not able to model the reading time pattern we found in our eye-tracking experiment. In order to test this prediction, we compare our character-level surprisal model to surprisal computed using a conventional word-based neural language model. Word-based models have a fixed vocabulary, consisting of the most common words in the training data; a typical vocabulary size is 10,000. Words that were not seen in the training data, and rare words, are represented by a special out-of-vocabulary (OOV) token. From a cognitive perspective, this corresponds to assuming that all unknown words (whether they contain errors or not) are treated in the same way: they are recognized as unknown, but not processed any further. We used a vocabulary size of 10,000. The hyperparameters of the word-based model were selected on the same English Wikipedia corpus as the character-based model.[6]

Results and Discussion

In this section, we show that surprisal computed by a character-level neural language model (CHARSURPRISAL) is able to account for the effects of errors on reading observed in our eye-tracking experiments. We compute character-based surprisal for the texts used in our experiments, and expect to obtain mean surprisal scores for each experimental condition that resemble mean reading times. We will also verify our prediction that word-based surprisal (WORDSURPRISAL) is not able to account for the effects observed in our experimental data, due to the way it treats unknown words.

Figure 2 shows the mean surprisal values across the different error conditions. We note that the pattern of reading time predicted by CHARSURPRISAL (solid lines) matches the first-pass times observed experimentally very well (see Figure 1), while WORDSURPRISAL (dotted line) shows a clearly divergent pattern, with error words showing *lower* surprisal than non-error words. This can be explained by the fact that a word-based model does not process error words beyond recognizing them as unknown; the presence of an unknown word itself is not a high-surprisal event (even without errors, 17 %

[5] 1024 units, 3 layers, batch size 128, embedding size 200, learning rate 3.6 with plain SGD, multiplied by 0.95 at the end of each epoch; BPTT length 80; DropConnect with rate 0.01 for hidden units; replacing entire character embeddings by zero with rate 0.001.

[6] 1024 units, batch size 128, embedding size 200, learning rate 0.2 with plain SGD, multiplied by 0.95 at the end of each epoch; BPTT length 50; DropConnect with rate 0.2 for hidden units; Dropout 0.1 for input layer; replacing words by random samples from the vocabulary with rate 0.01 during training.

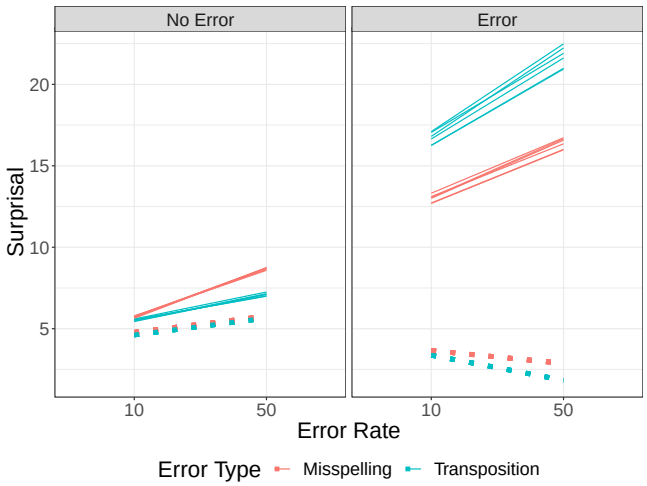

Figure 2: CHARSURPRISAL (full lines) and WORDSURPRISAL (dotted lines) as a function of error type and error rate, for correct (left) and erroneous (right) words. For CHARSURPRISAL, we show the means of all seven random initializations of our neural surprisal model.

of the words in our texts are unknown to the model, given its 10,000-word vocabulary).

To confirm this observation statistically, we fitted linear mixed-effects models with CHARSURPRISAL and WORDSURPRISAL as dependent variables. We enter the seven random initializations of each model as a random factor, analogously to the participants in the eye-tracking experiment. We use the same predictors that we used for the reading measures, except for LASTFIX. This predictor is not available: suprisal models compute a difficulty measure for each word (viz., its surprisal), but they are not able to predict whether a word will be skipped or not.

The results of the mixed model with CHARSURPRISAL as the dependent variable (see Table 4) replicated the effects of ERRORRATE, ERROR, and WORDLENGTH found in first pass and fixation rate, as well as the effect of ERRORTYPE found only in fixation rate (see Table 3). The same mixed model with WORDSURPRISAL as the dependent variable (see again Table 4), however, does not yield the correct pattern of results: Crucially, the coefficients of ERROR and ERRORTYPE have the opposite sign compared to both CHARSURPRISAL and the experimental data (though both effects are small, see dotted lines in Figure 2).

We have shown that character-based surprisal computed on the texts used in our experiment is qualitatively similar to the experimental results. As a next step we will test its quantitative predictions, i.e., we will correlate surprisal scores with reading times. For this, we performed mixed-effects analyses in which first-pass time and fixation rate are predicted by WLENGTH, LASTFIX, and character-based surprisal residualized against word length (RESIDCHARSURP).[7] Note that

[7]The correlation between word length and raw surprisal is 0.26.

Table 5: Models for reading measures with surprisal predictors. We compare model fit between a model with character-based surprisal (RESIDCHARSURP) and character-based oracle surprisal (RESIDCHARSURPORACLE), both residualized against word length.

we did not enter the error factors (ERRORTYPE, ERRORRATE, ERROR) into this analysis, as we predict that surprisal will simulate the effect of errors in reading.

It is known that surprisal predicts reading times in ordinary text not containing errors (Demberg & Keller, 2008; Frank, 2009); thus, it is important to disentangle the specific contribution of modeling errors correctly from the general contribution of surprisal in our model. We do this by constructing a baseline version of character-based surprisal that is computed using an oracle (RESIDCHARSURPORACLE). For this, we replace erroneous words with their correct counterparts before computing surprisal, and again residualize against word length.[8] If RESIDCHARSURP correctly accounts for the effects of errors on reading, then we expect that RESIDCHARSURP – which has access to the erroneous word forms – will improve the fit with our reading data compared to RESIDCHARSURPORACLE.

For RESIDCHARSURPORACLE, we use the same seven models as for RESIDCHARSURP, only exchanging the char-

[8]The correlation between word length and unresidualized oracle surprisal is 0.47.

acter sequences on which surprisal is computed. This ensures that any difference in model fit between the two predictors can be attributed entirely to the way RESIDCHARSURP is affected by the presence of errors in the texts.

The resulting models are shown in Table 5. For WLENGTH and LASTFIX, we see the same pattern of results as in the experimental data (see Table 3). Furthermore, regular surprisal (RESIDCHARSURP) and oracle surprisal (RESIDCHARSURPORACLE) significantly predict both first pass time and fixation rate. This is in line with the standard finding that surprisal predicts reading time (Demberg & Keller, 2008; Frank, 2009), but has so far not been demonstrated for texts containing errors. We compare model fit using AIC and BIC. Both measures indicate that RESIDCHARSURP fits the experimental data better than RESIDCHARSURPORACLE. Thus, character-level surprisal provides an account of our data going beyond the known contribution of ordinary surprisal to reading times, and correctly predicts reading in the presence of errors.

Conclusion

We investigated reading with errors in texts that contain either letter transpositions or real misspellings. We found that transpositions cause more reading difficulty than misspellings and explained this using a character-based surprisal model, which assigns higher surprisal to rare letter sequences as they occur in transpositions. We also found that in texts with a high error rate, all words are more difficult to read, even the ones without errors. Again, character-based surprisal explains this: computing word expectations is harder when the context of a word is degraded by errors, resulting in increased surprisal.

In future work, we plan to integrate character-based surprisal with existing neural models of human reading (Hahn & Keller, 2018). Models at the character level are necessary not only to account for errors, but also to model landing position effects, parafoveal preview, and word length effects, all of which word-based models are unable to capture.

Idea Generation and Goal-Derived Categories

Richard W. Hass (Richard.Hass@jefferson.edu), J. Colin Long, Joshua Pierce
College of Humanities and Sciences, Thomas Jefferson University
Philadelphia, PA 19144 USA

Abstract

Semantic search and retrieval of information plays an important role in creative idea generation. This study was designed to examine how semantic and temporal clustering varies when asking participants to generate ideas about uses for objects compared with generating members of goal-derived categories. Participants generated uses for three objects: brick, hammer, picture frame, and also generated members of the following goal-derived categories: things to take in case of a fire, things to sell at a garage sale, and ways to spend lottery winnings. Using response-time analysis and semantic analysis, results illustrated that all six prompts generally led to exponential cumulative response-time distributions. However, the proportion of temporally clustered responses, defined using the slope-difference algorithm, was higher for goal-derived category responses compared with object uses. Despite that, overall pairwise semantic similarity was higher for object uses than for goal derived exemplars. The effect of prompt on pairwise semantic similarity is likely the result of context-dependency of exemplars from goal-derived categories. However, the current analysis contains a potential confound such that special instructions to give "common and uncommon" responses were provided only for the object-uses prompts. The confound is likely minimal, but future work is necessary to verify that these results would hold when the confound is removed.

Keywords: Creativity; Divergent Thinking; Goal-Derived Categories; Latent Semantic Analysis; Semantic Memory

Creative cognition researchers often highlight the contributions of memory structure and process to creative idea generation. Though theories vary widely in explaining how existing knowledge is actually used to support the generation of creative ideas and products, there is sufficient evidence to suggest that in both laypeople (Ward, 2008), and in eminent creators (Weisberg, 2006) creative thinking operates within the bounds of an individual's system of knowledge. This study was designed to extend recent work (Hass, 2017a) exploring the degree of semantic clustering found among ideas generated when participants complete divergent thinking tasks. Divergent thinking tasks are heavily used as a proxy for creative thinking in a variety of behavioral (Snyder, Hammond, Grohman, & Katz-Buonincontro, 2019) and neuroscientific (Dietrich & Kanso, 2010) studies. There is a general consensus that dynamic interplay among executive search and control processes and semantic memory organization enables the generation of creative ideas (cf. Abraham & Bubic, 2015; Beaty, Christensen, Benedek, Silvia, & Schacter, 2017; Chrysikou & Thompson-Schill, 2011).

The central aim of the study was to extend prior results (e.g., Hass, 2017a; Hass & Beaty, 2018) by comparing semantic processing during object-uses generation to the generation of exemplars from goal-derived categories (Barsalou, 1985). Generating uses for objects is the core feature of the Alternative Uses task (Wilson, Guilford, Christensen, & Lewis, 1954), one of the most popular divergent thinking tasks, and its validity as a psychometric measure of creative thinking is enhanced by illuminating the underlying cognitive processes operating while people perform it. Creative thinking has also been described as related to goal-derived knowledge (Chrysikou, 2006), so it is natural to explicitly examine potential similarities between generating uses for objects and generating exemplars of goal-derived categories. The paper is structured as follows: first, research on the relationship between semantic memory retrieval and idea generation will be reviewed, along with a brief discussion of how divergent thinking tasks like object-uses generation relate to goal-derived category recall or generation tasks. Then, the analysis is presented in three phases: an analysis of cumulative response-time functions across conditions, an analysis of temporal clustering of responses, and an analysis of the semantic similarity of pairs of responses across two prompts, one from each condition.

Knowledge and creative generation

As mentioned, cognitive accounts of creativity tend to differentially emphasize the importance of associative processes of semantic organization and executive control of thought (cf. Chrysikou & Thompson-Schill, 2011; Mednick, 1962). In an early theoretical account, (Mednick, 1962) suggested that creative idea generation is underpinned by associative networks that afford more remote connections among concepts. Recent studies of creative thinking have shown support for this view, illustrating that individuals with flexible semantic networks tend to perform better on creative cognitive tasks and report a greater number of creative achievements (e.g. Kenett, Beaty, Silvia, Anaki, & Faust, 2016). Additional studies have highlighted the influence of executive control on the remote association process. For example (Beaty, Silvia, Nusbaum, Jauk, & Benedek, 2014) showed that the fluency and originality of uses for objects was almost equally well predicted by measures of remote association and associative flexibility, the latter thought to be an index of executive control over lexical association. Similarly, (Hass, 2017b) showed that the degree to which creative uses for objects were seman-

tically distant from the core of the prompt object concept was positively related to fluid intelligence.

Goal-derived Categories A key aspect of this study was to propose that goal-derived category exemplar generation can serve as a basis for understanding object-uses generation. Goal-derived categories constructed during goal-directed activities (Barsalou, 1983, 1985), like deciding which chair to sit on in a cafe or which personal belongings to keep from a childhood home. These categories can be distinguished from "natural" or "taxonomic" categories in several ways, though, we focus on two. First, goal-derived categories are constructed when performing decision-making tasks; defined by personal objectives and constrained by the environment or immediate context. Second, it can be argued that goal-derived categories such as "things to take with you in case of a fire" are not as well-established in memory as categories such as breakfast foods (Barsalou, 1983). Omelets and pancakes are within the same category (breakfast foods) because they are edible, made with eggs, served warm, are eaten in the morning, and relatively straightforward to cook. Attributes like those, such as times of consumption and ingredients, which are the basis of category discrimination (Rosch, Mervis, Gray, Johnson, & Boyes-Braem, 1976), do not co-occur as frequently in goal-derived categories. In addition, goal-derived categories are not as well used in the literature on semantic search and retrieval, so this analysis provides novel information about memory search dynamics when people name members of goal-derived categories. More importantly for this analysis, Barsalou (1985) suggested that retrieval of conceptual information for category processing involves generation of multiple conceptual representations, each held in working memory, when the category is encountered in normal life. This reliance on multiple conceptual representations could account for the effects reviewed above relating object-uses generation to fluid intelligence. Thus, comparing goal-derived category search to object uses search serves the dual purpose of exploring how context-dependent organization and executive control might interact during idea generation.

The current study

The primary focus of the current analysis was on semantic clustering. Because there are no established category norms for the prompts used in this study (cf. Troyer, Moscovitch, & Winocur, 1997), clusters were first identified using the slope-difference algorithm (Gruenewald & Lockhead, 1980). Latent semantic analysis (Landauer & Dumais, 1997) was then used to quantify the semantic similarity among sequential pairs of responses. The slope-difference algorithm identifies potential semantic clusters in terms of the difference between an actual IRT and the expected IRT given a mathematical relation between response time and output total. It was expected that slope-difference clusters would be more prevalent in the goal-derived response arrays, and that the pairwise semantic similarity of within-cluster responses would be higher in goal-derived response arrays. The reasons to expect that goal-derived response arrays would be more clustered than object-uses arrays are two-fold. First, response totals are usually quite low when people generate uses for objects, and though clusters appear, the number of responses per cluster is usually small. As cluster size decreases, output total should follow (Herrmann & Pearle, 1981), and the lack of success in finding newly retrieved clusters will ultimately lead to search termination (Raaijmakers & Shiffrin, 1981). Second, memory search is often described as a multiply-constrained problem (e.g., Polyn, Norman, & Kahana, 2009; Smith, Huber, & Vul, 2013), with multiple sources of information vying for attention in the process. It is plausible that goal-derived category generation is less constrained than object-use generation, such that a single context-dependent goal (e.g., "items to sell at a garage sale") remains in mind. This should enable the integration of contextual and semantic information in more efficient manner than in object-use generation, where the goal may change from response to response (e.g., "use a brick as a weight" $\rightarrow$ "use a brick as a pencil holder").

As will be described, the prompt used for object-uses in the current study was to "think of common *and* uncommon uses", designed to provide a more natural comparison to the generation of category exemplars (i.e., the word "creative" was not used in the instructions). That is, several studies have shown that instructing participants to "be creative" decreases fluency (output total), while increasing the average originality of their responses (Forthmann et al., 2016; Nusbaum, Silvia, & Beaty, 2014). Since the primary interest in the current study was the nature of the category itself (e.g., use of an object v. goal-derived category) and *not* whether participants were trying to engage in creative thought, we felt the special instruction was warranted. However, as we discuss, the inclusion of this "common and uncommon" instruction was not used in the goal-derived conditions, which presents a confound. The nature of our results do not suggest the confound is serious, it is important to keep in mind.

Method

Participants

A total of 32 participants were recruited from undergraduate psychology courses. Participants were offered extra credit or chocolate in compensation for their time. Participants ranged in age from 18 to 25 years old, and the demographics were consistent with a traditional undergraduate university in the northeastern United States. All recruitment and consent procedures were approved by the university's Institutional Review Board.

Materials

Participants completed the tasks using a custom Matlab interface on an Apple iMac. Instructions and prompts appeared as text on white background above a text-box where participants entered responses. Instructions were displayed and read to participants prior to each of three task blocks, the first

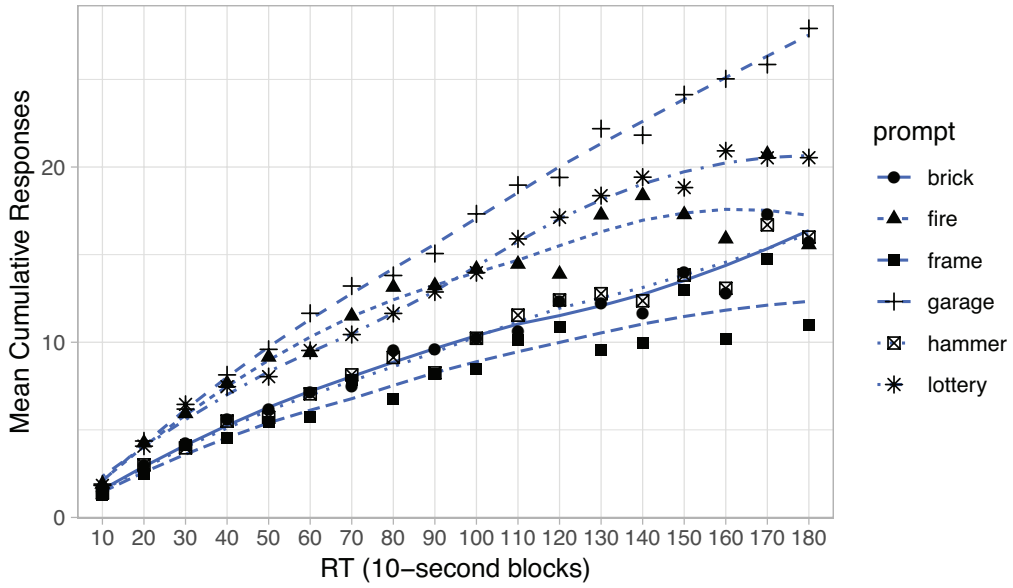

Figure 1: Mean number of cumulative responses per 10-second blocks for each of the six prompts. Object-uses prompts: brick, (picture) frame, hammer; Goal-derived prompts: fire = things to take in case of fire, garage = things to sell at a garage sale, lottery = ways to spend lottery winnings. Note: lines represent loess fits, not the exponential fits used in the next section.

of which was a practice block (naming colors). Instructions were not visible during response generation, but the prompt remained displayed for the entire duration of each response-generation interval. Demographic information was obtained using a pencil-and-paper survey after the experiment finished.

Procedure

Participants were greeted by the experimenter, and were told that the experiment was designed to test memory. The experimenter read general instructions about how the computer system worked and instructed participants to type responses on the computer keyboard, and to enter responses by pressing the return button. Participants then practiced this by naming colors (at least 3) for 30 seconds. The experimenter then answered any questions before the experiment began. Matlab recorded the time of the first keypress of each response, the time between the first key-stroke and the response entry, and the actual response.

The tasks were presented in two blocks of 3 prompts each, with a break in between each block. Both the order of the blocks and the order of presentation of prompts within the blocks were randomized by Matlab code. All participants responded to each prompt in each block. Each response interval was three minutes in length to permit valid comparison among the two prompt conditions (goal-derived categories, and object-uses prompts). The goal-derived category prompts began with "name examples of" and ended with one of the three categories: things to spend lottery winnings on, things to take from your house if it caught on fire, and things to sell at a garage sale. The object-use prompts began with "name common and uncommon uses for a" and ended with one of the three prompt objects: brick, hammer, and picture frame.

The entire prompt phrase remained on the screen above the text-entry box for the entire 3 minutes. When 3 minutes expired, the screen displayed a message indicating that the next prompt was loading for 5 seconds before the next prompt appeared. After the first and second blocks, instructions for the next block appeared on the screen, and the participant was given a 1-2 minute break before beginning the next block. After the final block, a thank-you message appeared and the participant filled out the demographic questionnaire, and the experimenter answered any questions the participant may have had. The entire process lasted between 20 and 25 minutes for each participant.

Analyses and Results

All analyses were conducted using the R Statistical Programming Language, and all data and algorithms are available for download (https://osf.io/fvne2/). Response times were defined in terms of the time (since presentation of the prompt) of the first key-press of each response, to be consistent with studies using voice-keyed response recording. Prior to analysis, data were examined for repeated responses and malfunctions in Matlab's execution of the experiment. Three participants were excluded due to Matlab malfunctions reducing the final sample size to 29. Repeated responses were those that were identified as the same response given more than once by the same individual to a specific prompt. When repeats were identified, the RTs for those responses were removed from the data set. Participants gave a total of 1746 responses to the three goal-derived prompts after the removal of 23 repeated responses. Finally, participants gave a total of 1012 responses

Table 1: Average response totals per category and intercorrelations (Spearman's ρ). Object Uses prompts are in the top half of the table. All correlations are significant, with $p \leq .01$, except the correlation between garage sale and hammer totals ($p = .06$).

			ρ				
Prompt	M	SD	1	2	3	4	5
1. Brick	12.76	4.66	-				
2. Hammer	11.86	5.09	.64	-			
3. Frame	10.28	4.40	.72	.78	-		
4. ... sell at garage sale	24.17	7.40	.35	.67	.46	-	
5. ... take from fire	17.17	5.33	.67	.52	.48	.53	-
6. ... do with lottery winnings	18.86	6.69	.50	.57	.46	.65	.55

to the object-use prompts after the removal of 11 responses.

Fluency and Cumulative Response Times

The mean number of cumulative responses was computed in 10-second blocks and plotted in Figure 1. Clearly there is nonlinearity, and not surprisingly, fluency is higher for the goal-derived prompts compared with the object-use prompts. The shape of the distributions in these plots is consistent with those found in normal memory retrieval studies. Table 1 further illustrates that response totals are uniformly lower for objects uses prompts, and that there is a relatively large degree of correlation among output totals.

Clustering

Clusters were identified using a modification the Slope Difference Algorithm (Gruenewald & Lockhead, 1980), that uses an exponential function rather than the hyperbolic function used by Gruenewald and Lockhead:

$$R(t) = N(1 - e^{-\frac{t}{\tau}}) \quad (1)$$

This is the "two parameter" exponential, with N being the estimated asymptote, or number of responses generated with an unlimited amount of time, and τ being the inverse of the rate parameter λ in an exponential distribution. Thus, τ is parameterized as the estimated mean response time.

The Slope-Difference algorithm works as follows: given the estimated N and τ parameters for each participant, calculate the difference between the predicted and observed instantaneous rates of change in responding. The predicted rate of change is just the derivative of Equation 1 calculated with each participant's parameters and the cumulative response times of that participant. The observed instantaneous rate of change is just the reciprocal of each inter-response time (IRT) (i.e., for R = cumulative number of responses, $\frac{\Delta R}{\Delta t} = \frac{1}{IRT}$). Gruenewald and Lockhead (1980) provided support for the validity of the algorithm, such that large, positive differences between observed and predicted rates were indications that responding was faster than predicted, and thus, faster than expected responses qualify as being within clusters. The threshold for slope-differences being categorized as "switches" was .10, which is the same as used by Grunewald and Lockhead.

To obtain slope-difference values, Equation 1 was first fit to each participant's cumulative response-time distribution *per prompt*, using ordinary nonlinear least-squares estimation. Parameter values along with response times were used to compute predicted rates of change to be differenced from the actual rates of change. Clusters were then identified as any IRT with a slope difference value less than .10, the threshold used by Gruenewald and Lockhead (1980). Exponential parameter estimates were not optimal for 1-3 participants per prompt, and data from those participants were excluded for the cluster analysis of each prompt.

Figure 2 shows that the proportion of responses identified as within cluster was significantly greater for goal-derived categories compared with object uses, $\chi^2(1) = 48.27, p < .001$. Of the 998 object-use responses, 18.8% were identified as within-cluster, while 31.3% of the 1567 goal-derived responses were identified as within-cluster.

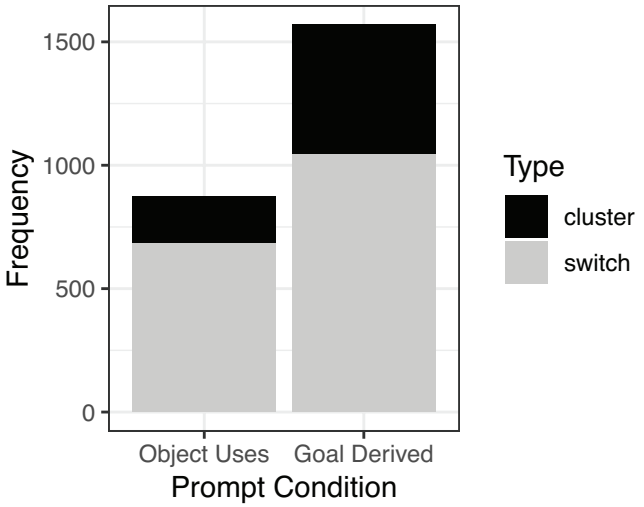

Figure 2: Number of responses classified as within cluster, or as a switch between clusters by the slope difference algorithm for the two types of prompts. See text for proportions.

Pairwise Semantic Similarity

The validity of the slope difference algorithm rests on further semantic analysis of its results. Here, the central question was whether responses in clusters corresponding to goal-derived category were more semantically similar than those in clusters corresponding with object-use generation. Pairs of sequential responses were analyzed for semantic similarity using the tools at the UC Boulder website (lsa.colorado.edu). The General Reading corpus, with 300 factors, was chosen as the basis for comparisons, and the term-to-term comparator was used.

Mixed-effects regression was used to examine the main-effects of clustering (within cluster v. between cluster response) and prompt-type (goal-derived v. object use) on LSA-derived cosine similarities, and the interaction of the two fixed effects. A random intercept term was added to account for participant variation, and another to account for variations across the 6 prompts. Table 1 contains the results of the analysis including 95% confidence intervals for the fixed and random effects terms. Rather surprisingly, on average the pairwise similarity of responses to the goal-derived prompts was less than the average pairwise similarity of object-uses responses. However, the slope difference algorithm seems to distinguish between semantic clusters such that on average, within-cluster responses were less similar (in terms of pairwise similarity) than between cluster responses. Figure 3 illustrates that there may be a small interaction between prompt type and clustering, and in Table 2, the estimate is a slightly smaller difference in similarity of clustered and non-clustered responses for object uses compared with goal derived categories, though zero remains a plausible value for the interaction.

A slightly different result is obvious if one plots pairwise similarity as a function of IRT. Figure 4 shows that, at the level of individual pairs of responses, the relationship between IRT and similarity is not linear, and that for a great many pairs of responses on all six prompts, there is a substantial degree of variability in pairwise similarity for short IRTs. A closer look at Figure 4 reveals that the garage prompt has the highest concentration of low-similarity pairs. This an interesting result on its own and is likely the result of context dependency for that prompt, as will be discussed next.

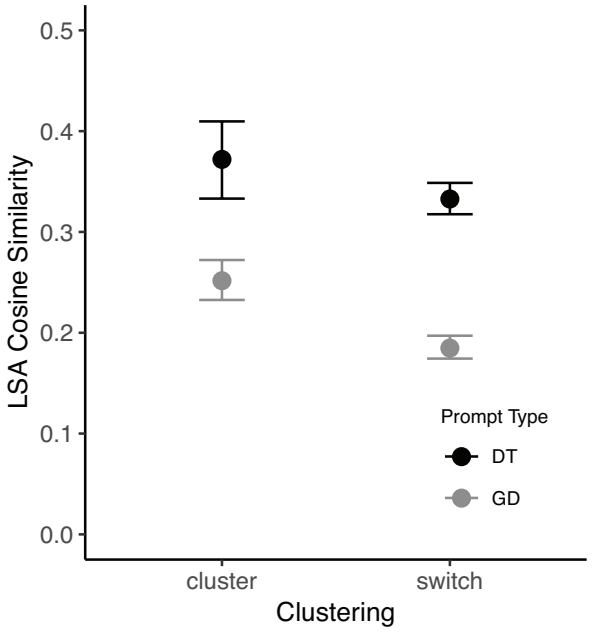

Figure 3: Average pairwise semantic similarity per prompt and per cluster category (in cluster v. switch). Bars are bootstrapped 95% confidence limits.

Discussion

The purpose of this study was to probe the differences between object-uses generation and goal-derived category exemplar generation in terms of semantic search and retrieval. Using measures of clustering and similarity, this analysis illustrated that there may be two key differences between responding to these two types of prompts. First, output totals for goal-derived categories were much higher than object uses, and also contained a greater proportion of faster than expected IRTs, identified by the slope difference algorithm.

Though semantic analysis of adjacent pairs of responses showed that the slope-difference clusters are indeed semantic clusters, pairwise similarity among goal-derived exemplars was surprisingly less than the similarity among adjacent pairs of object-use responses. One explanation for this result is that semantic relationships *across* clusters of goal-derived exemplars may be minimal because of the dependence of semantic similarity on context (e.g., Barsalou, 1982). Of course, that characterization might also be said of object-uses. More importantly, Hass (2017a) illustrated that LSA-derived cosine similarities may not accurately represent context-dependent relationships between object uses. Indeed, the main difference between the two types of prompts is that goal-derived prompts identify a context (e.g., a garage sale), which all items must relate to in some way, while object-uses prompts identify an exemplar (e.g., a brick) to which responses must relate. While object-uses responses will likely have context-dependency, it is also likely that context dependency will be greater among goal-derived categories such as those in this study, as the context itself is the main constraint on conceptual activation. That is, consider the example discussed in the introduction: electronics to sell at a garage sale. Say a participant activates electronics as a concept and exploits it for a bit, what is the likelihood that the next conceptual representation activated will be highly similar to electronics in a context-independent fashion? Contrast that with the activation of the attribute "heavy" in generating uses for a brick. What is the likelihood that the next conceptual representation used after "heavy" is going to be semantically similar to "heavy" in a context-independent sense. It seems plausible that the semantic similarity among all activated concepts

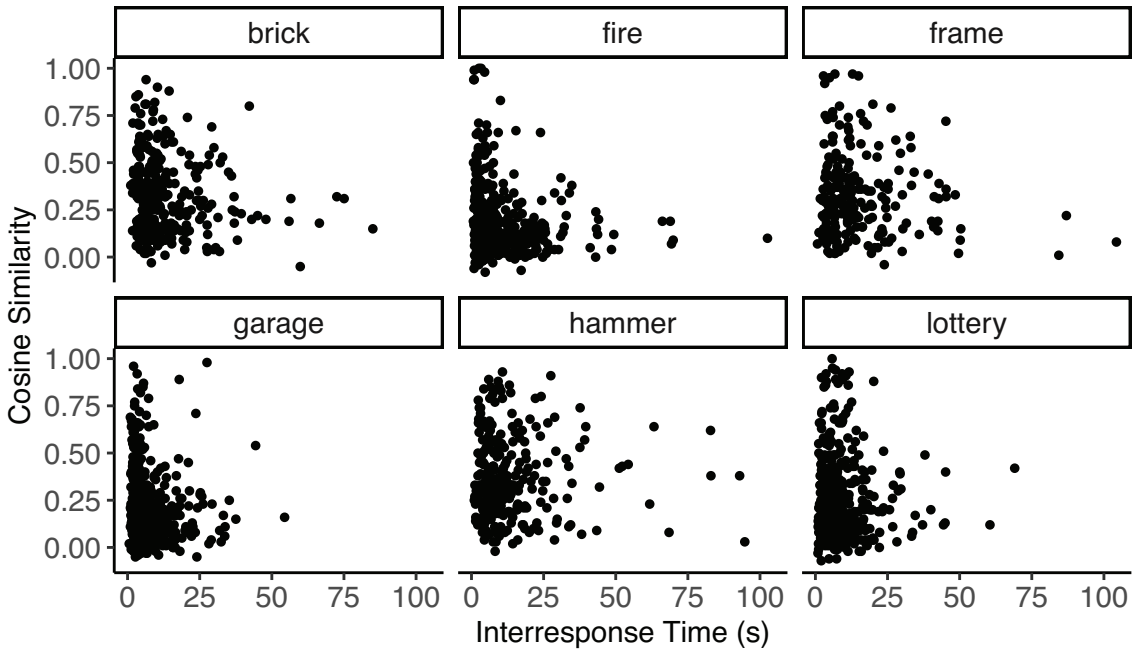

Figure 4: Scatterplots of the IRT-similarity relationship across all size prompts. Object uses prompts are in the top row, goal-derived prompts are in the bottom row

Table 2: Results of the mixed-effects regression with pairwise similarity as the dependent variable. The baseline prompt-type condition was object-use, the baseline cluster condition was Within Cluster.

			Confidence Interval	
Fixed Effects	b	*t*	2.5%	97.5%
Intercept	0.38	14.65	0.33	0.42
Prompt Type	-0.12	-3.88	-0.18	-0.06
Cluster	-0.04	-2.24	-0.08	-0.005
prompt × switch	-0.03	-1.49	-0.07	0.01
Random Effects	σ		2.5%	97.5%
Participant	0.04		0.03	0.06
Prompt	0.03		0.01	0.05
Residual	0.20		0.19	0.20

in the garage context might be lower than the semantic similarity among activated concepts in the context of a use for a brick because of the dependence on the garage context. The latter conclusion is still highly speculative, but it suggests that this is a fruitful avenue for future research to follow, as it will likely illuminate how semantic information is organized and used in both kinds of tasks.

Limitations and future directions

In this study, participants were explicitly instructed to *think of common and uncommon uses for objects* in an effort to obtain a greater total number of responses generated across the object uses prompts (i.e., the word "creativity" was not present in the instructions). In the recent study by Hass (2017a), participants were instructed to think of *creative* uses for objects, and indeed, their response totals were, on average, lower than the current study (about 7 responses). So it is likely that the instruction to be creative may limit the semantic similarity of clustered output when generating object uses. Indeed, the major motivation for the choice to avoid the word creative was to provide a baseline for future studies that would vary instructions, including "be-creative" conditions (e.g., Forthmann et al., 2016), and strategy inductions (e.g., Unsworth, Brewer, & Spillers, 2013). However, since participants were only given the "common and uncommon" instructions in one condition, the effect of prompt type on semantic similarity is confounded by the differing instructions. Specifically, our use of the phrase "common *and* uncommon" uses in the object use condition may have confused participants, or led some participants to approach the task differently from others, with some potentially assuming that they should be creative, or only think of uncommon uses. We believe that this can be remedied in future studies by changing all prompts to be of the form, "think of things to ..." and then appending the prompt (e.g., ... to sell at a garage sale; ... to do with a brick). Participants can then be instructed to perform the two tasks in the ways just mentioned (e.g., creatively, or using a certain search strategy), without the confound currently present. However, the current results are still informative, and it is likely that the confound presented by the "common or uncommon" phrasing was minimal.

Abstract

Drawing is a versatile technique for visual communication, ranging from photorealistic renderings to schematic diagrams consisting entirely of symbols. How does a medium spanning such a broad range of appearances reliably convey meaning? A natural possibility is that drawings derive meaning from both their visual properties as well as shared knowledge between people who use them to communicate. Here we evaluate this possibility in a drawing-based reference game in which two participants repeatedly communicated about visual objects. Across a series of controlled experiments, we found that pairs of participants discover increasingly sparse yet effective ways of depicting objects. These gains were specific to those objects that were repeatedly referenced, and went beyond what could be explained by task practice or the visual properties of the drawings alone. We employed modern techniques from computer vision to characterize how the high-level visual features of drawings changed, finding that drawings of the same object became more consistent within a pair of participants and divergent across participants from different interactions. Taken together, these findings suggest that visual communication promotes the emergence of depictions whose meanings are increasingly determined by shared knowledge rather than their visual properties alone.

Keywords: alignment; coordination; iconicity; sketch understanding; visual communication

Introduction

From ancient etchings on cave walls to modern digital displays, visual communication lies at the heart of key human innovations (e.g., cartography, data visualization) and forms a durable foundation for the cultural transmission of knowledge and higher-level reasoning. Perhaps the most basic and versatile technique supporting visual communication is drawing, the earliest examples of which date to at least 40,000-60,000 years ago (Hoffmann et al., 2018). What began as simple mark making has since been adapted to a wide array of applications, ranging from photorealistic rendering to schematic diagrams consisting entirely of symbols.

Even in the relatively straightforward case of drawing from life, there are countless ways to depict the same object. How does a communication medium spanning such a broad range of appearances reliably convey meaning? On the one hand, prior work has found that semantic information in a figurative drawing, i.e., the object it represents, can be derived purely from its visual properties (Fan, Yamins, & Turk-Browne, 2018). On the other hand, other work has emphasized the role of socially-mediated information for making appropriate inferences about what even a figurative drawing represents (Goodman, 1976).

How can these two perspectives be reconciled? Our approach is to consider the joint contributions of visual information and social context in determining how drawings derive meaning (Abell, 2009), and to propose that a critical factor affecting the balance between the two may be the amount of shared knowledge between communicators. Specifically, we explore the hypothesis that accumulation of shared knowledge via extended visual communication may promote the development of increasingly schematic yet effective ways of depicting an object, even as these *ad hoc* graphical conventions may be less readily apprehended by others who lack this shared knowledge.

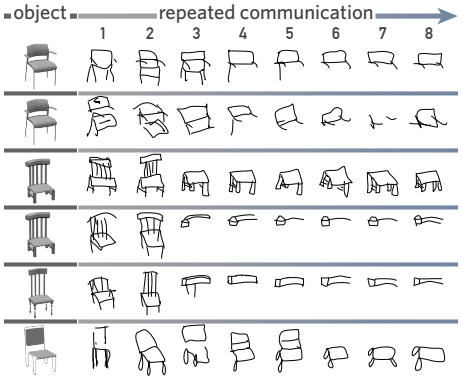

Figure 1: Repeated visual communication depicting the same object.

To investigate this hypothesis, we used an interactive drawing-based reference game in which two participants repeatedly communicated about visual objects. We examined both how their task performance and the drawings they produced changed over time (see Fig. 1). Our approach was inspired by a large literature that has explored how extended interaction influences communicative behavior in several modalities, including language (Clark & Wilkes-Gibbs, 1986; Hawkins, Frank, & Goodman, 2017), gesture (Goldin-Meadow, McNeill, & Singleton, 1996), and drawings (Garrod, Fay, Lee, Oberlander, & MacLeod, 2007; Galantucci, 2005). There are three aspects of the current work that advance our prior understanding: *first*, we include a control set of objects that were not repeatedly drawn but only shown at the beginning and end of the interaction, allowing us to measure the specific contribution of repeated reference vs. general practice effects; *second*, we measure how strongly the visual properties of drawings drive recognition in the absence of interaction history for naive viewers, while equating other task variables; and *third*, we employ recent advances in computer vision to quantitatively characterize changes in the high-level visual properties of drawings across repetitions.

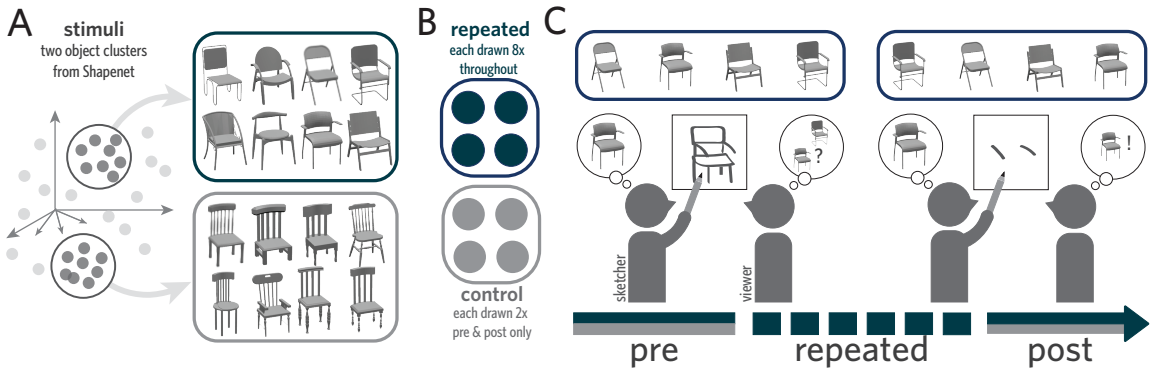

Figure 2: (A) Stimuli from ShapeNet. (B) Each pair of participants was randomly assigned two sets of four objects, each set from one of the two categories. (C) Repeated objects drawn eight times throughout; control objects drawn once at the beginning and end of each interaction.

Part I: How does repeated reference support successful visual communication?

Our first goal was to understand how people learn to communicate about visual objects across repeated visual communication. To accomplish this, we developed a drawing-based reference game for two participants. On each trial, both participants shared a *communicative context*, represented by an array of four objects. One of these objects was privately designated the 'target' to the sketcher. The sketcher's goal was to draw the target so that the viewer could select it from the array as quickly and accurately as possible. We hypothesized that learning would be *object-specific*: that over repeated visual reference to a particular object, participants would discover ways of depicting that object more effectively relative to non-repeated control objects.

Methods: Visual communication experiment

Participants We recruited 138 participants from Amazon Mechanical Turk, who were grouped into 69 pairs (Hawkins, 2015). Within each experimental session, one participant was assigned the sketcher role and the other the viewer role, and these role assignments remained the same throughout the experiment. Data from two pairs were excluded due to unusually low performance (i.e., accuracy $<$ 3 s.d. below the mean). In this and subsequent experiments, participants provided informed consent in accordance with the Stanford IRB.

Stimuli In order to make our task sufficiently challenging, we sought to construct communicative contexts consisting of objects whose members were both geometrically complex and visually similar. To accomplish this, we sampled objects from the ShapeNet (Chang et al., 2015), a database containing a large number of 3D mesh models of real-world objects. We restricted our search to 3096 objects belonging to the `chair` class, which is among the most diverse and abundant in ShapeNet. To identify groups of visually similar chairs, we first extracted high-level visual features from 2D renderings of each object using a deep convolutional neural network (DCNN) architecture, VGG-19 (Simonyan & Zisserman, 2014). This network had been previously trained to recognize objects in photos from the ImageNet database (Deng et al., 2009), containing 1.2 million natural photographs of 1000 different object classes. Trained DCNN models have been shown to predict human perceptual similarity judgments about objects (Kubilius, Bracci, & de Beeck, 2016; Peterson, Abbott, & Griffiths, 2018), as well as neural population responses in visual cortex during object recognition (Yamins et al., 2014; Güçlü & van Gerven, 2015). As such, they provide a principled choice of encoding model for extracting high-level visual information from images. Following previous work that has employed DCNN models to evaluate perceptual similarity (Peterson et al., 2018; Kubilius et al., 2016), for each image we extract a 4096-dimensional feature vector reflecting activations in the second fully-connected layer (i.e., `fc6`) of VGG-19, a higher layer in the network. We then applied dimensionality reduction (PCA) and k-means clustering on these feature vectors, yielding 70 clusters containing between 2 and 80 objects each. Among clusters that contained at least eight objects, we manually identified two visual categories containing eight objects each (Fig. 2A).

Task Procedure On each trial, both participants were shown the same set of four objects in randomized locations. One of the four objects was highlighted on the sketcher's screen to designate it as the target. Sketchers drew using their mouse cursor in black ink on a digital canvas embedded in their web browser (300×300 pixels; pen width = 5px). Each stroke was rendered on the viewer's screen in real time and sketchers could not delete previous strokes. The viewer aimed to click one of the four objects as soon as they were confident of the identity of the target, and participants received immediate feedback: the sketcher learned when and which object the viewer had clicked, and the viewer learned the true identity of the target. Both participants were incentivized to perform both quickly and accurately. They both earned an accuracy bonus for each correct response, and the sketcher was required to complete their drawings in 30 seconds or less. If the viewer responded correctly within this time limit, participants also received a speed bonus inversely proportional to the time taken until the response.

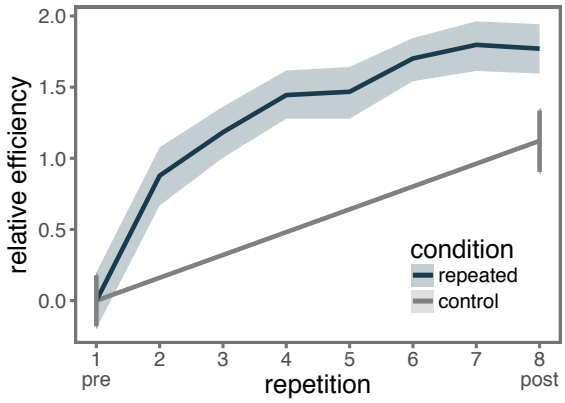

Figure 3: Communication efficiency across repetitions. Efficiency combines both speed and accuracy, and is plotted relative to the first repetition. Error ribbons represent 95% CI.

Design For each pair of participants, two sets of four objects were randomly sampled to serve as communication contexts: one was designated the *repeated* set while the other served as the *control* set (Fig. 2B).[1] The experiment consisted of three phases (Fig. 2C). During the repeated reference phase, there were six repetition blocks of four trials, and each of the four *repeated* objects appeared as the target once in each repetition block. In a pretest phase at the beginning of the experiment and a posttest phase at the end, both repeated and control objects appeared once as targets (in their respective contexts) in a randomly interleaved order.

Results

Because objects were randomly assigned to repeated and control conditions, we expected no differences in task performance in the pretest phase. We found that pairs identified the target at rates well above chance in this phase (75.7% repeated, 76.1% control, chance = 25%), suggesting that they were engaged with the task but not at ceiling performance. We found no difference in accuracy across conditions (mean difference: 0.3%, bootstrapped CI: $[-7\%, 7\%]$).

In order to measure how well pairs learned to communicate throughout the rest of their interaction, we used a measure of communicative efficiency (the *balanced integration score,* Liesefeld & Janczyk, 2018) that takes both accuracy (i.e., proportion of correct viewer responses) and response time (i.e., latency before viewer response) into account. This efficiency score is computed by first z-scoring accuracy and response time across repetitions within an interaction to map values from different interactions to the same scale, and then subtracting the standardized response time from standardized accuracy. It is highest when pairs are both fast and accurate, and lowest when they make more errors and take longer, relative to their own performance on other trials.

[1] In half of the pairs, the four control objects were from the same stimulus cluster as repeated objects; in the other half, they were from different clusters. The rationale for this was to support investigation of between-cluster generalization in future analyses. In current analyses, we collapse across these groups.

To evaluate changes in communicative efficiency, we fit a linear mixed-effects model including random intercepts, slopes, and interactions for each pair of participants. We found a main effect of increasing communicative efficiency for all targets between the *pre* and *post* phases ($b = 1.45$, $t = 14.3$, $p < 0.001$), reflecting general improvements due to task practice. Critically, however, this analysis also revealed a reliable interaction between phase and condition: communicative efficiency improved to a greater extent for repeated objects than control objects ($b = 0.648$, $t = 3.09$, $p = 0.003$; see Fig. 3). Analysis of changes in raw accuracy yielded a similar result: performance on repeated objects improved by 14.5%, while performance on control objects only improved by 7.1%. Together, these data show that there are benefits of repeatedly communicating about an object that accrue specifically to that object, suggesting the formation of object-specific graphical conventions.

Part II: What explains gains in efficiency?

Our visual communication experiment established that pairs of participants coordinate on more efficient and *object-specific* ways of depicting targets. This raises the question: to what extent do these gains in efficiency reflect the accumulation of *interaction-specific* shared knowledge between a sketcher and viewer, as opposed to the combination of task practice and the inherent visual properties of their drawings?

To disentangle the contributions of these different factors, we conducted two control experiments to estimate the how recognizable these drawings were to naive viewers outside the social context in which they were produced. Participants in one control group were shown a sequence of drawings taken from a single interaction, closely matching the experience of viewers in the communication experiment. Participants in a second control group were instead shown a sequence of drawings pieced together from many different interactions, thus disrupting the continuity experienced by viewers paired with a single sketcher. Insofar as interaction-specific shared knowledge contributed to the efficiency gains observed previously, we hypothesized that the second group would not improve as much over the course of the experimental session as the first group would.

Methods: Recognition Control Experiments

Participants We recruited 245 participants via Amazon Mechanical Turk. We excluded data from 22 participants who did not meet our inclusion criterion for accurate and consistent response on attention-check trials (see below).

Task, Design, & Procedure On each trial, participants were presented with a drawing and the same set of four objects that accompanied that drawing in the original visual communication experiment. They also received the same accuracy and speed bonuses as viewers in the communication experiment. To ensure task engagement, we included five identical attention-check trials that appeared once every eight trials. Each attention-check trial presented the same set of

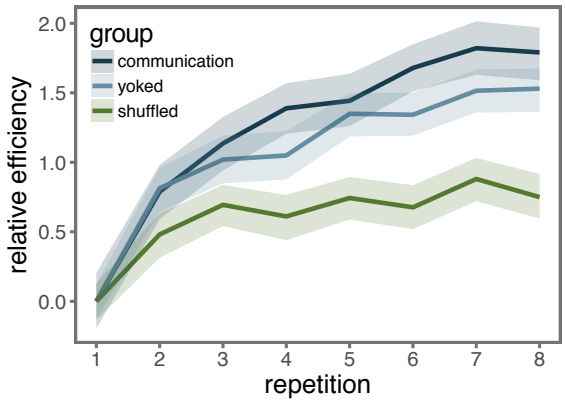

Figure 4: Comparing drawing recognition performance between viewers in communication experiment with those of yoked and shuffled control groups. Error ribbons represent 95% CI.

objects and drawing, which we identified during piloting as the most consistently and accurately recognized by naive participants. Only participants who responded correctly on at least four out of five of these trials were retained in subsequent analyses.

Each participant was randomly assigned to one of two conditions: a *yoked* group and a *shuffled* group. Each yoked participant was matched with a single interaction from the original cohort and viewed 40 drawings in the same sequence the original viewer had. Those in the shuffled group were matched with a random sample of 10 distinct interactions from the original cohort and viewed four drawings from each in turn, which appeared within the same repetition block as they had originally. For example, if a drawing was produced in the fifth repetition block in the original experiment, then it also appeared in the fifth block for shuffled participants.

At the trial level, groups in both conditions thus received exactly the same visual information and performed the task under the same incentives to respond quickly and accurately. At the repetition level, both groups received exactly the same amount of practice recognizing drawings. Thus any differences between these groups are attributable to whether drawings came from the same communicative interaction, which would support the accumulation of interaction-specific experience, or from several different interactions, where such accumulation would be minimal.

Results

Interaction-specific history enhances recognition by third-party observers We compared the yoked and shuffled groups by measuring changes in recognition performance across successive repetitions using the same efficiency metric we previously used. We estimated the magnitude of these changes by fitting a linear mixed-effects model that included group (yoked vs. shuffled), repetition number (i.e., first through eighth), and their interaction, as well as random intercepts and slopes for each participant. While we found a significant increase in recognition performance across both groups ($b = 0.18,\ t = 12.8,\ p < 0.001$), we also found a large and reliable interaction: yoked participants improved to a substantially greater degree than shuffled participants ($b = 0.10,\ t = 4.9,\ p < 0.001$; Fig. 4). Examining accuracy alone yielded similar results: the yoked group improved to a greater degree across the session (yoked: +15.8%, shuffled: +5.6%). Taken together, these results suggest that third-party observers in the yoked condition who viewed drawings from a single interaction were able to take advantage of this continuity to more accurately identify what successive drawings represented. While observers in the shuffled condition still improved over time, being deprived of this interaction continuity made it relatively more difficult to interpret later drawings.

Viewer feedback also contributes to gains in performance Unlike viewers in the interactive visual communication experiment, participants in the yoked condition made their decision based only on the whole drawing and were unable to interrupt or await additional information if they were still uncertain. Sketchers could have used this feedback to modify their drawings on subsequent repetitions. As such, comparing the yoked and original communication groups provides an estimate of the contribution of these viewer feedback channels to gains in performance (Schober & Clark, 1989). In a mixed-effects model with random intercepts, slopes, and interactions for each unique trial sequence, we found a strong main effect of repetition ($b = 0.23,\ t = 12.8,\ p < 0.001$), as well as a weaker but reliable interaction with group membership ($b = -0.05,\ t = -2.2,\ p = 0.032$, Fig. 4), showing that the yoked group improved at a more modest rate than viewers in the original communication experiment had.

To better understand this interaction, we further examined changes in the accuracy and response time components of the efficiency score. We found that while viewers in the communication experiment were more accurate than yoked participants overall (communication: 88%, yoked: 75%), *improvements* in accuracy over the course of the experiment were similar in both groups (communication: +14.5%, yoked: +15.8%). The interaction instead appeared to be driven by differential reductions in response time between the first and final repetitions (communication: 10.9s to 5.84s; yoked: 4.66s to 3.31s). These reductions were smaller in the yoked group, given that these participants did not need to wait for each stroke to appear before making a decision, and thus may have already been closer to floor.

Part III: How do visual features of drawings change over the course of an interaction?

The results so far show that repeated visual communication establishes object-specific, interaction-specific ways of efficiently referring to objects. An intriguing implication is that interacting pairs achieved this by gradually forming *ad hoc* graphical conventions about what was relevant and sufficient to include in a drawing to support rapid identification of the target object. Here we explore this possibility by examining how the drawings themselves changed throughout an interac-

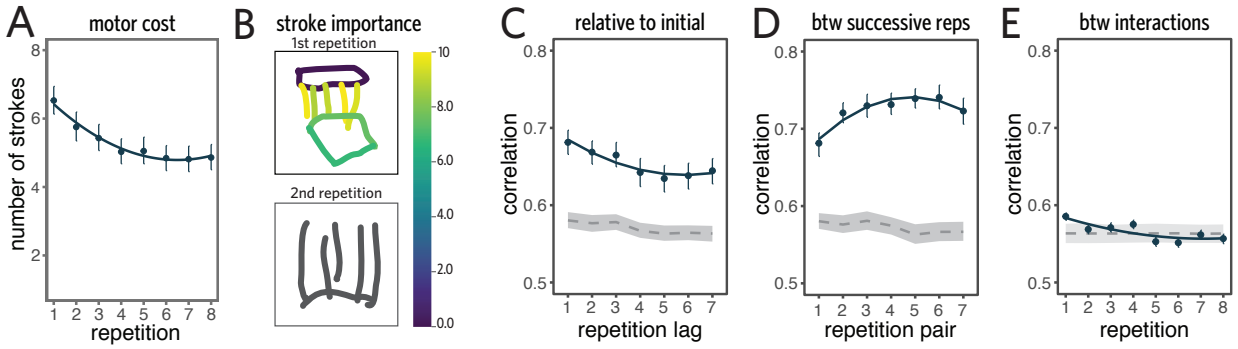

Figure 5: (A) Sketchers use fewer strokes over time. (B) Visualizing importance of individual strokes in successive drawings. (C) Drawings become increasingly dissimilar from initial drawing. (D) Drawings become more consistent from repetition to repetition. (E) The same object is drawn increasingly dissimilarly by different sketchers. Error ribbons represent 95% CI, dotted lines represent permuted baseline.

tion. Concretely, we investigated four aspects that would reflect the increasing contribution of interaction-specific shared knowledge: *first*, decreasing number of strokes used (i.e., reducing motor cost of each drawing); *second*, increasing dissimilarity from the initial drawing produced (i.e., cumulative drift from the starting point); *third*, increasing similarity between successive drawings (i.e., convergence on internally consistent ways of depicting objects within an interaction); *fourth*, increasing dissimilarity between drawings of the same object produced in different interactions (i.e., discovery of multiple viable solutions to the coordination problem).

Measuring visual similarity between drawings

Measuring visual similarity between drawings depends upon a principled approach for encoding their high-level visual properties. Here we capitalize on recent work validating the use of deep convolutional neural network models to encode such perceptual content in drawings (Fan et al., 2018). As when identifying clusters of similar object stimuli, we again used VGG-19 to extract 4096-dimensional feature vector representations for drawings of every object, in every repetition, from every interaction. Using this feature basis, we compute the similarity between any two drawings as the Pearson correlation between their feature vectors (i.e., $s_{ij} = {}^{cov(\vec{r}_i,\vec{r}_j)}/_{\sqrt{var(\vec{r}_i)\cdot var(\vec{r}_j)}}$).

Results

Fewer strokes across repetitions A straightforward explanation for the gains in communication efficiency observed in Part I is that sketchers were able to use fewer strokes per drawing to achieve the same level of viewer recognition accuracy. Indeed, we found that the number of strokes in drawings of repeated objects decreased steadily as a function of repetition in a mixed-effects model ($b = -0.216$, $t = -6.00$; Fig. 5A), suggesting that pairs were increasingly able to rely upon shared knowledge to communicate efficiently. This result raises a question about *which* strokes are preserved across successive repetitions during the formation of graphical conventions. In ongoing work, we are using a lesion method to investigate the "importance" of each stroke within a drawing for explaining similarity to the next repetition's drawing of that object. We re-render the drawing without each stroke and compute the similarity, yielding a heat map across strokes (see Fig. 5B for an example visualization). The more dissimilar the lesioned drawing without a particular stroke is to an intact version of the next repetition's drawing, the more "important" we consider that stroke to be.

Increasing dissimilarity from initial drawing Mirroring the observed reduction in the number of strokes across repetitions, we hypothesized that there was also cumulative change in the visual content of drawings across repetitions. Concretely, we predicted that drawings would become increasingly dissimilar from the initial depiction. We tested this prediction in a mixed-effects regression model including linear and quadratic terms for repetition as well as intercepts for each target and pair. We found a significant decrease in similarity to the initial round across successive repetitions, ($b = -0.62$, $t = -5.59$; Fig. 5C), suggesting that later drawings had moved to a different region of visual feature space. However, since the entire distribution of drawings may have drifted to a different region of the visual feature space for generic reasons (i.e., because they were sparser overall), we conducted a stricter permutation test. We scrambled drawings across pairs but within each repetition and target and re-ran our mixed-effects model. The observed effect fell outside this null distribution ($CI = [-3.53 - 0.88]$, $p < .001$), showing that successive drawings by the same sketcher deviated from their own initial drawing to a greater degree than would be expected due to generic differences between drawings made at different timepoints in an interaction.

Increasing internal consistency within interaction As sketchers modified their drawings across successive repetitions, we additionally hypothesized that they would converge on increasingly consistent ways of depicting each object. To test this prediction, we computed the similarity of successive drawings of the same object made in the same interaction (i.e. repetition k to $k+1$). A mixed-effects model with random intercepts for both object and pair showed that similarity between successive drawings increased substantially

throughout an interaction ($b = 0.53$, $t = 5.03$; Fig. 5). Again, we compared our empirical estimate of the magnitude of this trend to a null distribution of slope t values generated by scrambling drawings across pairs. The observed increase fell outside this null distribution ($CI = [-3.21, -0.60], p < .001$), providing evidence that increasingly consistent ways of drawing each object manifested only for series of drawings produced within the same interaction.

Increasingly different drawings across interactions Our recognition control experiments suggested that the graphical conventions discovered by different pairs were increasingly opaque to outside observers. This effect could arise if early drawings were more strongly constrained by the visual properties of a shared target object, but later drawings diverged as different pairs discovered different equilibria in the space of viable graphical conventions. Under this account, drawings of the same object from different pairs would become increasingly dissimilar from each other across repetitions. We tested this prediction by computing the mean pairwise similarity between drawings of the same object within each repetition index, but produced in different interactions. Specifically, for each object, we considered all interactions in which that object was repeatedly drawn. Then, for each repetition index, we computed the average similarity between drawings of that object. In a mixed-effects regression model including linear and quadratic terms, as well as random slopes and intercepts for object and pair, we found a small but reliable negative effect of repetition on between-interaction drawing similarity ($b = -1.4$, $t = -2.5$; Fig. 5E). We again conducted a permutation test to compare this t value with what would be expected from scrambling sketches across repetitions for each sketcher and target object. We found that the observed slope was highly unlikely under this distribution ($CI = [-0.57, 0.60]$, $p < 0.001$), even if the similarity at each round was not so unlikely.

Discussion

In this paper, we investigated the joint contributions of visual information and social context to determining the meaning of drawings. We observed in an interactive Pictionary-style communication game that pairs of participants discover increasingly sparse yet effective ways of depicting objects over repeated reference. Through a series of control experiments, we demonstrated that these conventionalized representations were both object-specific and interaction-specific: drawings were harder for independent viewers to recognize without sharing the same interaction history. Furthermore, by analyzing the high-level visual features of drawings, we found that they became increasingly consistent within an interaction, but that different pairs discover different equilibria in the space of viable graphical conventions. Taken together, our findings suggest that repeated visual communication promotes the emergence of depictions whose meanings are increasingly determined by interaction history rather than their visual properties alone.

A key experimental design choice was the use of visual objects as the targets of reference, by contrast with the verbal labels or audio clips used in prior work (Galantucci & Garrod, 2011; Fay, Garrod, Roberts, & Swoboda, 2010). As such, communication between the sketcher and viewer was grounded in the same visual information about the appearance of these objects, encouraging the production of more 'iconic' initial drawings that more strongly resembled the target object (Verhoef, Kirby, & de Boer, 2016; Perlman, Dale, & Lupyan, 2015). As their communication became increasingly efficient across repetitions, their drawings became simpler and apparently more 'abstract'. An exciting direction for future work is to develop robust and principled computational measures of the degree of visual correspondence between any drawing and any target object, thereby shedding light on the nature of visual abstraction and iconicity.

A second important design choice was the use of a speed bonus incentivizing participants to complete trials quickly. What role do such incentives play in the formation of graphical conventions? Recent computational models of visual communication have found that both how costly a drawing is to produce (i.e., time/ink) and how informative a drawing is in context are critical for explaining the way people spontaneously adjust the level of detail to include in their drawings in one-shot visual communication tasks (Fan, Hawkins, Wu, & Goodman, 2019). The consequences of this intrinsic preference for less costly drawings may be compounded across repetitions, as the accumulation of interaction history allows people to be equally informative with fewer strokes (Hawkins et al., 2017). The magnitude of these intrinsic costs may vary across individuals, however, and the speed bonus made them explicit.

A major open question raised by our work concerns how people decide what information to preserve or discard across repetitions. One possibility is that successful viewer comprehension is attributed to the most recent strokes produced, leading these to be more strongly preserved. For example, if the viewer was able to correctly identify the target only after the backrest was drawn, the sketcher may continue to selectively draw this part. Another possibility is that sketchers preserve what they judge to be the most diagnostic information about the target, regardless of when the viewer made their response. For example, sketchers may focus on drawing the backrest if it strongly distinguishes the target from distractors in context. Future work should disentangle these possibilities empirically and via development of computational models of visual communication that can learn from task-related feedback, as well as judge which strokes would be most diagnostic.

Visual communication is a powerful vehicle for the cultural transmission of knowledge. Over time, advancing our knowledge of the cognitive mechanisms underlying the formation of graphical conventions may lead to a deeper understanding of the origins of modern symbolic systems for communication and the design of better visual communication tools.

Abstract

Ambiguity has often been viewed as a hindrance to communication. In contrast, Piantadosi et al. (2012) argued that ambiguity may be useful in that it allows communication to be efficient, and they found support for this argument in the spoken forms of modern English, Dutch, and German. The historical origins of this phenomenon cannot be probed in the case of spoken language, but they can for written language, as it leaves an enduring trace. Here, we explore ambiguity and efficiency in one of the earliest known written forms of language: Sumerian cuneiform. Sumerian cuneiform exhibits extensive ambiguity, and for that reason it has been considered to be poorly suited for communication. We find, however, that ambiguity in Sumerian cuneiform supports efficient communication, mirroring the earlier findings for spoken English, Dutch, and German. Thus, the early stages of human writing exhibit evidence suggesting pressure for communicative efficiency.

Keywords: efficient communication; ambiguity; writing systems; cuneiform; information theory

Introduction

Ambiguity in language is often considered to be communicatively disadvantageous, because it can make a speaker's intention unclear to a listener. However, it has been argued (Zipf, 1949) that a certain amount of ambiguity in language is inevitable given the competing needs of speakers and listeners. Piantadosi, Tily, and Gibson (2012) pursued this idea further, and argued that ambiguity may be useful in that it can support efficient communication. They showed empirically that patterns of ambiguity in the spoken forms of modern English, Dutch, and German are consistent with pressure for efficiency in communication.

Given this finding, it is natural to wonder about the historical origins of this phenomenon. How quickly do languages come to exhibit efficient use of ambiguity? Was this phenomenon present near the beginning of language use? Such questions are unanswerable for the spoken form of language, which leaves no lasting trace — but they can be addressed with respect to written language, which does leave such a trace.

Sumerian cuneiform is one of the earliest known writing systems, and is one of the four 'pristine' writing systems of the world, meaning that its origins are not traceable to borrowing or influence from any previously existing writing system (Woods, 2015a). It is also known to be highly ambiguous, such that a given character often has numerous distinct semantic and/or phonological values (Cooper, 1996). Additionally, the distribution of meanings across forms in written Sumerian was not simply a straightforward reflection of spoken Sumerian; this means that any finding of efficiency with respect to the writing system cannot be dismissed as entirely derivative of the corresponding spoken language. Finally, Sumerian is unrelated to the languages studied earlier by Piantadosi et al., which are closely related to each other. For these reasons, Sumerian cuneiform suggests itself as a natural case study for probing the historical origins of the efficient use of ambiguity, in the accessible case of written language.

In what follows, we first provide a brief introduction to Sumerian cuneiform, and its relevance to the question of ambiguity and efficiency. We then restate the argument and results of Piantadosi et al. on modern spoken languages. Then, in three studies, we apply the logic and methods of Piantadosi et al. to the problem of assessing efficiency in Sumerian cuneiform. We find that ambiguity in Sumerian cuneiform bears the same signatures of efficiency as were found in modern spoken languages. We conclude that pressure for efficient communication may have been present near the earliest stages of human writing, and we discuss the implications of this conclusion.

Sumerian cuneiform

Cuneiform writing developed in southern Mesopotamia throughout the 4th millennium BC; first used for linguistic writing by the 31st century, the system survived roughly three thousand years, over which it was adapted into various languages of the Middle East (Veldhuis, 2012). The first language for which cuneiform was used was most likely Sumerian (Veldhuis, 2012), an agglutinative language with mild nominal morphology (case-marking suffixes) and rich verbal morphology, including a plethora of tense-aspect-mood and agreement affixes (Michalowski, 2004).

Cuneiform tablets compartmentalized text into columns, which were further divided into lines/cells, somewhat similar in layout to a modern-day spreadsheet; smaller items would only have one column (see Figure 1 for an example). The amount of information contained within a cell of a text had some degree of variation, but was at least at the level of a word and typically at the level of a phrase. Earlier scribal practice was not always concerned with preserving a consistent linear order of characters within a cell. By c. 2400 BC, however, scribes adhered to fairly strict and consistent linearity in spellings (Michalowski, 2004).

Figure 1: A sample text in Sumerian cuneiform. Since the text is small, it only has one column, which is divided into seven lines. Image from the Cuneiform Digital Library Initiative (2016), CDLI #102525. Image reprinted with permission of Robert K. Englund.

Spelling	Transliteration	Meaning
	paŋ	'breathe'
	asag	'demon'
	pa	'branch'
	ugula	'overseer'
	sag	'beat'
	rig	'boil down'
	rig	'donate'
	ensi	'governor/ruler'
	maškim	'administrator'
	*munsub*	'shepherd$_1$'
	*sipad*	'shepherd$_2$'

Table 1: Non-exhaustive list of words that contain the character in their spelling.

Written Sumerian was primarily logographic: the level of linguistic representation for a given graphical unit would usually be the morpheme (or some sub-morphemic, non-phonemic unit of information), although it also made use of phonography to some degree, with characters sometimes mapping more directly to (strings of) sounds, usually at the level of the syllable (Civil, 1973). A major feature of the system was its extensive use of ambiguity: any given character could have numerous distinct semantic and/or phonological values (Cooper, 1996). A non-exhaustive list of words containing the character can be found in Table 1; this list serves as an example of how a single character may occur in the spellings of words which do not all share semantic or phonological information. The table also demonstrates the lack of strict isomorphism between written form and corresponding spoken form, either in terms of phonemes, syllables, or morphemes. This point is important for our purposes because it means that if written Sumerian bears signs of efficiency, that efficiency cannot have been entirely inherited from spoken Sumerian.

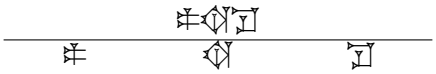
Two open questions concerning efficiency and ambiguity emerge from this overview. First, and most centrally: is the ambiguity of Sumerian cuneiform communicatively harmful, as might be expected given its extensiveness — or is it instead consistent with pressure for efficiency in communication? Second: is the shift to greater linearity in writing attributable to pressure for efficiency? We pursue these questions below.

The argument of Piantadosi et al. (2012)

To address these questions, we draw on the logic and methods of an earlier study that focused on modern spoken languages. Piantadosi et al. (2012) argued that "ambiguity is a functional property of language that allows for greater communicative efficiency" (p. 280). Their argument coheres naturally with a classic functionalist view that seeks to explain language structure and use in terms of efficient communication, and a growing body of recent research that pursues that idea with respect to various aspects of language (e.g. Aylett & Turk, 2004; Ferrer i Cancho & Solé, 2003; Piantadosi, Tily, & Gibson, 2011; Fedzechkina, Jaeger, & Newport, 2012; Kirby, Tamariz, Cornish, & Smith, 2015; Kemp, Xu, & Regier, 2018).

Piantadosi et al. (2012) pursued this argument as follows. First, they argued that context has the potential to resolve ambiguity. The communicative problem posed by ambiguity is that of the listener's (or reader's) uncertainty about the meaning of a given form, and they engaged this problem in information-theoretic terms, casting uncertainty as entropy. They noted that if context is informative about meaning, context will necessarily reduce uncertainty (entropy) about meaning. This means that context has the potential to alleviate the problem posed by ambiguity: a form that may be highly ambiguous in isolation may be much clearer when considered in context. A central assumption of their paper is that context is in fact informative about meaning, and therefore does help to disambiguate.

Piantadosi et al. then pursued the hypothesis that ambiguity in language is deployed in a manner that increases efficiency. The core idea is that if ambiguity is resolved by context, forms are free to take on multiple meanings — and the efficient way to do this would be to preferentially re-use forms that are low-cost, so as to minimize overall cost, or effort (Zipf, 1949). Forms may be low-cost in various ways: they may be short or otherwise simple; they may be frequent and therefore processed more quickly, and so on. Their paper considered several measures of form cost, and asked to what extent each predicts ambiguity of form. Specifically, using data on the spoken forms of German, Dutch, and English, they conducted quasi-Poisson regressions to establish the relationship between various count measures of form ambiguity and three properties of form cost: length, frequency (as negative log probability), and phonotactic surprisal. They found that in general, greater ambiguity was predicted by lower form cost (with the possible exception of phonotactic surprisal). Thus, shorter and more frequent forms were more ambiguous in



(RULER, 1) (RULER, 2) (RULER, 3)

Table 2: Example morpheme, meaning 'ruler'. The top row shows how this morpheme would be spelled in characters in the original text. The bottom two rows show the characters that appear in the spelling of this morpheme, each paired with the value of that character with respect to this morpheme, as defined in Equation 1.

German, Dutch, and English — consistent with the expectation that low-cost forms are preferentially re-used, as predicted by pressure for efficiency.

The present studies

We applied an analogous line of investigation to the question of ambiguity in Sumerian cuneiform.[1] Ambiguity arises when a form has more than one value, or symbolic function. Thus, to explore ambiguity in Sumerian cuneiform, we need to specify the relevant unit of form, and the corresponding values. It is natural to take the character as the relevant unit of form in Sumerian cuneiform, as it is characters that are often considered to be ambiguous. And given that characters are not defined either purely semantically or purely phonologically, but are used to specify morphemes, it is natural to define the values of a character in terms of that character's role in identifying morphemes, i.e. the character's role in spelling morphemes. A morpheme can have more than one spelling, so we first define the spellings $S(m)$ of a morpheme m to be the set of character strings that spell out that morpheme in Sumerian cuneiform. We then define the values *V(x)* of a character x as:

$$V(x) = \{\ (m,i)\ \mid\ x \text{ is the } i^{\text{th}} \text{ character in } s \in S(m)\ \} \quad (1)$$

That is, the values of character x are the set of all (morpheme, index) pairs (m,i) such that x is the i^{th} character in one of the spellings s of morpheme m. For example, the values of the character 𒁹 include the pairs (RULER, 1), (BRANCH, 1), and (DEMON, 2), among others. Table 2 illustrates a spelling of a specific morpheme, and the determination of character values from that spelling.[2]

Data

The data we used were from ORACC, the Open Richly Annotated Cuneiform Corpus (Tinney & Robson, 2014), an open-access corpus of cuneiform texts which is, to the best of our knowledge, the largest open-access corpus for Sumerian texts that has POS tagging and morphological annotation. Specifically, we used the texts in the Ur III Administrative Documents corpus within ORACC; this corpus is roughly 5.5 million cuneiform characters in length, and it consists of various administrative and transactional documents from the Ur III period (c. 2112-2004 BC). This corpus was chosen because it is the largest single-genre morphologically annotated corpus of third millennium Sumerian texts.

Substantial parts of the corpus had to be discarded. We omitted tokens that were damaged or for which the reading was unknown. In addition, most proper nouns had to be omitted.[3] The resulting cleaned data had roughly 3.3 million character tokens. We refer to this cleaned corpus as the 'dataset'.

Overview of the present studies

We conducted three studies to test whether ambiguity in Sumerian cuneiform is consistent with pressure for efficient communication. Piantadosi et al. (2012) assumed that much ambiguity could be resolved by context; we wished to test this question directly, so Study 1 asks to what extent context resolves ambiguity in Sumerian cuneiform. Study 2 asks whether context disambiguates more effectively in Sumerian cuneiform than it does in a number of plausible hypothetical variants of it; in so doing, this study explores whether increasing linearity in Sumerian writing may have resulted from pressure for efficiency. Finally, Study 3 applies the analyses of Piantadosi et al. (2012) to Sumerian cuneiform, to determine whether the signatures of efficiency they found in modern spoken languages are also found in cuneiform.

Study 1: Does context disambiguate?

To what extent does context resolve ambiguity in Sumerian cuneiform? We considered a simple version of this general question. We first determined the uncertainty concerning which value a character has when the reader knows only the current character (unigram condition). We then compared this to the uncertainty when the reader knows not just the current character but also the preceding character (bigram condition).

We took uncertainty concerning character values to be the conditional entropy of values V conditioned on context C:

$$H(V|C) = -\sum_{c \in C} P(c) \sum_{v \in V} P(v|c) \log_2 P(v|c) \quad (2)$$

Lower conditional entropy denotes greater certainty concerning character value.

We calculated $H(V|C)$ over the entire dataset, once taking C to be the current character alone (unigram), and once again taking C to be the current and preceding characters together (bigram). The results are shown in the top two lines of Table 3. Conditional entropy in the bigram condition is much lower than in the unigram condition. This demonstrates not only that context disambiguates, but also that just a single

[1] We believe we are the first to treat Sumerian in this way. However Civil (1973) informally explored the possibility of examining Sumerian cuneiform through the lens of information theory.

[2] We also ran all of the analyses using an alternate definition of a character's values: $V(x) = \{\ m\ \mid\ x \text{ is present in } s \in S(m)\ \}$. By this definition, a character x's values are simply the set of morphemes that contain x anywhere in any of their spellings. The results using this definition of character values were qualitatively the same as the results reported here.

[3] Proper nouns had no morphological annotation. Among other problems, this meant that inflectional morphology was not automatically separable from the rest of the word for proper nouns, as it was for other words in the corpus.

Table 3: Conditional entropy $H(V|C)$ of character values V given one character (unigram) vs. two characters (bigram) of text C, on attested and hypothetical data. Study 1: One added character of context results in a sharp decrease in uncertainty in attested data. Study 2: context disambiguates more effectively in attested Sumerian cuneiform than it does in some hypothetical variants of it. Value for WLSS is the average $\pm$ 1 SD, over 500 systems.

Study	Condition	$H(V\|C)$
1	Unigram, attested data	1.5281
1	Bigram, attested data	0.4584
2	Bigram, BWS	0.4719
2	Bigram, WLSS	0.9796 ($\pm$ 0.0004)

additional preceding character of context suffices to substantially reduce uncertainty. Since much more context than this would be available to readers, it is reasonable to expect that a competent reader of Sumerian would be able to infer with high certainty which value a given character was intended to have, in context. We conclude from this finding that context does effectively disambiguate in Sumerian cuneiform.

Study 2: Comparison with hypothetical systems

Given that context disambiguates in Sumerian cuneiform, we ask the follow-up question of whether plausible hypothetical variants of the system exhibit better, worse, or comparable results. Study 2 tested whether the consistency of spellings and strict linearity of Sumerian cuneiform demonstrate advantages over hypothetical competitors with regards to certainty of decoding character values in context.

We considered two hypothetical variants of Sumerian cuneiform. The first variant is 'backwards Sumerian' (BWS): this is a hypothetical variant of Sumerian in which the entire corpus is spelled backwards. Effectively this means that when considering a character in context, we take as context what would have been the following character in actual Sumerian, rather than the preceding character as in Study 1. The other hypothetical variant is 'within-line shuffled Sumerian' (WLSS): this is a system that is derived from our Sumerian cuneiform dataset by randomly shuffling the order of characters within a line. In this case, a neighboring character taken as context could be any other character within the same line in the original dataset. The latter hypothetical variant is motivated to some extent by actual scribal practices in earlier periods, in which characters were not always arranged in linear order. It is known that written Sumerian shifted towards more consistent linearity over time (Michalowski, 2004), and these hypothetical variants allow us to test the hypothesis that the greater linearity that we see in Ur III written Sumerian (the period of our dataset) may have aided disambiguation.

We first calculated $H(V|C)$ over the BWS datset. We then generated 500 WLSS datasets by randomly reordering characters and their respective values within each line, and calculated $H(V|C)$ over each resulting WLSS dataset. We considered only the bigram condition (in which C is the current character together with an immediately preceding character), because the unigram condition would yield identical results in the attested and hypothetical systems.

The results are shown in Table 3. Bigram conditional entropy is very slightly higher for BWS than it is for the attested system; thus, following context may serve as a marginally weaker disambiguator than preceding context, but the difference is small. Bigram conditional entropy is substantially higher for the WLSS systems than it is for the attested system, demonstrating that consistent linearity of spelling does confer an advantage on an ambiguous, logographic system such as Ur III written Sumerian, at least with respect to determining a given character's value based on immediately neighboring context. These results elaborate those of Study 1, and show that context disambiguates more effectively in Sumerian cuneiform than it does in at least some hypothetical variants of that system.

Study 3: Is ambiguity used efficiently?

We have seen that the ambiguity of written Sumerian is much reduced by contextual information, and that this is more true of actual Sumerian than it is of some possible variants of it. This sets the stage for a question directly parallel to that posed by Piantadosi et al.: given that context disambiguates, do languages use ambiguity efficiently, by reusing low-cost (simple, frequent) forms for a large number of meanings, thereby reducing system-wide cognitive costs?

We addressed this question in a manner that mirrors that of Piantadosi et al.: by asking whether the number of values associated with a specific character was predicted by the character's frequency of occurrence in the dataset, and by its simplicity.[4] Our measure of complexity (the opposite of simplicity) for a cuneiform character was stroke count: the number of strokes or wedges required to produce the canonical form of the character. For example, the character 𒐼 has 3 strokes. Stroke counts were coded manually by the first author based on forms in the Electronic Pennsylvania Sumerian Dictionary Project (ePSD; Tinney, 2009), an open-access online dictionary. Following Piantadosi et al., we transformed character frequency to negative log (unigram) probability, using add-one smoothing so that no character had frequency zero.

Figure 2 plots the number of values a character has (its character valence, $|V(x)|$, which is the size of the set $V(x)$), as a function of negative log probability based on unigram frequency, and as a function of stroke count. In both cases it appears qualitatively that lower-cost (more frequent, simpler) characters tend to have more values, consistent with pressure for efficiency.

To probe this pattern quantitatively, we conducted a quasi-Poisson regression to predict the number of values $|V(x)|$ associated with each character x, from that character's negative log probability and stroke count. We standardized the two pre-

[4]The third predictor considered by Piantadosi et al., phonotactic surprisal, is not applicable to Sumerian cuneiform.

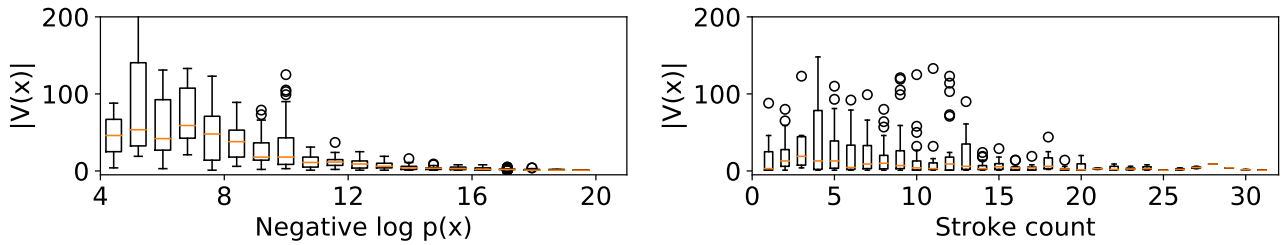


Figure 2: Box plots showing character valence $|V(x)|$ as a function of (left panel) negative log probability based on character frequency, and (right panel) character stroke count. Boxes extend from lower to upper quartiles; orange lines denote median; whiskers extend to 1.5 times the interquartile range beyond the lower and upper quartiles; all data points not in this range are treated as outliers and shown as empty circles. Both panels suggest that low-cost forms are preferentially re-used: more frequent (lower $-\log p(x)$) characters tend to have more values, and simpler (lower stroke count) characters tend to have more values.

dictor variables: for each variable, we subtracted the mean of that variable and divided by one standard deviation. This regression revealed significant effects both of negative log probability and of stroke count. Higher negative log probability (lower frequency) was negatively associated with number of values ($\beta = -1.249, t = -19.792, p < 0.001$), meaning that higher frequency characters were associated with more values. To make this outcome concrete, consider that the most frequent 180 characters, which make up only 27% of the total number of character types in the dataset, bear 66% of all values. Thus, a reader only needs intimate familiarity with a modest number of characters in order to be fairly literate. Higher stroke count was also negatively associated with number of values ($\beta = -0.127, t = -2.072, p < 0.05$), meaning that simpler characters (those with fewer strokes) were associated with more values.

Thus, characters with more values tend to be both more frequent and graphically simpler, as predicted by the hypothesis of efficiency: Sumerian cuneiform exhibits preferential re-use of low-cost material.

Discussion

The traceable origins and early years of written language offer a unique window into the role that pressure for efficient communication can play in shaping linguistic systems. For this reason, the present study has explored efficiency in one of the earliest known writing systems: Sumerian cuneiform, the written form of the Sumerian language.

We have seen that written Sumerian bears signs that are consistent with the hypothesis of pressure for efficient communication. Despite the high degree of ambiguity in written Sumerian, we have seen that a reader would only need a small amount of additional context to be able to decode a character's value with high certainty (Study 1). We have also seen that a comparison with hypothetical alternate systems which deviate from canonical linearity suggests that the system may have gravitated towards a more consistent linearity of spelling in a way that allowed for increased certainty of decoding (Study 2). Finally, we have seen that since context serves to reliably disambiguate character values, the system was able to use a single given form for several different values without sacrificing system informativeness — and that it appears to have done so in an efficient manner, preferentially re-using low-cost forms (Study 3). Taken as a whole, this evidence shows that written Sumerian was not an inefficient system.

Several general implications can be drawn from this observation. One of these concerns efficiency in writing systems generally. While factors such as medium (e.g. Woods, 2015b) and societal pressures (e.g. Veldhuis, 2012) are undoubtedly relevant to the development of a written language, our results demonstrate that pressures of communicative efficiency have acted on written systems since the earlier days of writing itself. Despite the relative disconnect between written Sumerian and its corresponding spoken language in terms of how values are distributed across contrastive units, the same signature of efficiency that Piantadosi et al. (2012) observed in three spoken languages in is also found in Ur III written Sumerian. This suggests that pressure for efficient communication is not unique to spoken or signed language, but is present in written language as well — critically, even when the written language does not closely mirror a corresponding spoken language. Thus, communicative efficiency may be viewed as a general principle of linguistic communication independent of medium or modality.

Another potential implication concerns the time course of the presumed cultural evolutionary process that produces efficiency in linguistic systems. The fact that our results were obtained in a linguistic system as young as 1000 years old suggests that these pressures may act upon a system from its inception and guide it toward greater efficiency within a comparatively short period of time. Since our analyses do not include actual data from periods earlier than Ur III we cannot be completely sure that earlier periods would have been less efficient. However, the fact that our hypothetical shuffled system performed poorly relative to the Ur III corpus is at least suggestive that earlier texts, which were analogously less consistent with their linearity, may not have evolved the specific communicatively useful features we have documented for Ur III Sumerian. Settling this question more definitively would require a thorough comparison of efficiency across ear-

lier time periods, tracking the progression of written Sumerian toward the system we have investigated.

In addition to a direct comparison of written Sumerian across earlier timer periods, future work on this topic would benefit from a more thorough consideration of the psycholinguistic evidence regarding recognition, decoding, and storage of graphical units. While we considered stroke count as a measure of visual complexity (which can be detrimental towards character recognition and processing, especially at lower frequencies; see e.g. Tamaoka & Kiyama, 2013), we did not consider other factors such as visual similarity between characters. Finally, future work could usefully consider the consequences of using the same (or similar) characters for phonologically or semantically related morphemes.

Firmer, broader, and more detailed conclusions will have to await the outcome of such possible future research. For now, however, we can conclude on the basis of the evidence we have seen here that one of the earliest known writing systems exhibits patterns of ambiguity that are consistent with pressure for efficient communication.

Abstract

When do children extend a construction ("rule") productively? A recent *Threshold* proposal claims that a construction is productive if and only if it has been witnessed applying to a sufficient proportion of cases and sufficiently few exceptions. An alternative proposal, *Communicate and Access* (C&A), argues that children extend a construction productively because they wish to express an intended message and are unable to access a "better" (appropriate and more conventional) way to do so. Accessibility, in turn, is negatively affected by interference from competing alternatives. In a preregistered experiment, 32 4-6-year-old children were provided with exposure to 2 mini-artificial languages for which the two proposals make opposite predictions. Results support the C&A proposal: children were more productive after witnessing 3 rule-following cases than after 5, due to differences in interference. We conclude that productivity is encouraged by a desire to communicate a message and is constrained by accessibility and interference.

Keywords: productivity, communication, accessibility, Tolerance Principle, Sufficiency Principle

Introduction

When children learn a new noun, *wug*, they are quite adept at producing its plural, *wugs* (Berko, 1958). On the other hand, the *-th* nominalizing suffix (*warmth, width)* is not generally added to new cases *(?coldth; ?oldth*) outside the domain of ordinal numbers (*gazilionth*). A recent *Threshold* proposal has attempted to predict when rules "go" productive and when they do not (Yang, 2016). In particular, in order for a rule to be productive, a Tolerance Principle offers a ceiling on the number of witnessed exceptions and a Sufficiency Principle suggests a floor on the number of cases witnessed following the rule. The required calculations are based on the following 3 numbers:

1) # of cases which potentially follow a rule: N
2) # of witnessed exceptions to a rule: e
3) # of witnessed rule-following cases: *M*

Specifically, the upper bound on exceptions and lower bound on rule-following cases have been proposed according to the thresholds in (1) and (2) (Yang 2016):

(1) Tolerance Principle (TP): $e \leqslant \mathrm{N}/\ln\mathrm{N}$
(2) Sufficiency Principle (SP): $\mathrm{M} \geq \mathrm{N} - \mathrm{N}/\ln\mathrm{N}$

For instance, in a domain of size 9, for a rule to be used productively, the minimum number of cases that must be witnessed following a rule is 5 (Sufficiency Principle) and the maximum number of exceptional cases is 4 (Tolerance Principle) (Table 1; Yang 2016; Schuler, Yang, & Newport 2016).

Table 1: The Threshold numbers predicted by Sufficiency and Tolerance Principles (Yang, 2016; SYN '16).

Domain Size (N)	Minimum # of rule-following cases (M): N- N/lnN	Maximum # of exceptions (e): N/ln N
9	**5**	**4**

A prior study (Schuler, Yang, & Newport, 2016, hereafter SYN '16), aimed to test the predictions in Table 1, but as explained below, the results are open to a different interpretation. The alternative proposal, which we refer to as Communicate and Access (C&A), takes as its starting point the idea that learners aim to convey their messages while obeying the conventions of the language as best they can (Goldberg, 2019). In order to *be able to* use a new language to express an intended message in an appropriate way, children need to be able to *access* the appropriate form. Accessibility is positively affected by the availability of a target form (Bybee, 2010) and is negatively affected by interference from contextually relevant competitors (Bates & MacWhinney 1987; Montag et al. 2017). We report new data involving two new experimental conditions that unconfound the predictions of the two proposals.

SYN '16 aimed to test the predictions in Table 1 by exposing 5-8-year-old children to a rule that could potentially apply to 9 cases in one of two conditions. In a **5R/1-1-1-1E** condition, the rule applied to 5 cases and 4 other cases were witnessed being exceptional, with each exception being exceptional in its own way. In this case, the domain size (N) was 9, the number of cases witnessed following the rule (M) was 5, and the number of exceptions (e) was 4. Because each exceptional case was unique, we represent the 4 exceptions here as 1-1-1-1. This 5R/1-1-1-1E condition satisfied both the Tolerance and Sufficiency principles and, as predicted by SYN '16, children treated the rule as fully productive. In a **3R/1-1-1-1-1-1E** condition, children saw a rule applied to 3 cases and 6 other cases were witnessed being exceptional. Here the Sufficiency Principle was violated (at least 5 rule-following cases should be required for productivity), and there were more exceptions than allowed by the Tolerance Principle. As predicted by SYN '16, children did *not* extend

the rule to new cases in this 3R/1-1-1-1-1-1-1E condition (see Figure 1).

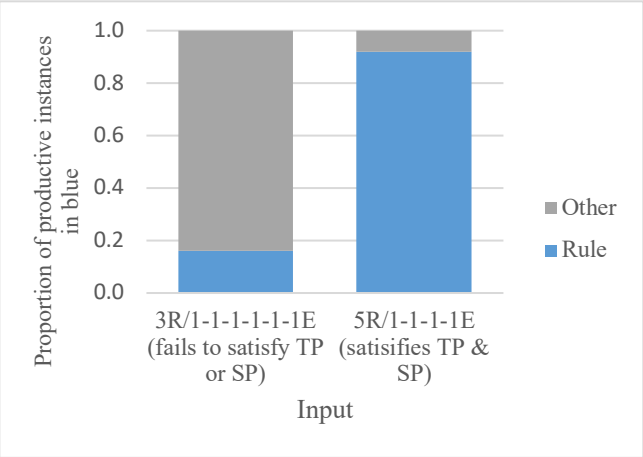

Figure 1: Data reported by SYN (2016): Proportion of productive rule-following (blue) and Other (grey) responses. Children exposed to a rule with 3 rule-following and 6 unique exceptions (left) or 5 rule-following and 4 unique exceptions (right).

Critically, the pattern of results reported by SYN '16 is equally consistent with the Communicate & Access proposal. That is, children extend a construction productively when they wish to express an intended message and are unable to access a "better" (appropriate and more conventional) way to do it. From this perspective, productivity is the effect of producing a "good enough" option when no conventional form exists, or when none is sufficiently accessible at the moment of speaking. Accessibility, in turn, is negatively affected by interference from competing alternatives, which themselves may be more or less accessible (Harmon & Kapatsinski, 2017; Macdonald, 2013; Montag, Matsuki, Kim, & Macdonald, 2017).

If we compare the 5R/1-1-1-1E and 3R/1-1-1-1-1-1-1E "rules" which children were exposed to in SYN '16, the C&A proposal likewise predicts that the 5R/1-1-1-1E rule should be more productive than the 3R/1-1-1-1-1-1-1E rule, but for different reasons than the Threshold proposal suggests.

Instead of viewing language as requiring abstract rules that are subject to numerical thresholds which render the rules either categorically productive or unproductive, the C&A approach predicts that learners record imperfect (lossy) memory traces that relate linguistic words and phrases to their meanings in context. Therefore, in what follows we refer to emergent generalizations as *constructions* instead of rules in describing the C&A perspective. Other things being equal, a construction is more accessible in memory after being witnessed with a greater variety of distinct cases because variability increases accessibility within the range of witnessed variability, and decreases it outside the range of witnessed exemplars (Tenenbaum & Griffiths, 2001; Suttle & Goldberg, 2011). This follows from the fact that memory is associative and content-addressable. The fact that memory is associative entails that new memories are integrated with existing memories; the fact that memory is content-addressable means that existing clusters of memories are activated to the extent that they are relevantly similar for the purpose of task demands.

Conversely, accessibility is negatively impacted by interference from competing constructions, with interference increasing as the accessibility of the competing constructions increases: witnessing 6 exceptional alternative cases *interferes* with a construction more than witnessing only 4 exceptional cases. Since other things were held constant in SYN '16, the availability of the construction was higher, and interference was lower in the 5R/1-1-1-1E condition relative to the 3R/1-1-1-1-1-1-1E condition. Therefore, the C&A proposal concurs that the 5R/1-1-1-1E condition should be more productive.

To summarize, the results reported by SYN '16 cannot distinguish between the proposal based on thresholds as determined by Tolerance and Sufficiency Principles, on the one hand, and the Communicate and Access proposal, on the other (Table 2).

Table 2: Convergent predictions are made by Threshold and C&A proposals for the productivity of an unconditioned "rule" with domain size of 9 in conditions tested by SYN '16 on 5-8-year-olds.

M vs. *e*, M = #Rule-following cases *e* = exceptional cases		**(Shared) Predictions and Results (SYN '16):**
3R/ 1-1-1-1-1-1-1E	Threshold: Neither TP nor SP are satisfied	No systematic productivity
	C&A: Tentative constructional generalization competes with many alternatives: no clear winner emerges	No systematic productivity
5R/ 1-1-1-1E	Threshold: TP and SP are satisfied	Productivity
	C&A: Constructional generalization is more accessible than any alternative	Productivity

In order to compare the two proposals directly, we report a new experiment for which they make *opposing* predictions. Specifically, we exposed a group of 4-6-year-old children to 2 new mini-artificial languages. In a **3R/0E condition**, a novel "rule" was witnessed applying to 3 out of 9 cases with 0 exceptions. The Threshold proposal predicts that children in this condition will not use the rule productively because an insufficient number of rule-following cases are witnessed: recall that in a domain of 9, a minimum number of *5* cases is required for productivity. The C&A proposal predicts, on the other hand, since 0 exceptions were witnessed, there should be no competition. Therefore, the C&A proposal predicts that as long as children understand the function of the construction and are able to access it, a construction that is

witnessed applying to 3 cases and 0 exceptions *will* be used productively.

In a separate **5R/4E condition**, a second novel rule was witnessed applying to 5 out of 9 cases, while 4 other cases were exceptional. The only difference between this 5R/4E condition and the 5R/1-1-1-1E condition in SYN '16 is that here the 4 exceptional cases behaved alike. In both cases, there were 5 rule following cases and 4 non-rule following cases. Therefore, the Threshold proposal predicts the 5R/4E rule should be as categorically productive as the 5R/1-1-1-1E rule of SYN '16 was. The C&A proposal, on the other hand, predicts that the "exceptional" construction—which was applied to 4 entities—should interfere with learners' ability to access the higher type frequency construction—which was applied to 5 entities. Because there is only a 25% difference in availability (and interference) between the two patterns, and no conditioning factors that could systematically distinguish the two, interference should render the (slightly) more dominant construction—the one witnessed applying to 5 entities—less than fully productive. C&A further predicts that when the more dominant construction is not used, the competing, less dominant construction will be used instead.

To summarize, the Threshold proposal predicts that when exposed to the 3R/0E rule, children should treat it as completely unproductive, and when exposed to the 5R/4E rule, they should treat it as completely productive. The C&A proposal, on the other hand, predicts that the 3R/0E pattern should be productive because it has no competition. As long as children are able to understand the task, they should use the pattern productively. In the 5R/4E condition, C&A predicts that the dominant pattern should be subject to interference from the less dominant pattern and should therefore be less than fully productive. Again, if children fail to use the dominant construction, C&A predicts that they will use the competitor, less-dominant construction instead. The predictions of the two proposals are represented in Table 3.

Table 3: Predictions of the Threshold and Communicate and Access proposals.

NEW CONDITIONS: M vs. e, (M= #Rule-following cases e = exceptional cases)		**PREDICTIONS:**
3R/0E	**Threshold:** SP is not satisfied	$Rule_3$ should not be productive
	C&A: Tentative constructional generalization has no interference from alternatives	$Construction_{(3)}$ should be productive
5R/4E	**Threshold:** TP and SP are satisfied	$Rule_{(5)}$ should be productive
	C&A: Dominant construction is only 25% more accessible than interchangeable alternative construction	$Construction_{(5)}$ and $Construction_{(4)}$ should compete

Experiment

Preregistration at Open Science Framework (OSF). We preregistered a plan to test 16 children without counterbalancing the constructions across conditions, and to use *t*-tests against full and 0 productivity (following SYN '16). We subsequently preregistered a second design with another 16 children in order to counterbalance the constructions (plural vs. classifier) and in order to preregister a more appropriate mixed model (glmer) analysis. Data was collected for each experiment only after it was preregistered. Results are combined below, as is appropriate, but both groups of participants were also analyzed separately (the first group with and without the 5 additional children tested with slightly different instructions). The pattern of results reported below remain unchanged in these subgroups.

Methods

Participants

32 children between the ages of 4 and 6 (M = 56 months) are analyzed below. We changed the instructions after an initial 5 children were tested and these children are excluded from analysis. All but one child provided four critical responses, two in each condition. One child opted out after the first condition (which happened to be 3R/0E for this child). All children were tested at the Princeton University Baby Lab, two were bilingual English speaking and the rest were monolingual English speakers. All had normal hearing and vision and were born at full term (38+ week gestation)**.** After each question, children received a sticker regardless of their response, and after the study, each child received a book and a prize, and the family received $10**.**

Procedure

The design was within-participants. In each of the two conditions, children were exposed to a mini-language that included 1 or 2 novel words, and 9 familiar English words naming each of 9 distinct kinds of animals or crayon colors. In the 3R/0E condition, a single novel form (*po*) was witnessed being used with 3 out of 9 items. In the 5R/4E condition, one form (*dax* or *fep)* was randomly assigned to 5 of the 9 items, and the other form was assigned to the remaining 4 items (see Figure 2).

The following were counterbalanced (in a nested fashion) across participants:

- order: whether children witnessed the 3R/0E or the 5R/4E condition first
- function: whether the rule/construction tested had a plural function or was used as a classifier
- item: whether the 9 items (or pairs of items) in the domain were crayons or animals
- dominant form: whether *dax* or *fep* was dominant form in the 5R/4E condition (*po* was consistently used in the 3/0 condition).

In each condition, the choice of which individual items (animals or crayons) was witnessed in the target

construction was randomly determined for each child, as was the order of presentation of items.

Pretest before each condition. Children were asked to count the 9 distinct entities in order to ensure that they recognized that the relevant domain size was 9. Children were then asked to name each distinct animal or crayon color. After each response, children received a sticker. All children succeeded in both tasks.

Exposure to a potential rule and exceptions. Children were then introduced to a puppet, Mr. Chicken, who, they were told, spoke a different language. Each child took part in both the 5R/4E and 3R/0E conditions as follows:

5R/4E condition: each child witnessed the rule applied once to each of 5 unique cases. 4 other cases were witnessed that were exceptional in that they did not follow the rule.

- When the novel forms were **classifiers,** Mr. Chicken picked up each of the objects and named the entity in "chicken language," saying the name of the entity immediately followed by a novel classifier, 5 of which followed the dominant pattern and 4 of which followed the exceptional pattern, ordered randomly. (*e.g., lion fep, monkey dax, zebra fep, giraffe dax…).* There were no conditioning factors that determined which novel classifier was used with each animal. Children were asked to repeat every novel form witnessed.
- When the novel forms were **plurals,** Mr. Chicken picked up one of each type of object, said its name and then picked up two of the same type, and used a novel suffix as a plural marker (e.g., *lion,* picking up one lion, *lion dax,* picking up two lions). Children repeated each singular and plural form. 5 entities were pluralized with one morpheme (*dax* or *fep*, counterbalanced) and the other 4 were pluralized with the other form. The items assigned to each novel plural marker were selected randomly, so there were no conditioning factors that determined which novel plural was used. Items were selected in random order (e.g., *lion, lion dax; monkey, monkey fep)*

3R/0E condition: each child witnessed the rule applied once to each of 3 unique cases. The other 6 entities were not witnessed either following the rule or being exceptional.

- When the novel form was a **classifier**, Mr. Chicken picked up 3 animals (or crayon colors) and named them with a novel classifier, *po* (e.g., *lion po, zebra po…*). Which animals were named was random for each child. Children were asked to repeat each label after hearing it.
- When the novel form was a **plural**, Mr. Chicken picked up and named one animal or crayon (e.g., *lion*) and then picked up two of the same animals or crayons which were labeled with the name and the plural morpheme, *po* (e.g., *lion po*). This was done for 3 types of animals or crayon colors, selected randomly. Children were asked to repeat each label after hearing it.

Production task

After initial exposure, children were asked to label another item the way Mr. Chicken would. Then, children were exposed again in the same way to the same condition and were asked to label a different item. This provided two responses for each condition. In the 5/4 condition, children were asked to label two never-before-seen items. In the plural condition, children labeled one of the remaining 6 items they hadn't heard labeled. Thus, children provided four critical responses, two in each condition.

Figure 2: Sample stimuli. 3R/0E condition with animals and 5R/4E condition with crayons. The two functions of the constructions, and animals vs. crayons were separately counterbalanced across

Results

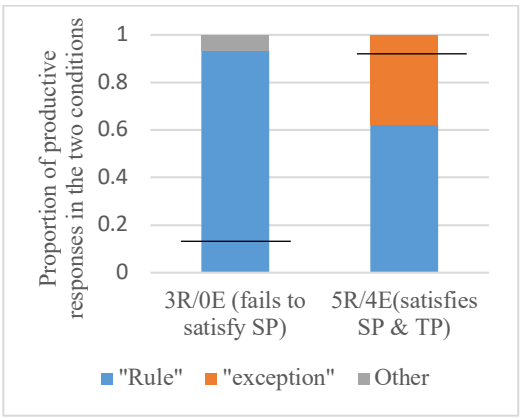

Figure 3: Proportion of responses in 3R/0E and 5R/4E conditions. Dominant form ("rule," blue); less dominant form (orange; relevant in 5R/4E condition), or other (gray). Domain size = 9. Black lines indicate Threshold predictions for height of the rule-following cases (in blue).

The values indicated by blue are the proportion of cases in which the rule was used productively. The Threshold

proposal's predictions for the expected proportion of rule-following cases (in blue) are indicated by the black lines in Figure 2; they are predicted to be identical to those in Figure 1. However, in the 3R/0E condition, the proportion of responses in which children used the novel form productively was near ceiling (M = .935; Figure 2, left). Specifically, 29 out of the 32 children consistently used the novel form productively, 2 children used it on one out of two trials, and only 1 child failed to use it at all.

In the 5R/4E condition, 14 out of 31 children consistently used the dominant form productively for new novel objects, 5 children consistently used the slightly less dominant form productively, and another 12 children produced both of the novel forms (one on each trial) (M = .625; Figure 2, right).

We analyzed the data using the glmer package with Condition (3R/0E or 5R/4E) as the predictor and by-subject random intercepts and slopes, and random intercept for Function-Assignment (plural or classifier first): Correct ~ Condition + (1 + Condition |Subject) + (1|Function-Assignment), family=binomial, data). Recall that other random factors were counterbalanced. The Threshold proposal predicted that the 3R/0E condition should be categorically unproductive and the 5R/4E condition should be categorically productive. However, results show a significant difference between the two conditions in the *opposite* direction ($\beta = 8.824, z = -2.918, p = 0.0035$). This is consistent with the Communicate and Access proposal which predicted that children should be productive in the 3R/0E as long as they understood the task, since there was no interference from a competing form; and children should be markedly less productive in the 5R/4E condition since the 2 forms witnessed would compete with one another, as there were no conditioning factors available to distinguish them.

Prior work has found children over-rely on *either* of two options when the difference in type frequency is not overwhelming (Hudson Kam & Newport 2005; 2009; Schwab, Lew-Williams and Goldberg 2018), and this occurred in the 5R/4E condition. In fact, 19 out of 31 children used only one form or the other: 14 children only used the more dominant form, and another 5 only used the less-dominant form. For this reason, it is not particularly meaningful to compare children's performance in the 5R/4E condition to chance. A majority of children chose one of the two options and simply repeated that option for all cases. But it also not appropriate to describe children's behavior as treating the more dominant form as a rule, given that fewer than half of the children consistently used the dominant form (14/31). Moreover, the remaining 12 children used one of each form, which is a pattern of behavior regularly seen in adults, when two options are witnessed with nearly equal type frequency (Hudson Kam & Newport 2005). In a comparison of the age of the 19 children who used a single form and the 11 children who used both forms, we find on average, that the latter group was 4 months older (M = 54 vs. 59 months). Using a 1-tailed t-test, this result is marginally significant (t = 1.61, p = .059).

Discussion

Critically, children were more productive in the 3R/0E condition than in the 5R/4E condition, directly contradicting the Threshold proposal's predictions, while being consistent with the predictions of Communicate & Access. Moreover, the Threshold proposal makes clear predictions that were disconfirmed in each condition considered separately.

In the 3R/0E condition, the Threshold proposal predicted that children should have been completely *un*productive, as they witnessed fewer rule-following cases than the number demanded by the Sufficiency Principle, given the domain size of 9: i.e., they only witnessed 3 cases, when 5 is predicted to be the minimum number required. Nevertheless, children overwhelmingly used the novel construction productively. The Sufficiency Principle has generally been argued to require an unrealistically high number of rule-following cases be witnessed in order for productivity to be realized (Goldberg 2018, 2019), and children's behavior in the 3R/0E condition confirms this. It is highly unlikely that children misjudged the size of the domain of the construction, since there were exactly nine entities (or pairs of entities) in the display (Figure 2) and children accurately counted them at the beginning of each condition. In fact, if children had assumed that the domain only included the three items that had been witnessed in the novel construction, with the other cases falling outside of the construction's domain, then the construction should not have been applicable to the other cases, and yet children overwhelmingly *did* extend it to the randomly selected new entities at test.

In the 5R/4E condition, the Threshold proposal predicted full productivity of the dominant form (which was witnessed with 5 out of 9 cases), as both the Tolerance and Sufficiency principles were satisfied. While 45% did use the dominant form productively, another 16% used the "exceptional" form productively. The rest, 39% of children, used both forms, one with each of the new entities. Defenders of the Threshold proposal might argue that the last group of children interpreted the input as evidence for *two* distinct and exceptionless rules, one of which applied to 4 cases and the other of which applied to 5 cases. However, this would require distinct domains for the two rules, and yet no conditioning factors were provided. Recall that instances that appeared with the dominant form and instances that appeared with the less dominant form were selected at random and differed across children. And, although the difference in type frequency between the dominant and less dominant constructions was close (5:4), it falls squarely within the thresholds that were proposed for the more dominant construction to become productive as children had done in the 5R/1-1-1-1 case reported by SYN '16.

Is it possible to defend the Threshold proposal on the grounds that the children in the current experiment were more adult-like? That is, the Threshold proposal is specifically aimed at young children's behavior rather than adults', since adults are recognized to behave somewhat differently than children in artificial language paradigms (Boyd & Goldberg 2012; Hudson Kam & Newport 2005, 2009), perhaps relying

on strategies or metalinguistic awareness that is unavailable to children as they learn their first language. Notably, however, the children in the current work were almost 3 years younger than those tested by SYN '16 (56 *vs.* 90 months).

Results in both conditions are consistent with the Communicate and Access proposal. In the 3R/0E condition, only one option was provided and so there was no interference from any competitors. C&A predicts that as long as children are able to appreciate the convention and access the form, they should use the form productively for new cases, as they overwhelmingly did. The results of the 5R/4E condition are also consistent with the C&A proposal. Since there were no conditioning factors to distinguish the two constructions, and since the forms were nearly equal in dominance (type frequency), C&A predicted that children would have no good way to resolve the competition between them. In fact, 14 children consistently used the more dominant option, while 5 used the less dominant form. This over-reliance on a single form recalls prior work that investigated children's productions when faced with unconditioned variation (Kam & Newport, 2005; Singleton & Newport, 2004), or when faced with variation that is conditioned, but by factors that the children fail to recognize (Schwab, Lew-Williams, & Goldberg, 2018). In those studies, children tended to rely on a single option in production tasks, but recognized both forms as acceptable in judgment tasks. The discrepancy between production and judgment tasks suggests that the over-reliance on one form during production results from the challenge of accessing and choosing between multiple forms without any reason to prefer one over the other (Harmon & Kapatsinski 2017; Schwab, Lew-Williams, and Goldberg, 2018).

Recall that the Communicate and Access proposal takes as its starting point the idea that learners aim to convey their messages *while obeying the conventions of their language as best they can*. While it is simpler to over-rely on one option in the face of unconditioned variation, it is more conventional to use both options, since both options were witnessed. As expected, then adults should be more likely to match the relative frequencies in the input even when faced with unconditioned variation between two alternatives, because they are better able to access both forms and choose between them. And in fact adults do tend to be more successful than children at matching the input veridically in mini-artificial language experiments (Kam & Newport 2005; 2009; SYN '16). We see evidence that an over-reliance on a single form is *simplification* in the current work, in that 12 out of 31 children used both novel forms in the 5R/4E condition. Moreover, the children who used both forms in their own productions were marginally older than those who over-relied on a single option, by an average of four months. We take that as an indication that children attempted to successfully produce both options, with older children simply being more successful.

We therefore conclude then that interference—the nature of the exceptional cases—played a key role in whether a competing form was used productively. That is, the difference between the 5R/4E condition here and 5R/1-1-1-1 condition of SYN '16 is that the current class of exceptions all occurred with the same form, making the "exceptional" form itself accessible. And since the exceptional case was just as appropriate for expressing the intended message (i.e., there were no conditioning factors that made either more appropriate), and the "exceptional" cases were nearly as accessible as the "rule," the C&A proposal predicted that the exceptions would interfere with the productive use of the rule. And this is evident in the current results in that children were significantly less productive in the 5/4 condition than in the 3/0 condition.

Conclusion

The present work investigated the factors that underlie children's productive use of a novel rule or construction. We compared two proposals that make contrasting predictions. The first, a Threshold proposal, argues that rules are used productively as long as two thresholds are met: the proportion of potential cases that are witnessed obeying a rule must cross a threshold in order to satisfy a Sufficiency principle and the proportion of potential cases that are witnessed behaving exceptionally must remain below a threshold in order to satisfy a Tolerance principle (Yang, 2016). A Communicate and Access proposal instead appeals to the idea that a speaker's goal is to convey her intended message while obeying the conventions of her language as best she can. On this view, children extend constructions in new ways when they need to express a given message and they are unable to access a more conventional or better match. Accessibility of a construction increases as the variability of witnessed cases increases; and accessibility of the construction decreases as the accessibility of a competing construction increases.

In the current experiments, 4-6-year-old children were exposed to 2 mini-artificial languages. Each language provided exposure to a potentially productive rule, which was assigned a plural or classifier function. In one condition, a novel construction was witnessed applying to 3 out of 9 cases and 0 exceptions. The Threshold proposal predicted that children would *not* use this 3R/0E rule productively, as too few instances were witnessed to satisfy the Sufficiency principle. The Communicate and Access proposal predicted that children *would* use the construction productively because there was no better way to communicate their intended message; i.e., there was no interference from any competing alternative. As predicted by the C&A proposal, the construction was overwhelmingly used productively.

The other condition exposed children to 5 out of 9 cases following a rule, the 4 other cases being exceptions to that rule. The Threshold proposal predicted that in this 5R/4E condition, children should be fully productive, since a sufficient number of rule-following cases was witnessed, and a low enough number of exceptions was witnessed. Unlike in previous work (SYN '16), here the 4 exceptional cases all behaved alike. The Communicate and Access proposal predicted that there would be competition between the two constructions, and that this would interfere with the productivity of both. In fact, there was markedly less

productivity in the 5R/4E condition than in the 3R/0E condition, counter to what the Threshold proposal predicted and consistent with the C&A proposal. Children in the 5R/4E condition over-relied on the dominant construction (45%), *or* on the less dominant construction (16%), *or* they used both constructions (39%).

To summarize, our preregistered experiment contradicts the Threshold proposal while being consistent with Communicate and Access. We conclude that productivity is encouraged by the desire to communicate a message while obeying the conventions of the language. On this perspective, we do not extend a construction productively unless we are unable to access a "better" (more conventional and appropriate) way to express our intended message. Productivity of a construction is contrained by the accessibility of the construction, and accessibility is affected by both the variability of witnessed exemplars and interference from a competing construction (Goldberg, 2019). When there is no better way or when we are unable to access a better way at the moment of speaking, we have no choice but to extend appropriate constructions that *can* be accessed.

The C&A proposal takes a different perspective on prior findings that children tend to "regularize" their input, making it more systematic and therefore in some sense better. The C&A proposal suggests that "regularization" arises from a failure to successfully access a more conventional and appropriate alternative. C&A takes the position that both children and adults aim to conform to the conventions used by others who are considered to be knowledgeable. Adults are more successful at reflecting the input veridically given very limited exposure, but children aim to--and ultimately do--learn the conditioning factors of the constructions they are exposed to, and to a remarkable extent, successfully conform to the speech patterns used in their language communities. In fact, we saw adult-like behavior in a subset of (somewhat older) children in the current experiment who, in the 5R/4E condition, used both options.

The Threshold proposal faces other outstanding issues that are not addressed here. For example, exceptions are assumed to be searched serially and before rule-following cases, despite a lack of psycholinguistic evidence for this claim (Hernandez, 2019; Wittenberg & Jackendoff 2018; Kapatsinki 2018). The proposal assumes that exceptions are listed in order of frequency so that neither exceptions nor rule-following cases are allowed to cluster within our associative memory as proposed by the C&A and other accounts (Ambridge et al. 2018; Bybee 2010; Goldberg 2019; Kapatsinki 2018; McClelland& Patterson 2002). Without allowing instances to cluster in memory, it is entirely unclear how children are able to determine the domain of a rule, let alone calculate the size of the domain, as is required for the Threshold proposal to make any predictions at all.

To summarize, constructions (or "rules") do not "go productive" by crossing predetermined numerical thresholds. Rather, people extend constructions for new uses when doing so provides an accessible way to best express their intended messages.

Linguistic syncopation: Alignment of musical meter to syntactic structure and its effect on sentence processing

Abstract

Language and music are structured at multiple temporal scales and have been characterized as having meter: a hierarchical and periodic alternation of the prominence of syllables/beats. Meter is thought to emerge from the entrainment of neural oscillators, affording temporal expectations and selective attention. Higher-levels of a metric hierarchy also tend to track syntactic phrase structure, however, it is not clear within the framework of temporal attending why this would be advantageous. Neural oscillations have recently been shown to also track syntactic phrases. We propose that meter aligns to phrase structure so as to make syntactic processing more efficient. In two experiments (both visual and auditory language), we show that certain alignments of meter to syntax influence sentence comprehension and we suggest potential mechanisms for why certain alignments tend to be preferred. Our results underline the rhythmicity of not only low-level perception but also of higher-level cognitive processing of syntactic sequences.

Keywords: Language, time, oscillations, musical meter, syntax, merge

Introduction

Music and spoken language present similar challenges to a listener in that structure at multiple temporal scales must be decoded from a continuous sound signal in real-time. It is, therefore, no surprise that there are some parallels in how this is achieved and, as such, also parallels in musical and linguistic structure that bear the mark of these shared processing means. One such parallel is metrical structure. Meter generally refers to the perceived hierarchical alternation of stress in syllables in speech (Port, 2003), or beats in music (for more detail, see: Lerdahl & Jackendoff, 1983). In this paper, we motivate a view of meter as being something emerging from, on the one hand, the computational problem of extracting a discrete structured representation from a continuous signal, and on the other hand, an algorithmic solution that fits within the implementational oscillatory-constraints of neuro-computation (Rimmele et al, 2018a).

In explaining what meter affords its perceiver, the predominant theory has been that it is a system for *predicting when* and that these temporal expectations then in turn afford the dynamic allocation of attention to expected points in time to optimize processing (Jones, 1976; Pitt & Samuel, 1990). These theories of 'dynamic attending' have been formalized in models using coupled neural oscillators to explain how meter is flexibly entrained to a signal and how the dynamics of hierarchical perceived stress emerge naturally from this mechanism (Large & Jones, 1999; Port, 2003).

More generally, there is an attractive isomorphism between the temporally multi-scaled structure of language and music, and the multi-scaled oscillatory paradigm of neural processing in the brain. The consensus seems to be that the entrainment of one to the other—'tuning the inside to the outside'—is, at least, important if not necessary to both basic perception and perhaps even to deeper analysis and comprehension. As such, the concepts of oscillation and entrainment have become central in recent cognitive and neuroscientific theories of language processing (Giraud & Poeppel, 2012), and in theories of music processing for both rhythm/meter (Large & Kolen, 1994) and tonality (Large et al, 2016).

Specifically for the case of speech, it is proposed that the auditory cortex entrains a cascade of oscillatory sampling windows to the speech envelope: phonemes sampled with gamma oscillations (>30hz), syllables with theta (3-8hz), and intonational phrases with delta (<3hz). And while delta-oscillations are normally observed to follow prosody (Bourguignon et al, 2013) they have recently been shown to track syntactic phrases, even in the absence of prosodic cues (Ding et al, 2016), thus demonstrating top-down linguistic knowledge. Meyer and colleagues (2017) additionally showed that when prosody and syntax are misaligned, delta tracks the syntactic rather than the prosodic phrase. How should this all be interpreted?

One consideration that has been neglected is how meter figures into this: perhaps what delta is really tracking here is meter. This is especially important as the paradigms used to show delta-tracking of syntax employ a frequency-tagging approach where the speech must be presented isochronously and thus may be particularly likely to induce a subjective percept of meter. Indeed, similar paradigms have also been used to show oscillatory tracking of meter where delta too tracks higher-metric levels not present in the acoustic signal (Nozaradan et al, 2011).

While the precise rhythmicity of naturalistic speech is still hotly debated (for example, two contrasting positions: Nolan & Jeon, 2014; Brown Pfordresher, Chow, 2017), and thus the extent to which strict parallels between speech and musical

rhythm/meter are valid, it is certainly clear that there many special cases of speech where the parallel with musical meter is clear, such as poetry and song (Lerdahl, 2001). And perhaps more importantly, it seems that rhythm and meter are especially important cues during early language development, in line with the framework of prosodic bootstrapping where infants rely on prosodic information to segment input. In line with this, it has been shown that the perception of meter is present in the first year of infancy and that meter supports the learnability of other structure in a signal such as rhythm and melody (Hannon & Johnson, 2004). More generally, this idea may explain the clear metric structures of nursery rhymes and in children's literature (Breen, 2018; Fitzroy & Breen, 2019).

In recent years, there has also been growing interest in the relationship between musical experience and language abilities (for recent meta-analyses see: Gordon et al, 2015a; LaCroix et al, 2015), with the underlying rationale of some overlap in neural implementation and that music may have certain properties that enable to it to preferentially strengthen these networks (Patel, 2011). Specifically, it seems that the subcomponent of meter is particularly crucial in mediating the transfer of musical abilities to the processing of speech and syntax in language (Gordon et al, 2015b; Jung et al, 2015). Relatedly, the syntactic deficits observed in Parkinson's Disease patients may actually be more to do with a deficit in the ability to process the meter of language than a deficit to syntax directly (Kotz & Schmidt-Kassow, 2008).

These findings are surprising: why should meter support syntax? While it is conceivable that the dynamic allocation of attention could support the processing of speech under noisy conditions (where signal and noise are time delimited) such as in 'cocktail party' paradigms where this oscillatory entrainment mechanism is implicated (Zion Golumbic et al, 2013). It is not clear how this mechanism would support syntactic processing specifically. Some recent work, however, has started to provide clues. Rimmele et al (2018b) have shown that delta is involved in chunking auditory short-term memory. And relatedly, the BUMP model (Hartley et al, 2016) has provided a mechanism by which entrained oscillators support auditory short-term memory for serial order, further supported by Gilbert et al (2017) who provided empirical support for a shared resource underpinning this aspect of short-term memory and temporal precision. In summary, metrical structure (especially in the delta-range) may support aspects of short-term memory, which would then in turn, support syntactic processing.

Another not mutually exclusive possibility is suggested by Nelson and colleagues (2017). Using intracranial electrophysiological recordings, they observed fine-grained neural dynamics of syntactic structure building. Specifically, they observed a monotonic ramping of activity for each new word presented in a sentence until a syntactic constituent could be formed, at which time there is a spike of activity proportional to the number of words then a sudden decrease of activity reflecting the freeing of working-memory resources. They interpreted this in terms of a Chomskian/Minimalist merge operation (see Friederici et al, 2017), however, these observations can also be interpreted in less theoretically committal 'chunking' terms. Regardless, this result captures real-time dynamics of processing demands that relate to syntactic structure building, and that these demands stack-up toward ends of phrases where ramping of activity reaches its summit and where there is a 'spike' of activity that merges/chunks the information. And importantly, these demands are time localized. Therefore, if the 'strong' and 'weak' of meter relate to oscillatory fluctuations in neural excitability then perhaps meter may also function to temporally align neural resources with these processing demands.

Some evidence linking delta-oscillations with such an idea is suggested by Meyer & Gumbert (2018), who found that the phase of delta-oscillations tends to align excitability with phrase-endings (however, they interpreted this as aligning delta with syntactic informativeness, nonetheless, their data are consistent with our idea here).

In summary, a more general way to make sense of this relationship between meter and syntax is in terms of prediction and efficiency of processing (Gibson et al, 2019), and how this is constrained by the oscillatory nature of the brain (Rimmele et al, 2018a). Syntax gives top-down prediction of "what next" (Levy, 2008) and meter/neural-resonance gives bottom-up prediction of "when next" (Large & Kolen, 1994). However, together they are more flexibly able to entrain to not just low-level acoustics but also higher-level structures, and thus enable more efficient processing of syntactically structured sequences as in language and music.

We now explore this idea in two experiments that manipulate the alignment of meter and syntax and measure the effect of this alignment on comprehension.

Experiment 1

Method

Our central hypothesis that is tested in both of the following experiments is that comprehension (measured by probe accuracy and response-times) is highest when the strong-beat of meter aligns most often with phrase-boundaries (see Figure 1). We also manipulate syntactic complexity by using both subject-extracted and object-extracted relative-clause sentence structures. The difference in complexity here is defined in terms dependency locality theory (Gibson, 1998), where object-extracted sentences require integrating over a greater number of words and thus pose a greater strain on resources. We predict an interaction between sentence complexity and congruency on the grounds that better-aligned resource allocation may be more needed in sentences that integrate over more words. Thus, this yields a 2 X 2 factorial design, manipulating syntactic complexity (subject- vs object-extracted relative-clause) and congruency (congruent, incongruent). While we also manipulate which clause of the sentence is probe (main or relative), we have no theoretical prediction about this other than the main clause would have higher accuracy.

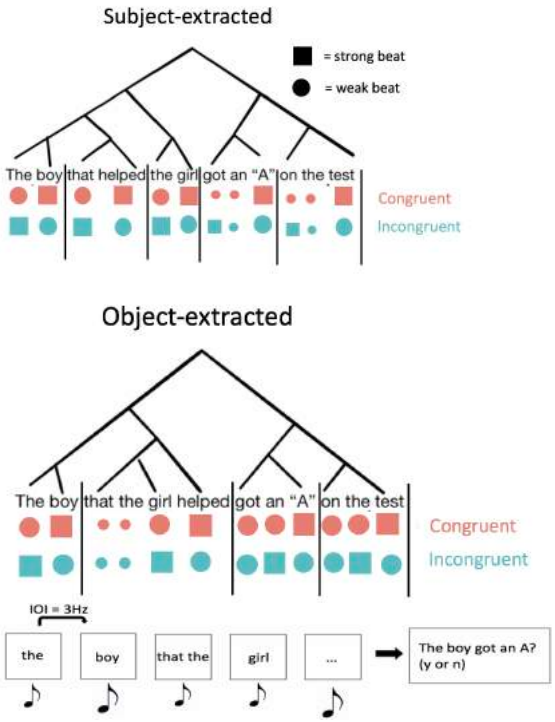

Figure 1, Top & Middle: examples of syntactic tree-structure for a sentence and possible alignment with meter defining congruencies. Bottom: trial presentation schematic

Participants 40 native English speakers (20 female) from the Sydney area took part in this study and were naive to its purpose.

Materials The language materials consisted of 48 sentences composed of largely monosyllabic words, each 12 words long. Each sentence had subject- or object-extracted versions. We used an additional 25 filler-sentences of assorted structure and length. Each sentence has an accompanying comprehension probe, which was balanced within participants as to probing either the main- or relative-clause and whether the correct answer was "yes" or "no". For example, if the sentence was "The boy that the girl helped got an A on the test", the probe was either "The boy/girl got an A?" or "The boy/girl helped the boy/girl?". The congruency manipulation was achieved by shifting the phase of the metrical pattern relative to the language presentation such that the strong beats fell on different positions in each phrase, e.g. "the BOY" or "THE boy" (see Figure 1). To fit the structure of the subject or object extracted forms, these sentences appeared in either binary or ternary meters respectively. Conditions were randomized over the sentences for each participant and presented in a random order.

The auditory materials were generated using a Python script and consisted of a 333Hz pure tone in which a 3Hz beat was induced by amplitude-modulating the signal with an asymmetric Hanning window with 80% depth and a 19:1 ratio of rise-to-fall time. Metrical accents were then applied by a 50% volume increase every 2 (binary) or 3 (ternary) tones.

Procedure The experiment was self-paced, and after an initial practice block, was completed in a single block where the participant was encouraged to take short breaks between trials. The experiment was run using software written in Python, using the PsychoPy library. Each trial begins with one full-bar of the meter (three strong beats) while a fixation-cross is shown center screen, after which the words begin appearing in the place of the fixation cross synchronized to the auditory tones. At the end of the sentence, the probe question appears center screen, and the participant is prompted to respond as quickly as possible with either "y" or "n" keys on a keyboard. If participants take longer than 5 seconds to respond, they will be prompted to speed up on the next trial. The participant also receives corrective feedback after each trial and is encouraged to balance speed with accuracy.

Results

Comprehension data were analyzed using a mixed-effects logistic regression including fixed-effects for congruency (congruent, incongruent), syntactic complexity (subject-RC, object-RC), probed clause (main-clause, relative-clause), and the interaction between congruency and syntactic complexity. We also included random intercepts for participants and items. Response times (RTs) were analyzed using a linear mixed-effects regression with the same structure. All analyses were done in R.

As seen in Figure 2, participants made fewer comprehension mistakes in the congruent conditions (χ^2 = 7.99, p = .005), fewer mistakes for the subject-RC sentences over the object-RC ones (χ^2 = 26.21, p = <.001) and fewer mistakes when the main clause is probed rather than the relative clause (χ^2 = 40.03, p = <.001). There was, however, no significant interaction between congruency and syntactic complexity (χ^2 = 0.43, p = .513). There was also no significant effect of congruency on reaction times (χ^2 = 1.20, p = 0.273). However, there were significant effects of syntactic complexity and probed-clause on RTs (χ^2 = 16.314, p = <.001; χ^2 = 35.796, p = <.001).

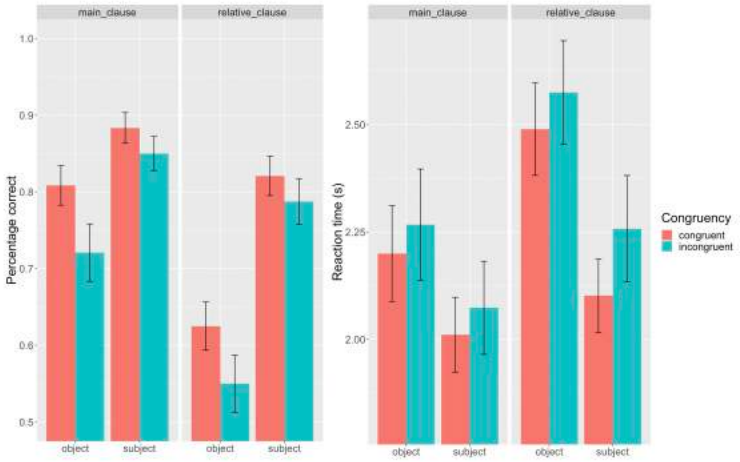

Figure 2, Experiment 2 results. Left: accuracy results as percentage correct. Right: response-time results in seconds.

Discussion

In line with our main prediction, congruency affected comprehension accuracy, however, there was no significant difference for response times. Against our initial prediction, there was also no significant interaction between congruency and syntactic complexity.

One limitation of the design was that the meter was induced passively with the auditory stimuli. Thus, we do not know to what degree participants actually interpreted the stimuli according to this meter. And although there was no significant interaction between congruency and syntactic complexity, one potential problem of the design was that object-RC sentences always had a ternary meter and subject-RC sentences always had a binary meter. This issue is an inevitable consequence of the phrase lengths in these respective sentence types, however, it may complicate the interpretation of an interaction. Further, reading sentences presented in an RSVP format is not a naturalistic way of processing language.

Experiment 2

Method

In our second experiment we wanted to build on the results of the first, replicate the congruency effect on accuracy, and address some of its limitations. Notably, we presented the sentence stimuli as auditory speech to make it more naturalistic and to check the robustness of the congruency effect to stimulus modality. As opposed to Experiment 1, where meter was induced *passively,* in Experiment 2 we induced meter *actively* by asking participants to tap on a drum-pad in time with the strong metric-beats while they listen to the speech stimuli (see for how tapping/motor actions entrain auditory attention: Morillon & Baillet, 2017). This also allows us to use tapping consistency as a DV, thus, we add the prediction that tapping will be most consistent in congruent trials (consistency being defined as the standard deviation of their accuracy). Finally, both subject and object extracted RC sentences were presented to the same ternary meter. This allows us to discount the possible meter by syntactic-complexity confound. Although, in order to make the subject-RC sentence fit a ternary meter, we had to introduce a new potential confound of inserting silences as in Figure 3. The main reason why we opted for a ternary meter, however, was to enable us to have three levels of the congruency condition for each sentence type (congruent, incongruent-1, incongruent-2). This came with the additional hypothesis that incongruent-1 would be the most incongruent metric alignment. That is, according to our delta-oscillation hypothesis, while incongruent-1 & 2 are both equidistant from the 'merge' position of the phrase, for incongruent-2, the merge would occur while attentional resources are rising, whereas for incongruent-1, the merge would occur while this attentional energy is falling (Figure 5).

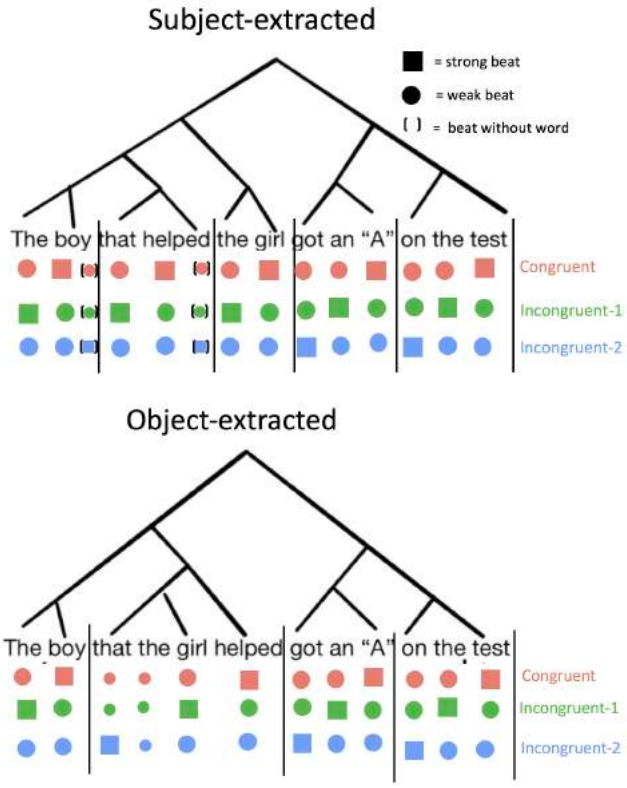

Figure 3, Congruency examples Experiment 4: syntactic tree diagrams for subject and object extracted sentences with accompanying alignments to meter defining the congruencies.

Participants (same specification as Experiment 1)

Materials Extending the 48 sentences and probes from Experiment 1, we created a further 24 of the same constraints, yielding a total of 72 sentences and probes. Speech stimuli were then generated and preprocessed from these sentence materials using a custom Python script, using Google's text-to-speech API to generate audio-files for each word individually. These stimuli were then volume normalized and cut and stretched to 2.5Hz (this new presentation-rate was based on piloting), then assembled into the sentences. Like Experiment 1, each trial starts with one full-bar of the tones to set the metric context. In a departure from Experiment 1, however, the tones drop-out when the speech stimuli start.

Procedure To ensure an active percept of the meter in Experiment 2, participants were required to tap on a drumpad in time with the strong-beats while listening to the speech (tapping once every three words). Participants used their right index finger to tap on a pressure sensitive MIDI drumpad. Before the main section of the experiment, participants completed a 'tapping-only' trial-block which estimated their tapping consistency without any language stimuli. This was then followed by practice trials for the language section and then the main trial block. Otherwise, the trial design followed that of Experiment 1.

Results

Comprehension and response-time data were analyzed using logistic and linear mixed-effects models as in Experiment 1, with the only difference being three levels of the congruency fixed-effect (congruent, incongruent1, incongruent2).

The results replicate the main effect from Experiment 1, showing that congruency significantly affected comprehension (incongruent1: χ^2 = 13.23, p = <.001, incongruent2: χ^2 = 8.30, p = .004). While the incongruent2 condition had a smaller cost on comprehension that incongruent1 (as predicted), the difference between these predictors was not significant (χ^2 = 0.533, p = 0.465). As before, there was also a significant difference between which clause is probed (χ^2 = 24.641, p = <.001). Surprisingly, however, there was no significant effect of syntactic-complexity (χ^2 = 0.101, p = .750). We believe this is a likely consequence of the added rhythmic complexity required to make subject-RC sentences fit a ternary meter.

As with Experiment 1, there was no significant effect of congruency on RTs (incongruent-1: χ^2 = 1.371, p = 0.242, incongruent-2: χ^2 = 0.837, p = 0.360) although syntactic-complexity and clause-probed had strong effects (χ^2= 19.900, p = <.001; χ^2= 49.801, p = <.001).

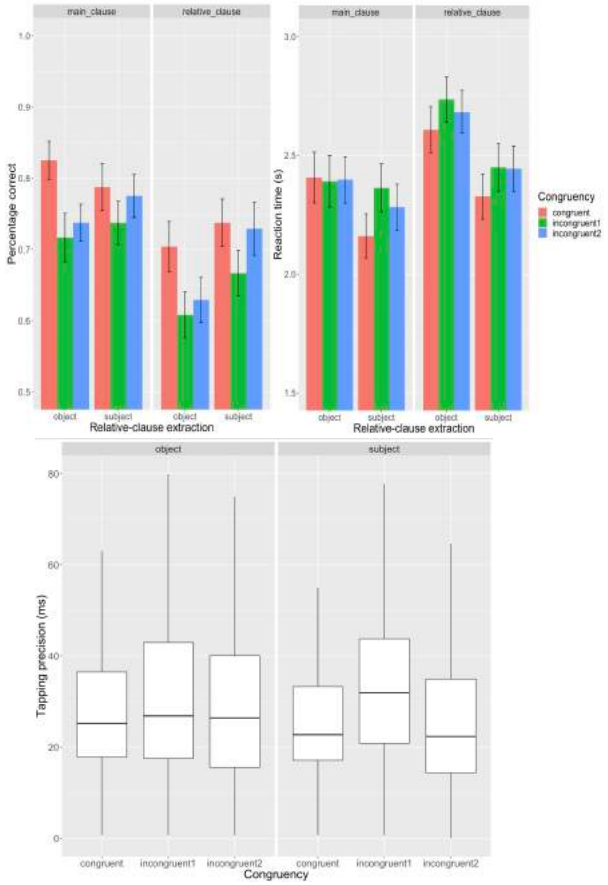

Figure 4: Comprehension results from Experiment 2. Left: accuracy. Right: response times. Bottom: tapping accuracy (standard deviation of asynchrony between tap and target tone)

For the tapping data during sentence processing, we also used a linear-mixed effects regression with congruency and sentence-extraction, and their interaction, as fixed effects, and participants as a random-effect.

Congruency had a significant effect on tapping precision in the incongruent1 conditions (χ^2= 10.27, p = .001) and only marginally significant for incongruent2 (χ^2= 3.25, p = .071). There was also a significant interaction between incongruent1 and syntactic complexity (χ^2= 12.72, p = <.001). However, it is problematic to interpret this interaction in light of the above-mentioned issues with rhythmic complexity, so we do not interpret it further.

General discussion

The results of both experiments support our hypothesis that sentence comprehension is optimal when metrical strong-beats align with phrase boundaries. We interpret this as supporting the more geneal idea that meter, and its alignment to phrase structure, plays a role in syntactic processing.

Jung and colleagues (2015) showed a similar effect of temporal expectancy on syntactic processing by having key words arrive early or late compared to an established rhythm. Kotz & Schmidt-Kassow (2015) showed that the syntactic deficit of Parkinson's Disease patients was actually due to a deficit processing the meter/timing of speech. In our study, however, each word was perfectly predictable from a rhythmic standpoint, and participants had no generalized timing deficit, however, we showed that the hierarchical distribution of attention embodied by meter, and its alignment with syntactic structure, was sufficient to show differences in comprehension.

We did not, however, find significant differences in response times. Although it is worth noting that the direction of the RT-effect was consistent with our hypothesis in both experiments. One possible explanation for this null-result is that top-down endogenous attention tends to affect accuracy, while bottom-up exogenous attention affects reaction-times (Prinzmetal et al, 2005). While lower levels of meter may be driven by bottom-up cues in the signal (Large & Kolen, 1994), it is likely that higher-levels increasingly rely on top-down phase-resetting of oscillations in response to syntactic structure or other structural cues (Rimmele et al, 2018a). Thus, this could explain why congruency had a stronger effect on accuracy over RTs. However, it may have also been that the effect was too small to detect for our sample size.

Comparison across the two studies also shows that this congruency effect is robust to modality (visual presentation in Experiment 1 and auditory presentation in Experiment 2), and thus is not specific to speech rhythms. A hypothesis that would need further experimentation to explore would be that any sequential stimulus that must incrementally form hierarchical structures would be influenced by this metric congruency effect. If this hypothesis were confirmed, it would suggest that meter is part of a more general cognitive strategy for the timely allocation of resources to process

structural relations, and that music and language are just the most prominent domains in which this plays out.

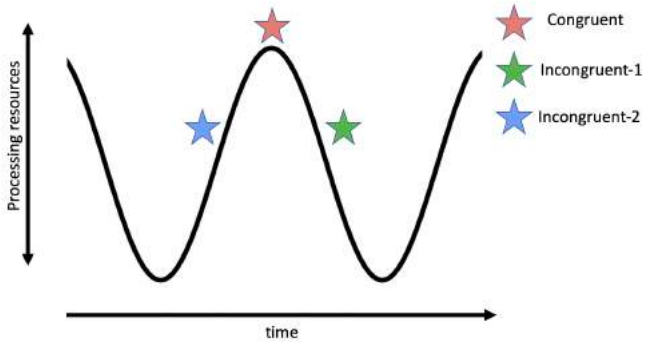

Figure 5: hypothetical oscillation of attentional resources. Stars represent the position of the phrase-ending word relative to this oscillation in each congruency condition.

Experiment 2 showed suggestive behavioral evidence of behavioral oscillations at the delta rate. Specifically, incongruent-1 conditions had a larger effect on comprehension than incongruent-2, in line with the differences in neuronal excitability predicted if the meter did phase-align delta to strong-beats (Figure 5). Although it is important to stress that this difference was not statistically significant, it was however consistent in direction across all conditions, including in the tapping data. It is also important to acknowledge that preferences for the alignment of meter to phrase structure may also be mediated by cultural factors relating to differences in language structure and preferences for grouping (Iversen et al, 2008). Future research is planned to further test these possibilities, including with more sensitive electrophysiological paradigms.

More generally, the idea that the analysis of syntactic phrases is somehow constrained by oscillatory processes is in line with the average phrase duration of speech at 2-3seconds (Vollrath, 1992), fitting within the delta-range. This may also be a neuronal constraint that results in Uniform Information Density (Levy & Jaeger, 2007), which stipulates that we, as rational communicators, attempt to spread information across a signal in a uniform way, and in a way that makes the most of our capacity (i.e. not undershooting). In other words, part of what defines our capacity to process linguistic information is these rhythmic processing constraints and the extent to which we can optimally entrain our internal rhythms to the rhythms of the information in the signal. Thus, delta sampling of syntactic phrases may define a crucial biologically grounded bottleneck that explains these patterns in human communication.

It is also likely that meter serves a similar function for the processing of harmonic syntax in music to the function articulated here for linguistic syntax (Patel, 2003). This would be consistent with some recent studies showing that harmonic structure is a strong cue for metrical strength (White, 2017). This would also accord with data showing an interaction between the processing of linguistic and musical syntax (Fedorenko et al, 2009).

Conclusion

We have shown that the alignment of meter to syntactic structure influences sentence comprehension. We have also discussed possible mechanisms from which this effect arises, namely, how delta-oscillations facilitate aspects of short-term memory processing that in turn allow for syntactic structure-building. These results imply that entraining the 'inside to the outside' may allow for more efficient processing of syntactic sequences. Future work will be required to further pick-apart the details of these ideas, ground them in neural measurement, and to explore their generality cross-linguistically and to other syntactically structured domains such as music and mathematics. In general, this work supports a co-dependency of "what" and "when" predictions, and grounds this in the biological implementational constraints of the rhythmic brain.

Iconicity and Structure in the Emergence of Combinatoriality

Matthias Hofer (mhofer@mit.edu), Roger Levy
Department of Brain and Cognitive Sciences, Massachusetts Institute of Technology,
43 Vassar St, Cambridge, MA 02139 USA

Abstract

One design feature of human language is its combinatorial phonology, allowing it to form an unbounded set of meaningful utterances from a finite set of building blocks. Recent experiments suggest how this feature can evolve culturally when continuous signals are repeatedly transmitted between generations. Because the building blocks of a combinatorial system lack independent meaning, combinatorial structure appears to be in conflict with iconicity, another property salient in language evolution. To investigate the developmental trajectory of iconicity during the evolution of combinatoriality, we conducted an iterated learning experiment where participants learned auditory signals produced using a virtual slide whistle. We find that iconicity emerges rapidly but is gradually lost over generations as combinatorial structure continues to increase. This suggests that iconicity biases, whose presence was revealed in a signal guessing experiment, manifest in nuanced ways. We discuss implications of these findings for different ideas about how biases for iconicity and combinatoriality interact in language evolution.

Keywords: phonology; language evolution; combinatorial structure; iterated learning; iconicity

Introduction

Combinatorial phonology is an important design feature of human language, allowing it to form an unbounded set of novel, meaning-bearing words from a small set of building blocks. How did it emerge in language? As part of a larger research program that attempts to explain linguistic properties through biases operating during language acquisition and use (Christiansen & Chater, 2016; Kirby, Cornish, & Smith, 2008), recent laboratory experiments have suggested how combinatorial structure could have arisen from continuous signals through a process called iterated learning (Verhoef, Kirby, & de Boer, 2014; Giudice, 2012). But while combinatorial structure might confer a range of advantages to language, it appears to be in conflict with another salient feature of communication systems: iconicity. In order to participate freely as primitives in larger composite forms that carry arbitrary meanings, the building blocks of a combinatorial system should be meaningless (Dingemanse, Blasi, Lupyan, Christiansen, & Monaghan, 2015). Iconic signs, on the other hand, are motivated by properties of the meanings they refer to.

Evidence suggests that iconicity plays an important role in bootstrapping communication. In a study where subjects had to develop novel communication systems, Fay, Arbib, and Garrod (2013), found that gesture was preferentially adopted over speech, and explained their findings in terms of gesture's

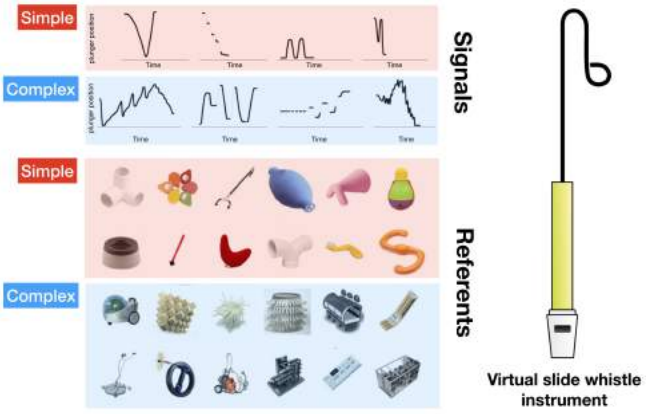

Figure 1: Depiction of stimuli and virtual slide whistle used in the iterated learning experiment to investigate the relation between iconicity and combinatoriality. Visual referent stimuli are from Lewis and Frank (2016).

stronger affinity for iconic representation. On the above account, signals tend to eventually lose these iconic origins as they develop into combinatorial systems. Goldin-Meadow and McNeill (1999) have similarly argued that iconicity is the default strategy and that combinatoriality is not adopted for the benefits it provides but to compensate when iconicity is not available. Consistent with this account, Verhoef, Kirby, and de Boer (2016) found that the onset of combinatorial structure in an iterated learning experiment was delayed when signal/referent mappings were scrambled between generations, making it harder for iconicity to develop, relative to a condition where mappings were kept intact.

Despite the possible loss of iconicity in the emergence of combinatorial phonology, many familiar forms of iconicity such as onomatopoeia or sound symbolism continue to play an important role in language (Dingemanse et al., 2015). How do these various forms of iconicity develop as signals undergo their transition from holistic to combinatorial structure? To reconcile the existence of iconicity at different stages of language evolution, we focus on a more subtle form of iconicity, recently described by Lewis and Frank (2016), that exists between word length and conceptual complexity. In their analysis of monosyllabic words across 80 languages, the authors

found that longer words are systematically associated with more complex meanings. Whereas the languages considered by Lewis and Frank (2016) are already fully combinatorial, we examine whether this form of iconicity also arises in continuous signal spaces and use it to address questions about the relationship between iconicity and combinatoriality. To this end, we conducted an iterated learning experiment where subjects evolved a set of signals through iterated reproduction. Participants learned artificial languages consisting of whistled signals that were paired with referents taken from Lewis and Frank (2016). Both signals and referents varied in complexity (Figure 1) but were paired in such a way that there was no systematic relationship between simple and complex items in the beginning. Based on the literature presented above, we predicted that such a relationship, indicative of iconicity, would emerge but eventually disappear as the communication systems become more combinatorial.

Using the languages resulting from the iterated learning study, we present results from a series of experiments designed to answer the following questions:

1. Did the languages evolve combinatoriality? This was assessed by asking subjects to rate the amount of combinatorial structure that existed in the languages.

2. Did the signals evolve iconicity? Iconicity, defined in terms of congruent complexity associations between signals and referents, was measured by collecting complexity judgments for the evolved signals.

3. Which underlying cognitive structures support our inferences about iconicity? Previous studies suggest the existence of strong biases for the development of combinatoriality and iconicity (Lewis & Frank, 2016; Verhoef et al., 2016). To better understand the role of iconicity biases and how they manifest in our experiment, we devised a guessing game where naive listeners were asked to choose the most likely referent for each signal.

After presenting our results, we close by discussing how our findings relate to different ideas about the evolution of iconicity and combinatoriality.

Experiments

To investigate how iconicity develops during the emergence of combinatorial structure, we conducted an iterated learning experiment. Miniature artificial languages were repeatedly acquired and subsequently transmitted by one 'generation' of subjects to the next. This took place across several independent transmission chains. We adopted the signal space used in Verhoef et al. (2014), in which subjects produced signals using a slide whistle instrument. Since we conducted the experiment online, we developed an on-screen, virtual version of the instrument, depicted in Figure 1. Pitch was controlled by moving the plunger up and down using the mouse. Sounds were produced by pressing down the space bar and continued until the space bar was released. Before the experiments started, participants were given an opportunity to familiarize themselves with this interface. Using the languages that evolved during iterated learning, we subsequently conducted four additional experiments to address the aforementioned questions about the emergence of combinatorial structure and iconicity.

Iterated learning experiment

The iterated learning experiment consisted of 15 independent chains, each consisting of 10 generations. Per chain and generation, a single subject learned and later reproduced an artificial language. The first subject in each chain was given a language constructed according to principles described below, while subsequent generations learned the language produced by the previous generation.

Materials Each language consisted of eight whistled sounds paired with different referents. Figure 1 shows which signals were used to initialize each experimental chain. The signals were obtained from whistles recorded and subsequently rated for their complexity in a pilot experiment. The signals were paired with unfamiliar visual objects selected from a stimulus set used in Lewis and Frank (2016), which was normed for complexity. Referents were categorized as either simple or complex. For each chain, four simple and four complex referents were selected at random from the stimuli depicted in 1 and assigned to signals with the constraint of counterbalancing between signal and referent complexity classes (half of the complex signals were paired with complex referents and while the other half was paired with simple ones and vice versa). This procedure ensured that the relation between signal and referent complexity was initially fully unsystematic.

Procedure Subjects were told that they had to learn an artificial language produced using a slide whistle with the goal of teaching the language to a computer program. After familiarizing themselves with the instrument, subjects engaged in five learning blocks, where they were shown each of the eight signal/referent pairs in random order. Each trial first displayed the visual referent, then the slide whistle playing back the corresponding signal. The whistle then stayed on screen and participants were instructed to repeat the signal. No feedback was given during learning. Subjects were admitted to the reproduction phase if they reached a learning criterion to assess how well they learned the language. The criterion test consisted of eight 2-AFC trials. Each of the eight signals was played to subjects once and they had chose the correct referent from a set of two. The distractor item was sampled from among the remaining three items of the same complexity class, preventing participants to identify the correct referent based on referent complexity alone. No feedback was given during these trials. To advance to the final stage of the experiment, participants had to correctly identify at least six of the eight items. Participants that reached the learning criterion advanced to the reproduction phase, which

was framed as a computer teaching paradigm. Subjects were asked to record each signal for a computer program that will attempt to learn the language from them. All referent stimuli were presented simultaneously on screen and subjects could chose the order in which they recorded signals by clicking on the corresponding item.

While chosen to prevent subjects from producing the same signal multiple times, the framing of the task as a teaching paradigm did not fully prevent a loss of expressivity (see, e.g., Kirby et al., 2008). Throughout the experiment, 7% of signals were identified as duplicates using a dynamic time warping-based similarity measure, and replaced with signal versions produced during learning with the constraint of being sufficiently distinct from the remaining test phase signals. This approach is conservative since signals produced during learning typically very closely resemble the input the participant was given and thus limit the amount of change (relative to the input) experienced by the next participant.

Subjects A total of 382 subjects were recruited on Amazon's Mechanical Turk. 250 subjects passed a preliminary headphone check (Woods, Siegel, Traer, & McDermott, 2017), implemented to ensure consistent listening conditions, and were admitted to the main experiment. Of those, 164 subjects reached the learning criterion. Data from 14 subjects was due to technical reasons, leaving us with 150 subjects, one subject per chain and generation.

Quantification of combinatorial structure

To answer whether signals evolved combinatoriality, we conducted a rating experiment. Naive participants were asked to rate the amount of structure present in the languages from the iterated learning experiment. Participants saw languages from either one of two conditions: In the intact condition, languages were randomly selected from across chains and generations in the iterated learning experiment. Participants were blind to which generation or chain a language came from. In the scrambled condition, participants were shown languages where signals from the different chains of each generation were randomly mixed together. Including this baseline condition allows us to assess to what extent combinatoriality judgment are about properties of the signals in the context of the language they evolved in, or simply about the structure of signals irrespective of their relation to the other signals in their language.

Subjects and Procedure Subjects were told that they had to rate the amount of structure of different newly discovered whistle languages. Structure was described as the existence of building blocks or principles that are shared among the signals in a language. Signals were presented visually in a presentation format similar to Figure 3 (but in a single row). This allowed subjects to make holistic judgments and facilitated comparisons between items in the language. Subjects were asked to report how structured a given language was, ranging from least to most structured, using a continuous slider. A total of 314 subjects took part in the rating experiment and each participant rated 24 items.

Quantification of signal complexity and iconicity

To address our second question, it was necessary to quantify signal complexity in order to assess if signals developed to match the conceptual complexity of their referents. Two experiments were conducted, one where signals were presented visually and one where they were presented auditorily.

Visual complexity ranking Similar to the previous experiment, languages were presented in the form of a visual array. Subjects were instructed to sort the signals from least to most complex. Complexity was defined as signals that have many parts and that are difficult to memorize or reproduce. 374 subjects took part in this part of the experiment and each subject rated 16 items. After realizing that effect sizes of the iconicity measure are likely too small and that the noise introduced from using a perceptual modality different from the original, auditory modality could potentially mask important differences, we conducted a second rating experiment.

Auditory complexity rating experiment Focusing on just the first five generations of iterated learning, in the second complexity rating experiment, signals were presented similar to the main experiment, with the slide whistle playing back the recorded signals. Signals were randomly selected from across chains and generations, which enabled us to obtain absolute complexity judgments (compared to the rank-level judgments obtained in the visual experiment). Subjects judged the complexity of each signal from least to most complex using a slider. 175 subjects took part in the experiment and each subject rated 16 items.

Evaluation of signal iconicity

Finally, do people exhibit iconicity biases that explain their productions during iterated learning? To develop further insight into the nature of the biases that support iconicity, we conducted a guessing game where subjects were presented all eight signals from a language (in random order) and had to identify the most likely referent per signal. Subjects were instructed that they should always choose the referent that they thought most likely belonged to the signal, and that the same referent could be chosen more than once. This allowed us assess the existence, and to quantify the strength of iconicity biases that exist in signal interpretation. 218 subjects took part in the experiment and each subject rated 8 languages.

Results

Emergence of combinatorial structure

The first question we address in our analysis is whether languages developed combinatorial structure, as described in prior experiments (e.g., Verhoef et al., 2014; Giudice, 2012). In summary, we observe that signals in all chains develop combinatorial structure. Figure 3 depicts a representative example language from the final generation of chain 1, giving

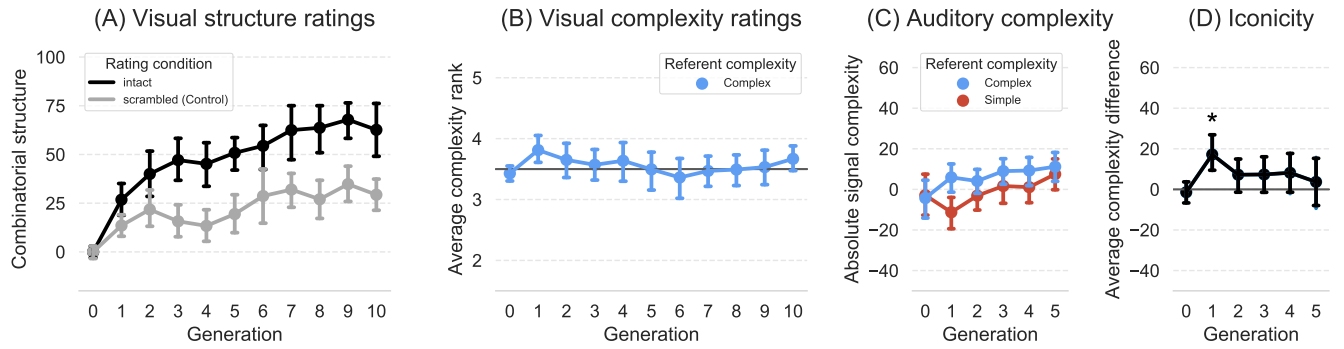

Figure 2: Results from the three experiments that we conducted to assess signal structure and complexity (visual and auditory), and the derived iconicity measure. Error bars are 95% confidence intervals.

a qualitative impression of the emergence of shared building blocks. Figure 2A shows the results from our combinatoriality measure. Across both the intact ($t(14) = 8.06, p < 0.001$) as well as the scrambled condition ($t(14) = 5.59, p < 0.001$), languages are judged to increase in structure over generations[1], but languages in the intact condition are judged to increase more ($t(14) = 2.5, p = 0.02$). This difference can only be explained by assuming that signals in the intact condition are structurally more similar to each other, which results in higher combinatoriality ratings compared to mixing languages across chains as in the scrambled condition.

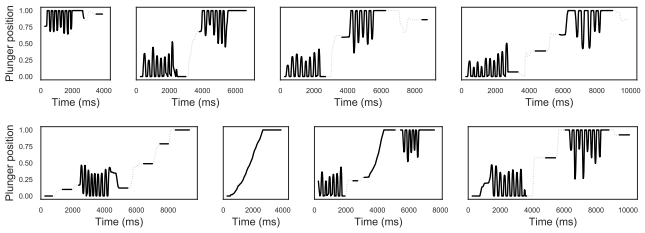

Figure 3: Set of stimuli from the last generation of chain 1. The language appears to consists of three building blocks: a short beep occurring at different pitch values, a long pitch sweep, and a wiggly segment of alternating pitches.

Development of iconic signal structure

Turning to our second question, Figure 2B depicts the results of the visual complexity ranking experiment where participants were asked to order signals from least to most complex (coded as 0 to 7). The depicted mean complexity rank represents the average rank of the four signals that were associated with complex referents. An at chance association between signals and referents corresponds to a mean rank of 3.5. While nearly all chains in the first generation have an average complexity rank of greater than 3.5, quantitatively this difference does not reach significance after correcting for multiple comparisons ($t(14) = 2.60, p = 0.02$ before, $p = 0.21$ after *Holm-Bonferroni* correction). Two features of the experimental measure could potentially mask this effect: the ranking score only captures ordinal differences and not differences in magnitude. Secondly, measurements may be noisy because the experiment was conducted in the visual instead of the auditory modality. While not posing a problem to the combinatoriality measure reported earlier (because of the larger effect sizes), this might hinder detection of iconicity in the languages.

To address these points, a second experiment collected complexity ratings in the auditory domain, restricting ourselves to the first five generations of iterated learning. Figure 2C shows the resulting ratings, grouped and averaged by associated referent complexity. These data were used to derive an iconicity measure, depicted in Figure 2D, by subtracting the average complexity of signals associated with simple referents from signals associated with complex referents. Positive values indicate the presence of iconicity in a congruent direction. As suggested earlier, we find that iconicity emerges immediately after initialization in generation one ($t(14) = 3.71, p = 0.002$ before, $p = 0.01$ after correction). While the return of the iconicity measure to chance is not significant within the first five generations of the auditory measure ($t(14) = -1.56, p = 0.14$), the visual complexity measure from 2C strongly suggests that iconicity drops back to chance in subsequent generations and thus, taken together, licenses the inference that iconicity eventually disappears from the languages.

Relationship between iconicity and structure

The previous analyses have demonstrated that languages develop both combinatoriality and iconicity over the course of the experiment. To develop insight into state-dependent trade-offs between iconicity and combinatoriality, we now look at the development of iconicity as a function of combinatorial structure instead of generation. Figure 4A shows the evolutionary trajectories of all fifteen languages in terms of their combinatorial structure and their iconicity (based on Figures 2A and D). The plots suggest that languages, while

[1] Analyses compare the regression coefficients fitted to the fifteen chains to a zero slope.

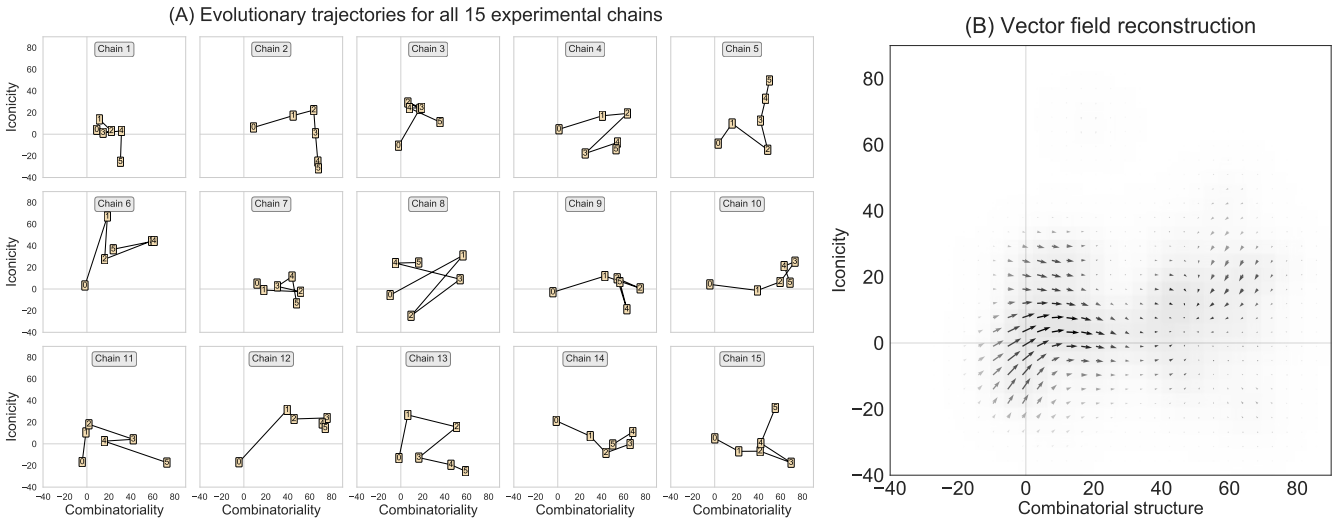

Figure 4: Visual representation of the evolutionary trajectories of all fifteen experimental chains, on the basis of which we constructed a vector field representation that shows inter-generational parameter changes for observed and hypothetical languages.

displaying common patterns, can vary substantially in terms of their developmental time constant. We summarize these data by constructing a vector field that shows extrapolated average magnitude and direction of inter-generational changes on a grid (based on the behavior of nearby languages). The model is constructed by considering all 75 vectors in Figure 4A that represent transitions from one generation to the next. For each grid point, an average magnitude and direction is estimated by computing the weighted linear combination of vectors using their distance, obtained with a multivariate Gaussian kernel centered around the grid point, as weights. Figure 4B shows the resulting vector space model. The total sum of Gaussian weights per grid point, superimposed in grey, corresponds to the number of vectors nearby that were used to construct the estimate. The model summarizes in which direction, and how much, hypothetical languages would change in terms of combinatoriality and iconicity, based on the observed data. Adding to the results reported above, gains in iconicity or maintenance of already existing iconicity is only observed when languages are still relatively unstructured. Languages loose their iconic structure as combinatoriality increases further. More sporadically observed 'extreme' levels of iconicity and combinatoriality appear to be unsustainable and eventually revert to lower levels.

Inductive biases for iconicity

Which underlying cognitive structures support our inferences about iconicity? We asked naive subjects in a guessing game to pick the most likely referent for each signal. Figure 5 shows the probability of listeners choosing a complex referent as a function of signal complexity, indicating a strong tendency for choosing referents that match the perceived complexity of the signal. (Note that the ground truth referent information in Figure 5 is displayed as additional information and not part of the reported analysis.) Crucially, this bias allowed subjects to reliably identify the correct referent complexity class for signals that exhibited the most iconicity ($t(9) = 2.77, p = 0.024$). We compared the probability of choosing the correct referent class with chance performance for the ten languages that scored highest in iconicity (measure taken from Figure 2D).

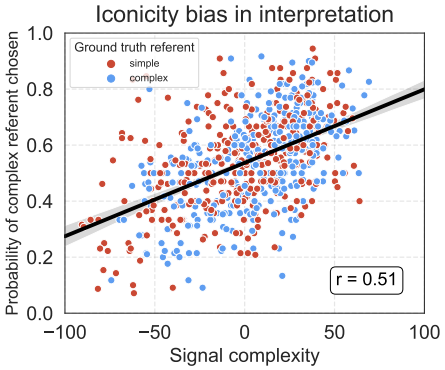

Figure 5: Results from the guessing game, conducted to quantify the strength of iconicity biases for the evolved signals.

Discussion and Conclusion

We conducted an iterated learning experiment to investigate how iconicity develops when combinatoriality emerges in initially unstructured, continuous signals. Signals gradually became more combinatorial over the course of the experiment. The emergence of iconicity, measured in terms of signals matching the conceptual complexity of their referents, was shown to develop immediately, but iconicity eventually disappeared while combinatorial structure continued to increase. This result is particularly strong because languages were initialized at a point of complete arbitrariness.

The largest increases in combinatoriality were seen in generation one. This is consistent with the idea that signal structure is a consequence of cognitive biases for combinatoriality. Because of having selected a diverse signal set for initialization, memory demands during learning and reproduction were arguably the highest in the first generation. Since this affords the greatest potential for prior biases to manifest, we would expect the largest increase in structure here.

The loss of iconicity is consistent with the hypothesis that iconicity is in complementary distribution with combinatorial structure (Verhoef et al., 2016; Goldin-Meadow & McNeill, 1999; Roberts, Lewandowski, & Galantucci, 2015), since the building blocks of such a system must be stripped of their iconicity when they participate in larger meaning-bearing units. It is important to note, however, that it is not clear why the particular kind of iconicity we investigated here must be lost in order for combinatorial structure to arise. In the transition from holistic to combinatorial structure, complexity in the signal domain could be expressed equally well in terms of number of building blocks (Lewis & Frank, 2016). The observation that iconicity is nevertheless lost could, however, provide important insight into the nature of the transition process. Zuidema and de Boer (2018) recently distinguished between analytic and synthetic routes to combinatoriality. In the synthetic route, preexisting signals are combined to form larger combinatorial signals, while in the analytic route, potentially overlapping parts of preexisting signals are used to form new signal. The present findings are consistent with the holistic account, which predicts that productive recombination leads to new signals that are composite, therefore complex, irrespective of the complexity of their referent but simply due to the mechanics of recombination.

While our guessing game suggests that people have strong biases for iconicity, our results indicate that these biases manifest in subtle ways. Smith et al. (2017) presented evidence that the strength with which cognitive biases manifest in cultural evolution depend on a number of factors. The authors focused on properties of the transmission paradigm, such as how many different agents subjects learn from, which shapes the input to learning. In the present study, we found evidence that the manifestation of otherwise strong cognitive biases, such as a bias for iconicity, can also depend on properties of the input more directly, for instance, on how much structure signals exhibit. Understanding how properties of the input can modify the expression of biases more broadly is an avenue for future research. In addition, the novel vector field analysis we present suggests the possibility of testing specific combinations of iconicity and combinatoriality to develop a more complete picture of trade-offs in parameter space.

One further aspect that is not addressed in our study is the role of modality on the form of iconicity studied here. In work that explored the structure of signals that subjects created when more or less signal dimensions were available, Little, Eryılmaz, and de Boer (2017) found strong modality effects mediating the relationship between iconicity and combinatoriality. Future work is needed to explore how our findings generalize to other signal modalities.

Finally, we note that the combinatoriality measure obtained via subject ratings is only an approximation to signal structure that emerged in the experiment. To better understand the patterns that exist in the evolved signals and how they are used productively, it is necessary to develop computational models. In ongoing work, we are developing statistical models of signal structure and learners' underlying inductive biases that will allow us to test more specific hypotheses about the evolution of iconicity and combinatoriality in language.

Separating object resonance and room reverberation in impact sounds

Abstract

Everyday hearing requires inferring the causal factors that produce a sound, as when we separate the acoustic effects of the environment (reverberation) from those of sound sources. Here we consider perceptual inferences from impact sounds, in which the resonance of a struck object provides cues to its material, but via acoustic effects that might be nontrivial to disentangle from reverberation. We investigated whether and how humans separate the effects of object resonance and reverberation in a material classification task. For comparison, we implemented a Bayesian observer that inferred material from a generative model of object sounds without reverberation. Humans were robust to reverberation, whereas the model was not. However, human robustness was specific to reverberation consistent with the statistics of natural environments. The results suggest that humans use internal models of room and object acoustics to determine their respective contributions to sound, providing an example of causal inference in audition.

Dark Forces in Language Comprehension: The Case of Neuroticism and Disgust in a Pupillometry Study

Abstract

We report on initial findings from a pupillometry study that investigated the influence of two extra-linguistic variables, namely Neuroticism and Disgust Sensitivity, on auditory language comprehension in adults. Results suggest that: (1) Language comprehension is influenced by extra-linguistic variables and individual differences; (2) the processing of different kinds of linguistic errors, as opposed to clashes with an individual's value or belief system, are influenced by different extra-linguistic variables; and that (3) Disgust Sensitivity at least partially predicts pupillary responses to utterances clashing with an individual's belief system. Results are discussed with regards to linguistic anticipation, cognitive effort and arousal, and resource allocation.

Keywords: psycholinguistics; extra-linguistic information; individual differences; pupillometry; language comprehension; personality; Disgust; neuroticism

Introduction

The field of linguistics has not traditionally focused on what is known as individual differences, or *hot cognition* - for example, emotion or personality. Instead, the focus has been on "abstracting away" or "averaging over" individual differences to be able to make inferences about a population. However, listeners appear to use the preceding discourse and their knowledge of the world immediately to interpret language (Van Berkum, Brown, Zwitserlood, Kooijman, & Hagoort, 2005), and extra-linguistic influences, such as personality, mood, or accent, are not just "noise," but can help reveal new information about language comprehension processes (Van den Brink et al., 2010). An individual's personality has also been found to influence aspects of general cognition and daily life, such as academic motivation and the choice of learning style (Busato, Prins, Elshout, & Hamaker, 1998; Jensen, 2015); use of language (Oberlander & Gill, 2004; Pennebaker, Mehl, & Niederhoffer, 2003); response to written errors (Boland & Queen, 2016); speech production in both native speakers and second language learners (Dewaele & Furnham, 2000); and the use of online social media (Park et al., 2015; Wehrli et al., 2008).

Results from experimental psycho-linguistic studies indicate that utterances such as "the girl comforted the clock" can be non-anomalous if the context warrants such an interpretation, from which Nieuwland and Van Berkum (2006) conclude that context can overrule grammatical violations. This is not strictly possible in a purely bottom-up model of language comprehension, where integration with the real world is thought to happen at a later stage. Research instead suggests that the language comprehension process involves at least some level of top-down processing, with contextual information rapidly being integrated into language comprehension (Kamide, Altmann, & Haywood, 2003; Levy, 2008; Sedivy, Tanenhaus, Chambers, & Carlson, 1999; Tanenhaus, Spivey-Knowlton, Eberhard, & Sedivy, 1995; Traxler, 2014; Van Berkum et al., 2005).

Van Berkum, Van den Brink, Tesink, Kos, and Hagoort (2008) analyzed ERP responses to statements colliding with a speaker's perceived identity, such as an adult male announcing that he wished he looked like Britney Spears, and found that such statements, clashing with Dutch stereotypes based on age, class, or gender, reliably elicited an N400 component. This component is generally elicited by all content words, but is significantly larger in amplitude for items that are difficult to integrate into the preceding context (Allen, Badecker, & Osterhout, 2003; Kutas & Federmeier, 2007).

Van Berkum, Holleman, Nieuwland, Otten, and Murre (2009) found that statements clashing with an individual's value system, such as "I think euthanasia is an acceptable..." when the participant opposed this practice, elicited a distinctive ERP response just 200-250ms after the onset of the critical word, in addition to an N400 component. These results suggest that, in addition to inferences about the speaker, the *listener's* values and beliefs also play a role in language comprehension.

Van den Brink et al. (2010) found that listeners with high empathy levels showed a significantly larger N400 component in response to socially contradictory information than those with low empathy scores, reasoning that the ability to empathize to a higher degree may encourage a more top-down behaviour, engaging in more prediction based on inferences about the speaker – and hence experiencing surprisal at an unexpected item.

Mood, a more transitory state than personality traits, was also found to affect language comprehension in an implicit causality experiment (Van Berkum, De Goede, Van Alphen, Mulder, & Kerstholt, 2013). Implicit causality verbs, such as "praise" or "apologize," bias participants as to which of the noun phrases in the sentence is the likely "cause" of an event (Pyykkönen & Järvikivi, 2010). A good mood caused listeners to engage in more prediction as to what the referent might be. This was reflected in a distinctive ERP component

in response to a bias-inconsistent continuation; a bad mood, on the other hand, effectively stifled anticipation. Even a *simulated* mood (Havas, Glenberg, & Rinck, 2007) appears to affect processing speed, such that processing is faster when an individual's simulated facial expression matched the valence of the sentence.

Summing up, recent research suggests that individual differences such as personality, mood, and world view affect language processing from a very early stage, and not only at a later stage, in what used to be considered a secondary step, referred to as "real-world integration."

In this paper, we report on initial findings from a pupillometry study that investigated auditory language comprehension in adults, correlating their pupil sizes in response to sentences (non-anomalous. vs. those containing errors or clashes) with measures of Neuroticism and Disgust Sensitivity. Pupil size is considered a non-invasive measure of autonomous nervous system activity (Partala & Surakka, 2003) that is especially responsive to – beyond ambient light levels – cognitive effort, mental workload, attention, and arousal (Gingras, Marin, Puig-Waldmüller, & Fitch, 2015; Goldinger & Papesh, 2012; Just & Carpenter, 1993; Rondeel, Van Steenbergen, Holland, & van Knippenberg, 2015), and that is largely free of task effects. In an auditory experiment with linguistic stimuli, pupil dilation can thus be used as an indicator of the intelligibility and complexity of an utterance (Ben-Nun, 1986; Lõo, van Rij, Järvikivi, & Baayen, 2016; Zekveld, Kramer, & Festen, 2010).

Disgust Sensitivity has, to our knowledge, not yet been investigated with regards to language comprehension. However, being considered one of the most primitive emotions that, for example, serves to protect and organism from novel pathogens, has been found to be strongly linked to feelings of morality, purity, political orientation, and voting behaviour (Inbar, Pizarro, Iyer, & Haidt, 2011; Smith, Oxley, Hibbing, Alford, & Hibbing, 2011). Higher Disgust Sensitivity is generally linked to a more conservative approach, relying more on established socio-cultural stereotypes rather than novel, more liberal ideas.

A proposed tie-in of language processing with cognition more generally comes from Havas et al. (2007), who relate their results to theories in which emotions are assumed to change affordances, the links between perception and action: In this view, a positive mood prepares the body to approach, whereas a negative mood prepares the body to avoid. Under this account, mood and personality could be assumed to influence how strongly a human engages in "approaching" or "exploring", or how much they stay put and rely on bottom-up information. A related take can be found in the *bio-energetic account*, which suggests that emotional states signal the amount of cognitive resources available for more "costly" behaviours, such as exploration and anticipation (Zadra & Clore, 2011; Van Berkum et al., 2013).

We show below that both Disgust Sensitivity and Neuroticism, as two extra-linguistic variables and components of an individual's world view that are not typically investigated in regards to language processing, indeed influence automatic language comprehension processes even in the absence of a conscious judgment or task.

Main Experiment

240 sentences were constructed, 32 of which were unrelated filler sentences. Clashes were distributed among the following conditions (examples are given in Table 1):

MO: 56 sentences total; 28 of which violated subject-verb agreement, resulting in a morpho-syntactic error;

SE: 32 sentences total; 16 of which created a semantic mismatch between the verb and the object, resulting in a semantic error;

SC: 120 sentences total; 60 of which clashed with established gender stereotypes, and as such the speaker's perceived identity; resulting in a socio-cultural clash (Van Berkum et al., 2008; Van den Brink et al., 2010).

Clash type	Example
MO	She usually **drive** her car slowly in the snow.
SE	People often read **heads** for pleasure at night.
S-C	♂I buy my **bras** at Hudson's Bay.

Table 1: The template used for item construction, with three example sentences.

All stimuli followed the same syntactic pattern to ensure comparability. Frequency of the critical region, i.e. the main verb plus the direct or oblique object directly following the verb, was controlled for frequency via the *Corpus of Contemporary American English (COCA)* (Davies, 2008).

Items were then recorded by one male and one female native speaker of Canadian English and distributed across four lists of just over 130 items each, counterbalanced for error condition and speaker gender.

82 participants, recruited from the university's undergraduate Linguistics pool and from the general population, participated in this experiment. Data from six participants (7% of all participants) was removed as their comprehension question accuracy rates were below 80%, and comprehension or attention to the experiment could hence not be guaranteed; or as information given on the language background questionnaire precluded their data from inclusion in the analyses. Data from 728 trials (8.6% of all trials) was removed due to issues during recording that resulted in more than 33% of sampling points on a given trial being recorded as NA. Thus, analyses below are based on the data from 76 participants (males/females = 18/58; native/non-native speakers of English = 61/15; age = 1783; mean [SD] = 25 [12.6] years).

Each participant was presented with one list and, accordingly, each item only once, in just one condition and spoken by one of the speakers. All items were previously rated for acceptability in a separate experiment, by a separate set of

participants, with the resulting average per-item ratings being fed into the statistical models below as a numerical predictor. The distribution of Big Five trait scores within the participants (raters) in this separate norming study was found to be in line with several others reported in the literature, such as those found in Srivastava, John, Gosling, and Potter (2003) and Schmitt and Shackelford (2008).

Each trial began with a one-point drift correct, and, immediately after, the display of a fixation cross at the centre of the screen. The size of the participant's right pupil was recorded at 250Hz, using an EyeLink 1000 system on a desktop PC, from that the start of the fixation cross onwards. 2000ms later, the audio stimulus began to play, with the latter half of this interval used to create participant-by-trial baselines. Pupil size was recorded until 500ms after audio offset. After a three-second break, in which participants were able to rest their eyes, the next trial began. Attention and comprehension were assessed via simple questions after approximately every fourth trial, and participants were given longer breaks approximately every thirty-five trials.

Post-Tests

Personality traits were assessed via the *Big Five* (John, Donahue, & L., 1991) personality inventory. The Big Five Inventory was chosen for its frequent and continued use in psychological research, and because it assesses various aspects of an individual's personality rather than just providing one overall score. Of special interest for this paper is the Neuroticism subscale, where high scores are typically associated with a higher tendency to feel anxious, nervous, or tense, and where low scores in contrast are associated with a more even temper (John et al., 1991), as these variables have traditionally been underresearched in regards to language processing.

The participants' Disgust Sensitivity was assessed via the Disgust Scale - Revised (*DS-R*) (Haidt, McCauley & Rozin, 1994, modified by Olatunji et al., 2007), also used in Ahn et al. (2014). Special interest is given to these two particular scales as prior research has largely focused on the "lighter," more positively loaded aspects of human personality and cognition, such as empathy. Data on the participants' language background was collected via a pen-and-paper questionnaire that included questions on items such as age, gender, and languages spoken.

Prior research has reported systematically higher Disgust Sensitivity among women as compared to men (Al-Shawaf, Lewis, & Buss, 2018; Sparks, Fessler, Chan, Ashokkumar, & Holbrook, 2018). In this study, only a non-significant tendency in this same direction was found in a two-sample t-test ($mean_{male} = 1.78, SD_{male} = 0.68; mean_{female} = 2.06, SD_{female} = 0.58; t(28.678) = -1.62, p = 0.12$).

Results

The raw pupillometry data was first downsampled to 125 Hz and then preprocessed in `R`. Blinks and the 20 adjacent data points were removed using Jacolien van Rij's `removeBlinks()` function.

Pupil sizes as the response variable were modelled using generalized additive mixed effects modelling (*GAM modelling*, or *GAMM*) with the `itsadug` (van Rij, Wieling, Baayen, & van Rijn, 2016) package in R. All models included random slopes for participant-by-time, and random intercepts by item, to account for individual differences within the stimuli, and for random variance between participants *beyond* the factors of interest. This makes the analyses markedly different from e.g. Van den Brink et al. (2010); Van Berkum et al. (2008), as GAM modelling can capture non-linear interactions between continuous predictors; as it does not assume linear relationships, an assumption that is often unwarranted (Tremblay & Newman, 2015); and as it allows to control for random participant and item effects. Additionally, GAMMs can comfortably model continuous measurements data, such as those obtained in pupillometry studies, without losing information in time-binning or averaging. GAM modelling has been used successfully in experimental psycholinguistics to model the influence of listener experience and the perception of foreign accents (Porretta, Tucker, & Järvikivi, 2016), and pupillary responses in a naming task (Lõo et al., 2016).

Data in a time window from 500ms before clash onset to 2000ms after clash onset was analyzed, and models included variables such as speech rate and the participant's progress in the experiment as control variables. Additionally, all numerical predictors were normalized and centered to avoid effects of differential order-of-magnitude scaling between predictors.

Morpho-Syntactic & Semantic Errors

While neither Neuroticism or Disgust were found to significantly influence the processing of semantic errors, Neuroticism was a significant individual difference predictor in a three-way interaction with time and item rating in the morpho-syntactic error model (dev. explained = 9.94%; see

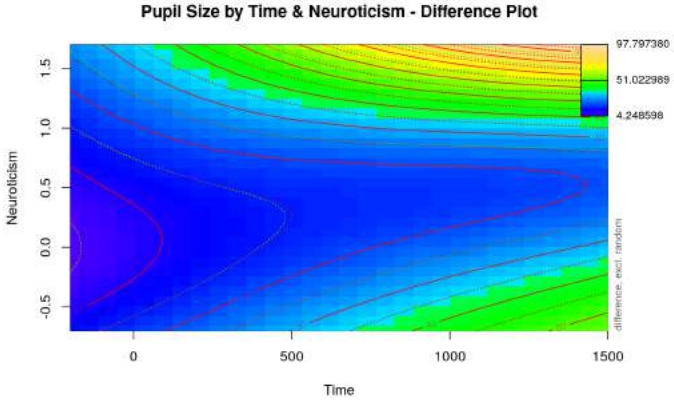

Figure 1: Difference in pupil size between the correct and clashing conditions in response to morpho-syntactic errors.

Table 3: Model output for socio-cultural clashes. Note that all numerical predictors, except time, were scaled and centered.

also Table 2).[1]

This three-way interaction shows that different Neuroticism scores are correlated with different changes in pupil sizes, which differ further between correct and anomalous items. Specifically, our findings indicate that high Neuroticism scores led to a much stronger pupillary response to morpho-syntactic errors as compared to low scores on this scale (cf. Fig. 1. Like all surface plots in this paper, this plot visualizes the difference in pupil size by time since clash onset (on the x-axis) and Neuroticism scores (on the y-axis) between the clashing and correct conditions. Pupil size is represented as colour on the z-axis: A blue/green hue indicates smaller a smaller difference in pupil sizes, and yellow/orange indicates larger dilation in the clashing compared to the correct condition).

Further significant main effects in this model include those of speech rate (faster $\rightarrow$ larger dilation), progress made in the experiment (early trials $\rightarrow$ larger dilation), item rating (lower $\rightarrow$ larger dilation), and Neuroticism (higher $\rightarrow$ larger dilation). It should be noted that the significant three-way interaction between Neuroticism, item rating, and time was found to be significant *beyond* these main effects, and beyond the random effects included in the model.

Socio-Cultural Clashes

In the modelling of socio-cultural errors, Disgust Sensitivity was found to be the single best individual difference predictor tested in an interaction with time and item rating (dev. explained = 9.65%; see also Table 3):[2] High values, indicating high Disgust Sensitivity, were found to correlate with the

[1]The remaining Big Five traits were tested as well; while elaborating on all results goes beyond the scope of this current paper, Agreeableness was found to be a significant predictor in this same three-way interaction in a model of equally good fit, with low Agreeableness associated with larger differences in pupil sizes.

[2]All Big Five traits were tested here as well; for socio-cultural clashes, Disgust emerged as the single best extra-linguistic predictor.

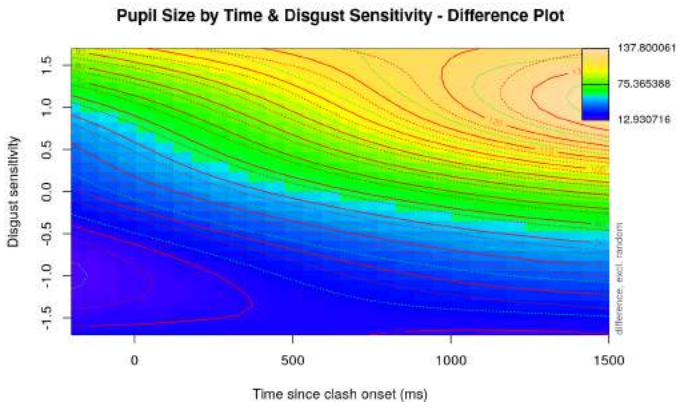

Figure 2: Difference in pupil size between the correct and clashing conditions in response to socio-cultural clashes.

largest pupil dilations in response to statements clashing with socio-cultural stereotypes (cf. Fig. **??**).

Further significant main effects include those of speech rate (faster → larger dilation), progress made in the experiment (early trials → larger dilation), item rating (lower → larger dilation), and Disgust Sensitivity (higher → larger dilation). Again, the significant three-way interaction between Disgust Sensitivity, item rating, and time was found to be significant *beyond* the main effects.

Discussion

Our results, specifically the three-way interactions including one of the two extra-linguistic variables, suggest that the processing of morpho-syntactic errors on the one hand, and stereotype-based clashes on the other, are influenced by individual differences and extra-linguistic information. Patterns of influence are not the same across the board, but instead are distinct between different types of errors and clashes. As an example, Neuroticism seemed to only influence the processing of morpho-syntactic errors, whereas Disgust Sensitivity best predicted pupillary responses to socio-cultural clashes. Neither of those two negatively loaded variables of individual differences were found to be significant predictors of pupil size in response to semantic errors.

These results lend further support to theories of language comprehension in which extra-linguistic information is considered early in the comprehension process (Kamide et al., 2003; Levy, 2008; Sedivy et al., 1999; Tanenhaus et al., 1995; Traxler, 2014; Van Berkum et al., 2005), and are not explained well within purely bottom-up theories: Larger pupil dilations for Disgust-sensitive individuals in response to socio-cultural clashes suggest that a statement that is at odds with one's expectations of purity and morality, and that hence triggers a visceral reaction, results in higher levels of arousal and/or requires more cognitive resources to "unpack." In this reading, extra-linguistic variables internal to the listener, such as feelings towards or the desire for purity and morality, affect the comprehension process right from the start, instead of being integrated with the sentence in a later step.

Considering the effect of Neuroticism on the processing of simple morpho-syntactic errors, our results add further support to models that include a top-down component; They also support the notion that, very generally, one's personality affects language comprehension, and that language comprehension does not take place in a vacuum (Van Berkum et al., 2008, 2009). Specifically, our results suggest that individuals that are more prone to feelings of anxiety or nervousness may experience greater distress when experiencing a simple grammatical error. Of note is that morpho-syntactic errors do not clash with experiences or value systems as such, but only violate intra-linguistic rules; This suggests that the listener's personality seems to affect linguistic processing even when the utterance in question does not directly require value judgments or beliefs to process.

Building on Ahn et al. (2014); Inbar et al. (2011); Smith et al. (2011), our results suggest that Disgust Sensitivity at least partially correlates with sensitivity towards stimuli that, as per existing cultural stereotypes, may be associated more with a progressive and liberal view of the world, and that may trigger stronger reactions in conservative individuals. In addition to further supporting models of language comprehension in which context and experience factor significantly early on, this also meshes with the idea of Disgust serving as a mechanism protecting the individual from novel pathogens carried by members of an out-group: Utterances indicative of out-group status appear to trigger higher levels of arousal, and/or demand more cognitive resources to process.

Within the context of affordances and the bio-energetic account (Havas et al., 2007; Zadra & Clore, 2011; Van Berkum et al., 2013), our results do not neatly tie in with previous research: They suggest that higher Disgust Sensitivity and higher Neuroticism scores may be associated with *more* context-based prediction and anticipation, and hence more surprisal at an unexpected continuation, than lower scores on these scales. These somewhat counter-intuitive results warrant further research, as prior studies have generally found *positive* emotions and moods, such as empathy or an elevated mood, to be associated with more resource availability, prediction, and exploration (Van den Brink et al., 2010).

It should be noted that our results should not necessarily be interpreted as a causal relationship, in that different values of Neuroticism or Disgust Sensitivity "trigger" differences in processing. It is conceivable that a common underlying variable, relating to e.g. resource allocation or to a general predisposition towards other-ness, is causing the effects.

In this fairly new field of research, there is lots of room for both broader and more targeted investigations; we are currently investigating the effects of other extra-linguistic variables, such as the remaining Big Five traits, on language comprehension.

More broadly, future research could, for example, assess the effects of extra-linguistic variables using additional

methodologies, or clashes with different aspects of the listener's identity. Research along those lines may be able to form a more coherent picture, for example in regards to whether it is anticipation or prediction that is modulated by a certain variable, or whether there may be an additional underlying variable that influences both a listener's personality and Disgust Sensitivity, *and* their linguistic processing at the same time.

Summing up, our results add further support to models of language comprehension that include a top-down component, and to extra-linguistic information and individual differences factoring in language comprehension from a very early stage; and they assessed the influence of Disgust Sensitivity as a "darker" cognitive force on language comprehension for the first time.

Detecting social transmission in the design of artifacts via inverse planning

Abstract

How do people use human-made objects (artifacts) to learn about the people and actions that created them? We test the richness of people's reasoning in this domain, focusing on the task of judging whether social transmission has occurred (i.e. whether one person copied another). We develop a formal model of this reasoning process as a form of rational inverse planning, which predicts that rather than solely focusing on artifacts' similarity to judge whether copying occurred, people should also take into account availability constraints (the materials available), and functional constraints (which materials work). Using an artifact-building task where two characters build tools to solve a puzzle box, we find that this inverse planning model predicts trial-by-trial judgments, whereas simpler models that do not consider availability or functional constraints do not. This suggests people use a process like inverse planning to make flexible inferences from artifacts' features about the source of design ideas.

Keywords: social cognition; Bayesian inference; explanation; social transmission; imitation; artifact; design; inverse planning

Introduction

We live surrounded by human-made objects, or artifacts. These artifacts are crucial to our lives not only as tools, but also as an omnipresent source of social information. Based on the objects a person owns, people make quick and accurate judgments about a person's traits, interests, and social affiliations (Gosling, 2008; Richins, 1994). The artifacts a person creates - like novel tools, art, music, or text - provide particularly rich information about the person and actions that created them (Gosling, 2008).

How do people reason about other individuals from the artifacts they create? Here we explore the nature of this reasoning, a form of *intuitive archeology*. In the same sense that archeologists use objects to make inferences about the people and cultures that created them, we propose that people also infer complex social-causal information from the design of artifacts, by integrating their mental theories of the physical-mechanical world with their theories of the social world (e.g. Battaglia, Hamrick & Tenenbaum, 2013; Gopnik, 2012; Baker, Saxe & Tenenbaum, 2009) to infer the most probable explanation for an objects' features.

Intuitive Archeology as Inverse Planning

Previous work in the domain of action understanding has proposed that people make inferences about the goals of others' actions based on a process of 'inverse planning' (Baker, Saxe, & Tenenbaum, 2009; Liu, Ullman, Tenenbaum & Spelke, 2018). The idea of inverse planning is that people have knowledge of the generative process behind actions from planning their own – and this planning process allows them to know what a rational agent would do, given the same goals and environmental constraints. Therefore, when reasoning about others' actions, people invert this generative process to infer the goals of another agent from its observed behaviors. Here we propose that a fundamentally similar inverse planning processing explains how we reason about the artifacts people create: People use their own generative model of how they would construct an artifact under a given set of constraints to infer the goals and decisions that led another person to create this artifact and its features. Such a reasoning process would allow people to flexibly infer a variety of social-causal information about others from the physical features of artifacts they create.

We focus on a foundational inference in this domain: Inferring whether *social transmission of ideas* has occurred (i.e. imitation, copying), or whether a particular aspect of a design was *generated independently* by an individual. The interaction of these two basic processes, termed imitation and innovation, account for cultural evolution of artifacts' designs over human history (Henrich, 2015; Tomasello, 1999; Legare & Neilsen, 2015). This inference also has real-world applications for understanding plagiarism detection – and what can be reasonably expected of jurors in plagiarism cases as they consider two designs and determine the likelihood that copying has occurred. Lastly, this inference is foundational to understanding how people infer social-causal information from artifacts, since designs that were created independently license different inferences than those that were copied. For example, a highly functional, complex design that was independently generated may tell you about the intelligence or creativity of a designer (Gosling, 2008), whereas a design that was copied may instead be informative about the designer's social history and cultural group (their source of shared knowledge; e.g. Schachner et al., 2018; Soley & Spelke, 2016). Thus, in the current work, we model and test how people infer whether or not copying (social transmission) occurred in the design of an artifact.

Inverse Planning, Or a Simpler Cognitive Process?

A natural alternative theory exists to the rich and structured explanation-based reasoning process proposed by inverse planning models. People may infer that copying occurred

using a simple heuristic based on perceptual similarity: If two things are more perceptually similar, then copying is more likely to have occurred. Notably, past work on detection of copying in music has relied on this type of simple similarity metric in formal models, to predict jury decisions in music plagiarism cases (Savage, Cronin, Müllensiefen, & Atkinson, 2018).

In contrast to these straightforward similarity-based models, other work has provided initial evidence that people detect copying via a more complex process of inverse planning or explanation- based reasoning (Schachner et al., 2018). In particular, this work found that people expect others to have a preference for efficiency, and factor this in when making inferences about copying. Thus, when two characters create identical train track designs that are also highly efficient ways to achieve the intended goal, observers use efficiency to 'explain away' the similarity – and thus judge copying less likely for identical efficient tracks than they would otherwise.

While this work is suggestive of a system of inverse planning, it is possible (and even plausible) that understanding of efficiency is unique and privileged in people's reasoning. Reasoning about efficiency, and expecting others to act rationally by moving efficiently toward their goals, is thought to be foundational to cognition: It develops early in infancy (Gergely, Nádasdy, Csibra, & Bíró, 1995, Skerry, Carey & Spelke, 2013), is shared with other species (Hauser & Wood, 2010), and is a foundation for the entire domain of action understanding (Dennett, 1987; Baker et al. 2009). Thus, rather than showing a rich and flexible process of reasoning that takes into account a wide variety of alternative explanations (as proposed by inverse planning models), the evidence thus far is consistent with a much simpler system, in which similarity metrics are selectively overridden by privileged efficiency-based explanations.

The Current Work

In the current work, we test whether people use a rich and flexible process of inverse planning that takes into account alternative explanations that go beyond efficiency. In particular, we ask whether people rationally consider two factors: the range of materials available to build with, which we term the *availability constraint*; and whether each of the available materials would function or fail to function to solve the problem at hand, which we term the *functional constraint*. Rationally speaking, if a larger set of materials are available to choose from, similarity should be seen as stronger evidence of copying than if there is a smaller set of materials available to choose from (as the probability of selecting the same item by chance is lower; similar to the suspicious coincidence mechanism sometimes referred to as the 'size principle'; Tenenbaum & Griffiths, 2001). Similarly, if many of these materials would solve the problem, similarity is more indicative of copying than if only one or a few of the options would solve the problem at hand – as clearly non-functional materials are unlikely to be used. We first formalize these constraints and then experimentally test their usage when people make copying inferences.

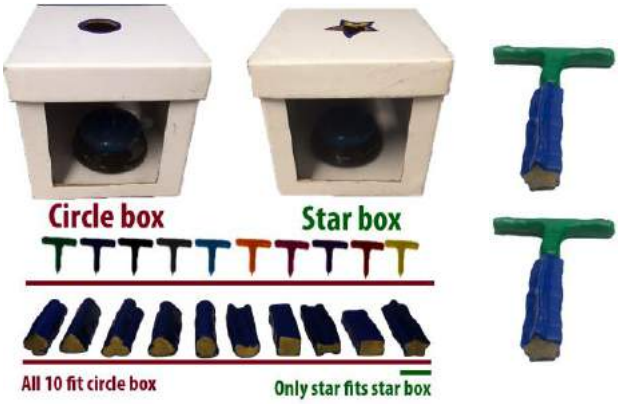

Figure 1: Left: Tool selection task with example handles (which differ in color), and rods (which differ in shape and therefore functionality). Right: Example of two identical tools people might be shown on a particular trial.

An Inverse Planning Model of Copy Detection

To provide a clear test of the inverse planning account, and tease it apart from simpler alternatives, we model and test a simple artifact-building task which crucially involved both availability and functional constraints. Consider a scenario where one is asked to solve a puzzle: A button is out of reach in a box, with the front covered by glass, so only the hole in the top allows access. You must build a tool to reach the button. To do so, you are given two sets of pieces: 10 handles, which differ by color; and 10 rods, which differ by shape. You can connect one handle to one rod to form a two-part tool (see Figure 1).

You may be asked to solve one of two puzzle boxes, which differ in one respect: How many of the rods would work to solve them. In particular, for one box, all of the 10 rods would fit through the box's circular hole and solve the puzzle (*unconstrained; circle box)*. In the other case, only 1 of the 10 rods fits (only the star-shaped rod fits into the star-shaped hole), and so only 1 of the 10 rods can be used to solve the puzzle (*constrained; star box*). This box thus introduces a functional constraint that applies selectively to rods, and not handles (which would all function in both cases).

Now, you observe two tools that other people have made: for example, two people built the same tool, choosing the same star-shaped rod and the same red handle. How likely are they to have copied each other? This task provides a simple instantiation of relevant issues people confront when making complex decisions about copying through inverse planning: Reasoning about the range of materials available to the builders; which pieces would work; and a multi-part decision process (choose a handle, choose a rod).

Formally, we can think of this task as having the following structure: You see a tool built by person 1, and a second tool built by person 2, in order to solve a puzzle box. You wish to

infer whether person 2 copied the tool's design from person 1, or independently created it.

Each tool consists of two pieces linked together – a rod, *r*, and a handle, *h* – each of which was selected from the set of available options. Formally, you are asked to make an inference, where if c indicates whether person 2 copied person 1, you wish to infer the probability of copying $P(c|r_1, h_1, r_2, h_2)$, given the observed rod and handle of person 1's tool (r_1, h_1) and the observed rod and handle of person 2's tool (r_2, h_2). Taking only the case of a rod being copied, and assuming copying judgments depend only on the rod and handle being identical or different (e.g., a binary notion of similarity), the posterior on copying is:

$$P(c \mid r_1, r_2) = \frac{P(c_r)\, P(r_2 == r_1 \mid c)}{P(r_2 == r_1)}$$

This is the probability that copying has occurred, given your prior likelihood on copying and the relative likelihoods that such an overlapping design would be generated under each of the possible mechanisms (copying, *c*, vs. independent creation, $\neg c$), where:

$$P(r_2 == r_1) = P(c_r)\, P(r_2 == r_1 \mid c) + \big(1 - P(c_r)\big)\, (r_2 == r_1 \mid \neg c)$$

In the current task this depends not only on the rod but on both the rod and handle, such that, when the rod is identical but the handle is not identical, this posterior on copying depends on $P(r_2 == r_1 \mid c, r_1)$, $P(r_2 == r_1 \mid \neg c)$, $P(h_2 \neq h_1 \mid c)$, and $P(h_2 \neq h_1 \mid \neg c)$. This has the structure of a Bayes net, including the key concept of explaining away: A given aspect of the design can be generated either via copying or independently, and evidence for one provides evidence against the other. Thus, if two people create identical tool designs, but this design is also likely to be created independently (due to either availability constraints or functional constraints), this provides weak evidence of copying despite the identical tools.

To make this model concrete, we need to specify 5 things:

(1) $P(c_r), P(c_h)$ - the a priori estimate of how likely person 2 was to have copied either the rod or handle (unconditional on the data; i.e. before we see either of the built objects). This depends for example on how close or distant the two people are from one another (Schachner et al., 2018). We assume the chance of copying is identical and independent for both rods and handles, e.g. $P(c_r) == P(c_h)$, and refer to this as $P(c)$, the prior on copying.

(2) $P(r_2 == r_1 \mid c)$ - the likelihood of the particular rod being used by person 2 matching that of person 1, given that person 2 was in fact copying from person 1's object. We formalize this as perfect copying plus a small error rate term, *e*, to account for the rate at which an individual might intend to copy but ultimately select a different rod: $P(r_2 == r_1 \mid c) = 1 - e$. Therefore $P(r_{2 \neq} r_1 \mid c) = e$.

(3) $P(r_2 == r_1 \mid \neg c)$ - the likelihood of rod r_2 being the same as r_1, given that person 2 was NOT copying from person 1's object, and independently generated the object with no reliance on r_1. When all pieces would function, this is simply *1/R*, where *R* is the total number of rod choices available. However, functional constraints also affect this factor: When only a subset of pieces will function, this effectively reduces the number of reasonable options. Accordingly, in the context of a functional constraint, the model treats only the functional pieces as options, reducing the value of R to the number of functional options (if only one rod functions, R=1).

4) $P(h_2 == h_1 \mid c)$ - the likelihood of the particular handle being generated by person 2, given that person 2 was in fact copying from person 1's object, and given h_1. This again is based on the same error rate *e*.

(5) $P(h_2 == h_1 \mid \neg c)$ - the likelihood of handle h_2 being the same as h_1, given that person 2 was NOT copying from person 1's object, and independently generated the object with no reliance on h_1. In contrast to the rods above, the handles differ only in color rather than shape; thus, all handles function equally well in both the *unconstrained (circle box)* condition, and the *functionally constrained (star box)* condition. This is therefore simply 1/H, where H is the number of handle options.

Comparing to Simpler Alternatives

This model of inference as inverse planning posits that people consider both the number of available options and the functional constraint of the puzzle box when judging whether copying occurred. To test whether each of these components are needed to predict participants' judgments, we compared this model to three simpler models.

These models followed a 2x2 structure, either taking into account or not taking into account the availability constraints (+/- availability) or the functional constraints (+/- functional). For example, the model that considers availability constraints but ignores functional constraints does not take into consideration the functional constraint of the star box, e.g., assumes people choose among all rods even in the star box condition. The model which ignored availability constraints did not take into account the number of pieces available in a flexible way. Instead, this model posited that people had a fixed a-priori idea of the number of pieces available to choose from, and that this number did not change based on the situation presented. Thus, rather than choose a rod with 1/R, where R is the number of options, a parameter N quantified this fixed number of imagined choices (e.g., regardless of how many were present). This model *did* take into account the functional constraint of the star box (assuming people only choose the star rod in this case). A final simplified model ignored both functional and availability constraints, and thus effectively instantiated a simple perceptual similarity heuristic. This model only took into account the extent to which the pieces were similar, without taking into consideration either functional constraints or availability constraints.

Testing the Models' Predictions

These models make quantitative predictions about the likelihood of copying for any given pair of tool designs, in a wide range of contexts. We next aimed to test how well the various models predict human behavior. The inverse

planning model predicts that for two identical tools, people will infer that copying is more likely to have occurred when (a) there were more pieces available as options to build with, thus creating more of a suspicious coincidence that the same piece was chosen twice; (b) there were no functional constraints on which pieces would work or not work, thus allowing all of the available pieces to serve as equally good options. By contrast, the simplest perceptual similarity model predicts that any identical objects will lead people to infer copying. Thus, we focused our data collection on these and other particularly informative trials.

Method

Full study design/analysis plan including model code was preregistered on the Open Science Framework (OSF), and is available at https://osf.io/y8u7t.

Participants

Using a pre-registered design, N=108 adults from the U.S. (57 male, 50 female, 1 other gender identity; *M* age=37.9, *SD*=10.9, range=20-72) were recruited through Amazon's Mechanical Turk. Sample size was preregistered and determined from power analysis of a pilot dataset with a slightly different design (N=20; tested a subset of the current test trials; with each subject completing all trials). The R "pwr" package was used to conduct a paired t-test power calculation on participant-level BICs with the goal of 90% power (Champely et al., 2018). Based on pre-registered exclusion criteria, additional participants were excluded due to: 1. Appearing to be non-native English speakers or a bot (n=13; determined by 2 independent coders' rating of free-response text answers) 2. Incorrectly answering any memory check question (n=49) 3. Incorrectly answering 50% or more of the attention check questions (n=12). The number of participants failing the preregistered memory check questions was higher than expected, thus we reanalyzed the data with these participants included, and found that our model results and conclusions remain unchanged in this case (see *Results*).

Design

Participants were shown tools that two target individuals designed, and were asked to judge whether or not one of those individuals copied the other's tool. Across trials we manipulated (1) the number of rod options available (2 versus 10); (2) the number of handle options available (2 versus 10); (3) The presence or absence of a functional constraint, i.e. whether they were trying to solve the circle or star puzzle box; (4) The extent of similarity of the two tools that were built (both rod and handle identical, one part identical and one part different, or both rod and handle different). As all designers were assumed to have successfully solved the puzzle, we did not include trials in the star box condition which had different rods, as this would involve building a tool that would not function. Thus in total there were 24 unique test trials. Because of the possibility of demand characteristics if all participants saw the full design, each participant completed only a randomly-selected subset of 4 trials, resulting in 18 unique participants completing each trial.

Procedure

Participants first received instructions regarding the puzzle-box task, and that they would see pairs of tools that people had built to reach the button. Instructions described an ambiguous situation, where copying may or may not have occurred ("While designing the tools the people were in the same room, facing away from each other"). They were instructed that different pairs of people had different numbers of handles and rods to choose from (10 or 2), received either the circle box or star box to solve, and that only one of the rod pieces could fit into the star-shaped opening.

On each trial, participants saw (1) the two tools that the two people had built; (2) which puzzle box the people were trying to solve; (3) the materials they had available to build with. Participants were asked to judge as a 2-alternative forced choice: Do you think someone copied, or they made them independently?

After each trial, an attention check question asked either what puzzle box was present, the number of rod options, or number of handle options. At the end of the task, memory check questions asked participants to select which rods would work, and which handles would work, to successfully solve each of the two puzzle boxes. Lastly, participants were asked to describe what they did in the experiment and guess the point of the study in free-response format, and complete demographics questions.

Analysis Plan

For each model, the best fitting parameters and likelihood of our data given those parameters were assessed via maximum likelihood estimation (MLE). We decided a priori that the prior on copying (range: 0-1) and number of imagined choices (for models that do not use the real number that participants were presented with; range 0-infinity) should be fully free to vary, while the copying error rate *e* was bounded from 0 to a maximum of 0.1. For all models, using this a priori specification, the MLE-derived value for the copying error rate was at max (0.1). To make sure this boundedness was not responsible for our findings, we also reran analyses letting the error rate parameter vary (0-1), and found the same results for comparative model fits in this case. To compare models, we use BIC (Schwarz, 1978), which penalizes models for complexity according to their number of parameters. We used bootstrapping to calculate standard errors (SEs) for each BIC.

Results

We first checked that participants took into account the perceptual similarity of designs in their assessments of copying, as predicted by all four models. As expected, participants inferred copying most often when the two tool designs were identical (M=51.4%, SEM=9.8%), and least often when the two tools were most different (M=5.6%, SEM=2.3%; $p<.01$).

Table 1: Maximum likelihood parameters for each model

Model	Copying Prior, p(*c*)	Error Rate	Imagined # Options
+Availability +Functional	0.09	0.10	
+Availability -Functional	0.06	0.10	
-Availability +Functional	0.09	0.10	5.31
-Availability -Functional	0.11	0.10	2.76

We next compared the fit of the four alternative models. The full model out-performed all competing models, with a difference in BIC of 35 (∓ SEM: 11-25) in comparison to the next-best-fit model and >400 to the other models (Table 2). Approximately the same results held when including individuals who failed the memory check: difference in BIC of 38 to next-best-fit model and >700 to the other models. In addition, the full model provided a good overall fit to participants' responses across trials (R^2= 0.75, Fig. 2A).

Note that while the model is relatively straightforward to specify, the predictions it makes are quite nuanced: because the model weighs and combines several factors, it predicts a continuous gradient of how likely copying should be, rather than simply saying people should never assume copying took place if there is any alternative explanation. The model thus goes well beyond verbal theories.

Use of Availability Constraints

Participants' judgements showed sensitivity to availability constraints (i.e. the number of pieces available to build with), and the use of availability constraints as an alternative explanation for similarity. For example, on trials where two people made identical tools and no functional constraint was present, participants judged copying more likely as the number of available options increased (circle box condition: 2 rods; 2 handles: 33% judged copied; 2 rods, 10 handles: 72%; 10 rods, 2 handles: 72%; 10 rods, 10 handles: 83%).

Use of Functional Constraints

Participants also showed sensitivity to functional constraints, and used functional constraints as an alternative explanation for similarity. In particular, on trials where two people used identical *rods*, participants judged copying less likely on trials where they were solving the star box (which added a functional constraint; Mean copied=21.5%), vs. when they were solving the circle box (Mean copied=52.8%, *p*=0.02, 2 tailed t-test). In contrast, on trials where two people used identical *handles*, participants' judgements did not differ for the star vs. circle box (Star box: Mean copied=36.8%, Circle Box: Mean copied=37.5%; *p*=0.97, 2 tailed t-test), as predicted since all handle pieces would function equally well for both puzzle boxes. Although the model without functional constraints did not perform that poorly as measured by BIC, it did systematically miss this aspect of the data (see also deviations of this model in Figure 2).

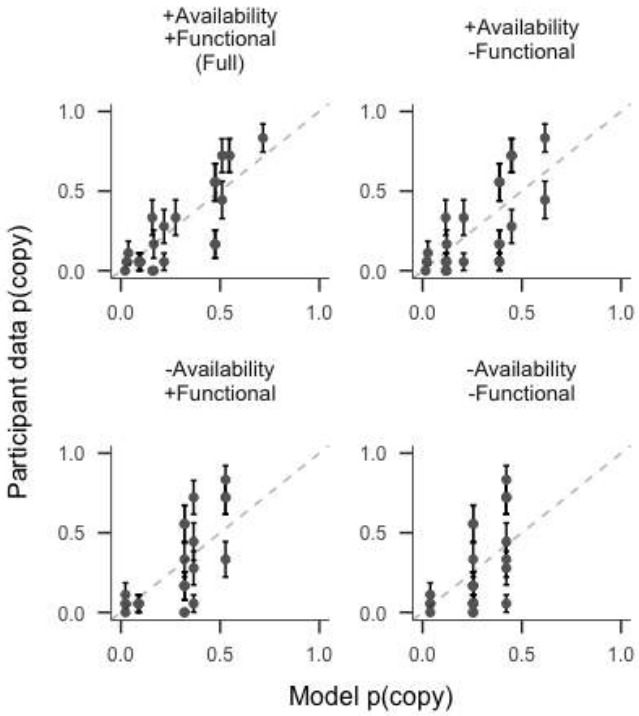

Figure 2: Fit of models' predictions to participants' ratings of whether copying occurred; each point represents one trial. The full inverse planning model appears top left; other plots show three simpler alternative models that do not consider either the availability constraints (-availability) or the functional constraints (-functional).

Table 2: Difference in BIC from best fitting model (higher BIC indicates worse fit)

Model	BIC Δ to full model	∓ SEM
+Availability -Functional	35	11 - 25
-Availability +Functional	467	422 - 490
-Availability -Functional	491	468 - 512

Participants' judgments deviated slightly from the full model's predictions in one regard: Participants appeared to under-weight the similarity of the handles, relative to the rods. For instance, the largest deviations between participants' judgements and the full model's predictions came on trials when the tools had different rods, but the same handle. To demonstrate this differential weighing of the rod vs. handle, consider trials where there are an equal number of rod and handle options, no functional constraint, and the built tools had only one similar piece. On these trials, people were considerably more likely to say the design was copied if the rod was similar than if the handle was (2 options: 0% vs.17%; 10 options: 17% vs. 56%). Thus, participants seemed to overweight evidence from the functionally-relevant component of the tool, even when functional constraints were not present.

Overall, however, the good fit of the inverse planning model – and the continuous range of predictions it makes –

supports the idea that participants use an inverse planning strategy in judging copying from artifacts.

Discussion

We find strong evidence that when reasoning about artifacts, people use a rich, flexible system of explanation-based reasoning to infer whether a design idea was copied or generated independently. We formalized such reasoning in a Bayesian model as a form of inverse planning. We compared this model to three simpler alternatives in a task where participants had to judge whether a pair of artifacts was copied or designed independently, to test whether each component of the full model was needed to predict judgments.

We found that the full inverse planning model best predicted participants' judgments of whether copying had occurred. In line with the model, we found that people considered two broad classes of alternative explanations for artifacts' similarity: the range of materials available to build with (availability constraints), and which of these materials would work to solve the problem (functional constraints). Both of these constraints 'explained away' similarity, making similarity weaker evidence of copying. This pattern of responses is the signature pattern of a Bayesian reasoner, in which a design can have different alternative explanations, and evidence for one provides evidence against the other (e.g., Gopnik et al. 2004).

The success of this model suggests people use a process of inverse planning to infer the source of design ideas from artifacts' features. In other words, people consider the generative processes involved in building the artifacts, including what the goal would be, what constraints they would be subject to, and what (as a result) they would be likely to build. By inverting this generative process, people rationally infer the source of other people's design ideas, taking into account goals and multiple kinds of constraints.

These findings show that inferences about the source of design ideas do not boil down to various simpler heuristics, or more limited systems of reasoning. First, copying judgments are not just based on the extent of perceptual similarity of the two objects, but take into account rational explanations for this similarity. This has implications for understanding how laypeople detect plagiarism in court cases, which has been previously formalized as a process of simple similarity detection (Savage et al., 2018).

Second, we show that this system of reasoning goes beyond efficiency: People can take into account multiple types of constraints as explanations for similarity, and are not limited only to reasoning about design efficiency as the only, privileged type of alternative explanation. This simpler efficiency-only account was consistent with previous findings, and plausible given the foundational role of efficiency in reasoning about intentional action (Schachner et al., 2018). The current data falsify this simpler account, showing that people flexibly take into account the materials available and the functional constraints of the puzzle boxes, which do not map to an efficiency metric (e.g. the length of a train track from A to B, used in Schachner et al., 2018).

More broadly, we provide evidence for a novel theoretical and formal framework for artifact cognition, as a form of inverse planning. Previous work has shown that people use inverse planning to understand the causal processes underlying others' actions (Baker et al., 2009; Liu et al. 2018). The current work extends this framework by conceptualizing artifacts as the products of intentional action. We suggest that people use fundamentally the same inverse planning process to understand artifacts as they do to understand actions themselves. Specifically, they rationally take into account people's goals and constraints not only when observing actions, but also when observing artifacts generated by these actions – even when the actions themselves are not observed. This work thus links together artifact cognition and theories of action understanding in a new way, points to a deep connection between reasoning about actions and artifacts, and provides a foundation for formalizing the processes underlying a domain of 'intuitive archeology' – social-causal reasoning about artifacts, as products of intentional action.

Abstract

The ability to recognize and make inductive inferences based on relational similarity is fundamental to much of human higher cognition. However, relational similarity is not easily defined or measured, which makes it difficult to determine whether individual differences in cognitive capacity or semantic knowledge impact relational processing. In two experiments, we used a multi-arrangement task (previously applied to individual words or objects) to efficiently assess similarities between word pairs instantiating various abstract relations. Experiment 1 established that the method identifies word pairs expressing the same relation as more similar to each other than to those expressing different relations. Experiment 2 extended these results by showing that relational similarity measured by the multi-arrangement task is sensitive to more subtle distinctions. Word pairs instantiating the same specific subrelation were judged as more similar to each other than to those instantiating different subrelations within the same general relation type. In addition, Experiment 2 found that individual differences in both fluid intelligence and crystalized verbal intelligence correlated with differentiation of relation similarity judgments.

Keywords: relational reasoning, similarity, semantic cognition, fluid intelligence, crystallized intelligence

Introduction

A house key and an email password are intuitively similar. This similarity is not based on any common attributes or constituent properties of individual objects; rather, it seems to be based on some common *relation* that a house key and an email password respectively bear to a house and to an email account (roughly, *providing access*). The ability to grasp and exploit similarity based on a wide variety of relations is an important and distinguishing trait of human intelligence (Penn, Holyoak, & Povinelli, 2008). This ability underlies much of human thought, including aspects of language (Gentner & Namy, 2006), categorization (Gentner & Kurtz, 2005; Goldwater & Schalk, 2016), and perhaps most prominently, analogical reasoning (Holyoak, 2012). The explicit representation of abstract relations is an indispensable explanatory construct in major computational accounts of human analogical reasoning (Doumas, Hummel, & Sandhofer, 2008; Falkenhainer, Forbus, & Gentner, 1989; Halford, Wilson, & Phillips, 1998; Hummel & Holyoak, 2003; Lu, Chen, & Holyoak, 2012; Lu, Wu, & Holyoak, 2019; Petrov, 2013). Empirical work on relational reasoning has provided compelling evidence that humans store representations of semantic relations in memory (Estes & Jones, 2006; Popov, Hristova, & Anders, 2017; Spellman, Holyoak, & Morrison, 2001).

A number of important research questions depend on finding an effective method to assess human judgments of relational similarity. A major source of complexity stems from evidence that relations are not represented as discrete all-or-none concepts, but rather exhibit internal variability. Just as instances of natural and functional object categories differ in typicality (Rosch, 1975), so too people reliably judge word pairs to be better or worse instantiations of relations (Jurgens, Mohammad, Turney, & Holyoak, 2012). For example, *fail:succeed* is considered to be a better example of the relation *reverse* than is *eat:starve*.

Given such variations in intra-relation "goodness", it is natural to hypothesize that inter-relation similarity will also have a graded structure. Indeed, a recent theory of relation learning (*Bayesian Analogy with Relational Transformations*, BART) claims that the specific relation between a pair of words corresponds to a distributed representation over multiple relations, each of which the pair instantiates with some probability (Lu et al., 2019). For example, *lid:bottle* seems to instantiate the relations *part-whole*, *on-top-of*, and *closure-of*. BART can be used to derive theoretical predictions about the degree of similarity between a wide range of word pairs that collectively instantiate multiple relations.

It would clearly be desirable to obtain reliable human judgments of relational similarity, which might then be compared to theory-based predictions. Such data could also be used to assess potential individual differences in relation representations. A great deal of research indicates that complex relational reasoning depends on working memory capacity and other aspects of fluid intelligence (for a review see Holyoak, 2012). In particular, there is evidence that performance on analogical reasoning tasks is positively related to fluid intelligence as measured by tests such as the Raven's Progressive Matrices (RPM; Gray & Holyoak, 2018). It is possible that fluid intelligence plays a role in maintaining and comparing relations in working memory in order to differentiate among relations that overlap in meaning. Similarly, crystalized verbal intelligence seems to play an important role in comprehending metaphors (Stamenković, Ichien, & Holyoak, 2019), and may be related to the differentiation of relational concepts in semantic memory.

A reliable measure of human judgments of relation similarity would clearly be very useful for testing theories of relation representation. However, in practice it is difficult to

find an efficient procedure to elicit similarities among large sets of items (since the number of pairwise comparisons becomes prohibitively large when the number of items is substantial). Here we explore the use of a *multi-arrangement* method (adapted from previous work on assessing object similarity; Kriegeskorte & Mur, 2012) for obtaining judgments that can be used to efficiently generate a map of the psychological similarity space for abstract semantic relations.

The present paper aims to offer a first step in the exploration of relational similarity, assessing the validity and reliability of a new method for collecting human judgments of relational similarity and conducting preliminary analyses of these similarity judgments. Experiment 1 sets the stage by testing whether the method can generate sensible patterns of relation similarity. Experiment 2 then extends the method to more fine-grained semantic distinctions among relations to examine potential gradations in relational similarity. Further, Experiment 2 assesses the potential association between judgments of relation similarity and individual differences in both fluid and crystalized intelligence.

Experiment 1

The major goal of Experiment 1 was to determine whether a novel method for eliciting human judgments of relation similarity is able to capture broad distinctions among semantic relations that have been posited on the basis of previous theoretical and empirical investigations.

Method

Participants

20 participants (mean age = 19.05 years; 17 female) were recruited from the Psychology Department subject pool at the University of California, Los Angeles (UCLA). All participants were self-reported fluent English speakers. Participants provided verbal consent in accordance with the UCLA Institutional Review Board and were compensated with course credit.

Stimuli

All stimuli were word pairs taken from the SemEval-2012 Task 2 dataset (Jurgens et al., 2012), which is in turn based on a taxonomy of abstract semantic relations developed by Bejar, Chaffin, and Embretson (1991). Word pairs in this dataset express one of 79 specific relations, each falling into one of 10 general types of relations. Experiment 1 tested examples drawn from relations in each of three different general relation types (*similar*, *contrast*, and *cause-purpose*). We will refer to the examples in Experiment 1 by the names of the specific relations: *synonymy*, *contrary*, and *cause:effect* (see Table 1). Each relation included 16 word pairs, consisting of one paradigm exemplar (a seed used by Jurgens et al. to define the relation) and the 15 most prototypical word pairs for that relation. Pairs were unique in that they did not include inversions of one another. Table 1 provides examples of the word pairs used in the experiment.

Relation types	Word pair examples
synonymy	car:auto
contrary	old:young
cause:effect	joke:laughter

Table 1. Relations and examples of word pairs used in Experiment 1.

Procedure

We acquired human similarity judgments of semantic relations by asking participants to perform a multi-arrangement task, a method for efficiently eliciting similarity judgments, especially for large sets of items (Kriegeskorte & Mur, 2012). The method, which can be viewed as an inverse of standard multidimensional scaling (Shepard, 1962), has previously been successfully used for judgments of object similarity (Kriegeskorte & Mur, 2012; Mur et al., 2013; Jozwik, Kriegeskorte, Storrs, & Mur, 2017). Here we extend it to judgments of relation similarity.

On each trial, participants were presented with a subset of the 48 word pairs on a computer screen. They were asked to first identify the relation between words in each pair, and then use a mouse to arrange word pairs in a two-dimensional circular space according to the similarity of their relations (see Figure 1). Participants were told, "word pairs that involve similar relations should be placed close together," "word pairs that involve very different relations should be placed far apart," and "the distance between two word pairs should represent how different their relations are." Participants were also instructed to use the entire space to arrange word pairs on each trial.

We aimed to obtain similarity judgments from each participant relating each of the 48 item pairs to each other (a total of 1128 pairwise measurements). Estimates of similarity were based on the *relative* on-screen distances between word pairs as arranged by participants on each trial. These estimates were calculated by scaling the distances between items arranged on a single trial to match a weighted average of these distances calculated across trials. This weighted average was iteratively recomputed until convergence.

On a given trial, participants were presented with a maximum of 20 word pairs. The multi-arrangement task involves adaptively selecting stimuli to present on each trial. On the first trial, participants arranged a random subset of 20 items from the entire set of 48 items. On subsequent trials, participants arranged a subset of 20 or fewer items selected based on item pairs with the weakest similarity evidence (see Kriegeskorte & Mur, 2012, for an extended discussion).

Previous uses of the multi-arrangement task have involved 1-hour sessions (e.g., Kriegeskorte & Mur, 2012; Mur et al., 2013; Jozwik et al., 2017), but these studies all asked participants to do a relatively easier task of arranging individual objects according to their similarity. Due to the higher demand on working memory in arranging word pairs according to their relational similarity, pilot experiments suggested that a 1-hour session length would likely result in fatigue and disengagement for naïve participants. Accordingly, we limited session length to 30 minutes.

Figure 1. Example trial of the multi-arrangement task used to generate a semantic space for relations.

Participants were allowed to spend as long as they needed to complete each trial. On average, participants completed 28.5 trials (SD = 11.86, range = 4-44) within the 30-minute experimental duration.

Results

All but five participants provided a full set of pairwise similarity judgments between all combinations of the 48 word pairs. Of the five who failed to complete all possible comparisons, four provided judgments for 98% of the pairwise combinations of word pairs. The fifth participant provided judgments for just 57% of the combinations; this individual's data were excluded from analyses.

We assessed the inter-subject reliability of our relational similarity judgments by calculating the Pearson correlation coefficients between individual participants' distance matrices. The mean correlation between any two participants' distance matrices was .50 (range = .11 to .83).

We then examined whether the multi-arrangement task provided a reliable measure of relation similarity (assuming that greater inter-pair distance implies lower similarity). The results showed that participants generated smaller distances between word pairs within a relation compared to distances between word pairs instantiating a different relation. Figure 2 depicts a mean distance matrix obtained by averaging across distance matrices generated by individual participants performing the multiple-arrangement task.

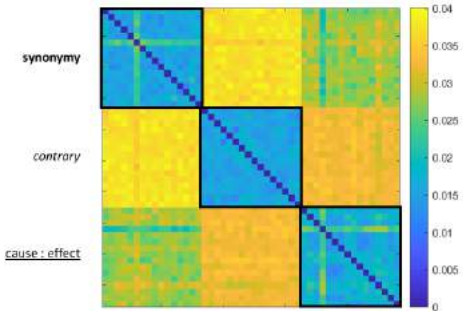

Figure 2. Mean distance matrix between the 48 word pairs used in Experiment 1. Cold colors represent smaller distances (i.e., greater pairwise similarity); hot colors represent greater distances (i.e., lesser pairwise similarity). Boxed regions represent pairwise distance measures between word pairs instantiating the same relation.

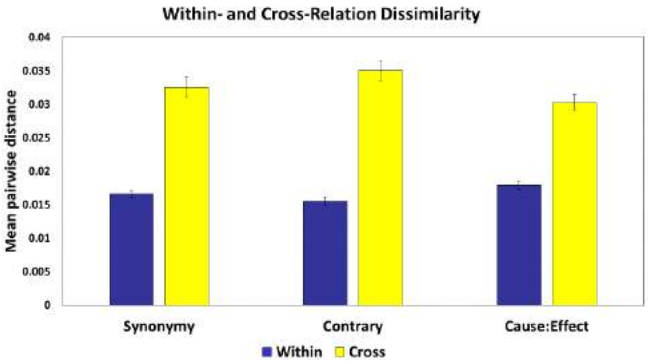

Figure 3. Mean within- and cross-relation distance measures for pairs instantiating each relation (Experiment 1). Higher bars indicate greater distance (i.e., lower similarity). Error bars indicate +/- 1 standard error of the mean.

We compared the mean distances between word pairs instantiating different relations (i.e., cross-relation distances) to the mean distances between word pairs instantiating the same relation (i.e., within-relation distances). To perform this analysis, we first calculated within- and cross-relation distances for each word pair for each individual participant. Next, we found the mean value of both of these distance measures averaged across word pairs within each relation. As depicted in Figure 3, cross-relation distances were greater than within-relation distances for each relation: for *synonymy* ($t(18) = 8.66$, $p < .001$, Cohen's $d = 1.99$); for *contrary* ($t(18) = 10.26$, $p < .001$, Cohen's $d = 2.35$); for *cause:effect* ($t(18) = 8.91$, $p < .001$, Cohen's $d = 2.5$). These findings thus establish that the multi-arrangement task is an effective method to obtain human judgments of relation similarity.

Experiment 2

Experiment 2 aimed to determine whether human judgments of relational similarity are sensitive to more fine-grained distinctions among relations than those examined in Experiment 1. In addition, we investigated whether relation judgments are systematically influenced by individual differences in cognitive capacity and/or semantic knowledge. To assess fluid intelligence, we administered a short version of the RPM (Arthur, Tubre, Paul, & Sanchez-Ku, 1999) adapted for computer administration using Matlab software. Participants are presented with a 3x3 grid of items with the item in the bottom right corner missing. They are asked to use the pattern instantiated by the presented items to select the most appropriate item to fill that bottom right corner from a set of 8 options. Prior research has shown that superior performance on this test is correlated with performance on tests of analogical reasoning (Vendetti, Wu, & Holyoak, 2014; Kubricht, Lu, & Holyoak, 2017). We hypothesized that the RPM measure would be associated with the degree to which people are able to differentiate word pairs that instantiate distinct relations.

In addition to fluid intelligence, the ability to differentiate among semantic relations may vary with crystalized verbal intelligence, particularly knowledge of semantic relations. As

a measure of semantic knowledge, we administered the Semantic Similarities Test (SST). This test was designed to be similar to the Similarities subscale of the Weschler Adult Intelligence Scale (WAIS), and is correlated with the Vocabulary subtest (Stamenković et al., 2019). Participants are presented with 20 pairs of verbal concepts and asked to describe how the concepts in each pair are similar. The concept pairs span a broad range of similarities: some are fairly specific (e.g., *bird-airplane*, which both fly), some are more general (e.g., *tavern-church*, which are both public buildings), and some are more metaphorical (e.g., *marriage-alloy*, which are both bonds between elements). Because the identification of more specific and fine-grained relations likely depends on greater semantic knowledge, we hypothesized that superior performance on the SST would also be correlated with greater differentiation of similarities among semantic relations.

Method

Participants

93 new participants (mean age = 20.17 years; 69 female) were recruited from the UCLA Psychology Department subject pool. All participants had normal or corrected-to-normal vision and were self-reported fluent English-speakers. Participants provided verbal consent in accordance with the UCLA Institutional Review Board and were compensated with course credit.

Stimuli

The multi-arrangement task in Experiment 2 used 27 word pairs drawn from the same norms as in Experiment 1 (Jurgens et al., 2012). Three word pairs were chosen from each of three specific subrelations of three general relation types (see Table 2). Note that the three relations used in Experiment 1 were included as specific subrelations used in Experiment 2. Whereas Experiment 1 did not manipulate the level of relation abstraction, Experiment 2 did. Specifically, Experiment 2 examined whether similarity judgments not only reflect broad distinctions at a high level of abstraction (i.e., between general relation types), but also fine distinctions at a lower level of abstraction (i.e., between specific subrelations within general relation types). Word pairs drawn from different subrelations of the same general type (e.g., *car:auto* instantiates *synonymy* and *rake:fork* instantiates *attribute similarity*, two subrelations of the relation type *similar*) are differentiated on the basis of relatively subtle relational differences. Each set of three unique word pairs consisted of one paradigm exemplar and the third and sixth most prototypical unique word pairs for that subrelation in the SemEval-2012 Task 2 norms (Jurgens et al., 2012).

Procedure

All participants completed three tasks in the following order: the multi-arrangement task, the Raven's Progressive Matrices (RPM) and the Semantic Similarities Test (SST).

General relation types	Specific subrelations	Word pair examples
similar	*synonymy*	car:auto
	attribute similarity	rake:fork
	change	discount:price
contrast	*contrary*	old:young
	directional	east:west
	pseudoantonym	right:bad
cause-purpose	*cause:effect*	joke:laughter
	cause: compensatory action	hunger:eat
	action/activity: goal	flee:escape

Table 2. General relation types, three specific subrelations chosen to exemplify each, and examples of word pairs used in Experiment 2.

Results

All 93 participants completed the multi-arrangement task. On average participants completed 19.51 trials (SD = 9.70, range 2-55). All but one participant provided pairwise similarity judgments for all 27 word pairs (351 pairwise comparisons). That one participant provided judgments for 86% of the pairwise combinations. Due to program failures, only 88 participants completed the SST, and 90 participants completed the RPM.

We again assessed the inter-subject reliability of our relational similarity judgments by calculating the Pearson correlation coefficients between individual participants' distance matrices. The mean correlation between any two participants' distance matrices was .38 (range = -.09 to .88).

Figure 4 depicts the mean distance matrix for all word pairs. We compared the mean distances of word pairs drawn from different general relation types (i.e., cross-type distances) to mean distances of word pairs within the same relation type (i.e., within-type distances). As depicted in Figure 5, cross-type distances were greater than within-type distances for each relation type: for *similar* ($t(92) = 10.53$, $p < .001$, Cohen's $d = 1.09$); for *contrast (*$t(92) = 18.32$, $p < .001$, Cohen's $d = 1.90$); for *cause-purpose (*$t(92) = 17.06$, $p < .001$, Cohen's $d = 1.77$).

To examine whether participants were sensitive to differences between specific subrelations within the same relation type, we compared the mean distances of word pairs instantiating different subrelations within the same general relation type (i.e., cross-subrelation distances) to the mean distances of word pairs instantiating the same subrelations (within-subrelation distances). For each relation type, mean cross-subrelation distances were greater than mean within-subrelation distances: for *similar* ($t(92) = 13.17$, $p < .001$, Cohen's $d = 1.37$); for *contrast (*$t(92) = 12.95$, $p < .001$, Cohen's $d = 1.34$); for *cause-purpose (*$t(92) = 7.35$, $p < .001$, Cohen's $d = 0.76$). These findings indicate that participants were not only able to differentiate between general relation types but were also sensitive to much more fine-grained distinctions within the same relation type. Further, these findings provide evidence of graded similarity structure among semantic relations. Specifically, word pairs instantiating the same general relation type were judged as

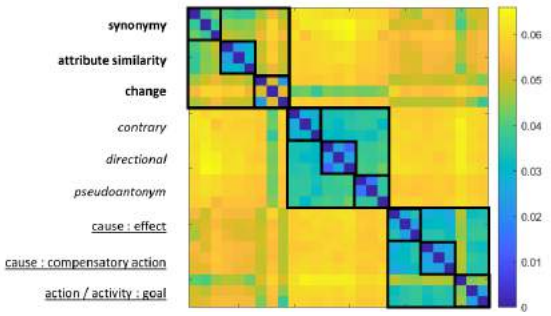

Figure 4. Mean distance matrix from Experiment 2. Cold colors represent smaller distances (i.e., greater pairwise similarity), whereas hot colors represent greater distance (i.e., lesser pairwise similarity). Larger boxed regions represent pairwise distance judgments between word pairs instantiating the same general relation type. Smaller boxed regions represent pairwise distance judgments between word pairs instantiating the same specific subrelation within a common relation type.

more similar to each other than those instantiating different general relation types, and word pairs instantiating the same subrelation were judged as more similar to each other than those instantiating different subrelations within the same general relation type.

Next, we performed analyses to determine whether individual differences in cognitive capacity (as assessed by the RPM) and semantic knowledge (as assessed by the SST) were associated with participants' sensitivity to differences among relations. Two independent raters scored the SST based on the criteria summarized by Stamenković et al. (2019). We assessed the reliability of these raters' scores by testing the average measure intraclass correlation coefficient across scores using a two-way mixed model (ICC = .971, $F(19,19) = 44.72$, $p < .001$, with a 95% confidence interval from .899 to .990). Given the reliability of these scores, we used the average score across these two raters in the following analyses.

In order to estimate individual differences in sensitivity to broad distinctions relation types, we computed a relation type discriminability index for each participant using the following steps. First, we found each participant's cross-type distance by calculating the mean distance for pairwise comparisons between word pairs instantiating different general relation types (e.g., *old:young* instantiates the relation type *contrast*, while *car:auto* instantiates the relation type *similar*). Second, we found each participant's within-type distance by calculating the mean distance for pairwise comparisons between word pairs instantiating the same general relation type (e.g., *old:young* and *east:west* both instantiate the relation type *contrast*). Third, we computed each participant's discriminability index by dividing that participant's cross-type distance by their within-type distance (range = 1.01 to 2.60). This relation type discriminability index reflects how well a participant discriminated between relation types in their similarity judgments. An index of 1 indicates complete lack of discriminability between word pairs instantiating different relation types and those instantiating the same relation type, whereas higher indices indicate judgments of greater similarity between word pairs instantiating the same relation type than between word pairs instantiating different relation types.

These discriminability indices for relation types were significantly correlated with RPM scores (Pearson's $r = .33$, $p = .005$, power = .90) and also with SST scores (Pearson's $r = .30$, $p = .014$, power = .82). Partial correlations revealed that these discriminability indices were significantly correlated with RPM scores after residualizing out SST scores (Pearson's $r = .236$, $p = .028$, power = .61), and that they were significantly correlated with SST scores after residualizing out RPM scores (Pearson's $r = .236$, $p = .028$, power = .61). These results indicate that there is an association between the discrimination of general relation types both with cognitive capacity and with semantic knowledge.

In order to estimate each participant's sensitivity to more fine-grained distinctions between specific subrelations within general relation types, we also computed a subrelation discriminability index using the following steps. First, we found each participant's cross-subrelation distance by calculating the mean distance for pairwise comparisons between word pairs instantiating different subrelations within the same general relation type (e.g., *old:young* instantiates the subrelation *contrary*, and *east:west* instantiates the subrelation *directional*, where both instantiate the relation type *contrast*). Second, we found each participant's within-subrelation distance by calculating the mean distance for pairwise comparisons between word pairs instantiating the same subrelation (e.g., *old:young* and *black:white* both instantiate the subrelation *contrary*). Third, we computed each participant's subrelation discriminability index by dividing each participant's cross-subrelation distance by their within-subrelation distance (range = .96 to 2.74). This subrelation discriminability index reflects how well a participant was able to discriminate between specific subrelations within a relation type in their similarity judgments. An index of 1 would indicate a complete lack of discriminability between word pairs instantiating different subrelations and those instantiating the same subrelation, whereas higher indices indicate judgments of greater similarity between word pairs instantiating the same subrelation than between word pairs instantiating different subrelations.

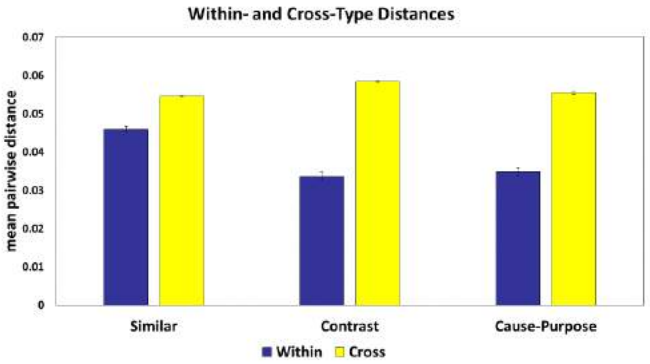

Figure 5. Mean within- and cross-type distances for each general relation type in Experiment 2. Error bars indicate +/- 1 standard error of the mean.

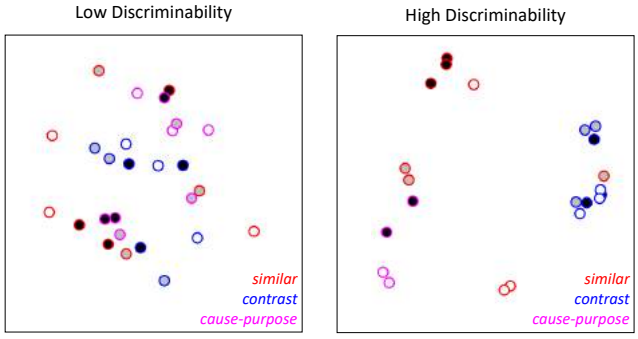

Figure 6. Visualization of relation similarities from two representative participants. Left: MDS solution for a participant with low discriminability indices (relation type discriminability index = 1.02; subrelation discriminability index = .98). Right: solution for a participant with high discriminability indices (2.08 and 2.74, respectively). Each marker indicates a single word pair. Marker outline color indicates word pair relation type, and marker shading indicates subrelation within relation type.

These fine-grained discriminability indices for subrelations showed a significant correlation with RPM scores (Pearson's r = .35, p = .003, power = .93), and also with SST scores (Pearson's r = .30, p = .014, power = .82). Partial correlations revealed that these discriminability indices were significantly correlated with RPM after residualizing out SST scores (Pearson's r = .291, p = .006, power = .79), but that they were not correlated with SST scores after residualizing out RPM scores (Pearson's r = .090, p = .408). These results indicate that there is a stronger association between the discrimination of specific subrelations within relation types with cognitive capacity than with semantic knowledge.

To provide a visualization of the difference between high and low discriminability, Figure 6 presents multidimensional scaling (MDS) solutions (Shepard, 1962) for the distance matrices of a participant with both a low relation type and a low subrelation discriminability index (left) and of a participant with both a high relation type and a high subrelation discriminability index (right). The latter solution shows a much greater degree of clustering into distinct relation types as well as into subrelations.

General Discussion

Across two experiments, we showed that a multi-arrangement task can be used to efficiently assess judgments of similarity among semantic relations. Human judgments obtained using this method have a clear interpretation. Judged similarity reflects not only broad distinctions between relation types, but also finer distinctions between subrelations within relation types. Moreover, the degree to which a participant differentiated between pairs from the same versus different relation types was positively correlated with measures of both fluid and verbal crystallized intelligence. At the more detailed level of subrelations, only fluid intelligence was a reliable predictor of discriminabilty. Future work should examine these associations further and assess directions of causality.

The present findings add to mounting evidence that semantic relations do not have discrete, all-or-none representations. Previous work has shown that word pairs instantiating a particular relation vary systematically in their *typicality* (Jurgens et al., 2012; Popov et al., 2017), much like instances of object categories (Rosch, 1975). Our findings reveal that *similarities* between relation examples (within and across subrelations) also vary in a graded fashion. In addition, the present study establishes that similarity gradients for relations show reliable individual differences across people who vary in either cognitive capacity or semantic knowledge of relations.

Note typicality judgments are importantly distinct from similarity judgments. Specifically, typicality is a relation between entities at different levels of abstraction (i.e., exemplar and category), and the typicality of a word pair is necessarily defined with respect to a particular relation. For example, *up:down* is typical of the relation *opposite*. In contrast, similarity is generally a relation between entities at the same level of abstraction (i.e., exemplar and exemplar), and relational similarity of a word pair can be defined with respect to another word pair. For example, *up:down* is similar to *light:dark*., Notably, whereas typicality judgments can be used to evaluate relational semantic representations *within* relations, similarity judgments can be used as a more holistic evaluation *across* relations.

This emerging picture of human relation concepts is consistent with models of relation learning and analogical reasoning that assume relations are coded by distributed representations (e.g., Lu et al., 2019). More generally, judgments of relation similarity provide a rich source of potential data that can be used to evaluate computational models. Specifically, a relation distance matrix generated from a theoretical model can be compared to a distance matrix obtained from human judgments of relation similarity, as described here. To the extent that a model-generated distance matrix approximates a human-generated distance matrix, the model's representation of semantic relations is descriptive of human semantic cognition. The same logic can be applied to test computational models as predictors of relational priming (Estes & Jones, 2009; Popov et al., 2017; Spellman et al., 2001), and of neural responses to relation processing (Kriegeskorte, Mur, & Bandettini, 2008).

The multi-arrangement method of collecting similarity judgments for relations may also prove useful in guiding studies of educational interventions (Goldwater & Schalk, 2016). The type of MDS solution that can be derived from similarity judgments can be related to the well-known technique of using "concept maps" to teach systematically related concepts. The degree of match between the clusters identified in an MDS solution obtained for an individual learner may provide a useful index of how well that learner's internal representation of a set of concepts maps onto the organization the teacher aimed to convey.

Abstract

In prior research, arguments using both anecdotal and statistical evidence are more persuasive than arguments using either alone (Allen, Bruflat, Fucilla, Kramer, McKellips, Ryan, & Spiegelhoff, 2000; Hornikx, 2005). However, it is less clear how people integrate information when the statistics and the anecdotes present conflicting information. In three preregistered experiments, we tested how people integrate conflicting information to judge the efficacy of a medicine in a clinical trial. Participants read either an anecdote from someone in the trial, summary statistics about the trial, or both types of information. We found that reading an anecdote from a member of the trial for whom treatment was ineffective reduced people's beliefs in a medical treatment even when participants received strong evidence that the treatment was effective. In Experiment 3, we found that introducing icon arrays increased the perceived efficacy of the treatment but did not eliminate the effect of the anecdote.

Keywords: anecdotal reasoning; medical decision-making; open science

Introduction

Making decisions about medical treatments can be a difficult and stress inducing process. When the decision concerns those we love, or those who are vulnerable, the stakes can make even obvious decisions seem paralyzing. People are inundated with popular press reports about medical research concerning what's healthy, get advice from doctors, and hear personal anecdotes from friends, relatives, and the media. How can people make appropriate medical decisions under these conditions? It might seem obvious that people's beliefs should reflect the scientific consensus, but when our own and our families' health is at stake, a compelling narrative or personal anecdote can be hard to ignore. For instance, vaccine hesitancy has been found to be driven by reliance on anecdotal evidence about the side effects of vaccines spread throughout online communities even though vaccines are among the safest medical treatments (Powell, Weisman, & Markman, 2018). Altogether making a medical decision is no easy feat, even for the epistemically diligent.

Prior research suggests that although people are capable of correctly integrating statistical information to make informed medical decisions (e.g., Allen & Preiss, 1997; Allen et al., 2000; Hornikx, 2005), they may nonetheless improperly attend to irrelevant anecdotal information, particularly when that evidence is salient and relates to uncertainty and risk (e.g., Allen et al., 2000; Shen, Sheer, & Li, 2015). Some researchers suggest that narratives are more engaging and comprehensive (Dahlstrom, 2014), but when learning about new scientific information, anecdotal information can distract from making proper scientific judgments (Rodriguez, Rhodes, Miller, & Shah, 2016). What remains unclear is how people integrate anecdotes *with* statistical information. When people are presented with both statistical summary information and anecdotes, how do they reason on the basis of this information? Can positive anecdotal information aid in the integration of statistical information when in concert with each other? Some research suggests that anecdotes do not impact the integration of statistical evidence about government policy (Hornikx 2018), but there is little research on this question in the domain of medical decision-making, where the stakes are high and thus anecdotes might may exhibit stronger effects.

In the present studies, we examined the effect of anecdotes on medical decision-making. We investigated the ways in which anecdotal information influences how people interpret a study describing the efficacy of a novel medical treatment (Experiments 1 and 2), and what other factors may weaken the effect of anecdotes on reasoning (Experiment 3).

General Methods

Preregistration We preregistered the data collection plan, analyses, and predictions for all three experiments. Experimental scripts, full analytic results, and supplementary online materials (SOM) are available on the Open Science Framework at https://osf.io/dkcwv/.

Analytic Approach We performed Bayesian estimation using the R package `brms` (Bürkner, 2018). We set regularizing priors for all population-level effects in our models, which we detail below. These priors are recommended because they provide conservative effect size estimates and reduce the likelihood of overfitting (McElreath, 2016). Following the recommendations of Liddell & Kruschke (2018), Likert data were modeled with a cumulative probability distribution.

Experiment 1

Experiment 1 examined how anecdotes affect people's reasoning about medical information. We sought to avoid polarizing medical treatments because beliefs about these topics may be particularly intransigent. Consequently, we focused on a plausible but relatively unknown medical treatment that people would not have strong beliefs about. Specifically, we examined people's beliefs about B-12 injections as means for treating chronic headaches.

Participants We recruited 497 participants through Amazon's Mechanical Turk (47% women, M_{age}= 38 years old). Participants were paid $0.50 for participating in a five-minute study. After excluding participants who missed questions checking their attention, 431 participants remained in our sample. Our exclusion criteria were determined a priori and were in accordance with our study preregistration.

Procedure In Experiment 1, we presented participants with either statistical evidence, anecdotal evidence, or the combination of both types of evidence about a medical trial testing the effectiveness of B-12 injections on chronic headaches. The study consisted of three parts: a pretest questionnaire, an intervention, and then a posttest questionnaire. After completing this portion of the study, participants completed medical individual differences measures and demographic questions. We describe each component below.

Pretest Questionnaire Participants answered a brief questionnaire examining their familiarity with B-12 injections, whether they are currently receiving or have received B-12 injections, and whether they are considering receiving B-12 injections as a medical treatment. After responding to these questions, participants were then asked on a five-point Likert scale whether they believe B-12 injections are an effective medical treatment (1 = "Not effective at all", 5 = "Extremely effective").

Conditions After completing the B-12 pretest questionnaire, participants were randomly assigned to one of four conditions: the Statistics condition, the Positive Anecdote condition, the Statistics + Positive Anecdote condition, or the Statistics + Negative Anecdote condition.

In the Statistics condition, participants were shown a description with summary statistics about a clinical trial examining the effects of B-12 injections on patients with chronic headaches. Namely, participants read that in a clinical trial with 1,000 subjects, B-12 injections were 87.3% effective as a medical treatment for chronic headaches.

In the Positive Anecdote condition participants did not receive the statistical information but were told "Jamie's [the protagonist in the anecdote] doctor recommended that she participate in a new clinical trial that was examining the effects of B-12 on headaches" and then were told that Jamie decided to receive B-12 and subsequently experienced a reduction in her symptoms.

In the Statistics + Positive Anecdote condition, participants first read the summary statistics demonstrating the efficacy of B-12 injections (that is, the only material presented in the Statistics condition). They were then told that they would read about the experience of one of the subjects in the study, after which they were presented with the anecdote from the Positive Anecdote condition.

Participants in the Statistics + Negative Anecdote condition were given the same materials as participants in the Statistics + Positive Anecdote condition, but now the anecdote is from a member of the trial for whom treatment was ineffective. Participants learned that "Jamie received a B-12 injection and her headaches, lack of energy, and inability to focus persisted." Critically, however, Jamie was not described as experiencing any side-effects as a consequence of her treatment.

Two design decisions are important to highlight: First, the anecdote contains no new information in the conditions that paired an anecdote with a statistic. This is because summary statistics already capture the success or failure of B-12 injections in the clinical trial and the anecdote concerns someone who was in the clinical trial. In other words, the anecdote contains no *additional* information over and above the statistic – the anecdote either describes the treatment as effective or ineffective and no other relevant information beyond this.

This point is related to a second design decision: Namely, in the Negative Anecdote condition, B-12 was described as failing as a treatment but not introducing any unwanted side-effects. Together, then, the negative anecdote should not affect participants' interpretation of the statistical information presented to them.

Posttest Questionnaire After completing the intervention portion of the task, participants completed a posttest questionnaire in which they were asked whether they believed B-12 injections were an effective medical treatment.

As noted, one possibility is that when the stakes are high for a given medical decision, people may be more susceptible to anecdotal information leading them to ignore strong statistical information. To this end, we also included two additional questions in the posttest questionnaire. First, participants were asked how likely it was they would try B-12 injections on a five-point Likert scale. Second, they were asked how likely they were to give B-12 injections to their child (if applicable). It's possible that a negative anecdote would exhibit a stronger negative effect on people's reasoning about their child compared to themselves because people are more risk averse when it comes to making decisions that impact their children's health (e.g., Brody, Annett, Scherer, Perryman, & Cofrin, 2005; Johnson, Özdemir, Mansfield, Hass, Siegel, & Sands, 2009).

Predictions

We predicted that participants in the Statistics + Positive Anecdote condition would be most likely to think that B-12

injections were effective as a treatment for chronic headaches—the positive anecdote would make salient the statistical summary information. This outcome would suggest that health communication experts could include similar positive anecdotes to increase people's uptake of statistical information (Allen et al., 2000). In contrast, we were unsure whether the Statistics condition or the Positive Anecdote condition would differ from each other, though the Statistics condition objectively contains much stronger evidence.

Of particular interest was how participants would respond to the negative anecdote in the Statistics + Negative Anecdote condition. One possibility is that presenting participants with a negative anecdote could raise the salience of the inefficacy of B-12 injections. However, we were unsure to what extent a single negative anecdote could impact people's use of the statistical summary information.

Results

We tested our predictions by fitting a Bayesian multivariate ordinal regression model regressing B-12 beliefs (i.e., efficacy beliefs, willingness to try B-12, and willingness to give these injections to their children) on Condition (Reference = Positive Anecdote condition) and pretest beliefs about the efficacy of B-12. Following the recommendations of Bürkner and Charpentier (2018), we modeled pretest as a monotonic effect because the ordinal nature of this predictor. The model is specified below in brms syntax:

```
mvbind(B12,TryB12,ChildB12) ~ Condition
+ mo(Pretest) + (1|p|Subject)
```

Bayesian analyses formulate model parameters as probability distributions wherein the posterior distribution for a parameter θ is computed via the prior and the likelihood of θ. To model the joint probability distribution of participants' responses, we specified the following regularizing priors over the possible effects each parameter could have on the response variable:

Experiment 1 - Priors

$\beta_{Intercept[1]} \sim \mathcal{N}(.5,.5)$
$\beta_{Intercept[2]} \sim \mathcal{N}(1.09,.5)$
$\beta_{Intercept[3]} \sim \mathcal{N}(2.94,.5)$
$\beta_{Intercept[4]} \sim \mathcal{N}(4.59,.5)$
$\beta_{Pretest} \sim \mathcal{N}(2,4)$
All remaining β were distributed as $\mathcal{N}(0,1)$
$\Omega_k \sim LKJ(1)$ where Ω_k is a correlation matrix of group-level parameters
Group-level parameters were distributed as $t(3,0,10)$

This model revealed that the Positive Anecdote, Statistics, and Statistics + Positive Anecdote conditions did not materially differ from each other (see Figure 1). However, the negative anecdote in the Statistics + Negative Anecdote condition caused participants to ignore the statistical information, despite the fact that (1) the statistic already summarizes the information contained in the negative anecdote and (2) the negative anecdote in no way suggests that the protagonist suffered a side-effect as a result of taking B-12 injections, $b_{B12} = -1.28$, 95% CI [−1.83, −0.73]; $b_{Try} = -0.79$, 95% CI [−1.44, −0.15]; $b_{Child} = -1.39$, 95% CI [−2.07, −0.72]. A subsequent analysis interacting pretest beliefs with condition provided no evidence for an interaction between these predictors.

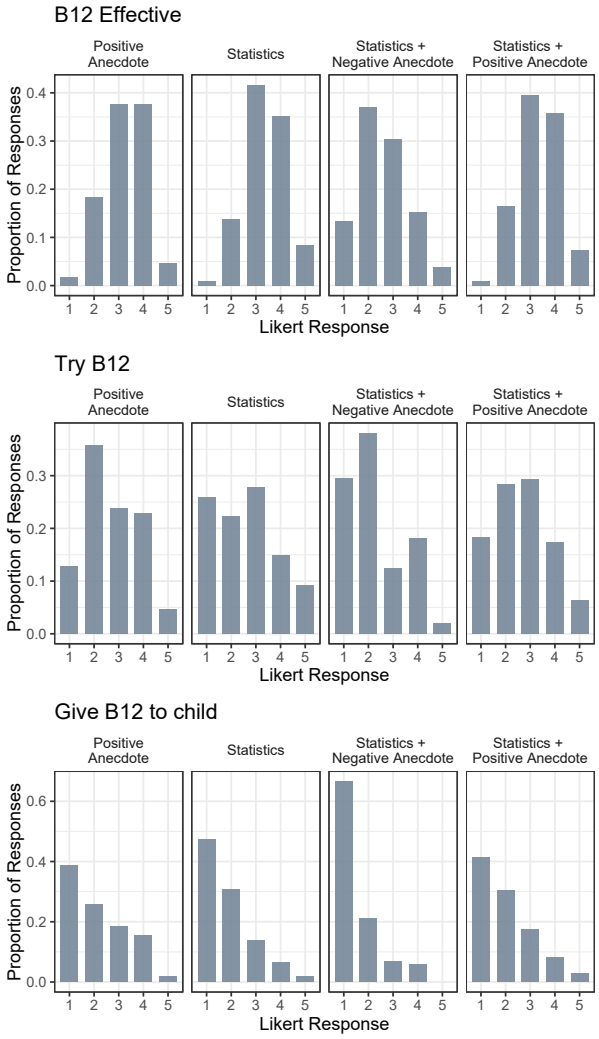

Figure 1: B-12 injection beliefs across conditions in Experiment 1. Higher Likert scale choices indicate more favorable attitudes towards B12 injections. The figure indicates that participants in the Statistics + Negative Anecdote condition had less favorable attitudes towards B12 injections after the intervention relative to participants in the other three conditions.

Altogether, these findings suggest that (negative) anecdotal information affected participants' beliefs. A single positive anecdote carried the same evidential weight as a study describing a double-blind clinical trial with 1,000 participants, though it appears that it did not affect beliefs

additively—the Statistics + Positive Anecdote condition did not differ from the Positive Anecdote condition nor the Statistics condition. More worrisome was the effect of the negative anecdote on participants' reasoning about compelling statistical evidence. One negative anecdote, in effect, caused people to dismiss strong statistical evidence, even though the anecdote implied no negative side effects and contained no additional information over and above the information carried by the statistics.

Experiment 2

Experiment 1 suggested that people's beliefs about the efficacy of B-12 injections are affected by anecdotal information. In Experiment 2, we sought to further understand the impact of anecdotes on medical decision-making. Given that a single negative anecdote can undo, as it were, strong statistical evidence, we sought to determine what would reduce the impact of this negative anecdote. Consequently, we tested whether presenting participants with both a positive and negative anecdote paired with statistical information would lead participants to primarily attend to the statistical information about the efficacy of B-12 injections in treating chronic headaches. Reading contradictory anecdotal information should indicate to participants that a different evidence source (in this case, the statistics) is needed to come to an informed belief about B-12 injections.

Method

Participants

We recruited 492 participants through Amazon's Mechanical Turk (50% women, M_{age}= 36 years old). Participants were paid $0.50 for participating in the study. After excluding participants who missed questions checking their attention, 431 participants remained in our sample. Our exclusion criteria were determined a priori and were in accordance with our study preregistration.

Procedure

The procedure of Experiment 2 was similar to Experiment 1, with the exception of the conditions participants were assigned to. Namely, we replaced the Positive Anecdote condition with a Statistics + Positive & Negative Anecdotes condition to determine whether including a positive anecdote in conjunction with a negative anecdote would lead participants to focus on summary statistics.

We made two other changes in Experiment 2. First, participants in the Statistics condition were explicitly told *both* the inefficacy and efficacy rates of B-12 injections in treating chronic headaches. We did this to better equate the salience of the inefficacy rate in the Statistics condition to the conditions in which the negative anecdote appeared. Specifically, participants read that "After a two-year trial with 1,000 participants, their study revealed that B-12 injections failed to work for 12.7% of participants and worked for 87.3%." Second, we changed the Likert scale for our posttest questions regarding the likelihood of trying B-12 injections and giving B-12 to one's child. These were changed to a six-point Likert scale which ranged from 1 = "Very unlikely" to 6 = "Very likely".

Predictions

As in Experiment 1, we predicted that participants in the Statistics + Positive Anecdote condition would tend to have the most positive beliefs towards B-12 injections. We predicted that when participants in the Statistics condition are explicitly presented with the rate of ineffectiveness, this would raise the salience of the inefficacy of B-12 injections. In turn, this may reduce overall endorsement of the efficacy of B-12 injections relative to the Statistics + Positive Anecdote condition. Finally, we sought to examine whether inclusion of the positive anecdote with the negative anecdote in the Statistics + Positive & Negative Anecdotes condition would cause participants to primarily attend to the statistical information they received. We suspected that the presence of the positive anecdote would not entirely undercut the effect of the negative anecdote on participants' judgments.

Results

As in Experiment, we fit a multivariate regression model regressing B12 attitudes on Condition (Reference = Statistics condition) and Pretest beliefs. We set priors on intercepts based on posterior estimates from Experiment 1.

Experiment 2 - Priors

$\beta_{Intercept[1]} \sim \mathcal{N}(-1.38, .5)$
$\beta_{Intercept[2]} \sim \mathcal{N}(1.09, .5)$
$\beta_{Intercept[3]} \sim \mathcal{N}(2.19, .5)$
$\beta_{Intercept[4]} \sim \mathcal{N}(4.59, .5)$
$\beta_{Pretest} \sim \mathcal{N}(2, 4)$
All remaining β were distributed as $\mathcal{N}(0, 1)$
$\Omega_k \sim LKJ(1)$
Group-level parameters were distributed as t(3,0,10)

These analyses replicated the effects of Experiment 1, showing that (1) the Statistics and Statistics + Positive Anecdote conditions did not differ from each other and (2) that participants in the Statistics + Negative Anecdote condition were more likely to discount the statistical evidence from the clinical trial (see Figure 2), b_{B12} = −1.34, 95% CI [−1.89, −0.80]; b_{Try} = −0.45, 95% CI [−1.22, 0.28]; b_{Child} = −0.94, 95% CI [−1.75, −0.19]. The positive anecdote in the Statistics + Positive and Negative Anecdotes condition, however, did not consistently improve participants' integration of the statistical information, and in some cases, did not differ at all from when participants only received the negative anecdote (see Figure 2), b_{B12} = −1.40, 95% CI [−1.93, −0.87]; b_{Try} = −0.22, 95% CI [−0.96, 0.52]; b_{Child} = −0.02, 95% CI [−0.74, 0.74]. These effects again did not interact with people's pretest attitudes towards B12 vaccines.

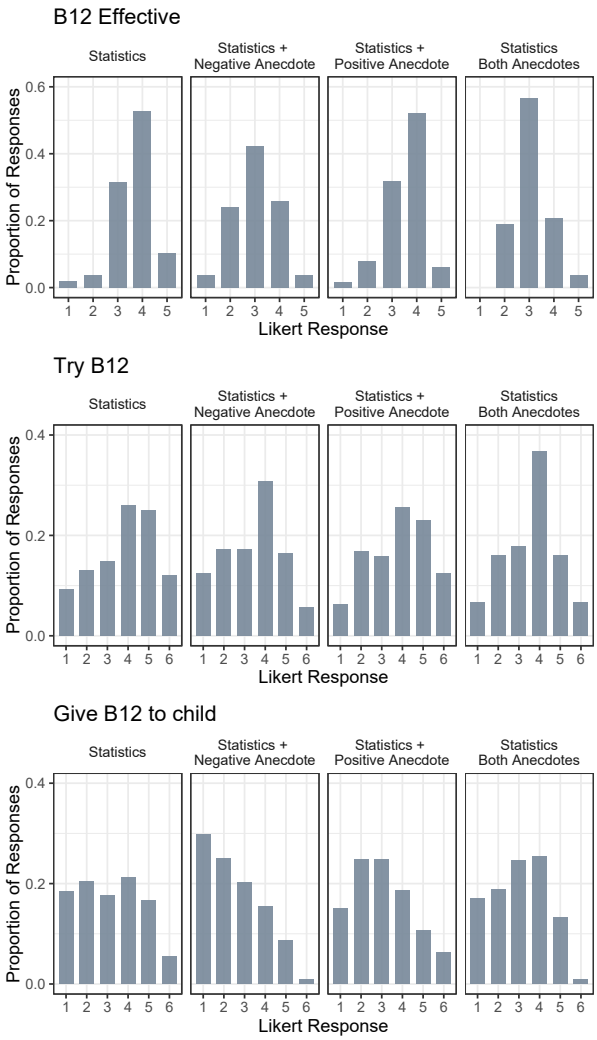

Figure 2: B-12 injection beliefs across conditions in Experiment 2. Higher Likert scale choices indicate more favorable attitudes towards B12 injections. The figure indicates that participants in the Statistics + Negative Anecdote and Statistics + Both Anecdotes conditions had less favorable attitudes towards B12 injections after the intervention relative to participants in the other conditions.

Experiment 3

Experiment 2 revealed that presentation of a negative anecdote raises the salience of the inefficacy of B-12 injections. This effect was not consistently negated by positive anecdotal information, raising the question of what means could undercut negative anecdotal information.

Experiment 3 sought to address two questions. First, we addressed the possibility that participants did not realize the anecdote they read was about a person in the study. Our hope was that by visually showing participants that the anecdote they read was about a person in the study we could rule out the possibility that a negative anecdote had its effects just in virtue of it being *new*, negatively-valenced information. Second, inspired by recent work, Experiment 3 tested whether a visual aid would reduce the impact of the negative anecdote on participants reasoning by making the strength of the summary statistics more salient. Several recent studies suggest that icon arrays, for instance, can improve understanding of scientific consensus (Lewandowsky, Gignac, & Vaughan, 2013; Nyhan & Reifler, 2018). Thus, Experiment 3 used an icon array to reduce the effect of the negative anecdote on people's beliefs.

Participants

We recruited 1,622 participants through Amazon's Mechanical Turk (54% women, M_{age}= 38). Participants were paid \$0.50 for participating in the study. After excluding participants who missed questions checking their attention, 1,539 participants remained in our sample. Our exclusion criteria were determined a priori and were in accordance with our study preregistration.

Procedure

The procedure of Experiment 3 was similar to that of Experiments 1 and 2. Participants were randomly assigned to one of four conditions in a 2 (Icon Array: Present or Absent) $\times$ 2 (Negative Anecdote: Present or Absent) between-subjects design. All four conditions included the summary statistical information from the Statistics condition in Experiment 1, allowing us to internally replicate our results in a larger sample.

In the Icon Array only condition, participants first read the statistic about the efficacy of B-12 injections as a medical treatment. They were then shown an icon array showing the success rate of B-12 in 100 people. Participants were then told:

> "This image is a depiction of the effectiveness of B-12 as a medical treatment. Imagine 100 people received B-12 injections. The blue figures represent participants that would benefit from the B-12 injections. The green figures represent participants who would fail to benefit from the B-12 injections."

In the Icon Array + Negative Anecdote condition, participants received the same information as the Icon Array only condition but were then told they would read about the experience of one of the subjects in the study and an icon array was displayed with one of the participants circled (see Figure 3), clearly indicating that the anecdote was from someone who participated in the clinical trial.

Predictions

We predicted that we would replicate the effect of negative anecdotes on participants' acceptance of strong statistical evidence, as we found in Experiments 1 and 2. We also predicted that in the Icon Array + Negative Anecdote condition, the presence of the icon array would weaken the effect of the negative anecdote (indicating an Icon $\times$ Anecdote interaction).

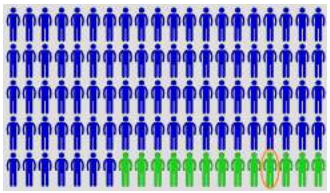

Figure 3: The icon array used in the Icon Array + Negative Anecdote condition in Experiment 3. For the Icon Array only condition, the same array was presented, but without the orange circle.

Results

We fit a Bayesian multivariate regression model regressing B12 attitudes on the interaction between Icon Array (Reference = No Array) and Anecdote (Reference = No Anecdote), controlling for pretest beliefs:

```
mvbind(B12,TryB12,ChildB12) ~
Anecdote*Array + mo(Pretest) +
(1|p|Subject)
```

Experiment 3 - Priors

$\beta_{Intercept[1]} \sim \mathcal{N}(-1.38, .5)$
$\beta_{Intercept[2]} \sim \mathcal{N}(1.09, .5)$
$\beta_{Intercept[3]} \sim \mathcal{N}(2.19, .5)$
$\beta_{Intercept[4]} \sim \mathcal{N}(4.59, .5)$
$\beta_{Pretest} \sim \mathcal{N}(4, 2)$
All remaining β were distributed as $\mathcal{N}(0, 1)$
$\Omega_k \sim LKJ(1)$
Group-level parameters were distributed as $t(3,0,10)$

We replicated the effects of Experiments 1 and 2, showing that a negative anecdote affected participants' integration of statistical information, b_{B12} = −1.49, 95% CI [−1.83, −1.16]; b_{Try} = −1.21, 95% CI [−1.74, −0.70]; b_{Child} = −0.87, 95% CI [−1.31, −0.45]. Consistent with prior work, we also found that providing an icon array improved people's integration of statistical information (b_{B12} = 1.02, 95% CI [0.69, 1.35]; b_{Try} = 0.89, 95% CI [0.39, 1.42]; b_{Child} = 0.86, 95% CI [0.42, 1.30]), but we observed little evidence for an interaction between these factors, b_{B12} = 0.00, 95% CI [−0.46, 0.45]; b_{Try} = −0.10, 95% CI [−0.77, 0.58]; b_{Child} = −0.33, 95% CI [−0.89, 0.24]. These results suggest that the negative anecdote nonetheless impacted people's reasoning even when an icon array was present and removed all ambiguity that the anecdote concerned someone who was in the clinical trial.

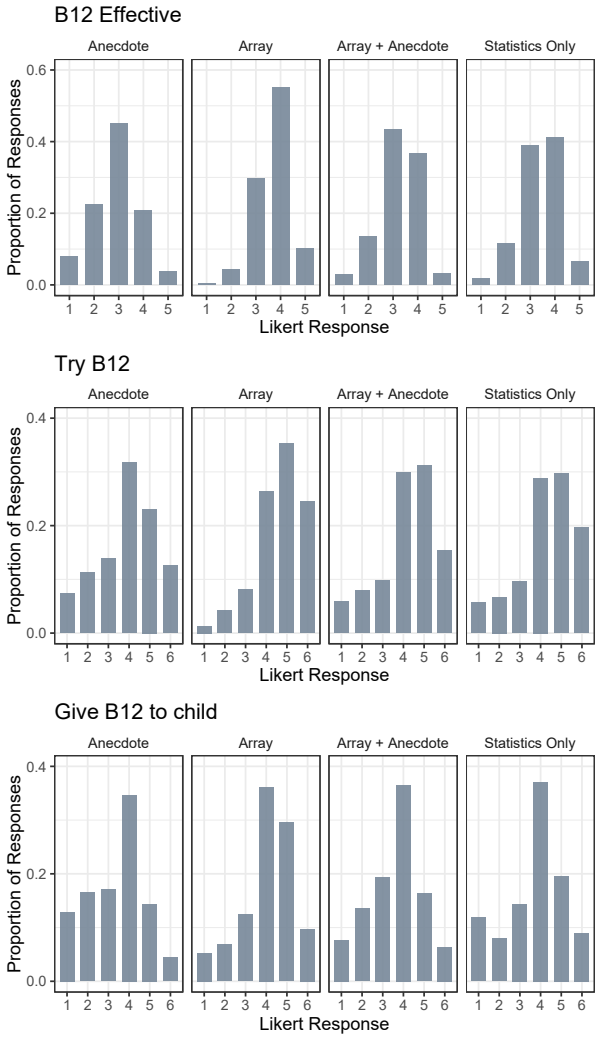

Figure 4: B-12 injection beliefs across conditions in Experiment 3. Higher Likert scale choices indicate more favorable attitudes towards B12 injections. The figure indicates that participants in the Anecdote condition had less favorable attitudes towards B12 injections than participants in the other three conditions.

Discussion

People have access to more medical information than ever before. From journal articles to online forums, people must determine what information is relevant and reliable to make medical decisions. How do people make these decisions? In three experiments, we tested how people reason about a medical treatment when provided with statistical or anecdotal information. In Experiment 1, we found that a negative anecdote caused people to ignore strong statistical information even though the anecdote involved no negative side effects—indeed, the information presented in the anecdote was already captured by the summary statistics presented to participants. In Experiment 2, we explored whether providing a positive anecdote in addition to a negative anecdote would counteract the effect of the negative anecdote. We found that emphasizing a positive outcome of a clinical trial did not consistently undo the effect of the negative anecdote. In Experiment 3, we found that introducing icon arrays improved integration of statistical information overall, but even in this case, anecdotal information negatively impacted people's beliefs. This

suggests that a single negative anecdote can carry substantial, unwarranted weight when making a medical decision.

It is striking that a negative anecdote led people to discount strong summary statistics even though the patient was described as suffering no negative side effects because of their treatment. Indeed, we were careful to describe B-12 injections as failing to benefit people who participated in the clinical trial. In reality, many medical treatments involve an element of risk, and some treatments can even involve severe side effects. In these situations, anecdotes that contain new information and highlight side effects would, if anything, yield a larger negative impact on people's ability to properly integrate statistical information. We can see evidence of these effects today: In 2019, vaccine hesitancy was listed as one of the top ten threats to global health (World Health Organization, 2019). In 2018 only 91.1% (compared to the recommended 95%) of children in the United States who were eligible for vaccines received the MMR (measles, mumps, and rubella) vaccine (Centers for Disease Control and Prevention, 2019). 2018 saw the second-highest number of measles cases since 2000. In part, vaccine hesitancy is a consequence of (1) people relying on discredited research linking vaccines to autism and (2) improper reliance on anecdotal information spread in forums purporting to demonstrate the side effects vaccines can wreak on young children (Powell et al., 2018). Our findings can help us make sense of this tendency. Anecdotes carry more weight than they should, as evidenced by the fact that they affected people's reasoning even when they were captured by summary statistics and involved no side effects, highlighting a serious obstacle to public health and demanding new interventions to overcome people's tendency to rely on anecdotal reasoning more than they should.

Controlling Attention To Solve Working Memory Tasks Using a Memory-Augmented Neural Network

Abstract

We introduce a memory-augmented neural network, called Differentiable Working Memory (DWM), that captures some key aspects of attention in working memory. We tested DWM on a suite of psychology inspired tasks, where the model had to develop a strategy only by processing sequences of inputs and desired outputs. Thanks to novel attention control mechanisms called *bookmarks*, the model was able to rapidly learn a good strategy—generalizing to sequence lengths even two orders of magnitude larger than that used for training—allowing it to retain, ignore or forget information based on its relevance. The behavior of DWM is interpretable and allowed us to analyze its performance on different tasks. Surprisingly, as the training progressed, we observed that in some cases the model was able to discover more than one successful strategy, possibly involving sophisticated use of memory and attention.

Introduction

Keeping information in mind after it is no longer present in the environment is critical for all higher cognitive behaviors. *Working memory* (WM) is the term used for this ability, which is distinct from the storage of vast amount of information in long-term memory (Baddeley, 2003; Oberauer, 2009). The two main distinguishing characteristics of WM are the limited capacity (3-5 items) (Cowan, 2001) and temporary retention (secs-minutes). Hence, WM is not a storage per se, but a mental workspace utilized during planning, reasoning and solving problems. Most psychologists differentiate WM from "short-term" memory because it can involve the manipulation of information rather than being a passive storage (Cowan, 2017). Along the same lines, Engle, Tuholski, Laughlin, and Conway (1999) argued that WM is *all about the capacity for controlled, sustained attention in the face of interference or distraction.* Attention-control is a fundamental component of the WM system and probably the main limiting factor for capacity (Conway & Engle, 1994; Engle & Kane, 2004). Consequently, the inability to effectively parallel process two-attention demanding tasks limits our multitasking performance severely.

Over the past several decades psychologists have developed tests to measure the individual differences in WM capacity and better understand the underlying mechanisms. These tests have been carefully crafted to focus on the specific aspects of WM such as task-driven attention control, interference and capacity limits (Oberauer & Lin, 2017). The best known and successfully applied class of tasks for measuring WM capacity is the "complex span" paradigm. The challenge presented by complex span tasks is recalling the list of items, despite being distracted by the processing task. Studies show that individuals with high WM capacity are less likely to store irrelevant distractors (Vogel, McCollough, & Machizawa, 2005) and they are better at retaining task-relevant information (Maxcey-Richard & Hollingworth, 2013). Developing task-driven strategies for cognitive control are essential for the effective use of WM.

In the past there were several attempts to build computational models that mimic the operation of a human working memory (Henson, 1998; Farrell & Lewandowsky, 2002; Oberauer & Lewandowsky, 2011; Lemaire & Portrat, 2018). For example, Burgess and Hitch (1999, 2005) used a shallow neural network and put the emphasis on Hebbian-like learning rules that enabled the model to achieve similar behavior to the one achieved by human subjects. In those works the experimental paradigm was the serial recall task, which is limited in testing the complex processing and attention component of WM. One notable exception was (Oberauer, Lewandowsky, Farrell, Jarrold, & Greaves, 2012), where the authors focused on the complex span task.

The power of maintaining information over time has also been recognized by the AI community. Starting with the basic recurrent neural network architectures (Elman, 1990; Hopfield & Tank, 1986) followed by the introduction of gating mechanisms (Hochreiter & Schmidhuber, 1997), the research has recently moved onto more complex architectures with memories (Graves, Wayne, & Danihelka, 2014; Joulin & Mikolov, 2015; Weston, Chopra, & Bordes, 2015; Graves et al., 2016; Santoro, Bartunov, Botvinick, Wierstra, & Lillicrap, 2016; Gulcehre, Chandar, & Bengio, 2017). These models are typically applied to tasks (e.g. associative recall, bAbI QA (Weston, Bordes, Chopra, & Mikolov, 2015)) that require a complex mixture of long-term memory (episodic and semantic) and working memory. In the human brain, these kinds of memory systems are distinct: working memory is instantiated in multiple interconnected areas with the prefrontal cortex playing a major role (Constantinidis & Klingberg, 2016), whereas for episodic memory the hippocampus is the critical structure (Fortin, Agster, & Eichenbaum, 2002). Studying these mechanisms separately is necessary to disen-

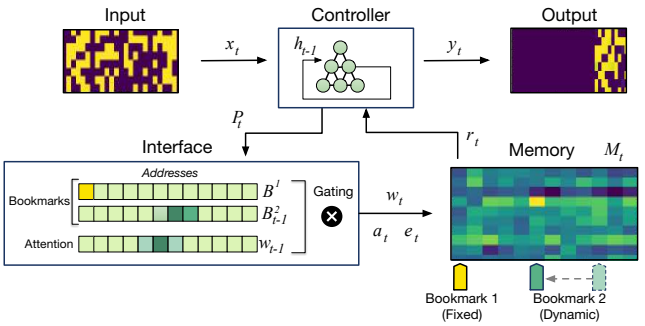

Figure 1: Illustration of the operation of the DWM Model

tangle the contributions of each memory system and develop a detailed understanding of human intelligence.

In this work, we take inspiration from biological and computational models of working memory to develop an *artificial* neural network model augmented with external memory, called *Differentiable Working Memory (DWM)*. We provide the DWM model a set of generic mechanisms to encode inputs, access the memory, and control its attention over the memory contents. Key to this design is a new attention control mechanism in memory, called *bookmarks*, which helps in dealing with interference. In contrast to previous works, we applied our model to a variety of psychometry-inspired tasks, each requiring the system to control its attention in a slightly different way. We show that the DWM is capable of solving these diverse tasks by looking only at input-output pairs using the provided attention mechanisms. The model is easy to train and accurately generalizes to sequences two orders of magnitude longer than the training data. We also describe the strategies that the DWM develops during training and demonstrate that the bookmarks can effectively deal with interference in complex tasks. Finally, we show that the DWM is also capable of learning multiple strategies during training and, moreover, develop better strategies in the presence of memory scarcity.

Differentiable Working Memory (DWM)

The operation of Differentiable Working Memory (DWM) model is presented in Fig. 1. As a memory-augmented neural network (MANN), the DWM has three main components: a *controller*, an *external memory* and an *interface* between the two (Zaremba, Mikolov, Joulin, & Fergus, 2016). The interface is composed of several *attention* mechanisms that the controller learns to use by generating appropriate parameters for accessing the external memory. The procedure is sketched in Algorithm 1. We describe the main steps, Lines 4–7, below in order of significance.

Attention control. The memory consists of N addresses, each storing a vector of real numbers of length L. Thus the memory contents are given by an $L \times N$ matrix of real numbers. The read and write operations share a single attention

Algorithm 1 Operation of Differentiable Working Memory

1: Initialize:
- the hidden state h_0 and memory array M_0
- the read/write attention vector w_0
- bookmarks $\{B_0^i : i = 1,2,\ldots,K\}$

2: **for** $t \in \{1,2,\ldots,T\}$ **do**
3: **Memory read**: $r_t \leftarrow M_{t-1} w_{t-1}$
4: **Controller**: $h_t, P_t \leftarrow \phi(x_t, r_t, h_{t-1})$
5: **Memory update**: $M_t \leftarrow \mathsf{update}(w_{t-1}, P_t, M_{t-1})$
6: **Attention control**: $w_t, \{B_t^i\} = \mathsf{attn}(w_{t-1}, \{B_{t-1}^i\}, P_t)$

mechanism. Further, we use *soft addressing*: let w denote a non-negative weight vector of dimension N whose components sum up to 1. Each component indicates the *relative strength* with which a value (i.e. a vector of dimension L) will be read/written at the corresponding address.

The behavioral studies indicate that people can access memories sequentially (Singh, Tiganj, & Howard, 2018). For that reason we have decided to add a mechanism based on circular convolution, similar to the one used in Neural Turing Machine (NTM) (Graves et al., 2014), enabling it to shift attention over memory:

$$w_t = \text{convolution}(w_t^g, s_t), \tag{1}$$

where w_t^g and w_t are the vectors of attention weights over cells in memory at time t before and after shifting, and s_t is a shift vector outputted by the controller. We also apply a weight sharpening step typically used after the shifting; as we observed, it seemed to be crucial for models using circular convolution to converge properly.

The Embedded-Processes Framework (Cowan, 1988) assumed the presence of Focus of Attention (FOA). In this model the items in the FOA were interpreted as pointers to the representations stored in the long-term memory rather then being the actual representations themselves. Inspired by this concept, we introduced a new attention mechanism called *bookmarks* that store the system's attention at previous time steps. This is recorded in K bookmark vectors $\{B_t^i : i = 1,2,\ldots,K\}$ at time t. The first bookmark $B^1 := B_t^1$ has a time-independent *fixed* attention to a single address so that the model maintains a reference frame for memory. The remaining bookmarks are *dynamic*: at time t, the DWM must decide whether to remember its previous (read/write) attention w_{t-1} by recording it in a bookmark, as:

$$B_t^i = g_t^i w_{t-1} + (1 - g_t^i) B_{t-1}^i, \quad i = 2,3,\ldots K, \tag{2}$$

where the gating parameter g_t^i is emitted by the controller. As discussed later, we found in our experiments that even limiting to only two bookmarks (one *fixed* and one *dynamic*), the model could still solve all tasks.

The DWM must also decide before moving sequentially whether it wishes to return to a previous bookmark. For this

purpose we once again use a gating mechanism, this time in a slightly more sophisticated form:

$$w_t^g = \delta_t^0 w_{t-1} + \sum_{i=1}^{K} \delta_t^i B_{t-1}^i, \tag{3}$$

where $\delta_t^i, i = 1,2,\ldots K$ are gating parameters emitted by the controller. These gating parameters are scalars, normalized using a softmax function.

The DWM attention control incorporates the presented mechanisms by applying equations (3), (2), and (1) in order.

Memory read and update. We use the standard formula for soft attention, e.g., (Weston, Chopra, & Bordes, 2015), that computes the read vector r_t from memory M_{t-1}:

$$r_t = M_{t-1} w_{t-1} \tag{4}$$

For memory update, we decided to use the simple erase-add scheme derived from NTM (Graves et al., 2014):

$$M_t = M_{t-1} \circ (E - e_t \otimes w_t) + a_t \otimes w_t, \tag{5}$$

where E is a matrix of all ones, e_t and a_t are vectors of content to be erased and added to memory, respectively. The parameters e_t and a_t are emitted by the controller.

Controller. The controller's role is to process inputs so as to produce outputs as well as interface parameters. In DWM we use a single-layer recurrent neural network controller:

$$h_t = \sigma(W_h[x_t, h_{t-1}, r_t]), \tag{6}$$

where x_t denotes the current input and h_{t-1} and r_t are the hidden state and vector read from memory in the previous time step, respectively. To prevent the controller from acting as a separate working memory, the hidden state size is chosen to be smaller than that of a single input vector (in all of our experiments it was set to 5). The output logits, y_t and interface vector P_t are produced similarly as:

$$y_t = W_y[x_t, h_{t-1}, r_t] \tag{7}$$

$$P_t = W_P[x_t, h_{t-1}, r_t] \tag{8}$$

W_h, W_y and W_P are the only trainable parameters of our DWM model. The interface vector P_t contains all of the parameters that control reading, writing, and the attention mechanisms. Denoting the unprocessed parameters from the interface with a hat, the full list of parameters in P_t is as follows:

- The write vector $a_t \in \mathbb{R}^{N_M}$
- The erase vector $e_t = \sigma(\hat{e}_t) \in [0,1]^{N_M}$
- The shift vector $s_t = \text{softmax}(\text{softplus}(\hat{s})) \in [0,1]^3$
- The bookmark update gates $g_t^i = \sigma(\hat{g}_t^i) \in [0,1]^{K-1}$
- The attention update gate $\delta_t^i = \text{softmax}(\hat{\delta}_t^i) \in [0,1]^{K+1}$
- The sharpening parameter $\gamma = 1 + \text{softplus}(\hat{\gamma}) \in [1,\infty]$

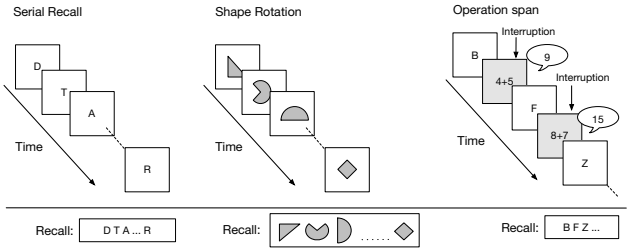

Figure 2: Exemplary tasks for testing the performance of human working memory

Psychometric tasks for working memory

Over last several decades cognitive psychologists have developed many psychometric tests (Conway et al., 2005) to measure the performance of human WM (See Fig. 2 for examples). These tasks are mainly sequential and typically divided into verbal and visuospatial domains. Given that diversity and various categorizations by different researchers, we built a taxonomy of tasks (Fig. 3) and carefully selected tasks that seem to be the most representative for a given category. First order categorization is based on the number and complexity of tasks. For simple tasks, the presence of data manipulation is the next level sub-category, with Serial Recall being a prime example of a task without manipulation. The tasks requiring manipulation we further categorized into spatial and temporal domains. The complex tasks involve multiple sequential inputs or sub-tasks but not necessarily imply "multi-tasking". We follow the framework of Clapp, Rubens, and Gazzaley (2009) to distinguish the sources of goal interference, i.e. Distraction (to-be-ignored) and Interruption (i.e. multi-tasking). For example, in Operation Span (Fig. 2c) the subjects had to attend and process the summation (Interruption) even though they did not need to recall the results afterwards, whereas in Reading Span (Daneman & Carpenter, 1980) subjects had to read sentences and recall the last word of each one. In addition to the classical psychometric tasks, we introduced several tasks testing the effectiveness of attention control in memory (Ignore, Forget and Scratch Pad). As a result, a suite of tasks presented in Table 1 emerged.

The input to every task is a sequence of items. As we wanted to be agnostic to audio/visual preprocessing, we have implemented those tasks using sequences of randomly generated *binary patterns* (vectors of bits) as items (instead of words/images). At a higher level, we view the input as a *concatenation* of various subsequences that represent different functional units of processing. For all simple tasks, there is only one type of subsequence, and the output will be reproduced from the memory with or without manipulation. The complex tasks may involve a secondary set of subsequences, optionally requiring immediate output as indicated in the Forget and Operation Span tasks.

Additionally, we use a constant-sized set of special items (called *command markers*) to both mark the beginning of a subsequence as well as indicate its functional type. It is im-

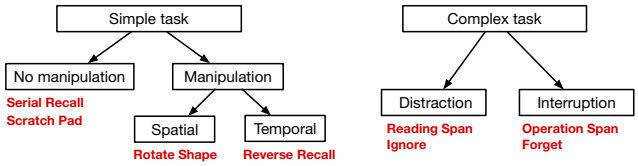

Figure 3: Taxonomy of working memory tasks

portant to note that the system does not know a priori what kind of operation is associated with a given type of marker and must learn that from data. We ignored markers in Table 1 to keep the description simple. Also, note that such markers are also commonly employed in the psychometric tests, e.g., see McNab and Klingberg (2008).

Experimental results

We evaluated the performance of DWM on the proposed tasks and compared it to two models: LSTM (Long Short-Term Memory) (Hochreiter & Schmidhuber, 1997), considered as a classical baseline for sequential problems, and DNC (Differentiable Neural Computer) (Graves et al., 2016) being one of the state-of-the-art MANN models. In our implementation we used the MI-Prometheus (Kornuta et al., 2018) framework built on top of PyTorch (Paszke et al., 2017). During training we used the Adam (Adaptive Momentum) optimizer (Kingma & Ba, 2014) and (average) binary cross-entropy as the loss function. We apply early stopping based on validation loss (10^{-4}). Additionally, we terminate training when the number of training episodes reach 100,000 where a single episode involves processing a batch of sequences. The size of batch was a hyper-parameter that was tuned along with training rate for each model using validation loss as the reference.

	Task		(I)input/(O)output sequences	
Simple	Serial Recall	I:	$x_1 x_2 \ldots x_n$	$\_\_\ldots\_$
		O:	$\_\_\ldots\_$	$x_1 x_2 \ldots x_n$
	Scratch Pad	I:	$\mathbf{x}_1 \mathbf{x}_2 \ldots \mathbf{x}_k$	$\_$
		O:	$\_\_\ldots\_$	$\mathbf{x}_k$
	Reverse Recall	I:	$x_1 x_2 \ldots x_n$	$\_\_\ldots\_$

Table 2: Summary of experimental results. The first column is the average of validation accuracies achieved by the models for 10 training runs on each task. The second column is the average of test accuracies achieved by models that converged during training. For the majority of tasks, the DNC and LSTM models did not converge. In those cases (indicated with *) we report scores of the best (even though diverged) model.

As stated in the introduction, the main question we wanted to answer was whether a model can learn an algorithm to solve a task. In case of tasks presented in Table 1, this implies that the model should generalize over the sequence lengths. For that reason, our methodology assumed that we will use different lengths of sequences for training (up to 10), validation (exactly 100) and testing (exactly 1000). Although human WM does not have the capacity to handle 1000 items, our goal was to show that the model truly generalizes in that actually develops an effective memory strategy, i.e., it learns an algorithm to solve the task.

All models achieved perfect accuracies on training sequences. However, as presented in Table 2, LSTM and DNC struggled with generalization to longer sequences. Besides, the DWM models converged faster, requiring less than 5000 episodes in most cases (exemplary convergence plot is presented in Fig. 4). The convergence speed is associated with number of trainable parameters of those models (the DWM controller had 1066, the DNC had 4,792, whereas for LSTM baseline we used stacked LSTM with 3 layers and over 5 million trainable weights). Please note that *fair comparison* simply made no sense, as the LSTM and DNC models with less trainable parameters could not even learn to generalize over short (i.e. training) sequences. Aside of that, we hypothesize that the DNC had problems with convergence because of the

complexity of its attention and memory management mechanisms (the *Temporal Link Matrix*, in particular).

Analysis of strategies for solving tasks

The proposed tasks require the models to develop different strategies for solving them. For example, ignoring distractions without encoding them in the memory is arguably the best strategy to minimize memory consumption. On the other hand, for a complex task with an interruption (i.e. multitasking), the secondary task cannot be ignored and may require extensive memory usage. In this case, the best strategy might be to forget (e.g. erase or overwrite) the secondary information as soon as possible in order to maintain sufficient memory capacity for the main task.

During the training and testing of all of the tasks reported in Table 2 we provided sufficient memory size, so that the system could store all the encoded input items in the memory (if it has chosen to). However, limitation of the memory size can force the system to develop more memory efficient strategies, thus we decided to investigate that issue further.

Strategies for the Scratch Pad task The goal of the Scratch Pad task is to recall only the last input subsequence.

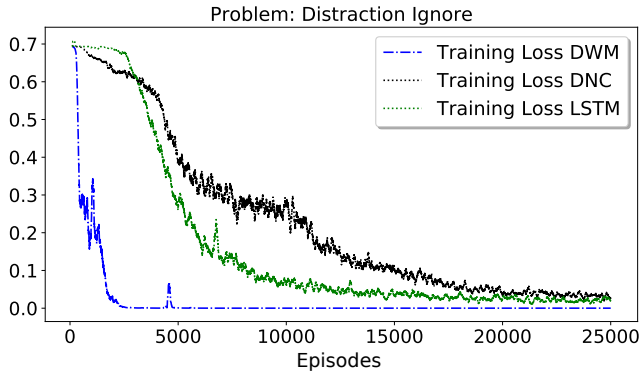

Figure 4: Convergence of the best models on Ignore task

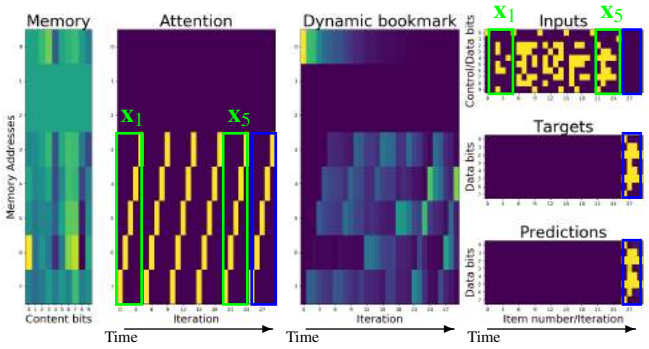

Figure 5: Overwrite strategy developed by DWM for Scratch Pad (episode 969). Memory plot contains a snapshot of the memory content from the last iteration, whereas the other ones present concatenation of states from consecutive iterations (evolution in time)

Given the DWM mechanisms, we expect two possible strategies for the model to learn in order to solve this task.

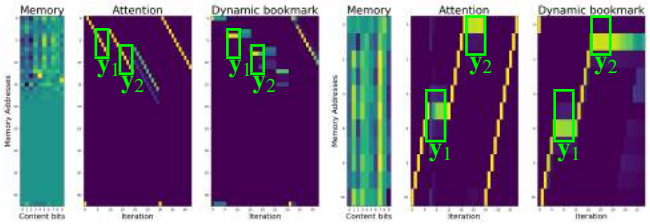
The "Expand" strategy exploits the fact that memory can be used in a similar way to a circular buffer, storing each consecutive subsequences one after the other in the memory. In this case the model should write each subsequence, then place the *dynamic bookmark* at the start of given subsequence, and then update the bookmark position to the beginning of the next subsequence. Finally, when the model receives a command marker indicating it needs to recall, it should recall the attention associated with that *dynamic bookmark* and then retrieve consecutive items one by one by shifting.

The "Overwrite" strategy for the Scratch Pad relies on the fact that when a new subsequence appears, the elements from the previous one can be discarded. The model could exploit this by learning to recall attention stored in the *fixed bookmark* every time it processes a command marker denoting the next subsequence, which will result in overwriting the previous subsequences until the system is told to recall. This strategy may be interpreted as memory saving, as the system reuses the same addresses and overwrites them repeatedly.

To our (initial) surprise, the model *always* developed the Overwrite strategy, irrespective of the memory size (i.e. as long as the memory size was sufficient to fit all the encoded items of a single subsequence). An exemplary run of an early training episode is presented in Fig. 5. Note that memory addresses 1 and 2 remain unchanged and the model stores consecutive items of subsequences $\mathbf{x}_1$ to $\mathbf{x}_5$ in the same addresses 3-7. After analyzing several runs, we hypothesize that overwriting was simpler to learn for this task because: a) both for storing and recalling the command markers, the model had to learn exactly the same behavior: recalling the attention stored in the *fixed bookmark*, b) for every other input item it had to shift by one address location with the circular convolution. As a result, it could converge rapidly by disregarding the control (update, recalling) of the *dynamic bookmark* (in the later training episodes the *dynamic bookmark* was typically "following" the current attention, despite it wasn't recalled at all).

Strategies for the Ignore task The main goal of the Ignore task is to test the retention capabilities of the system in the presence of distractors. For this task the input consists of two types of subsequences $\mathbf{x}$ and $\mathbf{y}$, where the system is supposed to ignore all $\mathbf{y}_i$ and at the end recall $\mathbf{x}_i$ one by one in the order of their appearance. The task can be solved with two strategies which we call "Overwrite" and "Skip".

The "Overwrite" strategy involves overwriting of the distractors, similarly to the "Overwrite" from Scratch Pad task. It assumes that model will store the consecutive items in memory and use the bookmark for moving its attention to the first address containing $\mathbf{y}$ to be overwritten. The difference is, however, that in here the model must learn to use the *dynamic bookmark* for that purpose. Our experiments with sufficient memory have shown that the system can learn this strategy. Exemplary plot from one of the final training episodes (Fig. 6a) shows that the *dynamic bookmark* re-



(a) Overwrite strategy (episode 17000)

(b) Skip strategy (limited memory, episode 5614)

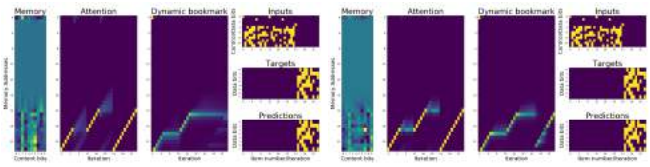
Figure 6: Strategies developed by DWM for solving the Ignore task (two different training runs)

tains its attention while processing items from $\mathbf{y}_1$ and $\mathbf{y}_2$. As soon as the command marker indicating $\mathbf{x}$ appears, the model jumps back its attention to the *dynamic bookmark* and starts to overwrite memory content. Finally, when the recall marker appears, it recalls the attention stored in the *fixed bookmark*.

The "Skip" strategy involves ignoring elements within the $\mathbf{y}$ subsequences, i.e. *skipping* writing them to memory. Our experiments with limited memory have shown that the model could also learn this strategy. Exemplary plots from the final episode from one of the training runs are presented in Fig. 6b. Note that in this case the model has learned to keep its attention focused on a single address for all items of $\mathbf{y}_i$ and shift attention only for items belonging to $\mathbf{x}_i$.

That behavior of the model that mastered the "Skip" strategy seems to be more difficult from the operational point of view. In the "Overwrite" strategy the system develops a reactive behavior, i.e. it always performs convolutional shift except for the rare cases when it hits the command marker – at that point it has to retrieve attention from one or the other bookmark. In the "Skip" strategy the command markers for $\mathbf{x}$ and $\mathbf{y}$ activate one of two distinct operation modes that will be executed for the whole subsequence until hitting the next marker, i.e. for $\mathbf{x}$ attention is supposed to move to the next address, whereas for $\mathbf{y}$ it is supposed to stay at the same position. The only way to perform this is that the controller must learn how to *carry the information about the current operation mode* from one iteration to another in its hidden state, which is more difficult to learn.

We performed several experiments to support that hypothesis. In Fig. 7 we present two episodes from one of the training runs when the operation of the system seems to be evolving from one strategy to the other. At the early stages of the training (Fig. 7a) we can observe that the attention shift with the circular convolution is active for both types of input subsequences, whereas the dynamic bookmark already learned how to *follow* attention for $\mathbf{x}$ and *freeze* for $\mathbf{y}$. As learning to shift attention is crucial for learning both storing and recall, model has to master that first. However, once achieved, it seems to switch to different operation mode. Obviously, learning two modes is simpler for *dynamic bookmark*, as it possesses simpler gating mechanism and cannot shift its attention. As the training progresses (Fig. 7b) the model finally learns to freeze its attention when processing $\mathbf{y}$ subsequences.



(a) episode 1757: utilization of Overwrite strategy

(b) episode 17685: utilization of Skip strategy

Figure 7: Evolution of the strategy developed by DWM, when learning the Ignore task (during a single training run, intentionally used the same verification sequence in both cases)

Conclusion

We have demonstrated that DWM has the appropriate attention mechanisms to tackle psychology-inspired tasks. When compared to existing models such as DNC, LSTM it appeared to manage generalization to much longer sequences. Besides, after careful step-by-step analysis we discovered that the model is able to develop more than one strategy to control attention and use its memory resources for a given task. While some strategies are harder to learn, DWM can develop them by first finding *any* working strategy and then gradually modifying it towards a different one as learning progresses. Why the model seems to prefer some strategies is intriguing and worth further investigation. Another direction is to incorporate this mechanism into a larger system in order to solve tasks that require both working and long-term memory.

Pedagogical Questions Empower Exploration

[2] National Institute of Education, Singapore

Abstract

Children are motivated to explore and learn about the world, but they vary in their degree of perseverance during exploration. A growing body of literature suggests that is malleable from an early age. Here, we ask whether pedagogical questions empower children to persevere during a difficult problem-solving task with a blicket detector machine. Previous research has shown that when presented with a blicket detector, asking children "pedagogical questions" promotes more exploratory behaviors compared to direct instruction. A pedagogical question is a question asked by a knowledgeable person, whose intention is to teach rather than to seek an answer to that question. The current study examines whether pedagogical questions influence the amount of time children spend problem-solving before seeking help, compared to direct instruction, overheard pedagogical questions, and overheard questions asked by a naive other. We predicted that children who were asked a pedagogical question prior to having the opportunity to play with a machine would persevere longer in trying to make it work, and would be less likely to ask for help. Results suggest that pedagogical questioning encourages children to attempt more hypothesis-test interventions in an effort to make the machine work. Results will be discussed in terms of the role of pedagogical questioning in promoting perseverance during problem-solving.

Keywords: pedagogy; pedagogical question; perseverance

Introduction

Young children are curious and creative problem-solvers. They are motivated to explore and learn about how things work, why they work, and, if necessary, how to fix them. However, there is a great deal of variation in children's perseverance during problem solving, and this characteristic is malleable. Children's perseverance during exploration is likely influenced by a number of factors, including the nature of their interactions with adults. For example, children are more likely to persevere during a difficult task after watching an adult model persevere (Leonard, Lee, & Schulz, 2017). Here, we investigate the particular qualities of adult instruction that may promote children's perseverance during exploration and learning.

Previous research suggests that when children are faced with a difficult task, they rely on their interactions with and observations of adults to guide their exploration and problem solving efforts. For example, preschool-aged children readily detect and utilize pedagogical cues (e.g., the teacher's knowledgeability; the intentionality of the teacher's demonstration; the social context of the learning scenario; etc.) to guide deductive reasoning, exploration, and learning about the world (Bonawitz, Shafto et al., 2011; Buchsbaum, Gopnik, Griffiths, & Shafto, 2011; Butler & Markman, 2014). For example, in Bonawitz, Shafto et al. (2011) children were assigned to one of a few conditions that differed in the social presentation of information. In the Pedagogical condition, a knowledgeable and helpful adult demonstrated one function on a complex-looking toy. After this, children were presented with the toy and allowed to explore. The Pedagogical condition was contrasted with several other conditions including an Accidental condition in which a naive demonstrator accidentally elicited the function, and an Interrupted condition in which the demonstrator was interrupted before it was clear they were completed. Results showed that children in the Pedagogical condition explored less than children in the other conditions, consistent with the explanation that the pedagogical demonstrations lead to high confidence that there was little to be learned beyond the demonstrated function.

Thus, children rely on adults' pedagogical cues to guide learning. What are the particular qualities of these cues that might be most relevant to perseverance during exploration? One pedagogical tool whose efficacy has been of particular interest as of late is *pedagogical questioning*. A pedagogical question is a question asked by a knowledgeable person, whose intention is to teach rather than to seek an answer to that question. Recent research indicates that pedagogical questioning yields effective knowledge transmission, while also promoting exploration (Yu, Landrum, Bonawitz, & Shafto, 2018). This is in contrast to *direct instruction*, another common pedagogical tool. In direct instruction, information is communicated directly from a knowledgeable teacher to a naïve learner. Past research shows that while direct instruction is beneficial for sharing information, this can come at the expense of children's subsequent exploratory learning (Bonawitz & Shafto et al., 2011). This is likely due to the expectation that is often brought into pedagogical learning scenarios that good teachers should provide all the necessary evidence for the learner to be able to solve the problem (Shafto & Goodman, 2008). However, these implications for exploration appear not to be induced by pedagogical questioning. For instance, in Yu et al. (2018), children were shown a novel toy, which had many possible functions, and were told that the experimenter knows all about the toy and how it works. In the direct

instruction (DI) condition, the experimenter told children to push the button on the novel toy; in the pedagogical question (PQ) condition, children were asked to think about "what does this button do?" While children were equally likely to discover the key function (i.e., the button) in both conditions, children also spent longer playing with the toy and discovered more additional functions in the PQ condition (Yu et al., 2018). These results support the claim that pedagogical questions empower children to engage in exploratory behaviors, while direct instruction may constrain exploration.

One limitation of this study however, is that children in both the PQ and DI conditions were at ceiling in their ability to discover the target function of the toy, so it is difficult to assess the extent to which pedagogical questions might differentially influence the pursuit of learning about queried information. In other words, when children are tasked with a simple problem, which was readily solvable (the button immediately generated the effect), it was not possible to explore the potentially different influence of PQs and DI on persistence for learning *targeted information.* Of course, once the goal was complete (in this case discovering the buttons function), it remained important to ask what next steps children would take with the toy. In Yu's paper, children in the PQ condition then went on to discover significantly more functions of the toy as compared to the DI condition, providing important insights into the power of PQs in supporting longer term exploration. Nonetheless, it remains unclear if pedagogical questions also empower children to persevere and engage in exploratory behaviors in service of the queried information. The current study addressed this question by presenting children with a more challenging problem (i.e., an unsolvable problem). Children were tasked with discovering how to make a (deactivated) blicket detector machine work, a procedure inspired by past literature (Gweon & Schulz, 2011).

We hypothesized that that pedagogical questions might promote persistence in problem-solving during a difficult task for a few reasons. First, pedagogical questions that are directed to the child may empower them to feel as though the expectation is that they can figure the machine out on their own, rather than having to seek help from an adult. That is, by asking "what do you think?" a Pedagogical Question could imply that the questioner believes the child can discover the answer. Second, pedagogical questions may encourage children to engage in exploratory behaviors during a difficult problem-solving task because questions do not limit the number or nature of potential solutions to the problem at hand. In contrast, direct instruction may hinder children's creative exploration of potential solutions by "over focusing" children in on the directed content.

One alternative to the claim that pedagogy is the driving factor behind pedagogical questions, is the possibility that *any* kind of question might lead to greater perseverance. In order to control for this possibility, we included a condition in which children overheard a *naive* confederate asking a question to an experimenter (Overheard Naive Question condition; ONQ). In this way, the exact language of the question is matched, but the crucial difference is that in the ONQ condition, the question-asker was not knowledgeable (i.e., was known by the child to have no knowledge of how to make the machine work), where as in the PQ condition, the question-asker was knowledgeable. A person who does not know the answer is not naturally thought of as a having the goal of teaching the outcome because they do not know the outcome. Thus, in the current study, any potential effects could be attributed to the pedagogical nature of the question, and not just the question itself.

Another alternative to the claim that pedagogy is the driving factor behind pedagogical questions, is the idea that any pedagogical question, no matter who it is being directed to, might promote greater perseverance. In order to control for this possibility, we included another condition in which children overheard an experimenter asking a pedagogical question to a confederate (Overheard Pedagogical Question; OPQ). In this way, the exact language of the pedagogical question is matched, but the pedagogical question is not child-directed This condition allows us to isolate the influence of the child-directed nature of the pedagogical question asked in the PQ condition form the mere influence of overhearing a pedagogical question as in the OPQ condition. . Although pedagogical questions have been found to promote exploratory behaviors in children, these questions may only influence exploration if they are child-directed.

Thus, we hypothesized that pedagogical questions, compared to direct instruction and overheard naive questions, would encourage children to persevere and play with the machine longer before seeking help than children in the DI, OPQ, and ONQ conditions, although we expect no condition differences in the amount of time it takes children to recognize that there is something wrong with the machine. We might expect that pedagogical questions promote perseverance in problem-solving during a difficult task for a few reasons. First, pedagogical questions may empower children to feel as though the expectation is that they can figure the machine out on their own, rather than having to seek help from an adult (i.e., the experimenter). The amount of time the child spends engaging with the machine before reaching out for help and the number of hypothesis tests the child performs during exploration could make this claim evident. Second, pedagogical questions may encourage children to engage in meaningful exploratory behaviors during a difficult problem-solving task because questions do not limit the number or nature of potential solutions to the problem at hand. The number of unique actions and the variability in the nature of hypothesis tests performed on the toy could make this claim evident. In contrast, DI may hinder children's creative exploration of potential solutions. We also predicted that children in all conditions would be equally quick to notice that something was wrong with the machine. The time to first look could make this claim evident.

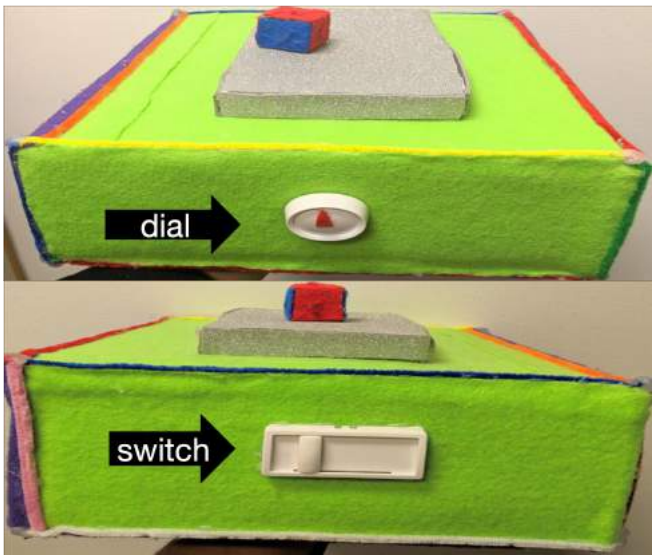

Figure 1. Blicket detector machine used by children in the experiment. The switch and dial "sliders" are highlighted. Another feature of the machine is the platform on the top of the machine. The multicolored block is the accessory that appears to activate the machine when placed on the platform, even though it's the remote control transmitter that's actually activating the machine.

Method

Participants

Participants were 100 4- to 6-year-old children (M_{age} = 57.91 months, *SD* = 6.62 months; Range = 48.26 - 78.77 months, 53% female) recruited from preschools and public sites located in Essex County, New Jersey, one of the most racially and socioeconomically diverse counties in the United States. Prior to the study, consent from the sites, participating families, and the Rutgers University - Newark internal review board were obtained. Based on a power analysis, and as preregistered[1], we recruited 25 children per condition. Children were only included in the final sample if they met the following criteria: 1) English was their primary language, and 2) there was no outside interference during the testing session. Participants were randomly assigned to one of four conditions: Pedagogical Question (PQ); Overheard Pedagogical Question (OPQ), and Overheard Naïve Question (ONQ), and Direct Instruction (DI). Age was matched across conditions.

Materials

A novel "blicket detector" machine that was approximately 13.25'' X 10.5'' X 5'' with a switch on one side and a dial on the other was created (Figure 1). A wireless doorbell receiver hidden inside the machine produced a C major arpeggio when the experimenter surreptitiously pressed the button on the remote control transmitter which connected to the wireless doorbell. The switch and dial "sliders" on either side of the machine were inert. There was also a multi-colored block whose sole purpose was to "activate" the machine when placed on a shiny platform on top.

Procedure

Children were introduced to the machine by the experimenter and told that "the way the toys works is, the way the toy works is, when the block is on the platform and the toy is all set up right, the toy goes". In all conditions, a confederate was seated next to the child during the introduction to the machine and the demonstration of its use. In the PQ and DI conditions, the experimenter first demonstrated directly to the child how the block can activate the machine (but did not show whether, and which of, the switch and the dial should be positioned for it to work.) The experimenter then showed the machine separately to the confederate in another location in the room, so that the child could not see what was being changed on the machine. In the OPQ and ONQ conditions, the child also observed the block activating the machine (but was not shown the role of the switch or dial like in the PQ and DI conditions), however in the OPQ and ONQ conditions, the confederate did not observe the role of the switch and dial. Specifically, the experimenter walked away from the child and confederate to a corner of the room to activate the machine while verifying with the confederate that they cannot see what the experimenter was doing with the machine. Thus, in the OPQ and ONQ conditions, the confederate was never shown how the machine worked with respect to the switch and dial. In all four conditions, the experimenter explained that something about the machine had been changed so that now the block would not activate the machine.

Critically, the prompt given to the child prior to the free play period varied by condition. In the PQ condition, the experimenter asked the child, "what happens if you change *these sliders?*" while moving the sliders (the switch and dial) on either side of the machine. In the DI condition, the experimenter instructed the child by telling them to "change *these sliders* to see what happens" while moving the sliders. In the OPQ condition, the experimenter asked the confederate, "what happens if you change *these sliders?*" while moving the sliders, controlling for the pedagogical nature of the question. In the ONQ condition, the confederate picked up the machine and asked the experimenter, "what happens if you change *these sliders?*" while moving the sliders, controlling for children's awareness of a knowledgeable other by having the confederate ignorant to how the machine works. Immediately, following these prompts, children engaged in a free play period described below.

Free Play

The child was then given five min to play with the machine and was informed that the confederate would be there if they needed anything. Specifically, children in all conditions

[1] Link to preregistration: https://aspredicted.org/j3ah7.pdf

were told, "You can go ahead and play with this. I have to go over there to write something down for a couple minutes, but [confederate's name] will be here if you need anything!" Then,the experimenter sat behind the child (out of sight) and pretended to write, while the confederate sat next to the child and pretended to read a book. During this play period, the machine would not activate at all, regardless of whether the child followed the experimenters' instructions or suggestions. Playtime was ended once one of the following occurred: five minutes elapsed, the child verbally requested help, the child did not interact with the machine for 15 consecutive s twice in a row, or the child asked to stop playing. All sessions were video-recorded.

Outcome Measures

All videos were coded by a trained coder for three outcome measures: (1) time to first look, (2) time before help-seeking, (3) number of unique actions, (4) number of hypothesis-test interventions and (5) variability of hypothesis-test interventions.

Time to first look The time to first look was the amount of time the child spent attempting to activate the machine before looking at the confederate or experimenter for the first time.

Time Before Help-seeking The time to help-seeking was the amount of time child spent attempting to activate the toy on their own before verbally requesting help from either the confederate or the experimenter.

Number of hypothesis tests (Perseverance) The number of hypothesis tests was the number of times a child performed any other intervention on the machine that may involve the traditional use of the switch or dial "sliders" right before attempting activation with the block on the machine. An intervention required a manipulation of some factor of the toy or block and critically an attempted activation that immediately followed whereby the child placed the block on the machine.

Number of unique actions The number of unique actions was the number of unique manipulations to the machine that did not involve the traditional use of the switch or dial "sliders."

Variability of hypotheses tested The variability of hypotheses tested was the number of unique hypothesis-tests performed on the machine. For example, if the child tried adjusting the dial and then placed the block on the activator, that would count as a single hypothesis test. However, a second manipulation of the same dial with a following block test would not count as a unique intervention and so would not additionally increase the total variability score beyond the initial attempt.

Table 1
Unique Actions

Unique Actions		
Placing the multicolored block on the platform	Placing the block and/or hand inside the toy	Flicking the block on top of the platform
Changing the colored side of the block to a different color	Removing the dial "slider" from the toy	Placing another toy/object on top of the platform
Placing the block on other parts of the toy	Removing the switch "slider" from the toy	Rolling the block like a dice
Moving the block on the platform without lifting up the block	Switching the tune of the toy by pressing the battery inside the toy	Placing the block on 4 corners of the platform
Rubbing the block on the shiny platform of the toy	Placing the switch "slider" on the platform of the toy	Lifting up the shiny platform foam paper
Lifting the toy up	Placing the dial "slider" on the platform of the toy	Shaking the toy
Placing the toy on its side	Playing with the block itself	Shaking the block
Putting the toy upside down	Touching the hot glue gun balls on a corner of the toy	

Results

Time to first look. Our first question concerned whether children were equally likely to visually "check-in" with the adults during the free play period. The rationale for this measure was that we hypothesized children might initially look to the confederate or experimenter when it became apparent that the machine was no longer activating as expected. Indeed, in all four conditions, on average, children looked to an adult within the first minute of play (PQ: 25 s; DI: 44 s; OPQ: 27 s; ONQ: 26 s), and there were no significant differences in the total amount of time before this first look, $F(3, 96) = 1.12$, $p = .347$, suggesting that children were equally capable of detecting the activation issue across conditions.

Overall time playing. Our second question pertained to whether children would stop playing with the toy earlier in the DI, OPQ and ONQ conditions. We hypothesized that children in the PQ condition might play with the machine longer than children in the DI, OPQ, and ONQ conditions based on previous research (Yu et al., 2018), in which children explored the novel (functioning) machine longer in the Pedagogical Question condition. However, we observed no significant differences between conditions in the amount of time children spent playing with the machine, $F(3, 96) = 2.53$, $p = .062$, indicating that children in all conditions played with the machine for approximately the same amount of time ($M_{PQ} = 240.72$; $SD_{PQ} = 95.78$; $M_{DI} = 188.16$; $SD_{DI} = 106.13$; $M_{OPQ} = 205.56$; $SD_{OPQ} = 112.03$; $M_{ONQ} = 159.52$; $SD_{ONQ} = 112.32$). However, the trend here for children to play longer in the PQ conditions is suggestive.

Number of hypothesis tests (Perseverance) Third, we asked whether the number of hypothesis-test interventions during children's play differed significantly between conditions. Specifically, if Pedagogical Questions both empower children to pursue a relevant learning goal (in this case to discern why the machine is failing to activate) in the face of repeated failure then we would expect children in the

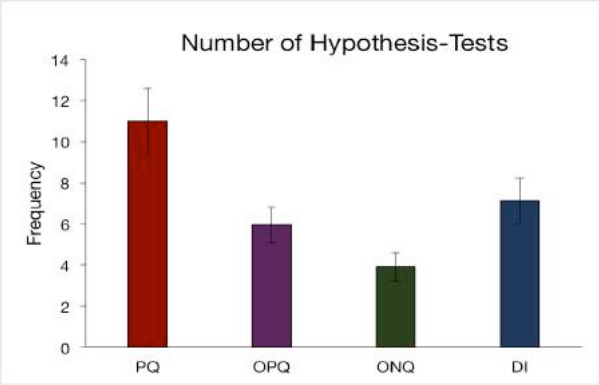

Figure 2. Children in the Pedagogical Question condition performed significantly more hypothesis tests during the play period than children in the Overheard Pedagogical Question, the Overheard Naive Question, and the Direct Instruction conditions.

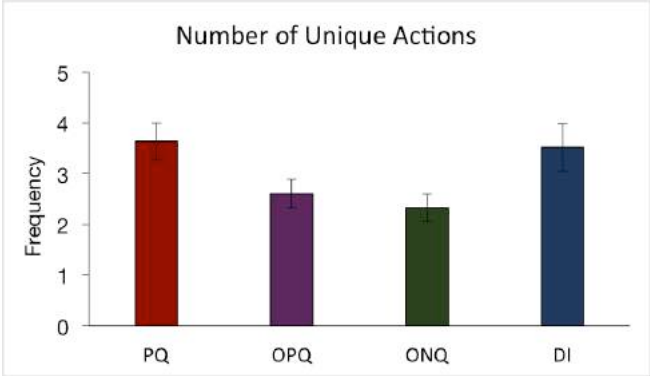

Figure 3. Children in the Pedagogical Question and Direct Instruction conditions performed significantly more unique actions during the play period than children in the Overheard Pedagogical Question and the Overheard Naive Question conditions.

PQ condition to perform more interventions on the machine. Indeed, the number of hypotheses tested significantly differed across conditions, $F(3, 96) = 7.03$, $p < .001$. Specifically, planned contrasts1 revealed that children in the PQ condition conducted significantly more hypothesis tests ($M = 11.00$; SD = 8.00) than children in the DI condition ($M = 7.12$; SD = 7.12), OPQ condition ($M = 5.96$; SD = 4.36) and ONQ condition ($M = 3.92$; SD = 3.49). There was no difference in the number of hypothesis tests between the children in the DI condition and children in the OPQ condition, $p = .417$, and there was no difference in the number of hypothesis tests between the children in the OPQ and ONQ conditions, $p = .074$. Thus, even though on average, children in all conditions were equally quick to notice something was wrong with the machine, and played with the machine for approximately the same amount of time, children in the PQ condition engaged in more hypothesis testing during this time, suggesting that PQs might both empower children to persevere in their exploratory causal testing attempts during play.

Number of unique actions Next, we asked if children were more likely to explore more different features of the machine overall depending on the type of instruction they were given. By virtue of pedagogical questions being questions, the variability in children's exploratory actions is not limited, leading us to predict children to show more variable exploration in the three question conditions. There were significant differences in the number of unique actions by condition, $F(3, 96) = 3.36$, $p = .022$. Planned contrasts revealed that children in the PQ ($M = 3.64$; $SD = 1.85$) and DI ($M = 3.52$; $SD = 2.37$) conditions performed more unique actions than children in the OPQ ($M = 2.60$; $SD = 1.44$) and ONQ ($M = 2.32$; $SD = 1.35$) conditions, $p = .003$. There were no significant differences in the number of unique actions between the PQ and DI conditions, $p = .842$, and there were no significant differences in the number of unique actions between the OPQ and ONQ conditions, $p = .481$. Contrary to our hypothesis, this suggests that the *child-directed* nature of pedagogical questions (and direct instruction), rather than the inquisitive nature of the input appears to promote variability during play. However, given that there were relatively few actions that might be attempted with the toy (unlike the Yu et al, 2018 novel toy study), this result should be interpreted with caution.

Variability of hypotheses tested Finally, we asked whether the variability of hypotheses tested specifically during children's play differed significantly between conditions. That is, if pedagogical questions both empower the pursuit of a relevant learning goal (in this case to discern why the machine is failing to activate), then we would expect children in the PQ condition to perform more different types of interventions on the machine. Overall, the number of different hypotheses tested significantly differed across conditions, $F(3, 96) = 4.08$, $p = .009$. Specifically, children in the PQ ($M = 2.28$; $SD = 1.21$) and DI ($M = 2.08$; $SD = 1.12$) conditions performed more variable hypothesis-tests than children in the OPQ ($M = 1.52$; $SD = .77$) and ONQ ($M = 1.52$; $SD = .65$) conditions, $p = .001$. There was no difference in the variability of hypothesis tests between the PQ and DI conditions, p = .546, and there was no difference in the variability of hypothesis tests between the OPQ and the ONQ conditions, p = .999 Again, *child-directed* conditions led to more variable exploration during play time.

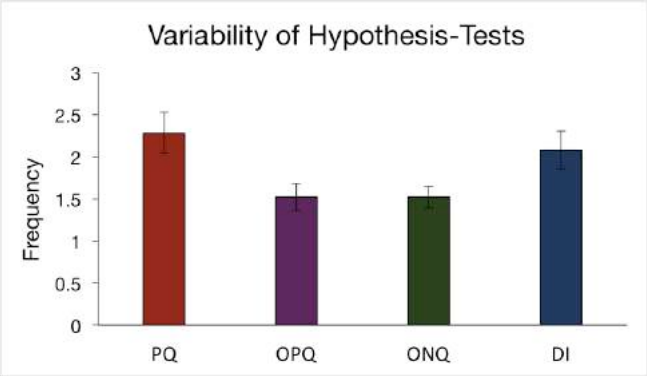

Figure 4. Children in the Pedagogical Question and Direct Instruction conditions demonstrated significantly more variability in their hypothesis tests during the play period than children in the Overheard Pedagogical Question and the Overheard Naive Question conditions.

Discussion

This study examined the effect of Pedagogical Questions on young children's perseverance during a difficult problem-solving task. First, we found that children in all conditions were equally likely to visually check-in with the adults during the free play period, thus children are equally quick to recognize that the machine was not functioning as expected. Second, we found that there were no differences in how long children played with the machine before reaching out for help. Despite recognizing a problem with the machine at equal rates and spending the same amount of time playing with the machine, , children in the PQ condition performed significantly more hypothesis tests, suggesting that prompting children with a Pedagogical Question may lead to their independently persevering through more failed attempts at problem solving before looking to others for help. Our results point to both the pedagogical nature of the question (rather than this effect being about questioning generally) as children in the ONQ condition demonstrated significantly fewer hypothesis tests prior to turning for help, and the child-directed nature of the question as children in the OPQ condition demonstrated significantly fewer hypothesis tests. Additionally, two surprising, but interesting findings indicate that when it came to promoting more variable exploration, as measured by the number of unique actions and the variability in hypothesis tests, the child-directed nature of the pedagogical input was crucial, as children in the two child-directed conditions(PQ and DI) demonstrated more variability during play time.s.

This study extends our understanding of the role of Pedagogical Questions in the preschool years by examining how pedagogical questions affect perseverance and variability during exploration when children are presented with a difficult problem. In the current study, there was a more obvious and specific goal for learners in contrast to Yu et al. (2018), which examined what additional, unbounded exploration children pursued after the initial goal was quickly completed. Classic debates contrast instruction with exploration in terms of their ability to foster learning (Bruner, Jolly, & Sylva, 1976; Csibra & Gergeley, 2009; Piaget, 1929; Singer, Golinkoff, & Hirsh-Pasek, 2008; Tomasello & Barton, 1994; Vygotsky, 1978). However, learning in the real world depends on myriad factors beyond learning content. Often learning comes down to hard work and trying many possible solutions. Whereas these previous debates centered around the material to be learned, at least as important is the effort required. Effective methods of promoting learning in the real world will engage both.

Pedagogical questions are particularly promising in this respect. Bonawitz and colleagues (2011) showed that instruction, though powerful for ensuring specific information is learned, has negative consequences for future learning by reducing exploration. Yu et al. (2018) showed that pedagogical questions offer a potentially promising solution by achieving the benefits of direct instruction without restricting exploration following completion of a goal. Here we have shown that pedagogical questions additionally foster learning by increasing the children's persistence in pursuit of solutions.

Pedagogical questions, questions asked by a knowledgeable person for the purpose of teaching, are a surprisingly simple approach. Demonstrations are easily converted into such questions. Given their simplicity, and the relevance to literatures in education and in question asking, it is interesting that they do not appear to have been explored previously. One possible reason is that these literatures tend to focus on behaviors that are easy to see. Pedagogical questions by definition depend on inferences about the questioner's knowledge and intent. For this reason, comparison with overheard questions is an important control and a powerful demonstration of the importance of latent social variables in understanding learning.

Our work on Pedagogical Questions is part of a broader movement beyond simple dichotomies such as direct instruction versus exploration. Recent research has proposed Guided Learning as a framework for considering learning as a dynamic, interactive, social activity (e.g. Hirsh-Pasek et al., 2015). Many aspects of this framework remain to be formalized; however, we believe Pedagogical Questions provide one compelling example of guidance. Pedagogical Questions foster learning not by telling the learner the answer, but by offering the learner strong guidance toward the answer. Many open questions remain regarding when Pedagogical Questions are most effective and how they fit into the broader Guided Learning framework. We leave these to future work.

In sum, this study supports the view that pedagogical questions promote learning. Children who are asked pedagogical questions persevere in service of a specific goal. These findings are particularly relevant for educators who can use pedagogical questions in their classrooms to enhance children's perseverance during challenging problem-solving activities.

Targeted Mathematical Equivalence Training Lessens the Effects of Early Misconceptions on Equation Encoding and Solving

Abstract

Many students fail to develop adequate understanding of mathematical equivalence in early grades, with detrimental consequences for later algebra learning. The change resistance account (McNeil, 2014) proposes that students struggle with equivalence because traditional arithmetic practice overexposes students to mathematical expressions where all the operators are on the left of the equal sign. Students erroneously believe the equal sign means to "do something" or "give the answer" – and fail to see equations as relations between two expressions. These operations-based misconceptions affect how they perceive, conceptualize, and approach math problems and interfere with developing correct understandings of equivalence. The current paper explores 1) are these misconceptions evident as encoding errors in second graders? 2) do item properties make specific error types more or less likely? 3) do misconceptions in encoding impact solving performance? and 4) can targeted training mitigate the effects of prior misconceptions on both equation encoding and solving? We identify a category of misconception-based encoding errors that negatively impacts equation solving and replicate findings that a conceptually rich research-based intervention program is maximally effective in training students to overcome problematic misconceptions.

Keywords: Mathematical representations; relational reasoning; mathematics education; randomized control trial

Introduction

How do early conceptions about equivalence impact children's ability to correctly encode, and later solve, arithmetic equations? Research suggests that understanding mathematical equivalence is a critical component of algebraic reasoning (Carpenter, Franke, & Levi, 2003; Charles, 2005; Knuth, Stephens, McNeil, & Alibali, 2006). However, the majority of US students fail to reason with and apply concepts of equivalence (McNeil & Alibali, 2005), making encoding errors when reconstructing mathematical equations (e.g., McNeil & Alibali, 2004), and interpreting the equal sign to mean "calculate the total" rather than "two amounts are the same" (e.g., Behr, Erlwanger, & Nichols, 1980).

McNeil and Alibali (2005; McNeil 2014) proposed a change-resistance account of children's difficulty with mathematical equivalence. Traditional arithmetic instruction, which focuses on procedures (i.e., solving problems such as 7 + 2 = _), reinforces a *misconception* of the equal sign as a request for an answer, which, in turn, interferes with the development of relational concepts. Most arithmetic problems in early elementary math curricula show operations (e.g., addition and subtraction) on the left of the equal sign and the "answer" on the right (Seo & Ginsburg, 2003; McNeil, 2008). Children detect and extract patterns from these examples and ultimately construct long-term memory representations. McNeil and Alibali characterize these representations as "operational patterns" as they reflect an understanding of arithmetic that focuses on the operators (e.g., +, -, ×, ÷) rather than the relational nature of mathematical expressions. Although default representations typically speed computation in the problem-solving contexts that children encounter most frequently, these representations may lead to difficulties when operational patterns are mistakenly transferred to similar, but non-applicable, problem types (e.g., Bruner, 1957).

Alibali and colleagues (Crooks & Alibali, 2013; McNeil & Alibali, 2004, 2005) have identified three different sub-patterns, described below, that reflect a distorted view of arithmetic and hinder conceptual understanding of equivalence and underlying mathematics. Once entrenched, children rely on these potentially misleading patterns when encoding, interpreting, and solving novel mathematics problems. In the current study, we group these three types of errors as "misconception errors" (see Table 2) to differentiate them from errors believed to stem from working memory constraints or performance demands.

Perceptual pattern errors. Through over-exposure to traditional arithmetic problems, children learn to expect math problems to have **all operations on the left side of the equal sign**, with the equal sign immediately before the answer blank on the right, an "operations = answer" problem format (McNeil & Alibali, 2004, Carpenter et al., 2003). Students who expect all problems to have operations on the left fail to correctly encode the problem before them. For instance, after briefly viewing the problem "7 + 4 + 5 = 7 + __" children who rely on their representations of the "operations = answer" problem format erroneously remember the problem as "7 + 4 + 5 + 7 = __" (McNeil & Alibali, 2004).

Conceptual pattern errors. Children learn to interpret the equal sign operationally as a symbol to do something (Baroody & Ginsburg, 1983; Behr et al., 1980). When asked

to define the equal sign—even in the context of a mathematical equivalence problem—many children treat it like an arithmetic operator (like + or -) **that means they should calculate the total of everything on the left side of the equal sign** (McNeil & Alibali, 2005).

Procedural pattern errors. Through early practice with traditional problems (e.g., all operations on the left of '='), children learn to **perform all of the listed operations on all given numbers in a math problem** (e.g., add up all the numbers in an addition problem, McNeil & Alibali, 2004, 2005). This incorrect representation of equations misleads students to solve the problem "7 + 4 + 5 = 7 + __" by performing all given operations on all given numbers and put 23 (instead of 9) in the blank (McNeil, 2007; Rittle-Johnson, 2006, Falkner et al., 1999).

A history of findings supports the hypothesis that children's difficulties with mathematical equivalence are partially due to inappropriate knowledge of the perceptual structure, conceptual meaning, and procedural routine associated with encoding and solving equations. The change-resistance account further suggests that these faulty representations are derived from overly narrow experience with traditional arithmetic. Recent studies have documented the effects of incorrect representations of equivalence in fourth-graders (McNeil & Alibali, 2004) and have induced similar error patterns in adults (Crooks and Alibali, 2013). We build on the work of McNeil, Fyfe, and Dunwiddie (2015), who examined the impact of an early intervention on second-graders multi-faceted understanding of equivalence, replicate and extending these findings to more closely examine the nature of early equivalence encoding and its relationship to equation solving in a large representative sample of students.

In the current study, we sought to more deeply examine the nature of second-grade students' encoding responses, looking for evidence of the misconception-based (i.e., perceptual, conceptual, and procedural) error patterns that have been theorized in past work from McNeil, Alibali, and others (McNeil et al., 2019, McNeil & Alibali, 2005), and induced in adults by Crooks and Alibali (2013).

We further explore the relationship between encoding and solving of equivalence problems, asking whether the specific misconceptions identified through encoding errors are predictive of equation solving performance. We then examine the impacts of research-based equivalence training activities on encoding and solving accuracy. Specifically, we randomly assigned classrooms to training using an intensive treatment intervention or an active control condition consisting solely of non-traditional mathematical practice and measured the training impact on students' ability to encode equations and solve equivalence problems post-training. We organize our findings to explore four related questions:

Do second-grade students make encoding errors consistent with overgeneralizing patterns from early arithmetic?

Do encoding errors systematically vary across items with different structure and length? How does the frequency of different types of encoding errors change with targeted training?

How do misconception-based errors in students' equation encoding predict equation solving?

Does targeted, conceptually rich equivalence training impact encoding and equation solving?

Measuring Equation Encoding and Solving. We assessed second-grade students' ability to correctly encode and solve non-traditional equivalence problems before and after the intervention training using the same measures of equation encoding, equation solving sign used in previous work by McNeil and colleagues (Johannes et al., 2017; McNeil et al., 2012; McNeil & Alibali, 2005b).

Equation encoding. The equation encoding measure consisted of recalling four math expressions (e.g., 2 + 6 =2 + _) presented one at a time. Each expression was visible for five seconds and students were instructed to remember and write down exactly what they saw. Responses were coded as correct if the student wrote the equation exactly as shown (i.e., the correct numbers and symbols in the correct order). We discuss the coding of relevant erroneous response types in the results.

Equation solving. The equation solving measure consisted of eight equations with operations on both sides of the equal sign (e.g., 3 + 5 + 6 = 3 + __). For a response to be coded as correct, a student needed to write the value that would make the equivalence relation hold.

Our sample of encoding and solving items is listed in Table 1. All items included one addend and a blank on the *right* side of the equal sign. The items varied on two dimensions: the number of addends (two or three) on the *left* side of the equal sign, and the position of the blank (at the end of the equation or directly after the equal sign).

Table 1. Equation encoding and solving items administered pre- and post-intervention

Addends	Position of blank	Encoding items	Solving items
Two	End of equation	4+5=3+_	3+7=3+_ 2+7=6+_
	After '='	7+1=_+6	5+3=_+3 8+2=_+6
Three	End of equation	2+3+6=2+_	3+5+6=3+_ 6+2+8=4+_
	After '='	3+5+4=_+4	7+2+4=_+4 7+4+6=_+3

ICUE: Improving Children's Understanding of Equivalence Intervention

As current math practice seems to promote the development of faulty representations, the change resistance account of "operational patterns" offers design principles for instruction to improve students' understanding of equivalence. Initially, researchers hypothesized that greater exposure to "non-traditional arithmetic" problems (e.g., presenting operations on the right side of the equation, "_ = 2 + 4" and using relational phrases such as "is equal to" instead of the equal sign in practice problems) may prevent students from developing operational patterns (McNeil et al., 2011). Though practice with non-traditional arithmetic led to improved outcomes over traditional instruction, a number of students failed to reach proficiency (McNeil, Fyfe, & Dunwiddle, 2015).

To further promote mastery of equivalence, McNeil and colleagues added additional design features beyond non-traditional arithmetic practice. The current version of the materials, dubbed Improving Children's Understanding of Equivalence (ICUE), consists of second grade student activities that reduce reliance on operational patterns and promote deep understanding of mathematical equivalence through four key components, outlined below, that have independently been shown to be effective. Multiple pilot studies have since found that the ICUE treatment intervention is successful in improving student understanding of mathematical equivalence (Byrd et al., 2015; Johannes et al. 2017).

1. Nontraditional arithmetic practice (McNeil, Fyfe, & Dunwiddle, 2015, Chesney et al., 2012),
2. Lessons that first introduce the equal sign outside of arithmetic contexts (e.g., "28 = 28") before introducing arithmetic expressions (e.g., Baroody & Ginsburg, 1983).
3. Concreteness fading exercises in which concrete, real-world, relational contexts (e.g., sharing stickers, balancing a scale) are gradually faded into the corresponding abstract mathematical symbols (e.g., Fyfe, McNeil, Son, & Goldstone, 2014), and
4. Activities that require students to compare and explain different problem formats and problem-solving strategies (e.g., Carpenter, Franke, & Levi, L. 2003).

Methods

Design

We used a cluster-randomized control trial design to examine the impacts of the ICUE intervention training relative to an active control program. Teachers were randomly assigned to use the either the ICUE Treatment intervention or Active Control materials. The Active Control consisted of workbook activities to control for time on task and contained non-traditional arithmetic practice but not the additional components present in the Treatment ICUE condition, described above.

Participants. 44 second-grade teachers (24 treatment, 20 control) used the activities in their classrooms in California. Class sizes ranged from 18 to 25, and we analyzed data from 482 students who completed the Treatment activities and 406 students who completed the Control activities and measures.

Procedure and Materials

The procedure for ICUE Treatment and Active Control conditions were identical, differing only in the content of the materials used by teachers and students. Each teacher received training on the study purpose, features of the activities, and strategies for integrating the activities into their typical mathematics curriculum.

Prior to starting the study, participating teachers completed online surveys assessing their mathematics teaching experience and classroom structure and dynamics.

After administering a pre-test, teachers used the study materials for approximately 15 minutes twice each week for 16 weeks. In both conditions, teachers were asked to use the study materials to supplement, rather than replace current math instruction, and to limit the duration of the activities to 20 minutes per session.

After completing the 32 sessions, teachers administered the same pre-intervention measure of mathematical equivalence understanding, which included the equation encoding and solving items reported here, along with an item prompting children to name and define the "=" symbol, not reported. Teachers administered additional post-intervention measures of transfer and computation fluency, we do not report these here.

Active Control. Teachers in the Active Control condition received a set of student workbooks and a teacher guide.

ICUE Treatment. Teachers in the ICUE Treatment condition received a set of student workbooks, a teacher guide, a set of classroom manipulatives including balance scales and flashcards.

Results

Do second graders make misconception-based encoding errors?

Crooks and Alibali (2013) identified three categories of errors in encoding and solving, reviewed above, which stem from different types of knowledge and misconceptions. We asked whether, after only one year of formal mathematics instruction, second graders produced erroneous encoding responses that align with these any of these three related facets of misunderstanding, grouping them together as "misconception errors". We examined the frequency with which theoretically-relevant types of encoding errors, which can be induced in adults (Crooks & Alibali, 2013) naturally occur in young students. We differentiated these misconception-based errors from other types of errors, including performance errors, which we hypothesize stem from memory-based constraints in this population.

We assessed students' accuracy in encoding four different equivalence problems (see Table 1 for items) and examined the frequency with which they made different types of errors. Student in both the Control and Treatment groups produced a range of responses for each encoding item and made multiple types of errors, including misconception-based errors, with different frequency. Examples and overall frequency of response types are listed in Table 2.

Students produced the misconception-based errors of interest in approximately 20% of their responses overall. The majority of misconception-based errors produced in both conditions aligned with the perceptual error type identified by Crooks and Alibali (2013); conceptual and procedural errors types were produced relatively infrequently.

Table 2. Response types and examples for encoding item 2+3+6=2+_, with overall frequency of response pre- and post-training.

Response type	*Examples*	*Control Pre/Post*	*Treatment Pre / Post*
Correct	2+3+6=2+_	0.25/0.47	0.35/0.56
Misconception errors	**2+3+6+2=_ 2+3+6=11+2 2+3+6=2+13**	**0.23/0.21**	**0.24/0.17**
Memory error	2+3+6	0.06 / 0.08	0.06/ 0.15
Other errors	2+3+7=6	0.39 / 0.21	0.28/ 0.09
No response	no response	0.07 / 0.02	0.05/ 0.03

How does the equation structure influence encoding errors?

We chose to focus on misconception-based and memory-based encoding error patterns and explored variation in error rates across the four encoding items that varied in A. the number of addends, and B. the position of the blank in the equation (see Table 1 for items). The larger number of addends was predicted to increase the working memory demands of the problem. The position of the blank at the end of the equation (e.g., 4+5=3+_) was predicted to increase the likelihood of perceptual pattern errors as these items are most perceptually similar to traditional arithmetic problems (e.g., 4+5+3=__), and may trigger operational, instead of relational, interpretations of the equal sign (e.g., as a symbol that means give the answer') that give rise to erroneous arithmetic procedures (e.g., add up all numbers and write the sum in the blank; see Crooks & Alibali, 2013; McNeil et al., 2011).

Students' pre-intervention encoding error frequency is displayed by item in Figure 2. The frequency of misconception- and memory-based errors varied based on both the position of blank (at the end of the equation – first and third items - or directly after the '=' sign – second and fourth items in Table 1) and the number of addends on the left side of the equation (two – first two items - or three – last two items in Table 1).

In line with our predictions, regression models confirmed that students in both conditions produced a reliably greater number of perception-based errors for items with the blank at the end of the equation (β=0.852, SE =0.12, p<.01), and this interacted with the number addends, such that students produced the greatest number of misconception errors for the three-addend item with the blank at the end: "2+3+6=2+_" (β=0.534, SE =0.09, p<.05).

Finally, students made a reliable number of memory-based errors, but only for items with three addends (β=0.472, SE =0.11, p<.05).

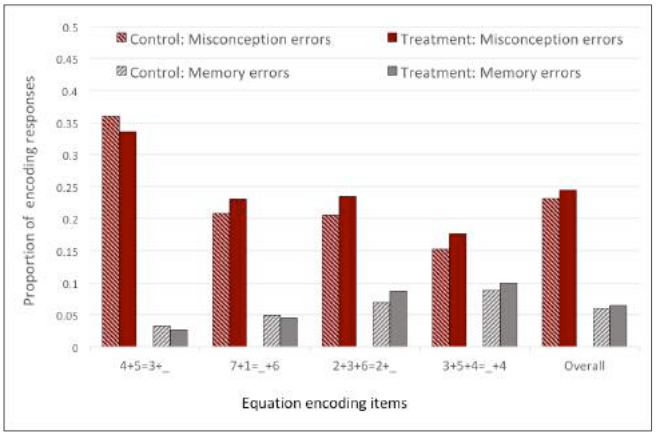

Figure 2. Pre-intervention patterns of misconception- and memory-based error responses for Treatment and Control students. Misconception errors were greatest for items with a blank space at the end of the equation (first and third items); memory errors were greatest for items with three addends (second and fourth items).

How does conceptually rich equivalence training change students' encoding responses?

We next examined the impact of the ICUE Treatment and Active Control training on misconception- and memory-based encoding errors. We asked whether exposure to non-traditional arithmetic, through the Active Control condition, was sufficient to maximally reduce these encoding errors, or whether more conceptually rich training, found in the ICUE Treatment intervention, would lead to greater error reduction. The change in students' encoding errors from pre- to post-intervention is displayed in Figure 3. Students in the Treatment condition showed a greater reduction, post-intervention, in misconception-based errors compared to students in the Control condition (β=0.921, SE =0.10, p<.01), and this reduction was greatest for items with a blank space at the end of the expression (β=0.633, SE =0.09, p<.05). Thus, for encoding, we find that conceptually rich training leads to greater reduction misconception-based errors. Training type did not significantly impact the frequency of memory errors for three-addend encoding items.

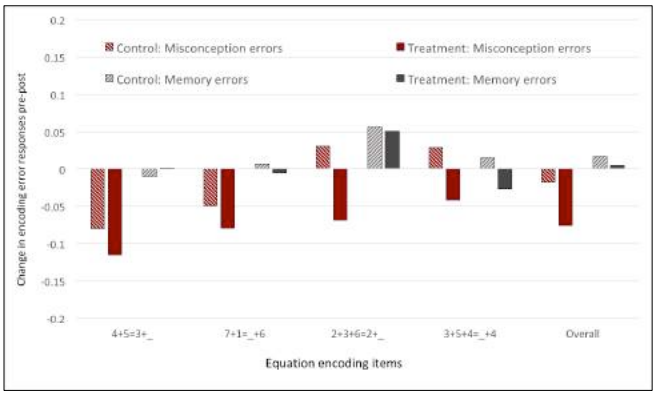

Figure 3. Pre- to post-intervention changes in error responses for Treatment and Control students. Students in the Treatment condition showed a greater reduction in misconception-based errors (solid red bars), which was greatest for items with a blank space at the end of the equation.

How do misconception-based errors in students' equation encoding impact equation solving?

Turning to equation solving, we tested whether perceptual errors in equation encoding reliably predicted students' equation solving performance before students had received any training through the Treatment or Control interventions. For each item type, students completed one encoding item and two solving items (see Table 1). Thus, for each type of item, a student could solve both solving items correct, one correct, or zero correct. We used ordinal regression models to capture this ordering and tested encoding performance (i.e., whether a student encoded that type of item correctly), error types (misconception- and memory-based), and item properties (number of addends and location of blank space) as predictors.

Pre-intervention solving performance was predicted by multiple aspects of encoding responses: students were more likely to solve an equivalence problem correctly if they had accurately encoded the same type of item correctly (β=0.778, SE=0.121, p<.05), and students were less likely to solve a problem correctly if they had produced a misconception-based error for that type of item on the encoding measure (β= -0.420, SE =0.097, p<.01).

Performance was also predicted by properties of the items: items with two addends were more likely to be solved correctly than those with three addends (β=0.360, SE =0.079, p<.01) and items with a blank space directly after "=" were more likely to be solved correctly than those with a blank at the end of the equation (β=0.226, SE =0.079, p<.05). However, pre-intervention solving performance was not reliably predicted by memory-based errors, or assigned condition (β=-0.061, SE =0.078, *ns*).

How does equivalence training impact equation solving?

We used a similar ordinal regression model to test the effect of training condition on students' post-intervention solving performance. Performance was best predicted by a combination of intervention condition and encoding responses; item properties (position of blank, number of addends) were not reliable predictors in the best-fitting model of solving performance. The strongest single predictor of post-intervention solving performance was training condition: students in the Treatment condition were more likely to correctly solve items post-intervention, compared to students in the Active Control condition (Figure 4; (β= 1.267, SE =0.074, p<.01)). As in the case of encoding, we found that conceptually richer training led to more accurate solving performance.

Students were also more likely to solve one or both equation solving problem correctly on the post-intervention measure if they had solved one correctly on the pre-intervention measure (β=0.636, SE =0.12, p<.01) and were increasingly likely to solve both items correctly if they had solved both items correctly pre-intervention (β=1.053, SE =0.15, p<.01).

Finally, as in the pre-intervention model, post-intervention solving performance was predicted by encoding responses: students were more likely to solve an equivalence problem correctly post-intervention if they had accurately encoded the same type of item correctly post-intervention (β=1.493, SE =0.08, p<.01), and students were less likely to solve a problem correctly if they had produced a misconception-based error for that type of item on the encoding measure (β= -0.749, SE =0.06, p<.05).

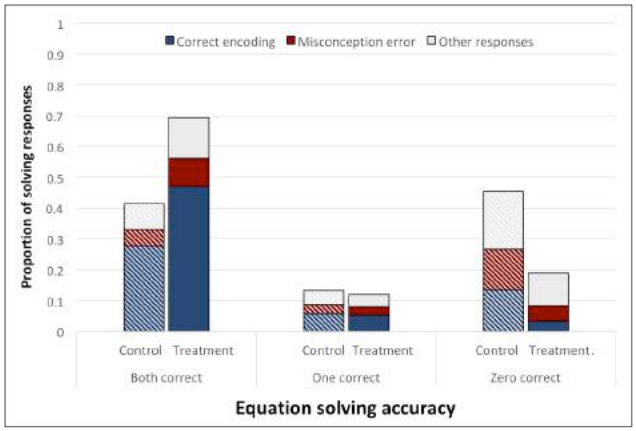

Figure 4. Treatment and Control students' post-intervention solving performance broken down by frequency of correct and misconception-based encoding responses. Conceptually rich training in the Treatment condition led to the greatest improvement in solving performance; students from both conditions were more likely to solve an item correctly if they had encoded the same type of item correctly, and less likely if they had made a misconception-based error in encoding.

Considering both our encoding and solving results, we found that, while manipulated item properties impacted students' ability to correctly encode and solve non-traditional equations pre-intervention, the magnitude of this impact was reduced, for encoding, and eliminated, for solving, by targeted conceptually rich training in mathematical equivalence. Specifically, students in the Treatment condition showed a greater reduction, post-intervention in misconception-based encoding errors compared to Control students, and this reduction was greatest for items with a blank space at the end of the equation (i.e., items that are perceptually most similar to traditional arithmetic problems). Treatment students were also more accurate on a post-intervention equation solving task (with no reliable condition differences pre-intervention) and, while encoding responses were predictive of solving performance, manipulated item properties (number of addends and position of blank space) were not.

Conclusions

Understanding equivalence is key for later mathematical understandings. The change-resistance account suggests that students fail to develop appropriate representations of equations and equivalence because instruction with traditional arithmetic problems encourages students to develop ineffective representations of problems.

In the current study, we explored the relationship between problematic representations and students' ability to accurately encode and later solve non-traditional equivalence problems. We examined encoding and solving abilities in second-grade students and found that a single year of formal instruction (i.e., first grade) with traditional arithmetic practice was sufficient to reliably lead to misconception-based errors at encoding, which predominantly consisted of perceptual pattern errors, in the framework of Crooks and Alibali (2013). Baseline performance on both tasks worsened when target problems perceptually resembled traditional arithmetic problems (i.e., when a blank was at the end of an equation), and when working memory load (number of addends) was increased. Misconception errors at encoding were predictive of solving performance, both at baseline (pre-intervention) and at post-intervention, suggesting that students who make these misconception-based errors at encoding may be activating similar faulty representations during the solving task. Finally, training improved both encoding and solving performance, demonstrating that erroneous response patterns can be overcome with intervention. However, students in the Treatment condition showed greatest improvements on both tasks, suggesting that deeper conceptual learning is required to resolve what, at first glance, might be thought of as a perceptual bias towards traditional arithmetic problem structure.

Interestingly, while manipulated properties of the encoding and solving items (see Table 1) predicted students' errors in the encoding task, these properties were only predictive of *pre-intervention* solving performance. Students' post-intervention solving performance was predicted by their post-intervention encoding responses, but not directly predicted by item properties, suggesting that any relationship between these manipulated item properties, such as the number of addends and position of blank space, and solving performance is potentially mediated by encoding. This is consistent with a mediation analysis performed by Crooks and Alibali (2013), in which the authors demonstrated that the impact of priming incorrect representations on adults' equation solving performance was mediated by problem reconstruction (or encoding). Future work will explore this relationship in more depth by using a greater number of items and possible combination of manipulated item properties.

Even after training, students in both conditions did not reach ceiling performance in either encoding or solving non-traditional equations. On the one hand, the equation encoding and solving assessment items were chosen to leave room for improvement and to avoid ceiling effects. However, in future work, we plan to explore how individual students resolve or persist in error patterns with training. We further plan to test whether different encoding errors give rise to specific solving responses, or whether any error simply creates noise in students' equation solving processes. Our preliminary findings suggest that misconception-based errors in encoding lead to greater error rates in solving, but a larger sample of items and responses may be required to support fine-grained conclusions about the nature of this relationship and, specifically, how perceptual, conceptual, and procedural misconceptions individually and collaboratively impact equation encoding and solving.

Moral Reputation and the Psychology of Giving: Praise Judgments Track Personal Sacrifice Rather Than Social Good

Samuel G. B. Johnson (sgbjohnson@gmail.com)
School of Management, University of Bath, Bath, BA2 7AY UK

Abstract

Do we praise altruistic acts because they produce social benefits or because they require a personal sacrifice? On the one hand, utilitarianism demands that we maximize the social benefit of our actions, which could motivate altruistic acts. On the other hand, altruistic acts signal reputation precisely because personal sacrifice is a strong, costly signal. Consistent with the reputational account, these studies find that in the absence of reputational cues, people mainly rely on personal cost rather than social benefit when evaluating prosocial actors (Study 1). However, when reputation is known, personal cost acts as a much weaker signal and play a smaller role in moral evaluations (Study 2). We argue that these results have far-reaching implications for the psychology and philosophy of altruism, as well as practical import for charitable giving, particularly the effective altruism movement.

Keywords: Moral psychology; reputation; decision-making; prosocial behavior; altruism

Introduction

Moral philosophers, as well as our inner ethicists, often recommend altruism as an essential component of moral behavior. Altruistic acts have a dual character—an altruistic act requires a *personal cost* and produces a *social benefit*. The most plausible arguments for the morality of altruism seem to place the emphasis on the social benefit. Consequentialism tells us that we should act to produce the greatest good for the greatest number (e.g., Bentham, 1907/1789; Mill, 1998/1861), which often entails altruistic acts. For example, if you live in a rich country, you probably gain far less from $20 than would a family in a poor country, suggesting that the moral act is to donate the $20 (Singer, 2015).

Because human survival depends on coordinated social activity, we have moral intuitions which sometimes appear to track the conclusions of moral and legal philosophy (e.g., Mikhail, 2007); moreover, people sometimes behave like intuitive consequentialists, particularly when they have time to reflect (Greene, Morelli, Lowenberg, Nystrom, & Cohen, 2008). So perhaps our intuitive praise for altruistic agents stems from the same underlying consequentialist psychology that animates moral philosophers.

But do we really value altruistic acts in proportion to the social benefit they produce? Or do we rely primarily on the personal cost entailed? In many situations this a moot question, since personal sacrifice and social good are often highly correlated. This is true in both our ancestral environment, where presumably our moral intuitions evolved, and our modern environments where our moral intuitions guide behavior. If you spend two hours gathering berries, you gather more than if you spend one hour; if you give $100 rather than $50 to Oxfam, the charity can accomplish double. But these dimensions are not always so tightly correlated. The *effective altruism* movement focuses on maximizing the social good accomplished per dollar donated, since effectiveness varies hugely across different causes (MacAskill, 2015; Singer, 2015). For example, one can prevent blindness in dozens of children in the developing world for the cost of training one service dog in the developed world. To effective altruists, a donation's *quality* is at least as important as its *quantity*.

Do ordinary people, like effective altruists, prioritize social good over personal sacrifice in evaluating prosocial acts? We propose that, conversely, personal sacrifice usually looms larger. Many argue that our intuitive morality evolved to induce cooperative behavior (Goodwin, Piazza, & Rozin, 2014; Haidt, 2007; Nowak & Sigmund, 2005; Sperber & Baumard, 2012; Uhlmann, Pizarro, & Diermeier, 2015). Praise by one's social group rewards prosocial behaviors while blame penalizes anti-social behaviors, and these judgments reflect changes in moral reputation. For example, people blame others for harmless actions accompanied by "wicked desires" (Inbar, Pizarro, & Cushman, 2012) because such desires can signal poor moral character. Character judgments depend mainly on intentions, not outcome (Cushman, 2008), serving to track reliable individual differences in social behavior. Beliefs about moral reputation even have an identifiable neural basis (Delgado, Frank, & Phelps, 2005), speaking to their psychological fundamentality.

On this view, praise judgments flow from evidence of good moral character. Personal sacrifice is a stronger signal of character than social good for two reasons. First, personal sacrifice is under an actor's direct control, whereas social good depends partly on uncontrollable factors. One can write a check to Oxfam for any amount, but what the charity accomplishes depends on their decisions and on luck. Inferences based on personal sacrifice avoid such sources of noise. Second, personal sacrifice is directly observable, whereas social good is often unobservable. We see the number on the Oxfam check, but usually not how many people were helped.

Given that our interest here is in people's moral evaluations of prosocial behaviors, the most directly relevant literature would seem to be moral judgment. However, this research has focused primarily on factors influencing blame for negative acts rather than praise for positive acts (e.g., Cushman, 2008; Inbar et al., 2012;

Mikhail, 2007). Research on charitable giving does provide some hints, however. People view prosocial acts unfavorably when those acts also benefit the actor (Ariely, Bracha, & Meier, 2009; Barasch, Levine, Berman, & Small, 2014; Newman & Cain, 2014), and these perceptions have negative downstream consequences for actual prosocial behavior (Ariely, Bracha, & Meier, 2009). This suggests that personal sacrifice is a necessary condition for positive evaluations of prosocial behavior. However, presumably sacrifice alone is not sufficient—it seems doubtful that purely self-sacrificial acts would be seen as praiseworthy in the absence of some broader social benefit. The film *The Seventh Continent* depicts a middle-class family in modern Europe that destroys itself for no apparent reason, flushing their money down the toilet and committing suicide. To this audience these acts are puzzling and horrifying, not praiseworthy. Thus, the prior literature together with common intuition suggests that some degree of personal cost and some degree of social benefit are required for a prosocial act to be praised; indeed, this may be part of the very concept of altruism.

Both cost and benefit appear to track judgments of praise when we are comparing some versus none. But would they track praise when comparing a larger amount to a smaller amount? In prior work, highly prosocial acts are not seen as more praiseworthy than slightly prosocial acts, although, interestingly, people were sensitive to the degree of harm in assigning blame (Klein & Epley, 2014). However, the effects of prosocial benefits versus costs have not been teased apart in observer's moral evaluations—people may well be insensitive to the degree of cost as well as the degree of benefit in evaluating prosocial acts. On the actor side, people are more moved to donate by the plight of one than of many (Small, Loewenstein, & Slovic, 2007) and are largely indifferent to the number of individuals helped (Kahneman & Knetsch, 1992). Conversely, people are likelier to donate money when paired with a painful sacrifice (explaining, arguably, the prevalence of charity runs; Olivola & Shafir, 2013). These results again are suggestive of possible insensitivity to the degree of benefit, but do little to clarify how prosocial actors respond to the degree of cost. Moreover, it is unclear whether these results would generalize to moral evaluations rather than prosocial behaviors themselves or when cost versus benefit are pitted against one another directly.

Overall, prior work does not tell us whether moral judgments of altruist acts track personal sacrifice or social benefit. We know that some amount of personal sacrifice and social benefit are necessary conditions, but not whether one of these factors has an outsized influence compared to the other, when pitted against one another directly. This issue is critical to understanding the psychological basis of moral praise (utilitarian admiration vs. character signaling) and likely has implications for the design of charitable appeals.

Thus, the current studies investigate this issue by testing judgments of praise in response to charitable donations. The studies orthogonally manipulate the amount of personal sacrifice (size of donation) and social good (number of individuals helped), measuring judgments of praise and character. In Study 2, independent reputational cues are available, whereas in Study 1 they are not. When strong reputational cues attest to a donor's robust character, personal sacrifice is uninformative about moral character and therefore should not influence praise; however, sacrifice should have a large effect when other reputational cues are absent.

Study 1

Study 1 tested whether, absent further information about a person, judgments of prosocial behavior depend mainly on the degree of *personal sacrifice*, but not *social good*.

Method

A total of 598 American participants (56% female, M_{age} = 37.4) were recruited for Studies 1A and 1B through Mechanical Turk. Participants were excluded if they failed an attention check (see below; N = 65).

Participants read about a charitable donation benefiting people in a developing country. The charities focused on blindness, hunger, education, or disaster relief. The donations involved a *low*, *moderate*, or *high* monetary contribution (to manipulate personal sacrifice), and were *low* or *high* in effectiveness (to manipulate social good), with both manipulations between-subjects. These conditions always differed from one another by one order of magnitude (a factor of 10). For two of the vignettes, the beneficiary was an individual in the low-effectiveness condition and a small group in the high-effectiveness condition. For example:

> Julia decided to make a donation to charity. She donated [$20/$200/$2000] to a charity focused on international health. Her donation was used to cure [a child's/10 children's] blindness in Ethiopia.

For the other two vignettes, the beneficiary was a small group in the low-effectiveness condition and a large group in the high-effectiveness condition. For example:

> Rob decided to make a donation to charity. He donated [$12.50/$125/$1250] to a charity focused on disaster relief. His donation was used to provide basic shelter to [10/100] people for one month after a hurricane in Guatemala.

On the same screen, participants rated the praiseworthiness of the action ("Please rate the moral praiseworthiness of Julia's action") on a scale from 0 ("Not very praiseworthy") to 10 ("Extremely praiseworthy"), and the actor's character ("Please rate Julia's moral character") on a scale from 0 ("Ordinary moral character") to 10 ("Saint-like moral character").

After the main task, participants checked whether each of the four donation targets was mentioned in the study; participants making any incorrect answers were excluded.

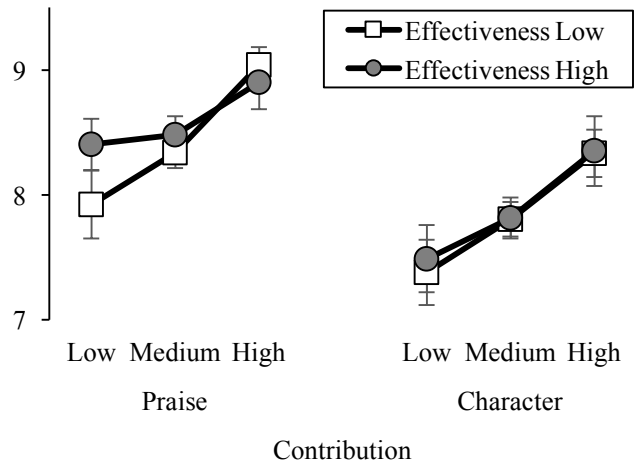

Figure 1: Results of Study 1 (character information absent). Bars represent 1 SE.

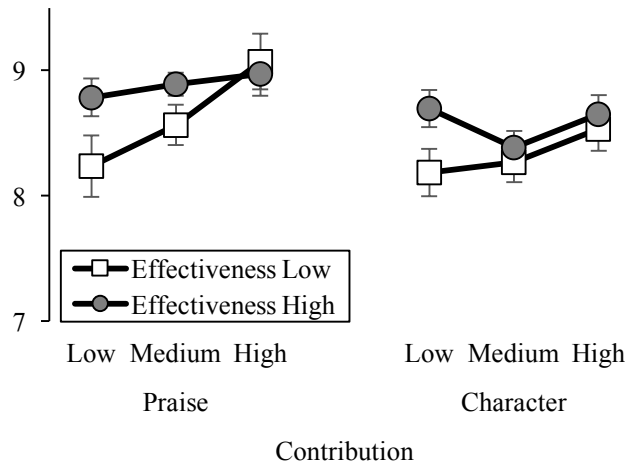

Figure 2: Results of Study 2 (character information present). Bars represent 1 SE.

Studies 1A and 1B were identical, except Study 1A included the low- and medium-contribution conditions, while Study 1B included the medium- and high-contribution conditions. Thus, both studies used 2 (personal sacrifice) x 2 (social good) designs. Given that the designs differed only in contribution levels, we combine them for analysis, to maximize statistical power and facilitate comparisons across studies.

Results

Overall, participants used the degree of personal sacrifice, but not of social good, to inform judgments of moral praise and character. The means are plotted in Figure 1.

Since contribution condition is equal-interval in log scale, it was coded as a continuous variable, (–1 = low, 0 = medium, 1 = high); effectiveness condition was contrast-coded (–1 = low, 1 = high). A linear regression was conducted, predicting moral judgments from contribution, effectiveness, and their interaction. There was a significant main effect of contribution, $b = 0.40$, $SE = 0.11$, 95% CI[0.18,0.61], $p < .001$, indicating that greater degrees of sacrifice were viewed as more morally praiseworthy. However, there was no effect of effectiveness, $b = 0.08$, $SE = 0.07$, 95% CI[–0.06,0.22], $p = .26$, nor a significant interaction, $b = –0.16$, $SE = 0.11$, 95% CI[–0.37,0.06], $p = .15$. Thus, people did not take account of social benefit in evaluating the moral praiseworthiness of the donations. Moreover, this effect did not depend on whether the less-effective donations benefited an individual or a small group: Adding this variable and its interactions to the regression model did not improve fit, $F(529,4) = 1.40$, $p = .23$. (Adding a factor for vignette also did not improve fit, indicating that there are no reliable differences in the effects across vignettes.)

The results were similar for character judgments. A regression analysis parallel to the above revealed a significant effect of contribution, $b = 0.45$, $SE = 0.12$, 95% CI[0.21,0.69], $p < .001$, but not of effectiveness, $b = 0.02$, $SE = 0.08$, 95% CI[–0.14,0.18], $p = .82$, or the interaction between these variables, $b = –0.02$, $SE = 0.12$, 95% CI[–0.27,0.22], $p = .84$. Once again, adding the individual vs. small-group dummy-code and its interactions to the model did not improve fit, $F(4,529) = 0.62$, $p = .65$, indicating that the effect does not depend on whether the less-effective donation benefitted an individual or small group.

Discussion

Praise judgments track the amount of money sacrificed by donors, but not the social good produced by those donations. This is consistent with a signaling theory of moral praise, which assumes (i) that moral praise derives from evidence of character and (ii) that personal sacrifice is a stronger (costly, controllable, and observable) signal of character.

This mechanism will be tested more directly in Study 2. Before doing so, however, let us consider a possible boundary condition: Whether the individuals helped are closer or farther within one's moral circle (Singer, 1981). People are parochial about their charitable giving (Baron & Szymanska, 2011; see also Nagel & Waldmann, 2013), favoring causes that benefit their in-group. Perhaps altruistic acts done to benefit others in distant countries are viewed as altruistic mainly due to the signaling value (i.e., their cost), but those done to benefit one's own society are seen in a more utilitarian way. It is plausible that one would praise an altruistic act to the extent that it helped one personally, so if one identifies with one's in-group, the effectiveness of in-group help may impact praise judgments.

To test this, a replication of Study 1 was conducted (Johnson, 2018), identical except for replacing the beneficiaries living in the developed world with beneficiaries living in America (e.g., a hurricane in South Carolina rather than Guatemala). This study found a very

similar pattern of results to Study 1: Contribution was a large and robust predictor of praise, $b = 0.39$, $p < .001$, while effectiveness had a small and marginal effect, $b = 0.11$, $p = .09$. Combining the data from this follow-up with the Study 1 data, there was no significant interaction between beneficiary (in-group vs. out-group) and either contribution or effectiveness on praise. This both replicates the results of Study 1 and suggests that parochialism is not a boundary condition on the findings.

Study 2

Personal sacrifice is typically under the actor's personal control and is typically visible; therefore it can be an informative, costly signal of moral reputation. In contrast, social good is less controllable and less visible. If this drives attention to costs rather than benefits, then independent evidence of an actor's pristine moral character should decrease the relevance of individual prosocial acts for evaluating character and attenuate the effect of personal sacrifice.

Method

A total of 600 American participants (57% female, $M_{age} = 36.6$) were recruited for Study 2. Participants were excluded if they failed the same attention check used in Study 1 ($N = 91$).

Studies 2A and 2B were identical to Studies 1A and 1B, respectively, except that the vignettes were altered to include information establishing the actor's altruistic moral character. For example:

> Rob works as a receptionist, earning about $31,000 per year. He donates about 30% of his salary each year to a variety of charitable causes.
>
> One of the donations Rob decided to make this year was [$12.50/$125/$1250] to a charity focused on disaster relief. His donation was used to provide basic shelter to [10/100] people for one month after a hurricane in Guatemala.

The moral judgment question was rephrased so it was clear that it referred to this *specific* donation, rather than the pattern of charitable donations (e.g., "Please rate the moral praiseworthiness of Rob's [$12.50/$125/$1250] donation"). Rephrasing this question to emphasize the contribution's magnitude should, if anything, *increase* the salience of this factor, working against the hypothesis.

Results

The effects of sacrifice on perceptions of moral judgment and character were less pronounced in Study 2, when the donor's strong moral character was established, compared to Study 1, where it was not. Figure 2 plots the means.

Effects of contribution and effectiveness. Conditions were coded following the same procedure as Study 1. A linear regression was used to predict moral judgments from contribution, effectiveness, and their interaction.

For character judgments, there were no significant effects for any of the variables—neither contribution, $b = 0.07$, $SE = 0.10$, 95% CI[–0.12,0.26], $p = .48$, nor effectiveness, $b = 0.10$, $SE = 0.07$, 95% CI[–0.03,0.23], $p = .13$, nor their interaction, $b = –0.10$, $SE = 0.10$, 95% CI[–0.29,0.09], $p = .32$ reached significance. This is essentially a manipulation check, demonstrating that the manipulation successfully eliminated the diagnosticity of the specific donation for character.

For praise judgments, there was a significant effect of contribution, $b = 0.25$, $SE = 0.10$, 95% CI[0.06,0.44], $p = .009$, albeit weaker than in Study 1 (see moderated mediation analysis below). Thus, moral judgments were more positive for actors making larger contributions, but this effect was less pronounced in Study 2, where moral character was established through independent evidence, compared to Study 1.

Interestingly, there was also a modest effect of effectiveness on moral judgments, $b = 0.14$, $SE = 0.07$, 95% CI[0.01,0.27], $p = .039$, driven particularly by differences between effectiveness conditions when sacrifice was low. (This interaction, however, did not reach significance, $b = –0.16$, $SE = 0.10$, 95% CI[–0.35,0.03], $p = .10$.) This was not predicted *a priori* and should be taken with caution. One possibility is that if one is known to have a strong reputation, it may require considerable evidence to revise this default belief. When a donation is low in both magnitude and effectiveness, the combination of these two cues may provoke a negative revision to beliefs about that actor's character. A second possibility is that personal sacrifice "crowds out" social benefit when reputation is unknown, but that there is room for social benefit to play a role when there is no need to establish reputation. However, these speculations are not tested directly, and these small, unpredicted effects should be interpreted cautiously until replicated.

Moderated mediation. To test whether differences in character inferences accounted for the difference across Studies 1 and 2, a moderated mediation analysis (PROCESS Model 7; Hayes, 2013) was conducted on the combined dataset ($N = 1042$).

As shown in Figure 3, character (the mediator) was predicted by contribution, $b = 0.26$, $SE = 0.08$, $p = .001$, 95% CI[0.11,0.41] and by character information (–1 = Study 1, 1 = Study 2), $b = 0.29$, $SE = 0.05$, $p < .001$, 95% CI[0.19,0.39]. Importantly, the interaction was significant, $b = –0.19$, $SE = 0.08$, $p = .015$, 95% CI[–0.34,–0.04], as contribution was a stronger predictor when character information was absent. Bootstrapping revealed that there was an indirect effect of contribution on praise judgments via character judgments for Study 1, $b = 0.23$, $SE = 0.07$, 95% CI[0.10,0.36], but not Study 2, $b = 0.03$, $SE = 0.04$, 95% CI[–0.05,0.12]. This led to a significant index of moderated mediation, $b = –0.20$, $SE = 0.08$, 95% CI[–0.35,–0.05]. Thus, character judgments mediate the effect of contribution magnitude on praise judgments only when the actor's moral reputation is unknown.

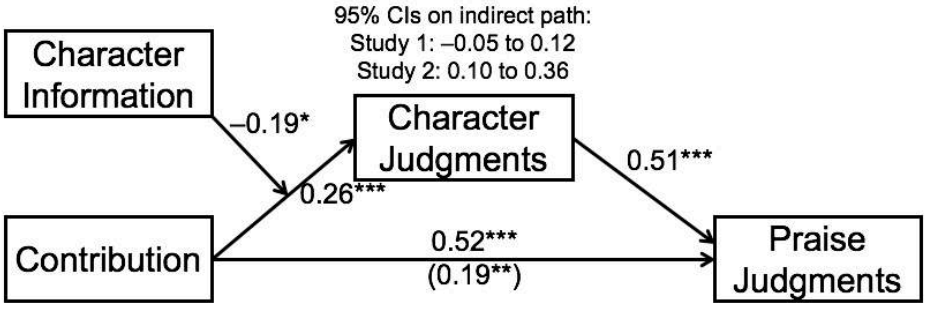

Figure 3: Moderated mediation model for Studies 1 and 2.

Discussion

Together, Studies 1 and 2 tell a clear story about moral evaluations of prosocial acts. Without evidence of reputation, prosocial behaviors are evaluated mainly by considering their personal sacrifice, rather than the social benefit. This occurs because personal sacrifice is a controllable and visible signal of cooperativeness and thus a useful input to reputational judgments. Thus, when reputation is available, personal sacrifice is less relevant to moral evaluations

One possible concern about the character information manipulation differentiating Studies 1 and 2 is that this manipulation also introduced a reference point (the donor's salary in dollars) in addition to establishing the donor's generosity. However, since the key finding of Study 2 is that people rely *less* on personal sacrifice (in terms of dollars), it seems unlikely that this result would be explained by introducing a reference point. If anything, a reference point should make contribution amounts more salient and more readily comparable to the reference point, leading people to rely on contribution more rather than less. Nonetheless, future work might further rule out this concern by manipulating character in other ways (e.g., mentioning that the donor also volunteers her time or has dedicated her career to prosocial causes).

General Discussion

Do we admire altruists because they make personal sacrifices or because they help others? The present studies found that, for altruistic donations of money, moral praise is driven almost entirely by sacrifice (Study 1). This occurs because personal sacrifice, but not social good, is taken as a signal of moral character (Study 2).

These results have implications for the psychology, philosophy, and practice of altruism. The findings are consistent with evolutionary accounts of moral psychology, according to which our moral faculties evolved to facilitate cooperation by tracking others' reputations and creating social rewards for those willing to act for the group's benefit (Nowak & Sigmund, 2005; Sperber & Baumard, 2012). If this is true, then our evaluations (e.g., praise and blame) of prosocial behaviors would track changes to the moral reputation or character of the actor. Since personal cost, but not social good, is usually under the actor's direct personal control, the former is a more reliable signal of cooperativeness.

How far would we expect these effects to generalize beyond this task? As discussed in conjunction with Study 1, the results do not seem to depend on the fact that the beneficiaries live in distant countries, as similar results are observed when the beneficiaries are Americans (Johnson, 2018). Other boundary conditions, however, may be plausible.

For example, the donors in the current studies may be seen as "outsourcing" the effectiveness of their charity to experts, and would thus not be seen as responsible for the outcome (e.g., Erat, 2013). This may be plausible, given previous work finding that people sometimes attribute more responsibility to individuals later in a causal chain (e.g., Brickman, Ryan, & Wortman, 1975; Spellman, 1997) as well as research documenting intransitivity beliefs about causal judgments (i.e., X causes Y and Y causes Z, but X does not cause Z; Johnson & Ahn, 2015). In that case, people may value effectiveness more when a prosocial agent contributes directly rather than indirectly. A more specific version of this possibility is that people think differently about the effectiveness of time- versus money-donations. Previous work has indeed documented differences in how people think about donations of money versus time (Johnson & Park, 2019; Liu & Aaker, 2008; Reed, Aquino, & Levy, 2007). Would effectiveness also loom larger for time-donations?

To test this, a replication of Study 1 was conducted, replacing the money-donations with time-donations (Johnson, 2018). The effects found in Study 1 were indeed reversed: Effectiveness but not sacrifice drove praise judgments. That is, unlike Study 1, contribution magnitude did not predict praise judgments, $b = 0.09$, $p = .32$, whereas effectiveness did, $b = 0.17$, $p = .007$. Thus, donation type (time vs. money) appears to be a boundary condition, such that effectiveness matters for time- but not for money-donations.

This is broadly consistent with the causal responsibility account, according to which effectiveness is only deemed irrelevant when it is outsourced to others. Indeed, low effectiveness in time-donations may signal incompetence as much as prosociality. This account alone does not

easily explain why personal sacrifice was not also used when evaluating time-donations. One possibility is that people place a greater psychological value on money than on other resources (Johnson, Zhang, & Keil, 2018), so that the sacrifice only looms large for money- but not time-donations. Future work might directly test these proposed mechanisms—the competence-signaling value of time effectiveness and the valuation difference between time and money sacrifices—in prosocial contexts.

These results are mainly bad news for effective altruism, whose *raison d'être* is improving the quality of prosocial acts, not merely their quantity. Effective altruists may receive no more social praise than *ineffective* altruists who make comparably large donations, even if the former do far more good for the world. This compounds a related problem, that people often view the importance of various causes as subjective, rather than objectively measurable (Berman et al., 2018). However, people may well be able to account for effectiveness in their moral evaluations when this factor is more salient and the causes are easily comparable. Websites like givewell.com, which directly compare charities in terms of metrics such as dollars per life saved, may be an important front on the battle for effective giving. More broadly, interventions that make both the quantity and quality of donations publicly observable may help to incentivize effective prosocial behavior.

Abstract

People assess others' moral characters to predict what they will do. Here, we study the computational mechanisms used to predict behavior from *uncertain* evidence about character. Whereas previous work has found that people often ignore hypotheses with low probabilities, we find that people often account for the possibility of poor moral character even when that possibility is relatively unlikely. There was no evidence that comparable inferences from uncertain non-moralized traits integrate across multiple possibilities. These results contribute to our understanding of moral judgment, probability reasoning, and theory of mind.

Keywords: Moral psychology; theory of mind; prediction; causal reasoning; categorization

Introduction

People intensely scrutinize others' moral characters. Is Hillary Clinton a bastion of moral sanity or a devious opportunist? Is Donald Trump a man of the people or a corrupt plutocrat? Is your neighbor Todd a good person because he donates 20% of his income to charity, or a bad person because he received a citation for reckless driving?

This obsession with moral character makes good evolutionary sense: People track reputation to assess who will cooperate (Sperber & Baumard, 2012). For this reason, some have argued that our moral judgments about individual acts are primarily determined by what those acts reveal about the actors' character, rather than the intrinsic properties of those acts (Goodwin et al., 2014; Uhlmann et al., 2015). This explains our interest in intentions when judging an act's wrongness (Cushman, 2008). More broadly, knowing another's character allows us to predict what he or she will do, just as knowing a thing's category tells you about its properties. A bird is likely to fly; a snake is likely to be venomous. A good person may lend a helping hand; a bad person may stab you in the back.

But often we do not know someone's moral character with any certainty. Todd gives money to charity, but might the charity be a money-laundering operation? He was driving at a reckless speed, but what if he may have been doing so because he needed to perform an emergency surgery? How do we predict Todd's actions when we cannot be sure of his intentions?

In this paper, we ask what computational principles govern our predictions of others' actions from uncertain beliefs about moral character. This work falls in a research tradition studying predictions from uncertain categories and uncertain beliefs about causation. For example, if you have uncertain evidence leading you to identify a bird as a heron with 65% probability and a crane with 35% probability, then when you predict the bird's behavior, you may assume it is definitely a heron, without hedging for the possibility it is a crane (Malt et al., 1995; Murphy & Ross, 1994). If you think there's a 75% chance that the Fed chair's statement implies a tightening of the money supply but a 25% chance it does not, you will act as though the Fed is certainly tightening the money supply when you are predicting the stock market (Johnson & Hill, 2017; Johnson et al., 2018). People often ignore uncertainty because it is computationally difficult to consider two possibilities simultaneously, considering the implications of each and integrating across those two possible worlds.

But perhaps people *would* integrate across possibilities when reasoning about moral character. First, we may have encapsulated, module-like mechanisms for aspects of mental-state understanding (Leslie, 1995) and moral judgment (Mikhail, 2007). Perhaps such domain-specific mechanisms perform more efficiently than domain-general mechanisms (Cosmides, 1989). Second, people *do* seem to integrate across possibilities for categories when one of the categories is dangerous (a shark) rather than neutral (a school of fish) (Zhu & Murphy, 2013).

By analogy, if you think an act is probably caused by a morally neutral motive, and then encounter evidence that the motive may actually have been immoral, you might take account of that motive when making further predictions about the person's future behavior. But if you instead encounter evidence that the motive may have been some *other* morally neutral motive, you may very well ignore that possibility when predicting behavior.

The Current Studies

Participants read scenarios about various actions taken by characters. For example, in one item, a driver struck a bicyclist while heading the wrong way on a one-way street. For each action, there were three possible explanations. One explanation was neutral (e.g., the driver did not know that the street was one-way; hypothesis H_{Neut}), one implied poor moral character (e.g., the driver hit the bicyclist deliberately to teach him a lesson; hypothesis H_{Imm}), and one implied that the person had some other, non-moralized trait, such as forgetfulness, risk-aversion, or poor eyesight (e.g., the driver had forgotten to turn her headlights on; hypothesis H_{Other}).

We developed a set of actions predicted by H_{Imm} or

H_{Other}. If H_{Imm} were true (the driver hit the bicyclist on purpose), then her immoral character would suggest other immoral actions (driving with expired registration; prediction Z_{Imm}). If H_{Other} were true (she forgot to turn her lights on), then her trait (forgetfulness) would suggest other related actions (leaving her windows open before a rainstorm; prediction Z_{Other}). In Pretest B, we obtained judgments of how likely each prediction was given each hypothesis. For example, we measured $P(Z_{Imm}|H_{Imm})$, the probability the driver would drive with an expired registration given that she had hit the bicyclist on purpose. We also measured $P(Z_{Imm}|H_{Neut})$, $P(Z_{Imm}|H_{Other})$, $P(Z_{Other}|H_{Neut})$, $P(Z_{Other}|H_{Imm})$, and $P(Z_{Other}|H_{Other})$.

For the Main Study, we were interested in predictions about these actions (Z_{Imm} and Z_{Other}) when participants had evidence rendering her motives (H_{Neut}, H_{Imm}, H_{Other}) uncertain, and how these predictions from uncertain motives would compare to the predictions from certain motives from Pretest B. We constructed two versions of each scenario. In one version (uncertain evidence U_{Imm}), the neutral explanation H_{Neut} was presented as most likely, but the immoral explanation H_{Imm} was also introduced as possible.[1] For example, the driver probably didn't know the street was one-way, but possibly hit the bicyclist on purpose. In Pretest A, we ensured that participants viewed the neutral intention (H_{Neut}) as likelier than the immoral intention (H_{Imm}) given the uncertain evidence—that she really *was* likelier to have forgotten about the one-way street—but also that H_{Imm} was still reasonably likely.

In the other-trait version (uncertain evidence U_{Other}), H_{Neut} was presented as most likely, but the other-trait explanation H_{Other} was also introduced as possible. For example, the driver probably didn't know the street was one-way, but possibly forgot to turn on her lights. Pretest A ensured that people viewed the neutral explanation as likelier than the other-trait explanation. Thus, Pretest A overall elicited judgments of $P(H_{Imm}|U_{Imm})$, $P(H_{Neut}|U_{Imm})$, $P(H_{Other}|U_{Other})$, and $P(H_{Neut}|U_{Other})$.

Our Main Study then tested whether people account for uncertainty about the actor's character given uncertain evidence (U_{Imm} and U_{Other}) when they are making predictions, measuring $P(Z_{Imm}|U_{Imm})$ and $P(Z_{Other}|U_{Imm})$. Would participants think the driver is likelier to perform an immoral act like driving with an expired registration (Z_{Imm}) when she possibly hit the bicyclist on purpose (U_{Imm}) than when she definitely did not (H_{Neut})? If people focus on the most likely hypothesis (i.e., ignore uncertainty about character), then they should view these immoral acts as equally likely regardless of whether there is a chance the driver behaved immorally. Moreover, they should view Z_{Imm} as much less likely if it is merely possible that the driver has poor moral character (U_{Imm}) compared to knowing this for sure (H_{Imm}). That is:

$$P(Z_{Imm}|H_{Neut}) = P(Z_{Imm}|U_{Imm}) < P(Z_{Imm}|H_{Imm})$$

Likewise, if people ignore uncertainty about non-moralized traits, the driver should be seen as equally likely to do other forgetful things regardless of whether it is possible that she forgot to turn on her lights:

$$P(Z_{Other}|H_{Neut}) = P(Z_{Other}|U_{Other}) < P(Z_{Other}|H_{Other})$$

But as mentioned earlier, people might attend to the lower-probability trait when it is moralized, but not when it is non-moralized. If so, people would think the driver likelier to commit other immoral acts even if it is merely possible that she hit the bicyclist on purpose. But people would not consider the driver likelier to commit other forgetful acts if it is merely possible that she forgot to turn on her lights:

$$P(Z_{Imm}|H_{Neut}) < P(Z_{Imm}|U_{Imm}) < P(Z_{Imm}|H_{Imm})$$
$$P(Z_{Other}|H_{Neut}) = P(Z_{Other}|U_{Other}) < P(Z_{Other}|H_{Other})$$

To test these hypotheses, Pretest A normed judgments of $P(H_i|U_k)$—inferences of character from uncertain evidence of intentions—and Pretest B normed judgments of $P(Z_i|H_j)$—predictions of future actions from certain knowledge of character. In the Main Study, we tested judgments of $P(Z_i|U_k)$—predictions of future actions from uncertain evidence of intentions, using the pretest norms to generate normative predictions for comparison.

Pretest A: Intentions from Uncertain Evidence

We first sought to norm the values of $P(H_{Neut})$ and $P(H_{Imm})$ given evidence U_{Imm} and the values of $P(H_{Neut})$ and $P(H_{Other})$ given evidence U_{Other}. That is, we evaluated the scenarios we constructed to be sure that readers interpreted them as intended. This serves two purposes. First, for an item to be included, we need the neutral explanation to be deemed likelier than the moral or non-moral trait explanations—that is, $P(H_{Neut}|U_{Imm}) > P(H_{Imm}|U_{Imm})$ and $P(H_{Neut}|U_{Other}) > P(H_{Other}|U_{Other})$. Second, these estimates are needed to compute normative responses in the Main Study.

Method

We recruited 100 participants from Amazon Mechanical Turk (50% female, M_{age} = 36.9). Participants were excluded if they incorrectly answered more than 30% of a set of 10 check questions (N = 9).

Each participant read eight items, with each item in one of two versions. In one version (U_{Imm}), the evidence suggested two possible explanations, H_{Neut} and H_{Imm}, with H_{Neut} designed to be more plausible. For example:

> Navigation through Tabbsboro is complicated by a set of one-way streets, which were put into place because the streets are too narrow to allow parking and traffic in both directions. The police recently reported on an accident that happened in one of them. One late afternoon, Cindy Harlan

[1] That is, U_X refers to a case in which the neutral explanation of the person's behavior is offered as likely, but X is mentioned as a less likely explanation. H_X refers to cases in which only explanation X is offered.

struck a bicyclist who was riding towards her car. The bicyclist was in her way and injured his hip in the accident. He was taken away in an ambulance.

[H_{Neut}] The police questioned Cindy, and she denied knowing that it was a one-way street. This was the first time she had driven on this road. There was no sign near the driveway, and she had not noticed that it was one-way when she arrived there.

[H_{Imm}] The reporting officer noted that the bicyclist, who was a teenager, had seen Cindy earlier that day, and that she seemed irritated when he and his friends didn't get out of the street fast enough when Cindy was driving to her acquaintance's home. The officer asked if Cindy went the wrong way down the road because she saw the bicyclist playing in the street again and wanted to teach him a lesson. Cindy denied this and said that she simply didn't know it was one-way.

Participants then estimated the probabilities of H_{Neut} ("Cindy hit the bicyclist because she didn't know she was driving the wrong way down a one-way street") and H_{Imm} ("Cindy hit the bicyclist because she was trying to teach the teenager a lesson"). These judgments were entered in separate text boxes on scales from 0 to 100. Since the hypotheses were not strictly exhaustive, the judgments did not have to sum to 100 (though most did).

In the other-trait version of each item (U_{Other}), the evidence suggested two possibilities, H_{Neut} and H_{Other}, with H_{Neut} again more plausible. For the item above, the last paragraph of the U_{Imm} version was replaced with:

[H_{Other}] The reporting officer noted that Cindy's lights were not on. He asked if she might not have seen the bicyclist because she had forgotten to turn her lights on. Cindy pointed out that the accident had happened almost an hour ago, when it was light out.

Participants then judged H_{Neut} and H_{Other} ("Cindy hit the bicyclist because she didn't have her lights on").

Participants saw one version of each item, with half of the items in version U_{Imm} and half in version U_{Other}, counterbalanced across participants. The order of the probability judgments was randomized for each item.

Results

All eight items met our desired conditions (see Appendix). Mean judgments of $P(H_{Neut}|U_{Imm})$ and $P(H_{Neut}|U_{Other})$ ranged from 65% to 82% across items (Ms = 75.1% and 74.3%, respectively), and judgments of $P(H_{Imm}|U_{Imm})$ and $P(H_{Other}|U_{Other})$ ranged from 17% to 32% (Ms = 24.2% and 25.3%, respectively).

Pretest B: Predictions from Certain Intentions

Next, we normed the values of the predictions, $P(Z_{Imm})$ and $P(Z_{Other})$, given certain intentions H_{Neut}, H_{Imm}, and H_{Other}. Once again this has two purposes. First, an inclusion criterion: We want the immoral prediction Z_{Imm} to be more plausible given the immoral than the neutral intention—that is, $P(Z_{Imm}|H_{Imm}) > P(Z_{Imm}|H_{Neut})$—and likewise for the prediction Z_{Other} to be more plausible given the other-trait than the neutral intention—that is, $P(Z_{Other}|H_{Other}) > P(Z_{Other}|H_{Neut})$. For example, since the immoral prediction Z_{Imm} in our example was driving with an expired registration, we needed to ensure that people agree that someone who hits a bicyclist on purpose (H_{Imm}) is more likely to drive with an expired registration (Z_{Imm}) than someone who hit the bicyclist accidentally (H_{Neut}). Second, these values—predictions given certain intentions—are needed for comparison with the Main Study, which measured predictions given uncertain intentions.

Method

We recruited 149 participants from Mechanical Turk (29% female, M_{age} = 33.9). Participants were excluded using the same criterion as Pretest A (N = 25).

Each participant read eight items, with each item in one of three versions. In one version, H_{Neut} was true. For the Tabbsboro example, the first paragraph was the same as in Pretest A, and the remainder of the item read:

Cindy didn't realize that it was a one-way road. This was the first time she had driven on this road. There was no sign near the driveway, and she had not noticed that it was one-way when she arrived there.

In a second version, H_{Imm} was true:

Cindy had pulled out of an acquaintance's driveway and turned left, even though that was the wrong way for this one-way street. She went the wrong way because she saw several kids who had irritated her earlier in the day for not getting out of the street fast enough, so when she saw them again, she wanted to drive close to them to teach them a lesson.

Finally, in a third version, H_{Other} was true:

Cindy had pulled out of an acquaintance's driveway and turned left, but she didn't see the bicyclist because she had forgotten to turn her lights on.

Participants then estimated five probabilities for each item. We included two versions each of Z_{Imm} ("What is the probability that Cindy would drive her car with an expired vehicle registration?") and Z_{Other} ("What is the probability that Cindy would forget to shut her window the night before a thunderstorm?"). For the Main Study, we chose the best version for each item to maximize the chance we could use a given item. We also included a filler item ("What is the probability that the city will install a clearer sign in the next week?") which would not necessarily vary based on Cindy's intention. These judgments were made using the same procedure as Pretest A.

Participants saw one version of each item, with the eight items distributed about evenly across the three versions, counterbalanced across participants. The order of the probability judgments was randomized for each item.

Results

The probability of Z_{Imm} was consistently judged higher given H_{Imm} than given H_{Neut}; that is, $P(Z_{Imm}|H_{Imm}) > P(Z_{Imm}|H_{Neut})$ for all items (Ms = 65.6% and 26.4%, respectively), with the difference between these conditional probabilities ranging from 26.7% to 53.4% across items (see Appendix). $P(Z_{Other}|H_{Other})$ was higher than $P(Z_{Other}|H_{Neut})$ for all items but one (Ms = 60.7% and 49.8%, respectively), with the difference between these probabilities varying from –1.5% to 23.2% across items.

Since all items satisfied the desired conditions for Z_{Imm}, we did not exclude any items for the Main Study. However, these results suggest two caveats. First, it is difficult to compare participants' inferences about moral versus other kinds of traits, since the morally laden predictions (Z_{Imm}) were much more responsive to knowledge of intentions compared to the non-morally laden predictions (Z_{Other}—see later discussion). Given this limitation, any conclusions about moralized versus non-moralized character traits must be provisional. Second, because some of these items were not very robust for the non-morally laden predictions, we repeat key analyses on individual items.

Main Study: Predictions from Uncertain Evidence

The Main Study tested inferences about people's future actions based on uncertain knowledge of their intentions. Participants saw the evidence normed in Pretest A, making predictions about the actions normed in Pretest B.

Method

We recruited 99 participants from Mechanical Turk (54% female, M_{age} = 37.5). Participants were excluded using the same criterion as in the pretests (N = 1).

Participants read the eight vignettes used in Pretest A, each in one of the two versions (either U_{Imm} or U_{Other}). For each item, participants were asked questions across two pages (with the vignette text displayed on the screen for both). On the first page, participants made predictions of Z_{Imm} and Z_{Other}, using the phrasing normed in Pretest B. On the second page, participants indicated which intention they thought was likelier. For the U_{Imm} version of the item, participants chose between H_{Neut} ("Cindy hit the bicyclist because she didn't know she was driving the wrong way down a one-way street") and H_{Imm} ("Cindy hit the bicyclist because she was trying to teach the teenager a lesson"); for the U_{Other} version, participants chose between H_{Neut} and H_{Other} ("Cindy hit the bicyclist because she didn't have her lights on").

Results

Overall, participants tended to place positive weight on the immoral explanation H_{Imm} when making predictions, even when they acknowledged that the neutral explanation H_{Neut} was likelier. This is a departure from most previous studies of predictions from uncertain beliefs. On the other hand, there was little evidence that participants placed any weight on the other-trait explanation H_{Other} when making predictions, which raises the possibility that people might attend selectively to evidence of immoral intentions. Finally, there was modest evidence that people underweighted H_{Imm} relative to normative standards, and considerable evidence for underweighting H_{Other}.

We tested reliance on H_{Imm} in two ways. First, we conducted an item-level analysis, averaging probability judgments across all participants (see Appendix). Unsurprisingly, mean judgments of $P(Z_{Imm}|U_{Imm})$ (31.9%) were lower than $P(Z_{Imm}|H_{Imm})$ in Pretest B (65.6%), $t(7) = 8.80$, $p < .001$, $d = 3.11$, reflecting the fact that H_{Imm} had a low prior probability given evidence U_{Imm}. More interestingly, mean judgments of $P(Z_{Imm}|U_{Imm})$ (31.9%) in this study were higher than $P(Z_{Imm}|H_{Neut})$ in Pretest B (26.4%), $t(7) = 3.37$, $p = .012$, $d = 1.19$. That is, when the evidence is uncertain between H_{Neut} and H_{Imm}, predictions of Z_{Imm} fall between predictions made when either H_{Neut} or H_{Imm} is certain. This shows that people take both H_{Imm} and H_{Neut} into account when predicting Z_{Imm}. (In English: When there are two possibilities, the induction will take both into account and therefore lie in between the predictions given either possibility alone.)

We can also use the data from Pretests A and B to calculate normative values of $P(Z_{Imm}|U_{Imm})$:

$$P(Z_{Imm}|H_{Neut})P(H_{Neut}|U_{Imm}) + P(Z_{Imm}|H_{Imm})P(H_{Imm}|U_{Imm})$$

These normative responses are given in the Appendix for each item (M = 35.7%). Participants' actual judgments (M = 31.9%) were marginally more conservative, $t(7) = 1.99$, $p = .087$, $d = 0.82$, compared to the normative responses, suggesting that participants underweighted H_{Imm}. Although statistically not very robust, this would be consistent with previous studies, finding that people underweight unlikely hypotheses, even when they do not ignore them entirely (Johnson, Merchant, & Keil, 2018).

This item analysis, however, can be criticized because it lumps together participants who agreed that H_{Neut} was likelier than H_{Imm} (which should be the dominant belief, based on Pretest A), with those who believed the converse. In fact, about 19% of responses disagreed with our assumption that H_{Neut} was likelier. Thus, the analysis above could be lumping together two populations: Those who believed H_{Neut} was likelier and assigned no weight to H_{Imm}, and those who believed H_{Imm} was likelier and assigned no weight to H_{Neut}. The item means would look like both hypotheses are being considered, but this is an illusion due to mixing two populations (Malt et al., 1995).

Thus, our second approach analyzed the data at the level of individual participants, including only participants for each item who agreed that H_{Neut} was the likelier than H_{Imm}. Using this approach, participants rated $P(Z_{Imm}|U_{Imm})$ numerically higher than the average pretest ratings of $P(Z_{Imm}|H_{Neut})$ for 6 of the 8 items, significantly so for three of the items (items 2, 5, and 6; ps < .02); one

item was significant in the opposite direction (item 7; p = .026). Overall, this evidence is moderately consistent with the idea that people often place weight on H_{Imm} even when they view H_{Neut} as likelier.

We also used this approach to test whether people would *underweight* H_{Imm} even when they assigned positive weight to it. For this analysis, we included all participants (even those indicating that H_{Imm} was likelier than H_{Neut}) because the estimates from Pretest A, used to calculate normative values, average across both kinds of participants. Participants rated $P(Z_{\text{Imm}}|U_{\text{Imm}})$ numerically lower than its normative value for 5 of the 8 items, but significantly for only one item (item 7); no items were significant in the opposite direction.

The above analyses focused on the U_{Imm} condition. What about the U_{Other} condition? The item analysis found that judgments of $P(Z_{\text{Other}}|U_{\text{Other}})$ (M = 45.2%) were lower than $P(Z_{\text{Other}}|H_{\text{Other}})$ from Pretest B (M = 60.7%), $t(7)$ = 2.85, p = .025, d = 1.01. But unlike the U_{Imm} condition, there was no evidence that people took account of H_{Other}, since $P(Z_{\text{Other}}|U_{\text{Other}})$ judgments (45.2%) did not differ from $P(Z_{\text{Other}}|H_{\text{Neut}})$ judgments from Pretest B (49.8%), and indeed were in the wrong direction on average, $t(7)$ = –0.86, p = .42, d = –0.31. That said, these judgments also did not differ significantly from their normative values (52.6%), $t(7)$ = 1.47, p = .18, d = 0.50 (although the normative values themselves did differ significantly from $P(Z_{\text{Other}}|H_{\text{Neut}})$; p = .023). These inconclusive results are probably due to the poor diagnosticity of intentions for predicting Z_{Other}, shown in Pretest B.

Since the diagnosticity differed across items, it is useful to conduct subject-level analyses for each item, as we did for the U_{Imm} condition. Looking at just those who agreed that H_{Neut} was likelier than H_{Other}, ratings of $P(Z_{\text{Other}}|U_{\text{Other}})$ were higher than the average pretest ratings of $P(Z_{\text{Other}}|H_{\text{Neut}})$ for only 3 out of the 8 items, with only one item reaching significance (item 1; p = .037), and three items reaching significance in the opposite direction (items 6, 7, and 8; ps < .001). Conversely, looking at all participants, ratings of $P(Z_{\text{Other}}|U_{\text{Other}})$ were lower than the normative scores for 5 out of the 8 items, with 4 items reaching significance (items 2, 6, 7, and 8; ps < .02). These results cast doubt on the idea that people place positive weight on the other-trait hypotheses when making predictions, suggesting that people underweight such hypotheses. However, this conclusion must be provisional given the poor diagnosticity of some of the non-moralized traits.

Discussion

Judgments of moral character are central to social life. They guide our decisions about who we interact with, inform our beliefs about what others are thinking, and help us to predict what others are going to do. But moral character is often ambiguous, since we often cannot know others' intentions with certainty. How do we predict others' behavior when their character is uncertain?

First, in contrast to other studies of predictions from uncertain beliefs (Johnson et al., 2018; Malt et al., 1995), we find that people have at least some ability to account for the possibility of immoral character, even when it is relatively unlikely. In vignettes where characters were assigned a 25% probability of a nefarious motive, people took this motive into account when predicting other immoral behaviors. Although this result was not consistent across all of our items, it was statistically robust for some of them and was significant overall.

Second, it is possible that this ability to account for uncertain traits is specific to moral traits. There was little evidence that participants weighted uncertain non-moral traits (e.g., poor eyesight) in predictions. This result is limited by the relatively poorer quality of our non-moral than of our moral items, suggesting the need for future research with more directly comparable items.

This problem, however, may reflect a real issue in making predictions about human behavior. When someone makes a mistake of some kind (as all these examples are), there are many factors that could be involved, and it may be hard to rule any out. If someone makes a wrong turn while driving, the person could well have not been paying attention, the sign might not have been very clear, the traffic might have been distracting, and so on. The presence of one of these explanations does not greatly reduce the possibility that one of the others also applied. Thus, such explanations based on non-moral character traits may not be very diagnostic about future actions. Morality, in contrast, may be of special interest to people precisely because it is thought to be diagnostic.

Third, we compared judgments to normative benchmarks. There was a trend toward underweighting the less-likely hypothesis. For the moral traits, this trend reached only marginal significance overall because participants' judgments were actually quite close to the normative benchmarks; only one individual item revealed significant evidence of underweighting. For the non-moralized traits, there was less room for reliable differences to emerge between actual and normative judgments overall, given the poor quality of some of the non-moral items. But there was considerable evidence for underweighting for half of the individual items. Thus, there seems to be more robust underweighting of unlikely non-moral traits than of unlikely moral defects.

These results contribute to several conversations in cognitive and social psychology. First, they add to our understanding of when people account (or fail to account) for uncertainty in probabilistic reasoning (e.g., Johnson et al., 2018; Zhu & Murphy, 2013). Second, they help to elucidate the mechanisms by which we compute others' mental states (Jara-Ettinger et al., 2016; Leslie, 1995). Finally, they sharpen our understanding of the interplay between domain-specific and domain-general computational principles in moral judgment (Cosmides, 1989; Mikhail, 2007). Moral reasoning may be more than just a special case of general-purpose thought.

Abstract

Since we rarely view our own body movements in our daily lives, understanding the recognition of self-body movement can shed light on the core of self-awareness and on the representation of actions. We first recorded nine simple and nine complex actions performed by individual participants, who also subsequently observed nine videos displayed on the screen and imitated these actions. After a delay period of 35-40 days, participants were asked to identify their self- body movements presented as point-light displays amongst three other actors who performed the same actions. Participants were able to recognize themselves solely based on kinematics in point-light displays. However, self-recognition accuracy varied according to the complexity of performed actions, with more accurate self-recognition for complex than simple actions. The ability of self-recognition with simple actions showed a significant relation with autistic traits (negative relation: poorer self-recognition accuracy with more autistic traits), schizophrenic traits (quadratic non-linear relation, participants with the median degree of schizophrenia traits performed better than participants at the extremes), and with imitation actions and motor imagery traits (linear relation: increased self-recognition accuracy with greater motor imagery). We also found that participants did not recognize actions that only required visual experience but could identify their self-generated actions that required motor experience, underscoring the importance of motor experience to the representation of self-body movements.

Keywords: self-recognition, body movement, action, individual differences

Introduction

Of the fundamental prerequisites of human existence, the recognition of the "self" is a crucial pre-reflective, automatic process, underlying human perception and cognition. The ability to self-recognize is fundamental to the construction of an identity, agency, self-awareness, and self-consciousness (Gallup, 1970), and impairments in self-recognition ability can impact the quality of social interaction and communication (Ornitz & Ritvo, 1968)

Constructing the "self" is complex, accounted for by various disciplines all attempting to instantiate a definition. For example, examining a singular construct such as self-consciousness, has been extensively studied in humans, other primates, dolphins, and even extended to non-human agents, such as robots. Importantly, most of these accounts of self-processing are rooted in recognition-based self-face processing (e.g., Uddin, Iacoboni, Lange, and Keenan, 2007), famously standardized by Gallup (1970) in his prototypical mirror mark test. However, only relying on self-face recognition as an index for identifying the self is limited to serve as a general account for the integrated self-processing based holistically on face, body, voice and even body movements.

Given the dynamism of our everyday environment and lack of privileged access to viewing our bodies in motion, movements of our own body may serve as a good measure without relying on rich visual experiences of the self. In this vein, several studies extended self-recognition from static faces to whole-body movements, with visual input reduced to dynamic dot movements, as in point-light displays. After participants' body movements were recorded with a motion capture system, participants were still able to recognize their own action, even with scant visual information (Cutting & Kowlowski, 1977). Such above-chance performance for self-recognition extracted from predominantly from body kinematics was found for many different actions that varied in complexity (Loula et al., 2005; Burling, Kadambi, Safari, & Lu, 2018).

The impact of intrinsic traits to self-recognition ability, on the other hand, is less studied in the literature. There are a number of reasons as to why it is important to measure individual difference traits in self-body recognition. First, the unique contribution of various individual difference measures can uncover critical information that could potentially be lost through group-level averaging (Peterzell, 2016). Additionally, self-recognition is a complex process, with its investigation particularly hampered by its own operationalization and resulting lack of objectivity (consisting of no clear-cut computational investigation).

What individual differences might impact self-recognition from body movements? The joint contribution of both action perception and understanding likely recruits a distinct neural system, with the most prominent account surrounding the mirror neuron system. The mirror neuron account of action understanding suggests that perception and action are tightly linked through a "mirroring", simulation-based mechanism that allows humans to understand the kinematic goals of actions (Rizzolatti & Craighero, 2004). Impairments in this mirroring mechanism may underlie social perception disorders such as Autism and Schizophrenia. Consistent with this view, previous behavioral research in biological motion perception has shown that individuals with Autism (Blake et al., 2003, Moore et al., 1997) and individuals with Schizophrenia demonstrate impairments in biological motion

perception, such as in discriminating communitive actions from non-communicative actions presented in point-light displays (Okruszek et al., 2015).

The ability to interpret social actions not only shows impairment in individuals clinically diagnosed with Autism Spectrum Disorder and Schizophrenia, but also individual differences amongst typical populations in those with varied degrees of autistic traits (Miller & Saygin, 2013; Ahmed & Vander Wyk, 2013; van Boxtel, et. al., 2017), as well as schizophrenic traits, which impacts self-face processing (Platek & Gallup, 2002). Given the individual differences in biological motion perception in the general population, it is possible that people may show differing ability in self-recognition of own body movements. To date, only one other study (Burling et al., 2018) has compared self-recognition performance of body movements between people with high degree of autistic traits and people with low autistic traits. This study found a significant difference at the performance level between the two groups of participants. However, no study has systematically mapped out any other individual difference measures and run a large sample of participants to examine the individual differences in self-recognition from body movements.

In the present study, we included three different individual difference measures: autistic traits, schizophrenic traits, and motor imagery traits, all of which are linked to both social perception and likely functions of the mirror neuron system. Three main research questions were addressed. First, how well can people identify themselves from only the kinematics of body movements, and does the performance of self-recognition depend on the complexity of performed actions? Second, to what extent does the interplay between motor (more mirror-based) and visual experience (more perception-based) determine the performance of self-recognition from actions? Finally, how do individual differences in the ability to recognize own-actions displayed in point-light stimuli relate to motor imagery ability and distinct socio-cognitive traits (autistic and schizophrenic)?

Experiment

Method

Participants 71 undergraduate students (M_{age} = 20.98) were recruited through the Subject Pool at the University of California, Los Angeles. The study was approved by the UCLA Institutional Review board. All participants were provided course credit for their participation, and were naïve to the purpose of the study. Participants had normal or corrected-to-normal vision and no physical disabilities.

Procedure The experiment was split into two sessions: motion recording and action recognition. The first phase consisted of a motion recording session, where participants performed various actions and were recorded with a motion capture system. The second phase, consisted of two action recognition components. The first component, the self-recognition session, occurred after a delay period of 30 – 45 days. The stimuli were first generated in the action recording session and subsequently tested in the self-recognition task. Immediately, following the self-recognition task, participants completed the final action recognition task, consisting of a visual recognition" task.

Materials

Apparatus Participants' body movements were recorded using the Microsoft Kinect V2.0 and Kinect SDK in a quiet testing room. Here, participants were instructed to perform the actions in a rectangular 2.5 x 5 ft space, in order to provide flexibility to perform the action, while remaining within recording distance. The Kinect was placed 5 ft above the floor and 8.5 ft away from the participant. The three-dimensional (X-Y-Z) coordinates of the key joints were extracted at a rate of approximately 33 frames per second and later used to generate point-light displays of actions (see Figure 1). Customized software developed in our lab was utilized to enhance movement signals, and to carry out additional processing and trimming for actions presented later in the testing phase (van Boxtel & Lu, 2013).

Stimuli Generation For each participant, 27 point-light displays performing different actions were captured based on their body movement recordings. The first nine actions were simple actions which included *grab, jump, wave, lift, kick, hammer, push, point, punch.* The next nine actions were complex actions, which included: *argue, macarena, wash windows, play baseball, get attention, hurry up, fight, stretch, and play guitar.* These actions were selected in part based on a previous self-recognition study (Burling et al., 2018), but four actions (*macarena, wash windows, play baseball, play guitar*) were modified to be more constrained from their original actions (*dance, clean, play sport, play instrument*) in order to reduce the impact of memory cues. The actions varied in complexity in order to characterize a broad range of common movements in daily life. During action selection, simple and complex actions were determined by whether the action was a simple goal (e.g., wave) or a complex goal (e.g., argue), and all actions were selected to be commonly encountered actions.

The final nine actions were labeled imitation actions, which included *jumping jacks, basketball, bend, direct traffic 1, direct traffic 2, conversation, laugh, digging a hole, and chopping wood.* The nine imitation actions were selected from the Carnegie Mellon Graphics Lab Motion Capture Database available online (http://mocap.cs.cmu.edu) and also captured a broad range of variability and goal-directed actions. Some imitation videos were easily recognizable to subject (e.g., basketball), while others were unclear in what they conveyed (e.g., directing traffic). Each video displayed a stick figure performing one of the imitation actions and was presented in three different angles to the subject, either to the right or left (+/- 45°) or facing forward (0°) by rotating the horizontal axis. The varying viewpoints were included in order to assess the inherent viewpoint dependence in self-recognition. Each imitation action was recorded twice: once after viewing the three different angles, and once more after viewing only the forward-facing angle. In the self-recognition phase, the first imitation recording served as

practice, and only the second imitation recording was utilized.

Following action recording and prior to the self-recognition session, we filtered noise from the movements by applying a double exponential adaptive smoothing filter (LaViola, 2003), in order to remove recording errors from the Kinect system (e.g., missing a joint due to occlusion or small jitter for some joints). Additionally, the stimuli were trimmed in order to display the point light-displays (van Boxtel & Lu, 2015) with their segmented action recording, which would be reiteratively looped in the self-recognition session.

Procedure

Motion Recording Session

For the 18 simple and complex actions in the first recording session, participants were provided verbal instruction and instructed to perform the actions as naturally as possible. As a result, the action was open to interpretation, in order to emphasize the lack of a systematic way to perform the action. For the remaining nine imitation actions, all the participants were naïve to the name of the action. Instead, participants were visually instructed to *imitate* the actions (however they chose to imitate), in order to emphasize their naturalistic response to "imitation." After completing the action recording, participants completed two questionnaires: Schizotypal Personality Questionnaire (SPQ) and the revised Vividness of Motor Imagery Questionnaire (VMIQ-2). The SPQ was administered to assess degrees of schizotypal traits among individuals in the typical population. The VMIQ-2 was included to assess motor imagery differences as a potential source of variability in biological motion perception. Since perception and motor imagery representations presumably share common resources, we hypothesized that there may be correlations between the two abilities (Miller & Saygin, 2013; Iacoboni & Dapretto, 2006).

Recognition Session: Self-Recognition Task

In the subsequent self-recognition task, participants returned after a delay period of 30-45 days later in order to minimize the effect of memory on performance. Participants were seated 2.5 feet in front of a monitor in a dimly lit room and were asked to select their own action amongst three other distractor actions spread out horizontally along the center of the screen, as shown in Figure 1.

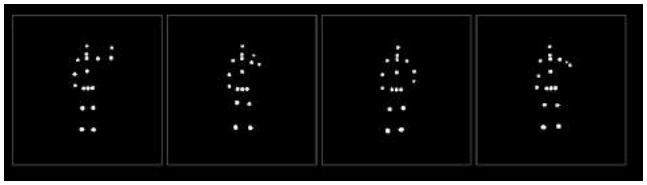

Figure 1. Illustration of a sample trial showing wave action (wave). One point-light display is the participant's action, while the other three point-lights are distractor actions normalized for gender, width, and height.

Each action was presented with 17 point-lights located at key joints, in three different orientations (rotated around the vertical axis 0°, (facing front), 45° (facing right), 225° (facing left), for a total of 81 trials. However, all of the actions within a trial displayed the same orientation. The actions were looped until the participant selected one of the four boxes, or until a time period of 30 seconds. Participants were not provided any feedback. Participants were instructed to select their own point-light action amongst four displays. The four animations included their own action and the corresponding actions performed by three other distractor actions that were normalized for height and gender.

Recognition Session: Visual Recognition Task

44 of the participants also participated in an additional visual recognition task consisting of nine trials displaying only the forward-facing imitation actions. The order of presentation of the visual recognition task was counterbalanced to either follow or precede the self-recognition task. Since imitation is a unique behavior that consists of both action observation and action performance, this additional task was included to assess whether performance would differ from the self-recognition task, and to understand the contribution of motor experience to self-recognition accuracy. Including this task could potentially allow us to contrast action observation in conjunction with execution (self-recognition task) with solely action observation (visual recognition task). Participants were instructed to identify the actor previously shown during the imitation recording amongst three other actors who performed the same action. Importantly, while the visual layout of the task was identical to the self-recognition session, the participants' own action was replaced by the original imitation actor from the Carnegie Mellon Database. As a result, participants' own point-light display was never amongst the four actions displayed on the screen. The remaining three distractor actions were maintained from the self-recognition session.

Following testing in the self-recognition and visual recognition task, participants were asked to complete an Autistic Quotient (AQ) questionnaire to assess the degree of Autistic traits (Baron, Cohen et al., 2001).

Individual Difference Measures

Autistic Quotient The Autism-Spectrum Quotient (AQ) questionnaire consists of 50 questions and is the most commonly used method to measure self-reported autistic traits (Baron-Cohen et al., 2001). Recent evidence has identified an overlapping genetic and biological etiology underlying ASD and autistic traits (Bralten et al., 2017) in addition to behavioral overlap (Baron-Cohen et al., 2001). Several studies of biological motion perception have reported an association between AQ scores and performance on various tasks (Miller & Saygin, 2013; Ahmed & Vander Wyk, 2013; van Boxtel et al., 2017). The AQ measures five different subtypes (social skill, attention switching, attention to detail, communication, and imagination).

Schizotypal Personality Questionnaire The Schizotypal Personality Questionnaire (SPQ) is a 74-question survey, designed to screen for schizotypal personality disorder in the general population. The SPQ is administered to assess

degrees of schizotypal traits among individuals in the typical population. It measures three constructs of schizotypy: cognitive, perceptual dimension (positive schizotypy), interpersonal dimension (negative schizotypy), and disorganized feature dimension (odd behavior, speech) based on DSM-IV criteria (Raine, 1991). The SPQ consists of nine different subtypes (ideas of reference, social anxiety, odd beliefs, unusual perceptual experiences, eccentric behavior and appearance, no close friends, odd speech, constricted affect, and suspiciousness/paranoid ideation).

Vividness of Motor Imagery Questionnaire The VMIQ-2 (Roberts, 2008) is designed to measure vividness of imagery in kinesthetic (movement simulation), internal (first person simulation), and external (third person simulation) visual imagery of 12 different actions in a series of three separate sections. Vividness of motor imagery is rated on a five-point Likert scale for each of the 12 actions in each of the three sub-areas (lower scores indicate more vivid images). According to simulation theory, perception and motor imagery representations share common resources (Miller & Saygin, 2013; Iacoboni & Dapretto, 2006). Therefore, the VMIQ-2 was included to assess motor imagery differences as a potential source of variability in biological motion perception.

Results

Self-recognition from body movements

Average self-recognition accuracy was .46 (SD = .12), significantly above chance level of .25 ($p < .001$), indicating that participants were able to self- recognize primarily on the kinematics of their body movements. As shown in Figure 2, participants were able to recognize all actions significantly above chance performance: for simple actions with verbal instruction (M = .40, SD = .15), for complex actions with verbal instruction (M = .56, SD = .16), and for imitated actions with visual display (M = .41, SD = .16). One-way ANOVA results revealed a significant main effect of action type (simple, complex, and imitation) on self-recognition performance, $F(2, 140) = 44.66$, $p < .001$, $\eta_p^2 = 0.389$. Specifically, self-recognition was more accurate for complex than simple actions ($t(70) = 9.026$, $p < .001$) and imitation actions ($t(70) = 7.749$, $p < .001$).

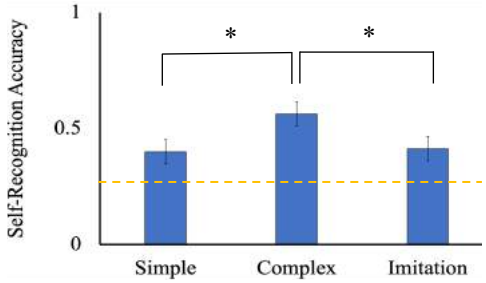

Figure 2. Self-recognition accuracy by the type of Action. Dashed line indicates chance performance (0.25). The error bars indicate standard error of means.

To examine whether the visual representation of own-body movements was viewpoint- invariant or viewpoint-specific, we conducted a one-way ANOVA consisting of orientation (facing left: 225°, front: 0°, right: 45°) on self-recognition performance $F(2, 140) = .335$, $p = .716$. We found that people recognized their own actions equally well from different viewpoints, suggesting a viewpoint-invariant representation of self-generated actions. A previous study similarly found that recognition of walking patterns from self-generated point-light displays was independent of the viewing angle. This is likely due to simulating the motor action through referring to three-dimensionally stored motor representations (Jokisch, Daum, & Troje, 2004).

We compared recognition of imitation actions from motor experience (as in the self-recognition task), and recognition of imitation actions from the visual experience task (where subjects had to identify the imitation action they observed but was not their own). We found people recognized actions less accurately from visual experience (M = .239) than from self-generated (M = .404) actions ($t(43) = 4.987$, $p < .001$). Due to around-chance performance for identical actions with only visual experience, prior visual experience does not appear to be sufficient for self- recognition. This suggests that motor experience may constrain visual experience and is critical to the recognition of one's own action. Importantly, every individual has experience with their own motor actions. Identifying oneself may require the ability to simulate the action onto one's own motor system, with self-recognition in turn dependent on a matching process- matching simulated action to performed action.

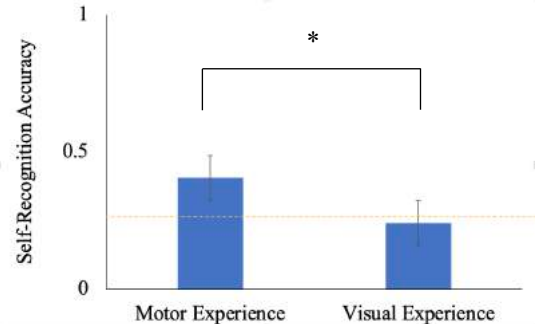

Figure 3. Self-recognition accuracy by experience type (visual vs motor). Significantly worse performance for imitation actions from visual experience than for self-recognition from performed actions. Dashed line indicates chance performance (0.25). Error bars indicate standard error of means.

Relations between self-recognition and individual difference measures

We did not find any significant correlations between self-recognition performance for complex actions and the individual difference measures. However, we found significant relations between self-recognition performance for simple actions with various individual difference measures. As shown in the top panel of Figure 3, a significant relationship was revealed between overall motor imagery

ability and self-recognition performance for imitation actions (spearman ρ = -.241, p = .043). For simple actions, a significant negative relationship emerged (Figure 3, middle) between the degree of autistic traits (AQ score) and self-recognition performance (spearman ρ = -.244, p = .040), revealing that people with more autistic traits performed less accurately in self-recognition with simple actions. To further probe the impact of autistic traits on self-recognition performance, we examined specific subtypes of the Autistic Quotient. We found a significant correlation between simple actions and the communication AQ subscale scores (spearman ρ = -.316, p = .007), but not with other subscale scores. For individual differences in schizophrenia traits, as shown in Figure 3 bottom plot, the trend analysis revealed a significant quadratic relationship between schizophrenia traits (SPQ score) and self- recognition performance, ($F(2,68) = 4.166$, p = .020) , with participants scoring near the median of SPQ scale performing better than participants at the extremes in self-recognition. More discussion about the non-linear relation is included in the discussion section.

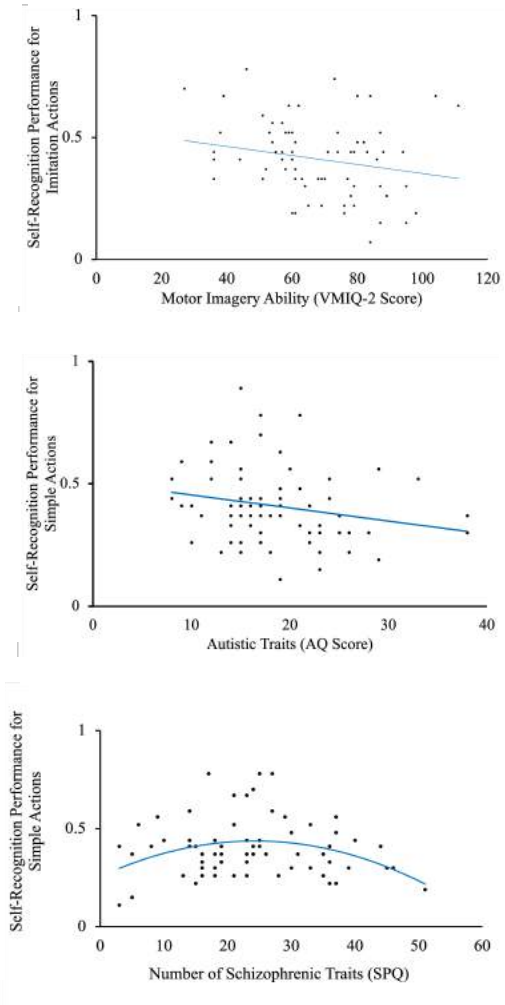

Figure 4. Relations between self-recognition performance and individual difference measures. Top: Positive relationship between motor imagery simulation and self-recognition for imitation actions. Middle: Negative relationship between autistic traits and self-recognition for simple actions. Bottom: Quadratic relationship between schizophrenic traits and self-recognition for simple actions (worse self-recognition at the extreme scores)

Discussion

The ability to self-recognize is integral to the construction of oneself as a unique entity, separate from the external world. Utilizing dynamic actions construed through self-generated point-light displays is a significant improvement over prototypical indices of self-recognition. Therefore, in the present study, we adopted the motion capture paradigm to examine how well people can identify themselves from only the kinematics of body movements from a range of commonly encountered actions. We found that participants were able to reliably self-recognize solely based on kinematics in point-light displays, in line with previous findings (Burling et al., 2018; Loula et al., 2005; Cutting & Kowlowski, 1977). Self-recognition accuracy also varied according to the complexity of performed actions, with more accurate self-recognition for complex than for simple actions, also corroborating a recent study (Burling et al., 2018). Since the complex and simple actions differed based on their variability, greater self-recognition for complex actions may be driven by the unique movement signatures available from these actions and increased motor planning (lack of automaticity) while performing complex actions. Importantly, the biometric identity cues in simple actions (e.g. walking) may not be readily apparent to the human visual system to recognize and differentiate these actions involving little variability (Dittrich, 1993; Loula et al., 2005). Therefore, participants exhibited greater self-recognition performance for the rich visual input conveyed by complex action sequences.

To assess the mechanisms underlying self-action recognition, we examined the contribution of visual and motor experience. Previous literature has indicated that people rely on motor experience when recognizing their own-body actions, as evidenced by greater recognition performance for self-generated point-light displays (reliant on motor experience) over close friends (reliant on visual experience) and strangers, presumably due to an internal simulation of the action (Loula et al., 2005). Conceptually, this is straightforward, as humans generally do not have privileged access to observe own locomotion movements from a third-person perspective, and consequently, experience little visual feedback (Jokisch, Daum, & Troje, 2004).

Therefore, to systematically contrast the relative importance of visual versus motor experience, we included an additional visual recognition task, wherein participants were asked to identify the imitation action they observed in the action recording session. We found that participants did not recognize actions that only required visual experience (actions they previously imitated, but that were not their own). Instead, participants were only able to identify their self-generated actions that required motor experience,

underscoring the importance of motor experience to the representation of self-body movements.

Finally, we measured individual differences in self-recognition performance. We looked at three correlates of variability in the general population: motor imagery (as measured by the VMIQ-2) and two social perception traits (autistic and schizophrenic traits). Both Autism and Schizophrenia are linked to dysfunctions of the mirror neuron system and impairments in social perception. Because action perception is presumed to involve an internal simulation on one's own motor repertoire, we hypothesized reduced simulation ability in individuals high on the Autistic Quotient and Schizophrenic Quotient.

Success in self-recognition with simple actions showed a significant relation with autistic traits (negative relation: poorer self-recognition accuracy with more autistic traits), schizophrenic traits (quadratic non-linear relation: participants with the median degree of schizophrenia traits performed better than participants at the extremes), and motor imagery traits (linear relation: increased self-recognition accuracy for imitation action with greater motor imagery).

We found that self-recognition performance for simple actions was affected by the participant's degree of autistic traits, in line with results from a recent study by Burling and colleagues (2018). One possible explanation could be due to a general processing style in autism, as decreased attention directed toward social stimuli in high-AQ individuals (see Chevellier et al., 2012) or weakened top-down influence (Lu, Tjan, Liu, 2006) and adaptability to social environment in autism (Thurman, et. al., 2016, van Boxtel, et. al., 2013). Although typical human adults are sensitive to social information in actions (Thurman & Lu, 2014; Su, van Boxtel & Lu, 2016), such ability is impaired in autism which could result in the worse performance in self-action recognition for people with high degree of autistic traits. Another explanation may pertain to a specific and mechanistic account, an underlying dysfunction in the mirror neuron system, with an impairment in self to other matching. A useful indicator related to the simulation-component of the mirror neuron system, is motor imagery, presumably reliant on an internal simulation of one's own motor system of the activated action (Jeannerod, 2001; Miller & Saygin, 2013). Specifically, the relationship between poorer self-recognition performance for simple actions and individuals with high autistic traits may be linked to worse motor imagery ability, as we found greater self-recognition accuracy with increased motor imagery ability. Additionally, in the clinical population, a previous study (Conson et al., 2013) found that subjects with Autism Spectrum Disorder exhibited alterations in mental hand rotation, specifically linked to impairments in motor action simulation. Further characterizing the link between motor imagery deficits and autistic traits in the general population may shed light on the underlying mechanisms of motor imagery and mirror neuron impairments in Autism.

We conjecture that worse performance for individuals with high schizophrenic traits may be due to over-simulation and motor imagery deficits (Sack et al., 2005), leading to delusions and hallucinations- a mark of positive schizotypy. For worse performance on simple actions with a low degree of schizophrenic traits, we hypothesize a lack of motor imagery ability as vividness of motor imagery is theorized to be an independent trait marker of Schizophrenia and simple actions may require a greater degree of simulation to dissociate between distractors (Sack et al., 2005).

Our study did not reveal any significant correlations between complex actions and the individual difference measures. Since complex actions may rely more on distinctive movement cues customized for different individuals, or long-term memory (specifically memory of how one would perform the action), it is likely that participants need not rely on motor simulation.

Collectively, the present results demonstrate that motor experience is an important component to understanding the core of self-body processing. Importantly, the perceptual representation of self-generated actions is affected by the degree of three key individual difference measures linked to the action understanding account of the mirror neuron system: autistic traits, schizophrenic traits, and motor imagery traits.

Abstract

Learning new words does not only require infants to find words in continuous speech, but also be remember recently segmented words and link them to meaning. Prior research has shown that statistical learning supports word learning. However, as infant statistical learning was typically tested immediately after familiarization with a speech stream, we know very little about whether infants experience with statistical regularities supports long-term memory and future word learning. The current study was designed to shed light on the relationship between statistical learning, word learning, and memory. We found that while both co-occurrence statistics and syllable frequency information support word learning in the moment, co-occurrence information alone supports long-term memory for recently segmented candidate object labels.

How do infants start learning object names in a sea of clutter?

Abstract

Infants are powerful learners. A large corpus of experimental paradigms demonstrate that infants readily learn distributional cues of name-object co-occurrences. But infants' natural learning environment is cluttered: every heard word has multiple competing referents in view. Here we ask how infants start learning name-object co-occurrences in naturalistic learning environments that are cluttered and where there is much visual ambiguity. The framework presented in this paper integrates a naturalistic behavioral study and an application of a machine learning model. Our behavioral findings suggest that in order to start learning object names, infants and their parents consistently select a set of a few objects to play with during a set amount of time. What emerges is a frequency distribution of a few toys that approximates a Zipfian frequency distribution of objects for learning. We find that a machine learning model trained with a Zipf-like distribution of these object images outperformed the model trained with a uniform distribution. Overall, these findings suggest that to overcome referential ambiguity in clutter, infants may be selecting just a few toys allowing them to learn many distributional cues about a few name-object pairs.

Keywords: infancy; early word learning; machine learning; Zipfian distribution.

Introduction

The natural environment is visually cluttered with multiple namable objects in view (Clerkin, 2017). To learn their first object names, infants must link a heard object name to the referent object (Bloom, 2000). But for any heard object name, from the infant's perspective, there are multiple potential referents in view. This referential ambiguity has defined a major theoretical problem to be solved in early word learning (Quine, 1960). Despite a sea of clutter, infants already know the names of many objects by the time of their first birthday. We know this because they look to the named objects in laboratory tests (Bergelson, 2012; Swingley & Aslin, 2000) and because they begin to say object names in the contexts of those objects (Fenson et al, 1994). How does this work? The current paper integrates behavioral and modeling frameworks to explore how infants learn object names despite the referential ambiguity in their natural learning environments.

One explanation for solving referential ambiguity is the distributional cues in the language and visual input (Aslin, 2017). According to this explanation, infants track the frequencies of word-object co-occurrences to aggregate the most likely referent (Smith, Smith, & Blythe, 2011; Kachergis, Yu, & Shiffrin, 2017). A large collection of laboratory paradigms has demonstrated that infants can rapidly learn from distributional cues of visual and auditory input (e.g., Cartwright & Brent, 1997; Mintz, 2003; Mintz, Newport, & Bever, 2002; Reeder, Newport, & Aslin, 2013). However, it is still unclear how learning from distributional cues of words and objects in laboratory settings transfers to the distributional cues in the natural environment. Laboratory paradigms are typically highly controlled, presenting uniform word-object frequencies (Aslin, Saffran, & Newport, 1998; Kurumada et al., 2013). In contrast, for natural languages, word frequencies are known to follow a Zipfian distribution, in which a small number of words occur very frequently (e.g. boy, car), while many words occur rarely (Zipf, 1965). These so-called Zipfian distributions, are universal across human languages (Zipf, 1949; Piantadosi, 2014), including nouns and all words in infant-directed speech (Hendrickson & Perfors, 2018). Furthermore, recent studies show that even the distribution of objects in infants' natural visual environments follow a Zipfian distribution, where a few objects appear highly frequently and most objects are rare (Clerkin et al., 2017).

Nevertheless, the sensitivity of infants and adults to distributional cues highlights an intriguing, but as of yet untested, benefit for learning from Zipfian distributions. Theoretically, learning from a Zipfian distribution should be more difficult than a uniform distribution, as there is not enough information in a Zipfian distribution to link the referents for words that occur rarely (Blythe et al., 2010; Vogt, 2012; Reisenauer et al., 2013; Blythe et al., 2016). However, a recent adult study demonstrated that adults learn word-object links more easily from Zipfian distributions than from uniform distributions of word-object occurrences (Hendrickson & Perfors, 2018). Those results suggest that Zipfian distributions improve adults' learning by providing more statistical cues for the highly-frequent words, which in turn reduces the referential uncertainty associated with the unknown rare words. Yet, how infants learn from Zipfian distributions is still unknown.

The approach in this paper is that the natural training data for learning new object names are generated by the behaviors of the learner from the mature social partner who provides the

name. Here we demonstrate that during infant-parent interactions, objects being handled and named by the parent create Zipfian frequency distributions, in which very few events occur very frequently, forming a very small set for learning.

Recent studies of infant naturalistic environments suggest that Zipfian distributions provide a balance between *consistency* of a few high-frequent events with *diversity* of rare events (Clerkin et al., 2017; Smith & Slone, 2018; Montag, Jones, & Smith, 2017). Here we hypothesized that the parent and infant consistently select to play with a few objects, generating a training data set balanced with rare exploration of diverse objects. In other words, parents' and infants' selective and exploratory behaviors naturally generate name-object experiences that form Zipfian distributions, which is hypothesized to reduce ambiguity and optimize learning.

In this study we demonstrate infant naturalistic learning, while infants and parents were engaging with objects in a cluttered and an unstructured environment. The play sessions were recorded from the infant's egocentric perspective. From these visual experiences we report the frequency distributions of the objects with which infants and parents engaged during toy play. We subsequently applied a machine learning model to evaluate the structure of the visual "training data" produced from these play experiences. The model was tested for detecting the play objects with a training dataset of uniform distributions compared to Zipf-like distributions of infants' egocentric object views.

Behavioral Methods

To evaluate how infants learn early object names in a naturalistic environment, we conducted a toyplay experiment allowing infant-parent dyads to freely engage with object toys.

Participants

The final sample included 16 infant-parent dyads with 12 month-old infants (8 female) ranging from 12.2 to 12.5 months (*M*=12.3, *SD*=1.12) were included in the final sample.

Stimuli and Experimental Setup

Parents and their infants were invited to play in a naturalistic setting for a duration of approximately 10 minutes. Parents and infants both sat on a carpeted floor in a playroom environment. To create an unstructured environment, a random assortment of 33 toys were randomly distributed on the floor (see Figure 1). The toy objects' themes were not related in any particular way; thus, any selection and exploration of objects emerged naturally from infant and parent behaviors. The same toys were used in each session. The instructions were to play freely as they normally would at home.

Figure 1: (A) Stimuli set. (B) Experimental setup (left to right) infant wearing a Looxcie camera, infant ego-centric views from camera during toyplay.

Egocentric View

To collect infant egocentric view, we used a commercially available, lightweight (22 g) wearable camera (Looxcie). The camera was secured to a hat that was custom fit to the infant so that when the hat was securely placed on the infant's head, the lens was centered above the nose and did not move (see Figure 1).

The head camera captured the scene in front of the viewer but did not provide direct gaze information, which in principle could be outside of the head camera image (Smith et al., 2015). However, head mounted eye-tracking studies have demonstrated that under active viewing conditions, human observers, including infants, typically turn both heads and eyes in the same direction and align heads and eyes within 500 ms of a directional shift to maintain head and eye alignment when sustaining attention (Yoshida & Smith, 2008; Smith, Yu, & Pereira, 2011). Therefore, it can be expected that a high proportion of gaze during active viewing is highly concentrated in the center of the head camera image (Yoshida & Smith, 2008).

Data Processing

The raw videos were coded using Datavyu by sampling frames at 0.2Hz (1 frame every 5 sec; 2,008 frames total). To describe the dyadic behaviors of engagement with objects, the corpus of frames was coded for (1) objects in view, (2) objects handled by the infant or parent and (3) objects named by the parent. The *objects in view* were defined as the number of objects in the field of view from the infant's perspective. The *objects handled* were coded for both the parents and infant and defined as any hand contact with objects. Finally, parents' speech was manually transcribed and then annotated for *objects naming* when objects were named explicitly (*N*=580).

We measured the statistics for objects in parents' and infants' hands and parent naming events over the entire 10-minute period. Since there were individual differences among the infants in terms of the objects they played with, we constructed rank-ordered frequency histograms (see

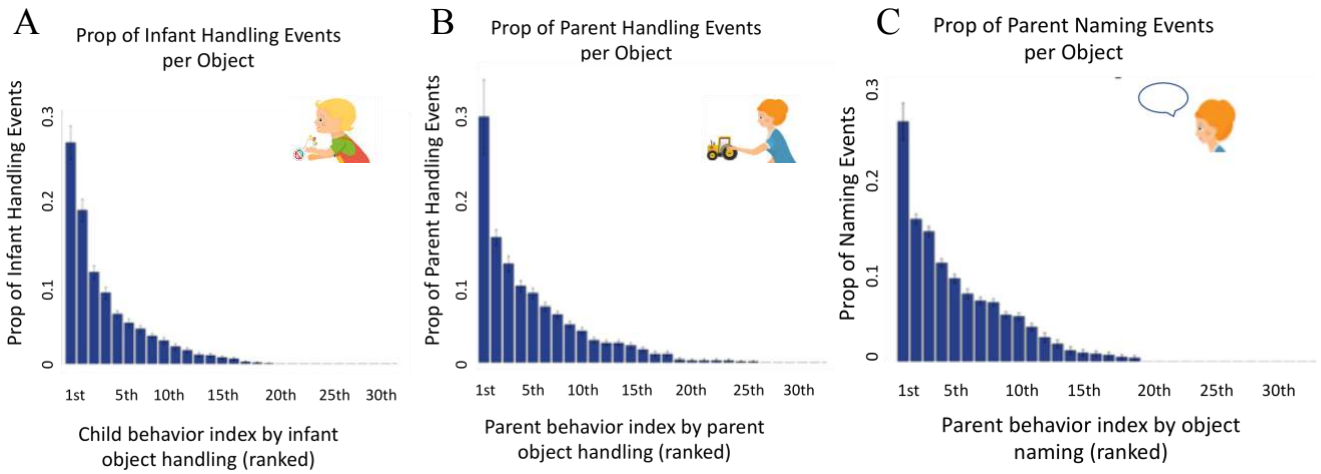

Figure 2: Ranked order histograms of the objects infant and parent handled and named (objects' ranks across these histograms are not necessarily the same). (A) histogram of infant object handling, showing the proportion of instances infants handled each object. (B) histogram of parent object handling, showing the proportion of instances parents handled each object. (C) histogram of parent object naming, showing the proportion of instances parents named each object. Error bars indicate 95% confidence intervals.

Figure 2). The rank-ordered frequency was measured independently for each infant and then combined since the most frequent object in view, handled or named differed for different infants. The objects are annotated by their rank-ordered frequency ranging from the 1st most frequent to least 33rd frequent object.

Behavioral Results

The experimental setup of dyadic play was visually cluttered as there were on average 13 objects in view every frame (*Min*=1, *Max*=30, *M*=13.18, *SD*=6.16). Figure 2 shows ranked order histograms of infant and parent object handling proportions, as well as parent naming proportions. The histograms display a Zipf-like pattern which is indicative of behavioral selectivity of objects in the scene. Specifically, these zipf-like distributions follow an approximate power-law, in which a small set of objects are handled and named very frequently and most objects are rare. Six objects (*Min*=9, *Max*=19, *M*=13.70, *SD*=3.13) account for over 80% of the total proportion of infant's object handling events. Six objects (*Min*=9, *Max*=24, *M*=15.5, *SD*=3.8) account for over 80% of the total proportion of parents' object handling events. Eight objects (*Min*=10, *Max*=48, *M*=24.20, *SD*=10.23) account for over 80% of the total proportion of parents' object naming events. These Zipf-like distributions likely reflect a balance between the parents' and infants' stability and exploration of objects, which may benefit object learning.

Modeling Methods

A machine learning model was used to test whether the distributional properties of infants' visual object experience impacted learning. In particular we wanted to understand the learning mechanism by which infants learn new object names in clutter environments.

The data

The collected corpus of 2,008 infants' egocentric views were used to construct two different toy object training sets, as detailed in Table 1. Six of the objects were selected for our machine learning study: baby doll, ball, chair, bucket, boat, and duck (see Figure 1). One of the two training datasets had a uniform frequency distribution of object images, and the other was with a Zipf-like frequency distribution. There were a few reasons for only using six specific objects for the modeling framework. First, from the raw corpus of images, only 1,200 images included at least 1 of the 6 objects for detection in the scene. Second, Bounding boxes indicating the objects' location and label were annotated for the set of 6 objects intended for detection. Note that some images were removed from the corpus due to low image quality such as high blur. The corpus was augmented by 180-degree rotation and horizontally flipped, yielding a final corpus of about 3,000 images: 2400 split into training and validation and 600 for testing.

Figure 3: Example of cluttered training images, including multiple objects for detection, labeled and annotated with a bounding box.

Each training dataset (the uniform and Zipf-like) was formed by a subset of the 2400 images for training. Due to the nature of the cluttered scenes, many images included more than 1 detectable object as seen in Figure 3. These images that included multiple objects for detection were counted toward the frequencies of more than one object when forming the datasets of uniform and Zipf-like frequency distributions (see Table 1). The final training data sets included 2,154 images each. In the *uniform* dataset, each object was present in 400 images. The *Zipfian* dataset included high frequency and low frequency images of objects. In the *Zipfian* dataset the baby doll had the highest frequency (1000 images), and the duck was the rarest (100 images).

Table 1: Distribution of object images among the uniform and right-skewed datasets for training

Images Per Object	Uniform	Zipf-like
Baby Doll	400	1000
Ball	400	600
Chair	400	320
Bucket	400	240
Boat	400	140
Duck	400	100
Total	2,154	2,154

Model Parameters

The applied machine learning model was the Faster R-CNN, Region-based Convolutional Neural Network (Ren, Girshick & Sun, 2015), a well-known, state-of-the-art machine learning model for object detection. The model is essentially a network composed of three main components: a feature extractor, a region proposal network (RPN), and a classifier. First, for the feature extraction part, we adapted a pretrained CNN VGG16 on the ImageNet data set which includes approximately 1.2 million images (Russakovsky et al., 2015). The model has 16 layers and classifies images into 1000 object categories (e.g. keyboard, mouse, coffee mug, pencil). The input images (size 224X224) are inputted into the VGG16 network. The network evaluates the distinctive visual features for the whole image, which allows us to detect multiple objects in each image. Second, after feature extraction the regions are proposed, therefore only running one CNN over the entire image instead of multiple CNN's for each proposed region. Finally, a single softmax layer, outputs the class probabilities directly for each region. The last fully connected layer and classification layer were adjusted for the number of classes in the data set applied in this framework (N classes= 7, including 'background').

Training

The Fast-RCNNs were trained with two different datasets that varied in the frequency distributions of object images: the Zipf-like and uniform distributions. The network was trained for 1000 epochs (iterations).

Modeling Results

To determine whether infants' selective behavior benefits learning, we applied a machine learning model trained with Infants' egocentric views. We compared the model's performance of object recognition when trained with a Zipf-like vs. a uniform distribution of infants' egocentric views as seen in Table 2. Overall, the model trained with the Zipf-like dataset had a significantly higher (t=-3.35, p<0.05) mean average precision (mAP=40%) compared to the model trained with the uniform dataset (mAP=23%). This pattern of results suggests that a Zipf-like distribution of data yields higher accuracy and benefits learning.

To further evaluate whether the Zipf-like distribution of objects in infants' egocentric views reduce ambiguity we evaluated the average precision of each object (see Table 2). For the baby doll and the ball there were more images in the Zipf-like dataset relative to the uniform distribution and there was accordingly a higher average precision for these objects in the Zipf-like trained model (AP=56% and 48%, respectively). The chair had a similar number of images in both datasets and had a similar average precision in the Zipf-like (AP=23%) and uniform datasets (AP=21%). For the rest of the objects (the bucket, boat and the duck), there were less images in the Zipf-like dataset, yet a higher average precision in the Zipf-like trained model (AP= 29% and 38% and 43%, respectively) compared with the model trained on the uniform distribution. These patterns of results, where there is higher precision despite less training images suggests that information has been shared among objects reducing likely competing objects and reducing ambiguity.

Discussion

In the real world, the sea of visual clutter provides multiple competing referents for every heard object name. This paper explored how infants solve this referent ambiguity in a cluttered environment to learn first object names. Here we presented a behavioral study of infants and their parents playing freely with objects and applied a learning model to explore the 'behind the scene' learning machinery.

To observe how infants learn object names in a cluttered environment, we recorded the play from infants' egocentric view. In order to describe experiences relevant for object name learning, we reported the frequency distributions of the

Object AP	Baby Doll	Ball	Chair	Bucket	Boat	Duck	mAP
Uniform	0.25	0.23	0.21	0.19	0.28	0.24	0.23
Zipf-Like	0.56	0.48	0.25	0.29	0.38	0.43	0.40

Table 2: Model test results: average precision per object for the uniform and Zipf-like datasets

objects infants and parents handled, as well as the objects parents named. We found that the frequency distributions of objects handled and named approximated a right-skewed Zipf-like distribution with few highly frequent objects along with many low frequency objects. This finding suggests that in a cluttered environment, infants and parents consistently select a set of a few objects for learning and rarely explored the other objects. The consistent object handling and naming behaviors during early word learning offers repetition, a key component for learning (Hintzman & Block, 1971, Vlach, 2014).

The infant-parent dyads consistently created datasets that were highly selective and focused on just a few objects. These dynamic patterns of selection may be due to the influence of other systems such as human memory or attention which decays in a power-law pattern (e.g., Wixted & Ebbesen, 1991; Wixted, 2004; Baronchelli, Ferrer-i-Cancho, Pastor-Satorras, Chater, & Christiansen, 2013). These non-uniform distributions have been shown as optimal conditions for adults and may help solve learning problems across many domains (Schuler, Reeder, Newport & Aslin, 2017; Hendrickson & Perfors, 2018; Caron & Vincent, 2002; Salakhutdinov, Torralba, & Tenenbaum, 2011).

As we could not directly observe infants' learning machinery, we applied a machine learning model to explore how infants may be learning from a Zipfian distribution. The application of the model was weaved with the behavioral study by using infants' egocentric object views from the behavioral study of play as the training images for the learning model. The learning machinery from Zipfian distributions was evaluated by comparing a training apparatus of a Zipf-like and a uniform frequency distribution of object images. The testing demonstrated that the training using a Zipf-like distribution yielded higher accuracy than a uniform distribution. Interestingly, the testing also demonstrated that low frequency objects were learned at higher rates when trained in the Zipf-like distribution.

The Zipf-like model's patterns of results were consistent with machine learning and adult studies of Zipfian learning (Schuler, Reeder, Newport & Aslin, 2017; Hendrickson & Perfors, 2018; Caron & Vincent, 2002; Salakhutdinov, Torralba, & Tenenbaum, 2011). These studies suggested that the learned features of highly frequent items are shared with the low frequency items to reduce referent ambiguity. For example, when learning to recognize a rare vehicle such as 'bus', the exemplar shares features of wheels and window shields from an already learned 'car', a highly frequent vehicle. It has also been suggested that low frequency items such as 'napkin' may benefit from co-occurrences with high frequency objects such as 'bowl'. These model's results coincide with infants laboratory studies demonstrating that infant early word learning is tuned to statistical cues of word-object co-occurrences. These findings also suggest that infants may be able to learn object names not only from uniform distributions of word-object occurrences but also from a Zipfian distributions.

Beyond previous early word learning studies, the findings in this paper suggest that infants solve referential ambiguity in a sea of clutter by consistently selecting a few objects and rarely exploring a large subset of objects. This behavior may benefit learning and reduce ambiguity in clutter by allowing to learn a lot of statistical cues about a few objects. Finally, this paper offers a methodological framework of incorporating behavioral paradigms with computational modeling to stretch our understanding of cognition.

Abstract

Spoken language often includes ambiguity in meaning. Compounds such as "green teacup" can be interpreted with two different meanings: "green colored teacup" and "cup for green tea." We can assume there are two different underlying syntactic structures. Phonetic aspects have been studied in the disambiguation process of such ambiguous phrases, but the roles of nonlinguistic information such as gestures have not been explored yet. We investigated whether people use gestures differently when they were asked to describe the meanings of Japanese compounds that can be interpreted as two different meanings. We found that the偏ming of gestures in relation to the target words of accompanying speech was different between right branching compounds and left branching compounds. Gestures seem to be used to suggest upcoming two words (adjective and noun) as a unit in branching. Gestures can be a useful means to disambiguate the meanings of compounds.

Keywords: Gestures; Disambiguation; Branching; Compounds

Introduction

A phrase consists of concatenation of words that are produced sequentially. It is known that compounds can be interpreted to have multiple meanings. For example, "green teacup" can be interpreted either as a green-colored teacup or as a cup of green tea. A phrase structure with the meaning "teacup for green tea" can be classified as left branching (LB); that is, "green" and "tea" are first grouped to "green tea" and then together play an adjective role in "cup." The phrase structure with the meaning of "green-colored teacup" can be classified as right branching (RB); that is, "tea" and "cup" are first grouped together, and the word "green" plays an adjective role in "teacup" (Figure 1). Because speech is produced sequentially, the surface structure does not have enough information to show the underlying syntactic structure. Therefore, phrases inevitably have ambiguity in meaning. Nevertheless, people usually seem to have little difficulty in discerning the meanings of such phrases. Humans may use some disambiguation cues to resolve ambiguities in such ambiguous structures.

Previous studies have focused on prosodic cues as a means of disambiguation (Ito, Arai, & Hirose, 2015; Hirose & Mazuka, 2015; Venditti, 1994). Native Japanese speakers prefer LB interpretation over RB interpretation for slightly simpler Japanese compound constructions and to make RB interpretation more accessible. A clear prosodic demarcation that raises the pitch range of the second word has been found effective (Ito, et al, 2015; Hirose & Mazuka, 2015; Venditti, 1994). However, the exact disambiguation cues are still unknown. In the present study, we focused on nonverbal cues, in particular, gestures that have not been examined yet in the disambiguation mechanism of syntactic structures.

Figure 1: Two different syntactic structures, left branching (left) and right branching (right), in the compound "green teacup"

Gestures play an important role in communication. Humans simultaneously use gestures and language to convey information to others. Gestures are usually produced slightly earlier than associated speech, and this can make the hearer anticipate the information in the upcoming speech (MacNeill, 1987). Iconic gestures (e.g., depicting objects by movement trajectories) and pointing gestures can reflect aspects of the speaker's nonlinguistic spatial representations (Majit, Bowerman, Kita, Haun & Levinson, 2004). Gestures can spontaneously accompany speech and make communication smooth (Kita & Saito, 2002). Representational gestures (i.e., iconic and deictic gestures) can express spatial contents or metaphorically express temporal concepts (Kita, 2009). Additionally, gestures express information even when it is difficult to express in language (Alibali, Evans, Hostetter, Ryan & Mainela-Arnold, 2009). Various functions are known about gestures, but the topic of whether gestures can contribute disambiguation mechanisms of syntactic structures has been largely unexplored.

Previous studies on interpretation of compounds of possibly different branching structures have showed that people prefer a certain branching over other branching when two (or more than two) different branchings are possible (e.g., Ito et al., 2015). In our study (accepted) on Japanese participants' interpretation of Adjective_1 + Noun_1 + Adjective_2 + Noun_2 compounds, we found that some adjectives are interpreted more dominantly than other adjectives for certain nouns. For example, "long" can be a

typical adjective for "tail," but an atypical one for "cat." It is possible that "long cat" may mean that the cat's body is long, but this sounds somewhat strange. The typicality of the adjective + noun combination may affect the predominant interpretation.

The present study investigated whether gestures are used as a clue to resolve ambiguities in branching structures of Japanese compounds. We examined whether the productions of participants' gestures differ in the case of compounds of either LB or RB. Our prediction was that participants might make gestures with different timings when verbally producing the compounds of LB or RB.

We also examined whether people may exaggerate their gestures by taking more time for relevant gestures when they are aware that more than one interpretation is possible for ambiguous compounds. To examine this exaggeration aspect, we compared a one-picture condition (Alone condition) that denoted either LB or RB meaning and a two-picture condition (side-by-side condition) that denoted both LB and RB meanings side by side so that people could more easily notice the different interpretations.

Further, we also examined another source for possible exaggeration, the combination of nouns and adjectives. We decided to compare the two adjectives "big" and "long." The adjective "big" can be typically applied to "cat" (big cat) or "tail" (big tail), whereas the adjective "long" can be typically applied to only "tail" (long tail) and not "cat" (??long cat). We expected the participants to feel less ambiguity when they interpreted phrases with "long" rather than phrases with "big," so the participants would take less time for "long" condition and the timing of the gestures may also be different between the "big" and "long" conditions.

Method

Participants

Sixteen Japanese monolingual students who spoke Japanese as a first language participated (M age = 21.6, SD = 1.32; 1 female). This study was approved by the ethics committee of the participants' university.

Stimuli

A total of 32 slides were prepared using Adobe Illustrator. Sixteen slides were prepared for the side-by-side picture condition, and another 16 slides were prepared for the alone picture condition. In the side-by-side condition, two comparable objects were drawn side by side in each slide (Figure 2). One was the object (animal) according to LB interpretation, and the other was the object (animal) according to RB interpretation. The slide in the side-by-side condition consisted of one target phrase on the top, two illustrations (i.e., LB and RB interpretations) in the middle, and explanatory notes for each illustration on the bottom (Figure 3). A compound had two possible interpretations: an LB interpretation and RB interpretation. For example, [Kuroi] [Sippono] [Ookina] [Neko] in Japanese (i.e., [Black] [Tailed] [Big] [Cat]) can be interpreted either as "a big cat with black tail" (LB) or as "a black cat with a big tail" (RB)[1]. The difference of meaning can be explained as follows: in the case of LB, the "tailed" branch connects to "black" branch. In the case of RB, the "tailed" branch connects to the "big cat" branch (Figure 4). The position of the LB object and RB object in each slide was counterbalanced. In the alone condition, there was only one object of either LB interpretation or RB interpretation on each slide. There were eight side-by-side slides and eight alone slides. The slide in the alone condition consisted of one target phrase on the top, one illustration in the middle, and an explanatory note for the illustration on the bottom.

In the stimulus compounds, 16 slides included the adjective "big," and another 16 slides included the adjective "long."

English	|black	|tail		| big	|cat

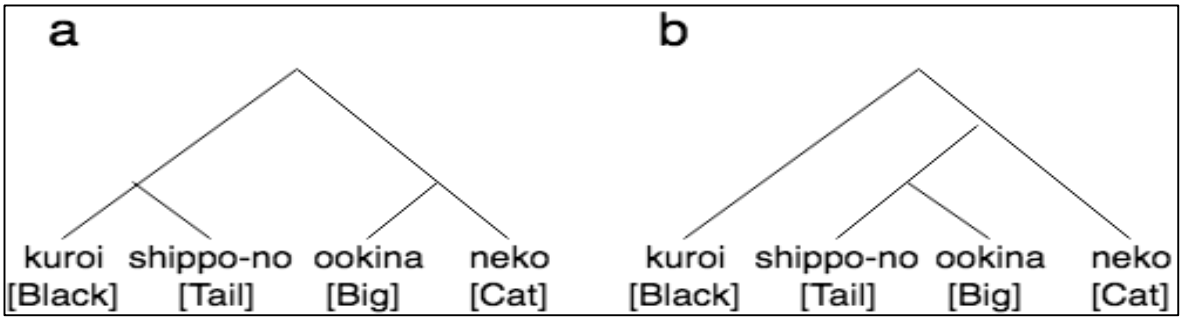

Figure 4: Branching structure. (a): LB interpretation; (b): RB interpretation

Procedure

The participants were divided into two experimental groups: alone slide group and side-by-side slide group. Each group looked at eight slides on a computer monitor.

After filling in the consent form, the participants were seated in front of a monitor (Figure 5).

The participants took part in one practice trial to be familiarized with the task, and then the experiment was started. On each trial, a fixation cross appeared in the center of the monitor. After the cross was fixated for one second, a slide appeared for 10 seconds. Then, only the top phrase was displayed. At that moment, participants were asked to make gestures to describe the presented picture while verbally producing the phrase (Figure 6).

Participants' gestures and utterances participants were recorded by a video recorder (Microsoft LifeCam). In the side-by-side slides, one of the two objects was presented with a surrounding red frame, and the participants were asked to describe the indicated object.

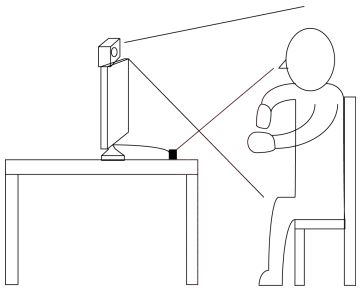

Figure 5: Experimental layout

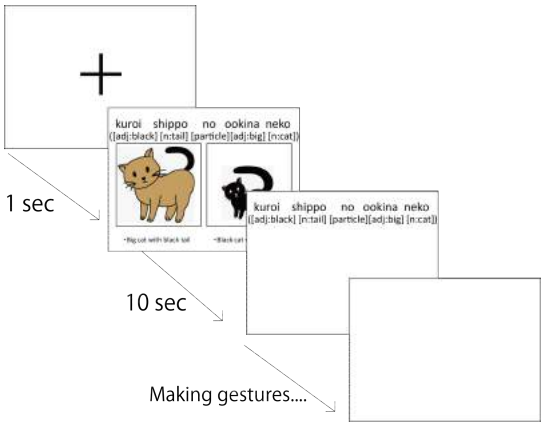

Figure 6: Flowchart of slides

Coding

We annotated utterances and gestures using ELAN 2017 (Version 5.1). The timing and duration of each gestures were recorded (Figure 7). We used the coding scheme modified version of Kita, Gijn, and Hulst's (2014) gesture coding. In this scheme, a gesture consists of a preparatory movement, followed by a stroke, and then finally, a finishing movement. We recorded the time of onset and end of each gesture stroke to determine the timing and duration of each gesture. The third word was the critical adjective "big" or "long" that was grouped with either the second word (e.g., "tail") or the final word (e.g., "cat").

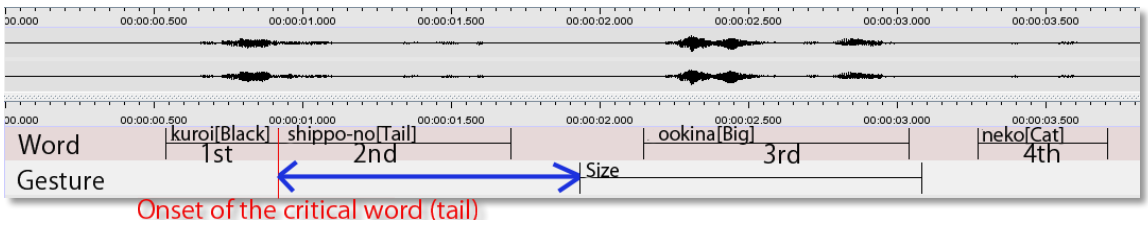

Figure 7: An example of the annotation using ELAN

Results

Timing of the first gesture

To find out whether the onset of gestures differed between LB and RB, between the alone slide and side-by-side slide, and between the adjectives "big" and "long," the difference in time (seconds) between the onset of the critical word "shippo (tail)" on the branching point and the onset of the first gesture in each slide in the participant's performance was measured and taken as a dependent measure. A 2 (Slide: Alone, Side-by-side) × 2 (Adjective: Big, Long) × 2 (Branching: LB, RB) three-way ANOVA was performed on the measure. Slide (Alone, Side-by-side) was the between-participants variable. Adjective (Big, Long) and branching (LB, RB) were the within-participants variables.

There was a marginally significant effect of branching ($F(1,14) = 3.6925$, $p = .075$, $\eta^2 = 0.0956$). This meant that the onset of the first gesture was earlier in RB (M= -0.55) than in LB (M= -0.07). Furthermore, there was a significant Slide × Adjective × Branching interaction ($F(1,14) = 6.3258$, $p < .05$). To explore the significant Slide × Adjective × Branching interaction, the simple interaction effects of Slide, Adjective, and Branching within each condition were calculated (Figure 8).

The simple main effect of branching in the "long" condition was marginally significant ($F(1,14) = 3.1574$, p = .097, $\eta^2 = 0.0842$). This meant that when the third word was "long," the onset of the first gesture tended to be earlier in RB (M= -0.49) than in LB (M= -0.08).

There was a simple Slide × Branching interaction in the "long condition" ($F(1,14) = 4.9359$, $p < .01$). Simple-simple main effects of Slide and Branching within the "long" condition were calculated. There were simple-simple main effects of branching ($F(1,7) = 7.0215$, $p < .05$) and slide ($F(1,14) = 4.4872$, $p = .052$, $\eta^2 = 0.2427$). The simple-simple main effect of slide was marginally significant. It meant that when the third word was "long" and the slide was "alone," the onset of the first gesture was earlier in RB (M= -0.88) than in LB (M= 0.04). When the third word was "long" and branching was RB, the onset of the first gesture was more behind when slide was side by side (M= -0.11) than when slide was alone (M= -0.88).

Total duration of the gestures

Using the video recordings, we calculated the total duration of gestures (seconds) produced in each slide. We predicted that the duration of gestures was different between LB and RB.

A 2 (Slide: Alone, Side-by-side) × 2 (Adjective: Big, Long) × 2(Branching: LB, RB) three-way ANOVA was performed on the total duration of gestures.

There was a marginally significant effect of slide ($F(1,14) = 3.935$, $p = .067$, $\eta^2 = 0.0512$). The total duration time of gestures was longer when the slide was alone (M=2.16) than when the slide was side by side (M=1.82). There was also a significant Slide ×Adjective × Branching interaction ($F(1,14) = 15.9588$, $p < .01$). To explore the significant Slide × Adjective × Branching interaction, simple interaction effects of slide, adjective, and branching within each condition were calculated.

There was a simple main effect of Slide in the "big" condition ($F(1,14) = 5.6515$, $p < .05$) and adjective in the alone condition ($F(1,7) = 4.8931$, $p = .062$, $\eta^2 = 0.0171$). The simple main effect of the adjective in the alone condition was marginally significant. When the third word was "big," the total duration time of gestures was longer when the slide was alone (M= 2.27) than when the slide was side-by-side (M= 1.70). When the slide was alone, the total duration time of gestures was longer when the third word was "big" (M=2.27) than when the third word was "long" (M=2.06).

There were simple Adjective × Branching interactions in the alone condition ($F(1,7) = 6.9771$, $p < .05$, $\eta^2 = 0.0368$) and in the side-by-side condition ($F(1,7) = 9.1492$, $p < .05$, $\eta^2 = 0.1196$). The simple-simple main effects of adjective and branching within the alone condition and side-by-side condition were calculated. There were simple-simple main effects of the branching in the alone condition ($F(1,7) = 33.2153$, $p < .001$, $\eta^2 = 0.1386$) and in the side-by-side condition ($F(1,7) = 7.6180$, $p < .05$, $\eta^2 = 0.2495$). When the slide was alone and branching was LB, the total duration time of gestures was longer when the third word was "big" (M= 2.39) than when the third word was "long" (M= 1.89). When the slide was side by side and the third word was "long," the total duration time of the gestures was longer in LB (M= 2.32) than in RB (M= 1.55).

There was a simple Slide × Branching interaction in the "long" condition ($F(1,14) = 5.0550$, $p < .05$). The simple-simple main effect of slide and branching within the "long" condition was calculated. There was a simple-simple main effect of branching that was marginally significant ($F(1,14) = 4.0335$, $p < .05$). When the third word was "long," and branching was RB, the total duration time of the gestures was longer when the slide was alone (M= 2.23) than when the slide was side by side (M= 1.55).

There was a simple Slide × Adjective interaction in the LB condition ($F(1,14) = 7.8598$, $p < .05$). The simple-simple main effect of slide and adjective within the LB condition was calculated. There was a simple-simple main effect of slide ($F(1,14) = 5.9902$, $p < .05$). When branching was LB and the third word was "big," the total duration time of the gestures was longer when the slide was alone (M= 2.39) than when the slide was side by side (M = 1.60).

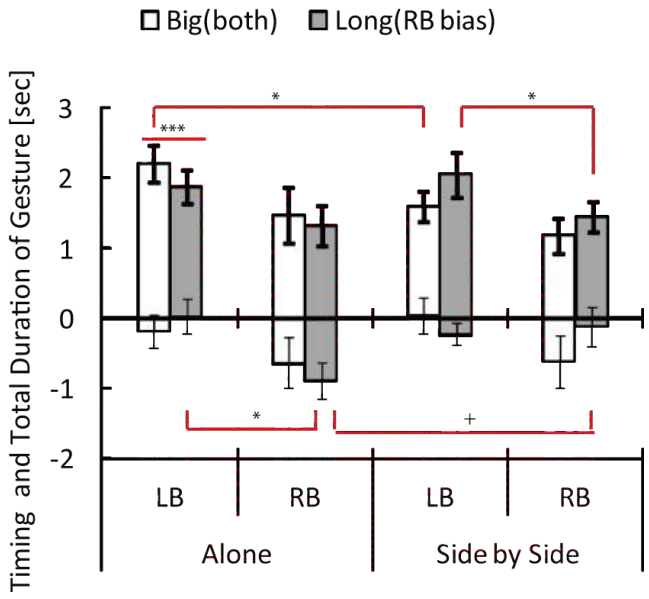

Figure 8: The start time point, the end time point, and the duration of the gestures in each condition. Zero denotes the starting time point of the target word "shippo (tail)" in accompanying speech. The thin error bars denote standard errors in the onset of gesture. The thick error bars denote standard errors in the duration of gesture.

Discussion

The most important finding was that the onset of the first gesture in relation to the critical word (the second word "tail") was earlier in the RB condition than in the alone slide. This means that the participants started a gesture earlier when they wanted to mean "a black cat with a big tail" (RB) than they wanted to mean "a big cat with a black tail" (LB). We interpreted this result as follows: in RB, the meaning "the tail is big" is important to convey, so participants started the gesture earlier to easily bring "tail" and "big" together as words that belonged to the same branch. Usually, the participants' gesture in this RB slide involved extending and moving their arm horizontally to describe a long big tail. Thus, the participants seemed to emphasize "big tail" by this gesture. In contrast, the gesture used in LB slide involved moving both hands widely up and down to describe the shape of the big cat. Thus, the participants seemed to emphasize "big cat." The point is that the critical adjective "big" must be grouped with either "tail" (RB) or "cat" (LB). As for the duration data, we found that the duration of the gestures was shorter in the side-by-side slides than in the alone slides. The participants might have thought that certain gestures would be enough for disambiguation when an alternative picture was explicitly presented. In the side-by-side/long/RB condition, participants might not have thought that disambiguation was necessary because "long cat" (LB interpretation) sounded too atypical compared with "long tail" (RB interpretation).

In conclusion, using Japanese compounds, we found that the timing and duration of gestures in relation to the target words in accompanying speech were different between RB compounds and LB compounds. Gestures seemed to be used to suggest two upcoming words in speech (adjective and noun) as a unit in branching. Gestures can be a useful means to disambiguate the meaning of compounds.

Abstract

Despite decision science have increased our understanding of human decision-making in different contexts, voters' decision has been studied less from this point of view. Therefore, we investigated, how electorate- and candidate-related factors affect electorate's (N=1334) valuation to the Prime Minister candidates (N=11) on the multiparty democracy. Electorates valuated candidates individually and through pairwise candidate comparison. We collected the data by using anonymous questionnaire and sent it via mass emailing and social media. We applied linear mixed-effects and Bayesian network models to analyze the data. Electorate-related variable Valence and candidate-related variables Trustworthiness and Righteousness was found as the strongest main effects. The pairwise analysis comparison highlighted voters' personal characteristic. In particular, the interactions associated to valence, arousal and gender had high effect only in pairwise comparisons. Our results suggest that the pairwise comparisons - which is typical for elections, e.g., in USA - highlights the importance of emotional and gender-related factors.

Keywords: decision making; politics: valuation; voting; linear mixed-effects model; Bayesian networks

Introduction

Mainstream scholarly research assumes that voting decision is driven by rational preferences over policy proposals offered by political parties (Bischoff, Neuhaus, Trautner, & Weber, 2013; Hibbing, Smith, & Alford, 2014; Knutson, Wood, Spampinato, & Grafman, 2006). However, recent decision science studies have suggested that decision involves, besides explicit processes, psychological, social and cultural processes (Blouw, Solodkin, Thagard, & Eliasmith, 2016; Tymula & Glimcher, 2016). Whereas these studies have increased our understanding about human decisions in the marketing-, social- and risks contexts (Tymula & Glimcher, 2016), voters' decision have been less studied from decision science point of view. In addition, the multiparty democracies have been less studied compared to two-party democracies, especially USA (Walther, 2015). Therefore, we investigated, how electorate-related and Prime Minister candidate-related factors affect electorate's valuation. We chose eleven Prime Minister candidates (three females) on the multiparty democracy which were valuated using judgements of each candidates' directly and in pairwise comparison between candidates. We used linear mixed-effect models (Gelman & Hill, 2007) and Bayesian networks (Borgelt, Steinbrecher, & Kruse, 2009) to test statistical dependencies between candidate valuation and battery of ratings for features of both candidates and the rater himself/herself. Below we describe these dimensions more specifically.

Electorate-related Factors and Voting Decision

Political orientation has been studied with The Big-Five framework (Gosling, Rentfrow, & Swann, 2003; Hibbing, Smith, & Alford, 2014). Current study (Sibley, Osborne, & Duckitt, 2012) found, that political conservatism had negative correlation to Openness to Experience and positive correlation of Conscientiousness variables. In the same vein, Carney et al. (2008) showed that both low Openness to Experience and high Conscientiousness were associated with participants' self-reported conservatism. Thus, conservatives are more orderly, conventional, and better organized, whereas liberals are more open-minded, creative, curious, and novelty seeking (Carney, Jost, Gosling & Potter, 2008).

People with different political orientations have been found to resolve risk-decisions different ways (Hibbing, Smith, & Alford, 2014). Relative to liberals, politically conservative individuals are remembered which stimuli have bad value and pursued a more risk-avoidant strategy to the game. On the contrary, Liberals have greater tendency to explore, take more risk by choosing more unknown possibilities than Conservatives have (Shook & Fazio, 2009).These studies indicate that Conservatives show greater sensitivity to threatening stimuli in the environment than Liberals and have to tendencies to behave without risk-taking.

Prime Minister Candidate-related Factors and Voting Decision

In most of democracies the party leaders are also prime minister candidates and influential electoral force in election campaigns (Bean & Mughan, 1989). This candidate-centered politics (Garzia, 2011; Wattenberg, 1991) is accompanied by a great importance of leaders' personal characteristics in the eyes of voters. Thus, this study concentrates electorate's opinions about politicians' leadership skills and their opinions about the suitability of these candidates to the prime minister in the multi-party democracy country.

Previous studies have found that trustworthiness is one of the most important attribute for a political leader (Barisione, 2009; McAllister, 2000; Rule et al., 2010) as well as communication and collaboration skills (Barisione, 2009). In addition, voters want that political leader is one of them and works for their benefits (Garzia, 2011). Moreover, the voters give values for the fair leaders as well as "traditional" hard leadership skills like the capacity to make decisions (Bean & Mughan, 1989; Rule et al., 2010).

Second important dimension is electorate's emotional reactions to politicians' faces. Valence and arousal are two independent dimensions of emotion. When subjects anticipate pleasurable events, positive arousal increases, and when they anticipate unpleasant event, negative arousal increases. Studies have found that positive arousal has important effect on people's behavior towards the issues, which trigger these positive arousal (Knutson & Greer, 2008). Thus, we measured participants' valence and arousal as they imagined each candidate as a prime minister. We used above described individual and Prime Minister candidate–related factors as the framework for questionnaire. The faces of politicians have many learned symbolic and cultural meanings (Knutson et al., 2006). Therefore, we used politicians' faces as basic stimuli in order to clarify how much each politician's face can produce emotional reactions. Judgements of each candidates' direct valuation and pairwise candidate comparison were used as dependent variables.

Methods

Participants

Participants were recruited via mass emailing and social media to participate in the research. Total 1653 full responses were received over 4 months from which we removed 50 responses with missing/corrupted data, 9 duplicates (same subject), 176 responses with unrealistically fast response times (median time <7s per page) and 84 responses with zero of very low response variance. This resulted in 1334 responses (503 males) in final analysis. Filling the full questionnaire allowed participants to join lottery of 20 gift cards (each worth 25 euros).

Questionnaire Procedure

In the questionnaire, electorate-related variables included gender, age-group (between 18 and 60+) and eight self-spaced personal qualities. Variables dependable/self-disciplined and disorganized/careless measure characteristic conscientiousness, whereas variables open to new experiences and conventional/uncreative measure characteristic openness to experiences from Big Five personality scale. In addition, participants' opinions about his/her level of conservatism and level of liberalism were measured separately. Finally, participants' risk-sensitivity was measured by using social and investment risk variables from Weber et al. (2002) risk-attitude scale.

Prime Minister candidate-related variables included candidate's gender, candidate's familiarity and candidate's leadership skills. Leadership skills included variables trustworthiness, communication skills, fairness, tendency to work for nation, and decision skills. All candidates were established figures for their parties, i.e., the name and face were familiar to majority of people on national level. In addition, the emotional components valence and arousal were measured by showing candidates face with his name and party. Below of the face was two statements "She/He has just been elected Prime Minister of Nation X. What is the emotion (valence) of the choice in you? How intensive this emotion is (arousal)?"

In summary, the questionnaire contained four mandatory sections with following questions (variable labels in parenthesis):

1. Responder's background (x_{1-10}^{b}): Gender [binary], age [Likert scale; 1-7] and 8 personal qualities [1-7].
2. *Individual* candidate valuation (x_{1-8}^{r}): candidate gender [binary], 5 ratings, familiarity and suitability scores [1-7].
3. Emotion ($x_{1,2}^{e}$): Valence and arousal assuming the candidate was chosen as a Prime minister [1-7].
4. *Pairwise* candidate valuation (x^{c}): Preference between two randomly chosen candidates [-4-4].

Suitability score (x_{8}^{r}) and pairwise comparison score (x^{c}) were considered as the *responses* (valuations). Variables x_{1-7}^{r} encoded the *feature vector* of a candidate (1334 vectors in total, one from each subject). Candidate's order was randomized in all parts of the survey. In part 4, out of the pool of 55 possible candidate pairs, we presented randomly chosen 20 (randomized for each subject). In the analysis, genders (responders and candidates) were one-hot encoded using "female" label as the (arbitrary) reference level.

Data Analysis

Linear Mixed-effect Models First we fitted linear mixed-effects models (Gelman & Hill, 2007; Wu, 2009) to the data using Matlab (R2018a). Subject *id* and response date (*month*) were set as random effects of no interest. We fitted total of 4 models; two for the direct valuation and two for the pairwise valuation. Two of these models contained all variables (*full models*) and the remaining two (*reduced models*) did not include valence (x_{1}^{e}). Valence was highly correlated with valuations, hence it was deemed useful to repeat fitting without it. As there was no variation in background variables

(x_i^b) within a subject, those were entered into models through interactions.

For the individual valuation, using Wilkinson's notation (Wilkinson & Rogers, 1973), the formula of the full model was:

$$x_8^r \sim 1 + (x_1^r + \cdots + x_7^r + x_1^e + x_2^e) : (1 + x_1^b + \cdots + x_{10}^b) + (1|id + month),$$

where the total number of non-constant fixed terms (aka *predictors*) was 99 with 1338 random-effects intercepts. We used maximum likelihood criterion to fit parameters (Wu, 2009). The equation for the reduced model was similar, but without the valence term (88 fixed-effects terms).

For the pairwise valuations, the formulas were identical, but as the valuation was indirect, the features were transformed into differences, i.e., $x_i^r := x_{i,A}^r - x_{i,B}^r \;\; \forall\, i = 1, \ldots, 7$ (same for $x_{1,2}^e$ and x^c), where A and B correspond to two candidates in comparison. In this case the random-effects term id also covers the randomness related sampling of candidate pairs. Note that a linear model is invariant for the order of candidates in the differencing, i.e., flipping the order also flips the predictors and response. As a result, interpretation of the coefficients remains similar to direct valuation.

Statistical significance of linear models and their predictors were estimated using permutation testing scheme where responses were randomly shuffled while preserving subject-level grouping hierarchy. Original, un-shuffled t-values of each predictor were compared against distributions of 10.000 t-values obtained via permutation. False Discovery Rate (FDR; Benjamini & Hochberg, 1995) was applied to adjust for multiple comparisons over fixed-effects predictors. Overall model performance was measured with Mean Squared Error (MSE) compared against constant-only null models (with MSE_{null}) and those obtained via permutations.

Bayesian Network Models Next we dropped the assumption of the linearity and fitted Bayesian network probabilistic graphical model to the data (Borgelt, Steinbrecher, & Kruse, 2009; Nagarajan, Scutari, & Lèbre, 2013). For this, we used *bnlearn*[1] toolbox. Bayesian network models allow estimation of a full probability distribution via Directed Acyclic Graph (DAG) structure that represents relationships between data variables (nodes in the graph). Here we were mainly interested in the structure of DAGs and causal relationships between variables.

We adopted the approach of Scutari et. al (2017) with network bootstrapping and cross-validation to estimate DAGs and the quality of models. The aim was to find networks that fit the data best. We used Tabu and Hill-Climbing (HC) structure search algorithms with Akaike and Bayesian Information Criteria (AIC and BIC) scoring, which allow both fast computations and are robust in modeling real data (Beretta, Castelli, Gonçalves, Henriques, & Ramazzotti, 2018; Olmedilla, Rubio, Fuster-Parra, Pujals, & García-Mas, 2018). By varying scores and search methods, we build 1200 candidate networks using bootstrapped dataset by keeping 80% of all samples in each iteration. We restricted the size of network search space by blacklisting total 137 causally unfeasible directed edges. Variables related to subject's background were allowed to be parents for the candidate-related choices. All variables related to age and gender were only allowed to serve as parents. After model bootstrapping, we varied the edge frequency threshold and estimated the classification accuracy of the resulting DAG for the responses (individual or pairwise) using 10-fold cross validation.[2] For the model inference, we used maximum likelihood criterion and in validation we used posterior classification error loss (Nagarajan, Scutari, & Lèbre, 2013). Above steps were repeated separately for individual and pairwise response data. All variables, including valence, were kept in the data in this analysis.

Results

The relative valuation scores of candidates' for individual and pairwise valuation methods and pooled over all subjects are depicted in Fig. 1. Individual scores were computed by averaging over all ratings (x_8^r) for each candidate. Pairwise scores were computed by averaging over rows of an anti-symmetric pairwise rating matrix where each element was the sum of pairwise ratings (x^c) for all 55 combinations of candidates. As the scale of the scores was arbitrary, score distributions were standardized before plotting. Distributions were highly similar (Pearson correlation 0.958), thus confirming that both methods resulted in similar relative valuation of candidates.

From now on, as we report the modeling results, all variables (predictors) are referred with their alphabetic abbreviations. Variables x^r and x^e, which we consider as *main-effects*, are capitalized. The alphabetic abbreviations for the responses were SUITABILITY for x_8^r and SELECTION for x^c.

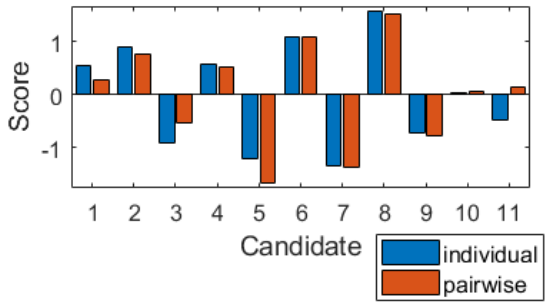

Figure 1: Mean valuation scores of all 11 candidates measured by individual (direct) and pairwise (indirect) method

[2] Note that until this point all nodes were equal and no "response" nodes were specified during bootstrapping

Linear Mixed-effect Models Results for the full and reduced linear models for the individual and pairwise responses are listed in Table 1. Positive t-values indicate increase of valuation (and vice versa). Total 6+7 individual and 24+26 pairwise fixed-effects terms surpassed p<0.05 (FDR adjusted over 99 and 88 terms) for full and reduced models. All predictors that were significant for at least one of the four models are shown in table (total 44 terms). Total 14 predictors were significant for at least two of the four models. Three of these were the main effects including variables TRUSTWORTHINESS, VALENCE and RIGHTEOUSNESS. Models reached MSE/MSE$_{nul}$ ratios 0.292-0.405 (smaller better) in 10-fold cross-validation. All models were also significant at p<0.0001 against permutations. Raw Pearson correlation between valence and responses were 0.802 (x_8^r) and 0.813 (x^c), which accounted lots of the variation in the full models.

Table 1: T-values of the linear mixed-effects model using individual (Ind.) and pairwise (Pair.) valuation for full and reduced models. The main effects are capitalized and interactions (if any) marked with "**:**". Here * and ** indicate p<0.05 and p<0.01 (both FDR adjusted).

Bayesian network models In the Bayesian network analysis we found no major differences between search methods (HC or Tabu). AIC scoring, which tends to add more edges, resulted in generally smaller classification losses (i.e., better models). In general, higher edge density (bootstrapping frequencies <50%) resulted in higher classification accuracies. Here we present results obtained with Tabu and AIC. Results of bootstrapping are depicted in Fig. 2. Fig. 2a show all (undirected) edges with at least 5% frequency (i.e., 0.05) where upper triangular part is for individual and lower triangular for pairwise valuation. Weight 1.00 indicates very strong causal connection. The difference of the two triangular matrices is depicted in Fig. 2b (no thresholding), where all positive values correspond to higher frequency obtained for the pairwise valuation. The results indicate that most direct connections were within main effects (20 and 28) and subject-dependent characteristics (38 and 41), than between the two (only 6 and 14). While the individual valuation resulted in more subject-to-candidate edges (14 vs. 6), the

edges were generally weaker (<0.5) than those for the pairwise valuation (three edges with weight 1.0).

Finally, an example DAG for the SELECTION response is depicted in Fig. 3 with edge weight threshold 0.5 (with AIC and Tabu). The edge line weight corresponds to frequencies between 0.5 and 1.0 (thicker line = higher value). Node size indicates total number of incoming and outgoing edges (here between 2 and 9). The classification accuracy loss for this network was 0.581, while the (adjusted) baseline accuracy loss was 0.828. The *Markov blanket* for SELECTION included eight variables: gender, age, conservativeness, GENDER, VALENCE, TRUSTWORTHINESS, CO-OPERATION and RIGHTEOUSNESS. In other words, the SELECTION had direct causal connection with three background variables.

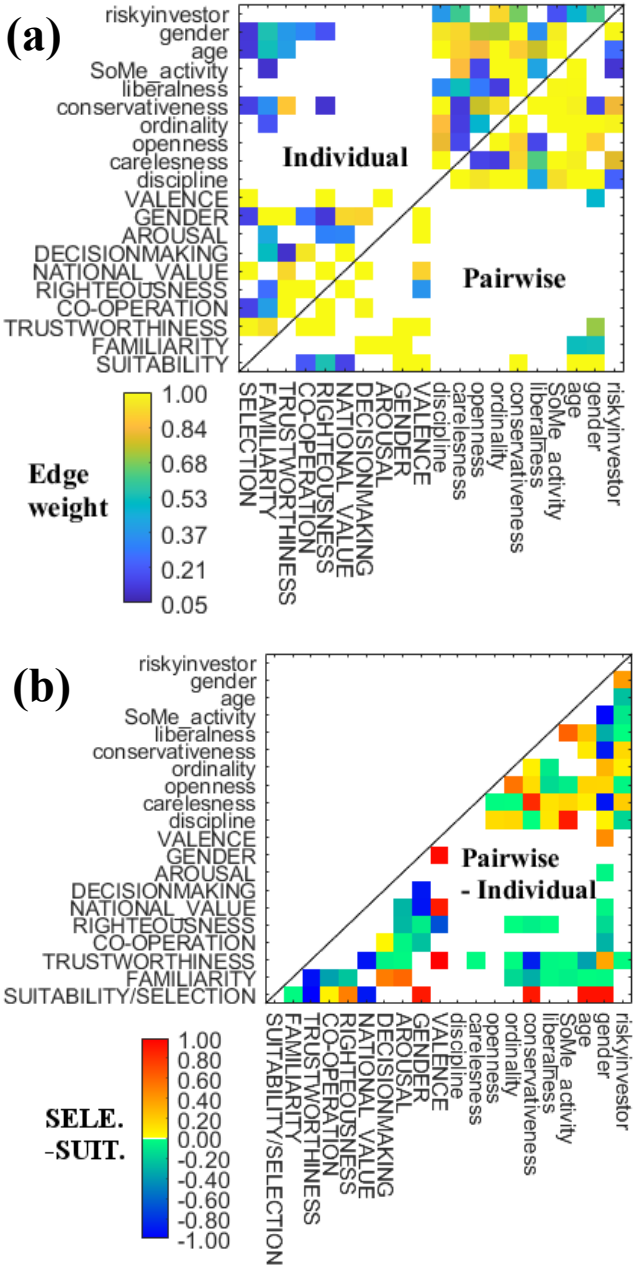

Figure 2: Bayesian network bootstrapping results for individual and pairwise valuation. **(a):** Occurrence rate of edges for individual (upper triangular) and pairwise valuation (lower triangular), only edges with at least 0.05 frequency are shown. **(b):** Difference of the two matrices (both unthresholded).

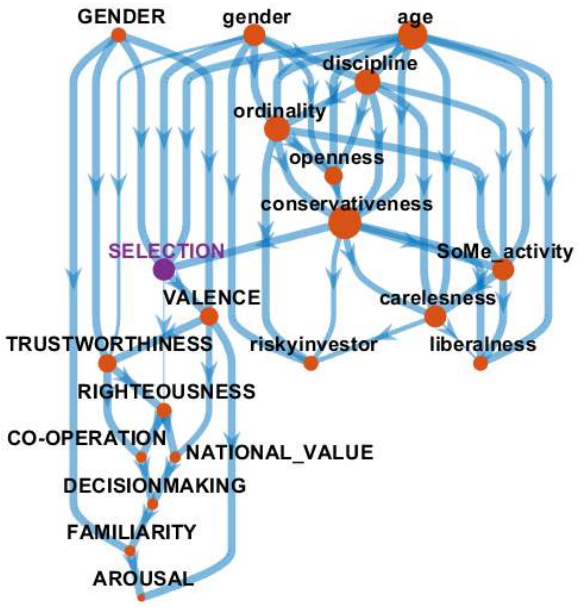

Figure 3: An example of a directed acyclic graph with 50 ed ges (at density >0.50) estimated using pairwise valuations of candidates. Line widths correspond to bootstrapping strength and node size to total number of connections.

Discussion

We collected behavioral questionnaire data on how voters valuate and judge politicians and their presumed suitability to serve as Prime Ministers. Aim was to pinpoint candidate and subject dependent factors that influence the valuation. We used linear mixed-effects models and Bayesian networks to analyze the data. We build two flavors of models; one for direct candidate valuation and the other for indirect valuation based candidate pairwise comparison. Although the average valuation scores of candidates were similar between direct and indirect approaches (Fig. 1), the models revealed differences in how the subjects arrived in their valuations.

In linear models, the pairwise valuation emphasized between individual- and candidate -related interactions with higher t-values magnitudes (Table 1). While the results for the main effects were similar (both highlighted trustworthiness, righteousness and valence), pairwise analysis resulted in more interaction terms surpassing significance (by the factor 3). While this can partly result from differences in number of samples (20 pairwise vs. 11 individuals per subject), it also reflects the difference in valuation processing when forced to choose between two choices. In particular, the interactions associated to emotion (valence and arousal) and gender (both candidate and subject)

had high impact in pairwise comparisons. Male responders favored male candidates and national value score of the candidate.

In order to complement our linear models, we also applied Bayesian network analysis. This framework allowed building full (nonlinear) probabilistic models for the data; however, here, we mainly used it as an exploratory tool to pinpoint causal connections between variables. The analysis also resulted in notable differences between individual and pairwise valuation (Fig. 2). In comparison to linear models, the candidate-related variable valence had direct causal effect only with electorate-related gender, but only for pairwise valuation. For individual valuation, causal connection between candidate valuation and electorate-related variables were more numerous (14 vs. 6), but were generally weaker. The strongest causal connection with the valuation score were found with conservativeness, age and gender of the electorate. These three had direct connections also with various other candidate-related properties, e.g., trustworthiness and familiarity.

In conclusion, we found that the background factors with strongest effect on the valuation of candidates were conservativeness, gender, age, ordinality and activity in social media of the voter. Emotion, especially valence, was strongly associated with valuation both directly and via interactions with voters' conservativeness, gender and ordinality. For males, higher arousal and valence strongly reduced the valuation. Emotion was found generally more important in pairwise candidate valuation.

Our results highlight the importance of how one measures the valuation of candidates (individual vs. pairwise) and how one analyzes such data (linear vs. nonlinear). Multiple views related to the data and methods are needed in pinpointing the most relevant effects. Previous studies have shown, that stimuli which trigger positive arousal increases the probability that people will behave according to the stimuli's suggestions in the future. Our results suggest that pairwise comparison – which is typical in USA elections – could enhance emotional and gender-related valuation of candidates.

Abstract

Seasonal patterns vary dramatically around the world, and we explore the extent to which systems of season categories support efficient communication about the local environment. Our analyses build on a domain-general information-theoretic model of categorization across languages, and we identify several qualitative predictions that emerge when this model is applied to season naming, including the prediction that systems with even numbers of categories should be more common than systems with odd sizes. We test the model quantitatively using a collection of season systems drawn from the linguistic and anthropological literature and data specifying temperature and precipitation in locations associated with these systems. Our results support the predicted even-odd asymmetry, and we also find that the model makes a number of successful predictions about the locations of boundaries between seasons.

Keywords: categorization; efficient communication; information theory

Imagine an alien geographer who has detailed knowledge about the natural environment in one part of our planet. The geographer knows how temperature, rainfall, humidity, wind speed, and wind direction vary over the course of the year. The geographer knows about clouds, fog, dew, storms, and lightning, and about the water levels in local streams, rivers and lakes. The geographer is intimately familiar with the flowering patterns of local plants and the breeding and migration patterns of local animals. In all of these cases the geographer knows about long-run averages as well as the variability that can be expected year to year. Before meeting any of the local people, what predictions could the geographer make about the categories named in their language? We focus on a special case of this question, and consider the extent to which named seasons reflect properties of the local environment. For example, we ask whether the geographer could predict how many seasons the local people might recognize, and where the boundaries between these seasons might lie.

Our approach builds on a growing body of work that explores ways in which languages support efficient communication (Rosch, 1978; Corter & Gluck, 1992; Gibson et al., 2019). Particularly relevant to our approach are information-theoretic accounts of variation in named categories across languages (Baddeley & Attewell, 2009; Kemp, Xu, & Regier, 2018). Regier, Kemp and colleagues have developed an information-theoretic formulation of the idea that named categories achieve a near-optimal tradeoff between complexity and communicative cost, and have applied it to domains including color (Zaslavsky, Kemp, Regier, & Tishby, 2018) and kinship (Kemp & Regier, 2012). Here we use the same formal framework to study season naming across languages.

Our work addresses an important question that is largely absent from previous formal treatments of categorization and efficient communication. The information theoretic framework that we adopt allows for different languages to reflect different communicative priorities. For example, the framework allows that systems of color categories may vary in part because speakers of different languages are embedded in environments (e.g. desert vs rainforest) with very different colour distributions, which may produce different local communicative needs. Previous authors acknowledge this point but typically implement models that assume that speakers all around the world encounter the same distributions over colors (Zaslavsky et al., 2018), kin types (Kemp & Regier, 2012), and other elements of their environments.

A notable exception is a project that explored words for ice and snow, and found that languages with a term that covers both of these concepts tend to be found in warm regions (Regier, Carstensen, & Kemp, 2016). That work focused specifically on environmental variation, but the naming behavior considered is extremely simple (one term versus two for frozen precipitation). Here we focus on environmental variation in a domain that offers the potential to make detailed predictions about not just the number of categories, but the locations of the boundaries between these categories.

Season naming has previously been studied by researchers from disciplines including linguistics, anthropology and geography. In a pioneering project Orlove (2003) compiled systems of season terms from twenty eight languages, and used them to document general tendencies in season naming. For example, Orlove suggests that seasons are usually characterized in terms of atmospheric phenomena such as rainfall, wind, and temperature. In some cases, however, seasons are based on changes related to plants (e.g. the flowering of a certain species), animals (e.g. the first appearance of a given species), or water levels in local rivers and lakes. Our approach builds on the work of Orlove and others by using computational methods to probe the relationship between season naming and the local environment.

A small amount of previous work has taken a computational approach to season naming. Hatfield-Dodds (2016) gives a detailed description of Yolngu seasons from the north east Arnhem land in Australia, and describes a computational model that uses climate data to detect when the seasons start and begin. Our work provides much less detail about any single language, but complements the approach of Hatfield-Dodds by using computational methods to explore season naming across a relatively large set of languages.

Previous authors have also discussed the notion of an optimal set of seasons for a given area. Entwisle, for example, proposes a set of five seasons for southeastern Australia that fits the local climate better than the four traditional European seasons (Entwisle, 2014). Proposals like these are often based in part on climate data, but are not typically derived from computational models. Our work builds on these approaches by connecting season naming with a domain-general account of categorization across languages.

Theoretical framework

This section introduces an information-theoretic approach that measures the extent to which a system of season terms supports informative communication about the environment. Consider a speaker who is talking about an event that falls within a standard year of 365 days. Let d indicate the day of the event. The prior distribution $p(d)$ captures the probability that the speaker will talk about an event that occurs on day d. For simplicity we assume that $p(d)$ is uniform.

Each day is associated with a distribution $p(\vec{s}|d)$ over a vector of season variables. We will consider three—precipitation (s^p), temperature (s^t), and temporal location within the year (s^y)—so that $\vec{s} = [s^p, s^t, s^y]$. Many other factors are relevant to season naming, and in principle we would like to include additional variables that capture information about the local climate, food sources, and bodies of water. In future it may be possible to include some of these variables, but for now we work with two climate variables (precipitation and temperature) that are readily available for locations all around the world.

Each day is also associated with a distribution $p(w|d)$ over words for seasons. The speaker labels day d by sampling from the distribution $p(w|d)$. After hearing the label the listener uses Bayesian inference to compute a distribution over the season variables:

$$p(\vec{s}|w) = \sum_d p(\vec{s}|d)p(d|w) \propto \sum_d p(\vec{s}|d)p(w|d)p(d).$$

We assume that communication succeeds to the extent that the speaker distribution $s = p(\vec{s}|d)$ resembles the listener distribution $l = p(\vec{s}|w)$, and formalize this idea using the same information-theoretic measure of communication cost used by previous work on domains including color and kinship (Kemp & Regier, 2012; Zaslavsky et al., 2018). Communication cost is defined as the Kullback-Leibler divergence $KL[s||l]$ from the speaker distribution s to the listener distribution l, and is low when the distributions are similar to each other. This cost measure can be used to assess the overall communication cost associated with an entire system of season terms. This overall cost is defined as the expected cost when the speaker communicates about an event:

$$\text{system cost} = \sum_d P(d)KL[s||l] = \sum_d P(d)KL[p(\vec{s}|d)||p(\vec{s}|w)].$$

There is a tradeoff between the communication cost of a system of categories and its complexity. Complexity can be formalized in different ways (Kemp & Regier, 2012; Zaslavsky et al., 2018) and here we define the complexity of a system as the number of terms that it contains. A system with many terms (high complexity) can allow the listener to reconstruct the speaker distribution very precisely (low communication cost), but a system with few terms (low complexity) means that the listener is typically able to approximate the speaker distribution only roughly.

Previous work suggests that systems of kinship terms (Kemp & Regier, 2012) and color terms (Zaslavsky et al., 2018) are efficient in the sense that they achieve near-optimal tradeoffs between communicative cost and complexity. An optimal tradeoff is achieved if the communicative cost of a system cannot be reduced without increasing the system's complexity, and vice versa. We will explore the extent to which attested season systems support efficient communication by comparing them to hypothetical systems of equal complexity.

Synthetic climate data

To illustrate some qualitative predictions of the model we first apply it to a simple synthetic data set that specifies how a single climate variable s^c varies over a hypothetical 48 day year. Fig 1a shows a climate variable s^c that rises smoothly then falls over the course of the year, as temperature does in many parts of the world. We combined this climate variable with a temporal variable s^y so that $\vec{s} = [s^c, s^y]$. Fig 1a includes season systems that minimize communication cost for different levels of complexity. For example, when $n = 2$ the optimal categories divide the year into days when $s^c < 0.5$ and days when $s^c > 0.5$

Although the model allows categories to be disconnected the categories in these optimal systems are always connected regions of the year. This result emerges because connected categories ensure that category members have similar values of the two season variables s^c and s^y.

A second qualitative result is that the turning points of the climate variable (i.e. the peak and trough) always lie within a category rather than at a category boundary. Because the days on either side of a turning point have similar values of s^c and s^y, assigning them to the same category minimizes communication cost. A related but more subtle result is that for a fixed value of the system size n, categories containing turning points are longer than categories without turning points. For example, when $n = 4$ the categories that contain the peak and trough have 13 days each, and the remaining categories have 11 days each. In general, combining two intervals of length k

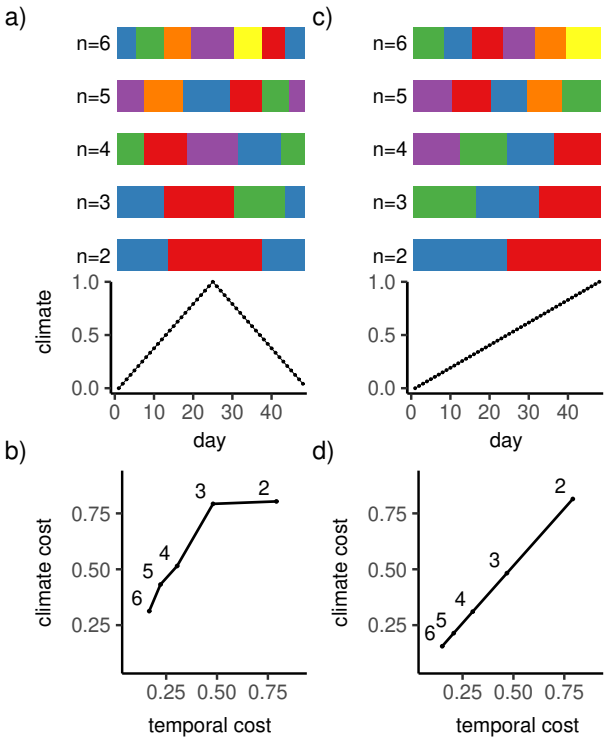

Figure 1: Analyses of synthetic climate data over a 48 day year. (a) Optimal systems of different sizes given a climate variable that varies smoothly. (b) Communication costs relative to the climate and temporal variables for the optimal systems in a. Labels indicate the sizes n of the 5 systems. (c), (d) Analogous results when the climate variable has a discontinuity at the end of the year.

that lie on either side of a turning point produces a category of size $2k$ that has the same coherence (in s^c) as a category of size k in a region without a turning point.

A final qualitative result is that *even systems* (i.e. systems with even numbers of categories) are more effective than *odd systems* at capturing information about the climate variable. The $n = 2$ system in Fig 1a distinguishes naturally between low and high values of s^c, but distinguishing between low, medium and high values turns out to be less straightforward. If only three categories are used, then the medium category must have two disconnected components (not shown in the figure). If all categories are connected regions of the year than four categories (as for the $n = 4$ system in Fig 1a) are actually needed to distinguish between low, medium and high values of s^c. More generally, if categories are connected then at least $2k-2$ categories are needed to distinguish k levels of s^c. As a result, distinguishing between levels of s^c in a parsimonious way naturally leads to an even system.

Fig 1b compares the even and odd systems in Fig 1a by plotting communication cost with respect to variables s^c (climate cost) and s^y (temporal cost). Although communication cost was defined earlier with respect to the entire set of season variables $\vec{s}$, here we use the same approach to define communication cost with respect to one variable at a time. Fig 1b shows that moving from 2 to 3 categories produces a relatively small improvement in climate cost, but moving from 3 to 4 categories produces a relatively large improvement. A similar but less pronounced kink in the curve is visible when moving from 4 to 5 to 6 categories. Moving from 2 to 3 categories does allow a speaker to convey additional information about s^y, but Fig 1b shows that this increase in complexity provides little additional information about s^c.

Most of the qualitative results just discussed depend critically on the assumption that s^c varies smoothly over time. Figs 1c and 1d show analogous results if s^c increases smoothly over the year then drops very sharply to its original value before the year starts again. In this case optimal categories are still connected regions, but the turning point always lies at a category boundary, the categories within each system have equal sizes, and there is no even-odd asymmetry.

The simulated environment in Fig 1a is simple and highly stylized, and it is not clear whether qualitative results like the even-odd asymmetry still apply if the climate variable rises and falls at different speeds, or if additional climate variables are added. Even so, we propose that seasonal variation in real-world climates is more like Fig 1a than Fig 1c. Our analyses therefore identify several characteristics of real-world systems that might be expected purely on the basis that these systems support communication about periodic variables that vary smoothly through time.

Season naming data

We next evaluated the model using real-world naming and environmental data. Orlove's (2003) ethnoclimatology database was not available and we therefore consulted the primary literature to assemble our own data set.

The data set includes 53 languages in total. For 25 of these languages the set of season terms was described in enough detail to be roughly positioned relative to the Western calendar year, and the data set includes season boundaries for each season in each of these systems. Four examples of systems with boundaries are shown in Fig 2. For the remaining 28 languages the data set specifies only the number of season terms in each language. Our data have a strong Australian focus because our two biggest sources are collections of indigenous Australian seasonal calendars compiled by the Commonwealth Bureau of Meteorology and the CSIRO.[1]

The data set inevitably reflects a number of decisions that are somewhat arbitrary. There is no universally accepted definition of a season, and it is likely that our sources adopted slightly different notions of what qualifies as a season. Some of the systems are hierarchies with two levels: they include a number of major seasons which are in turn divided into minor

[1]Unless specified otherwise, all season systems discussed in this paper (including three of the four in Fig 2) are drawn from one of these resources (`http://www.bom.gov.au/iwk/index.shtml` and `https://www.csiro.au/en/Research/Environment/Land-management/Indigenous/Indigenous-calendars`).

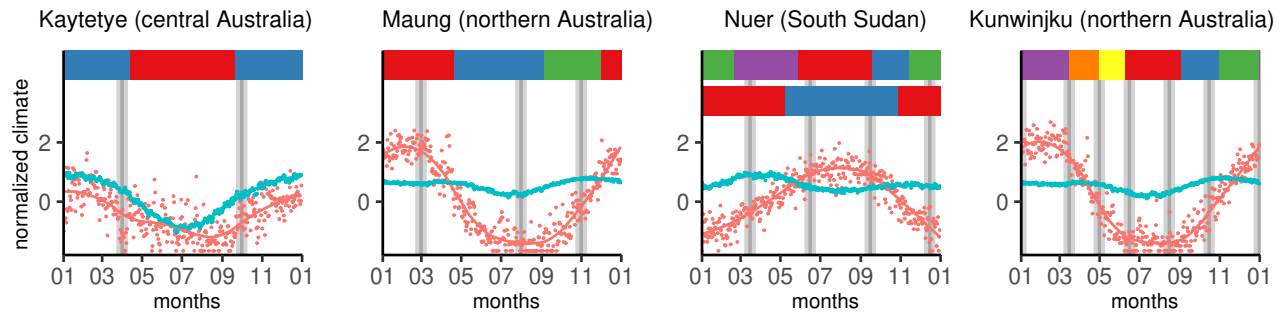

Figure 2: Climate data, seasons and optimal systems for four languages. Precipitation and temperature are shown using pink and cyan respectively. A cube-root transform has been applied to precipitation, and both variables are normalized to have zero mean and unit variance across the entire data set. Empirical season boundaries are shown using vertical lines. The colored bars across the top show optimal systems according to the model with sizes matched to the linguistic systems. Two systems are shown for Nuer for comparison to the two major seasons and the four minor seasons recognized in this language.

seasons. Judgments about subjective seasons are likely to be especially subjective. For example, the Tiwi system includes three major seasons and thirteen minor overlapping seasons, including *Kurukurari* ("season of the mangrove worm", when these worms are easy to find) and *Tawutawungari* ("season of the clap sticks," when special yam ceremonies are held). It seems likely that some of the languages in our data set have minor seasons that are not documented in our sources.

Although 25 of the languages in the data set include season boundaries, our sources repeatedly stress that mappings of indigenous seasons onto the calendar year are approximate only. Seasons are often fuzzy categories with no sharp boundaries, and the boundaries between seasons often shift from year to year as a result of variability in the local climate and other factors.

Some of our sources describe overlapping seasons, and this overlap is preserved in our data set. When seasons overlapped the distribution $P(w|d)$ over season terms for a given day was taken to be uniform over all seasons including that day. None of our sources describes gaps (i.e. unnamed periods) between seasons, and as a result each system in our data assigns each day to at least one season.

Among our systems with season boundaries, seasons always correspond to connected regions of the year, but exceptions are known outside our data set. For example, Rukiga has two words for seasons, *orugazi* (rainy season) and *ekyanda* (dry season), but these seasons may alternate over the course of a calendar year so that there are two rainy seasons and two dry seasons (Orlove, 2003). For languages included in our data set, season terms may pick out disconnected regions of the year when actually applied by native speakers. For example, if an unusually cold spell occurred during the summer months, a Yolngu speaker might say that one season had "interrupted" another (Hatfield-Dodds, 2016). These interruptions mean that seasons can occur in different orders during the year, and that a particular season could occur multiple times. For all of these reasons the representations in our data set are best viewed as crude approximations of bodies of knowledge that are both rich and subtle.

Season variables

The precipitation (s^p) and temperature (s^t) variables are based on global gridded data available from the Climate Prediction Center (CPC) in the USA.[2] Our analyses used daily precipitation and daily temperature averaged over the period from 1979 to 2005 and excluding leap years. Following a common practice in climate modeling we applied a cube-root transform to the precipitation data. We then normalized both variables to have zero mean and unit variance; normalized variables for four locations are shown in Fig 2.

We assigned Glottocodes manually to each language in the data set then retrieved the position (i.e. latitude and longitude) associated with each language in the Glottolog data base (Hammarström, Forkel, & Haspelmath, 2018). We then used these positions to extract precipitation and temperature data for each language from the CPC data.

The distribution $p(\vec{s}|d)$ for a given day and location was defined as a multivariate Gaussian distribution over a three-dimensional space. Two of the dimensions were the normalized precipitation and temperature dimensions already described, and the temporal dimension ran from 1 to 365 days and wrapped around so that day 366 was identical to day 1. The covariance was an axis-aligned distribution with standard deviation of 0.1 along the precipitation and temperature dimensions and standard deviation of 40 along the temporal dimension. The relative magnitudes of these standard deviations capture assumptions about the extent to which season categories should be informative about the three dimensions. For example, increasing the standard deviation along the temporal dimension would mean that there is less pressure for season categories to convey precise information about the location of an event within a year. As a result the temporal dimension would become less important and precipitation and temperature would effectively become more important. The numerical parameters used in our analyses (i.e. 0.1 and 40) were intended to give precipitation and temperature equal

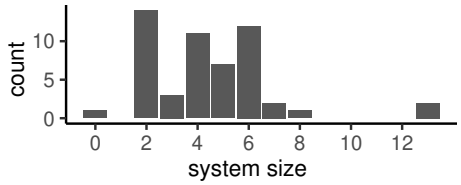

Figure 3: Distribution of system sizes.

weight, and to capture the idea that season categories locate events within the calendar year only roughly.

Because climate data are noisy we smoothed the distributions $p(\vec{s}|d)$ using a linear kernel with a width of 9 days. This smoothing process meant that the distribution $p(\vec{s}|d)$ for a given day (e.g. Jan 15) was defined as a weighted average of distributions for Jan 11 through 19. As a final step we discretized these distributions over a regular grid for use in our information-theoretic analyses.

Analysis of system sizes

Fig 3a shows the distribution of system sizes across our data set. For languages with hierarchical systems, the system size is defined as the number of seasons at the finest level of resolution. The system of size zero corresponds to the Grand Valley Dani, who constitute "a significant exception to [the general statement] that all cultures recognize seasons" (Heider, p 212). The two systems of size 13 represent Tiwi (described earlier) and Ngan'gi, and both feature ecological seasons defined with respect to the local plants and animals. Other languages in the data set almost certainly have ecological seasons that were not documented in our sources, and our Fig 3 therefore likely exaggerates the difference between Tiwi and Ngan'gi and the other languages in our data set.

As suggested earlier the model predicts a preference for systems with even sizes, and Fig 3a reveals that 2, 4 and 6 are the most common sizes. Leaving aside the three systems with sizes of zero or 13, 38 out of 50 systems or 76% have even sizes. We evaluated the significance of this result using a Bayesian mixed effects binomial model based on the `rstanarm` package and its default priors (Goodrich, Gabry, Ali, & Brilleman, 2018). The binary outcome variable indicated the parity (even or odd) of a system, and we included both a fixed intercept and a random intercept for language family to acknowledge genetic relatedness between languages.[3] The median of the fixed intercept indicates a probability of 0.77 that a random system would have an even size, and the 95% posterior credible interval ($[0.59, 0.94]$) excludes the probability (0.5) that makes even and odd systems are equally likely. Our data therefore support the conclusion that even systems are more common than odd systems.

Orlove (2003) previously noted that systems with odd sizes are rare, and in his data 23 out of 28 systems, or 82% have an even size. He did not offer an explanation for this asymmetry, but we have argued that it emerges from a pressure for season systems to support informative communication about factors that vary smoothly over time.

[3]The model call was `stan_glmer(parity ~ 1 + (1|language_family), family='binomial')`. Language families (e.g. Pama-Nyungan) were extracted from Glottolog.

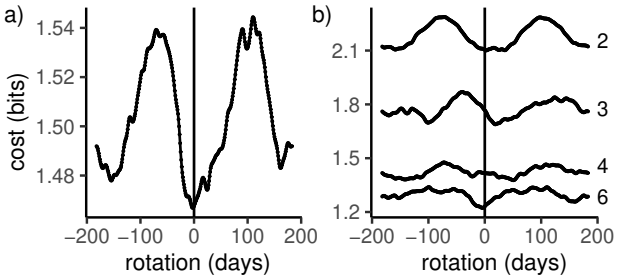

Figure 4: (a) Average rotation curve across all languages. (b) Averages across 2-term systems (4 languages), 3-term systems (3 languages), 4-term systems (8 systems) and 6-term systems (10 languages). The curve for 5-term systems (2 languages) is not shown because it overlaps the 6-term curve.

Analysis of season boundaries

Our remaining analyses focus on the 25 languages for which we have season boundaries. Four of these languages are shown in Fig 2 along with optimal systems according to our model.

Kaytetye has two seasons — *Watangka* (hot season) and *Yurluurp* (dry season) — and the boundaries between these categories roughly match the model predictions. Maung has three seasons: *Walmatpamalat* (heavy rain), *Wumulukuk* (cold weather) and *Kinyjapurr* (hot and humid). The model predicts three categories of roughly the right duration—in particular, the category that includes the steep increase in precipitation is shorter than the other two. The predicted season boundaries, however, are all shifted later in the year relative to the Maung system. Fig 2 also suggests that two of the Maung season boundaries lie close to simultaneous turning points in both temperature and rainfall. The Maung system therefore challenges the qualitative prediction that turning points in the climate data should lie within categories rather than at category boundaries.

Nuer has two major seasons: *tot* (mid-March to mid-September) and *mei* (mid-September to mid-March), each of which is divided into two minor seasons. The Nuer system provides additional evidence that season boundaries can be aligned with turning points in the climate data. Evans-Pritchard (1939, p 191) notes that "the *mei* season commences at the decline of the rains—not at their cessation." At the beginning of *mei* the Nuer start to anticipate the life they will lead when the dry weather arrives, and Evans-Pritchard (p 191) writes that their classification of seasons "aptly summarizes their way of looking at the movement of time, direction of attention in marginal months being as significant as actual climatic conditions."

Kunwinjku has six terms: *Kudjewk* (monsoon season), *Bangkerreng* (knock'em down storms), *Yekke* (start of dry time), *Wurrkeng* (cool weather time), *Kurrung* (hot, dry time), and *Kunumuleng* (humidity builds). The boundaries

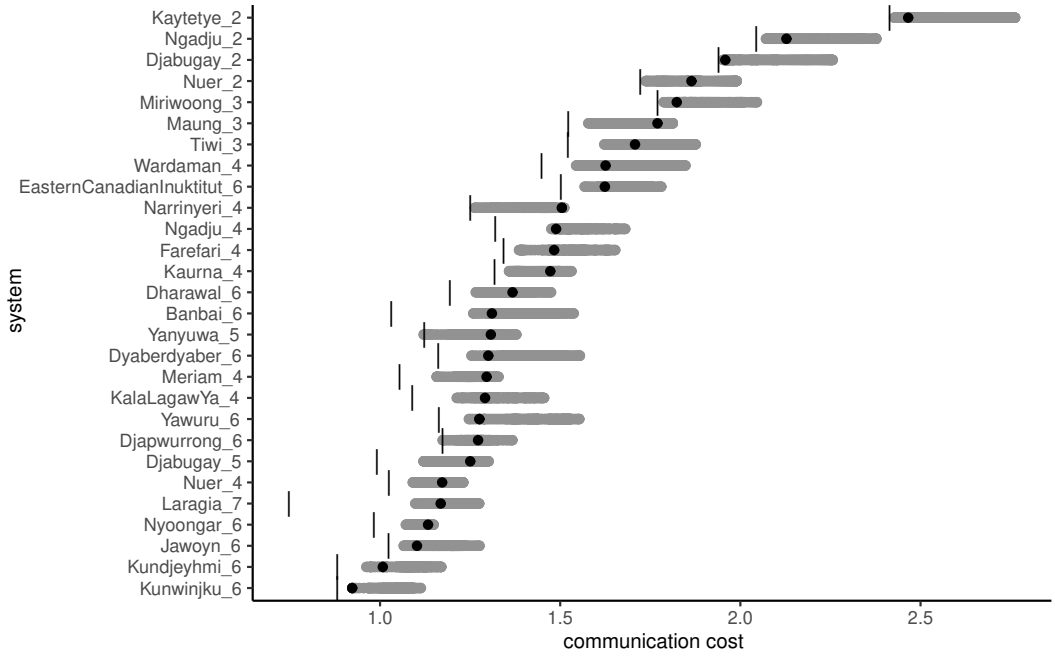

Figure 5: Attested systems (black dots) compared to rotations (grey dots) and size-matched optimal systems (black lines).

in the model system roughly match the linguistic data, and the model correctly predicts that there should be two short adjacent seasons during the part of the year when rainfall is declining sharply. Much more could be said about Kunwinjku and about each specific language in Fig 2, but we now turn to analyses that range more broadly across the entire data set.

A first general question is how closely season categories are aligned with variation in the two environmental variables (temperature and precipitation) included in our model. If a given system is closely aligned with the environmental variables, then rotating the system through the calendar year (i.e. incrementing all season boundaries by a constant while allowing for wrap around) should disrupt this alignment. Fig 4a plots communication cost against rotation size, and suggests that attested systems (i.e. systems rotated by zero days) tend to achieve lower communication cost than rotations of these systems. As shown in Fig 4, 0 day rotations score better than 99% of the 365 possible rotations. Fig 4b shows separate rotation curves for systems of size 2, 3, 4 and 6. The 2 term systems make an especially large contribution to the average result in Fig 4a, but a clear trough at zero days is visible also for the systems of size 6.

Fig 5 summarizes rotation results for individual languages. The three languages with hierarchies are included twice in the plot, once for each level of the hierarchy. Some systems (black dots) score better than most of their rotations (gray bar), including Kaytetye and Kunwinjku from Fig 2), but others (in particular Narrinyeri) do not. On average, each system scores better than 64% of its rotations.

Fig 5 also compares each system to the optimal system according to our model. Again, the pattern of results is mixed. Some systems (including Kaytetye and Kunwinjku) achieve scores close to the optimum, but others (including Laragia) do not. A likely explanation is that our model was given only two environmental variables even though language groups around the world use many markers of seasonal transitions other than changes in precipitation and temperature. For example, Narrinyeri seasons are distinguished by factors including "the growth of particular plants" and the "appearance of various creatures" (Berndt et al, 1993, p 76), and the lack of these factors in our analyses may explain why Narrinyeri achieves a sub-optimal score in Fig 5.

Conclusion

We developed a computational model that assumes that systems of season terms are near-optimal at conveying information about the local environment. The model helps to explain why systems with odd numbers of terms are relatively rare, and makes a number of successful predictions about the locations of season boundaries.

Our results do not provide strong support for claims about optimality but nevertheless demonstrate the value of the efficient-communication approach to naming and categorization. Most interesting to us are the qualitative issues exposed by the model. We have touched on some of them already, including the even-odd asymmetry, and the relationship between season boundaries and turning points in environmental variables. Many others arise: for example, our approach could be used to test the hypothesis that systems with large numbers of terms are especially likely to be found in regions with variable climates, and the hypothesis that boundaries are more likely to be aligned with sharp transitions (e.g. the first major rainfall of the year) than gradual changes in variables such as temperature. Although our current model is extremely simple, we have found it to be a useful conceptual tool for thinking about season naming across languages.

Abstract

A substantial body of research has demonstrated that children and adults (both native and non-native speakers) are sensitive to the statistics of multiword sequences (MWS) and rely on knowledge of such statistics to facilitate their language processing and boost their acquisition. However, this research was primarily aimed at determining whether and to what extent speakers can develop sensitivity to MWS statistics of a single type of linguistic input: that of spoken language. Recently, there has been a growing awareness of the key role of written input in the development of linguistic knowledge, as it provides a source of substantial change in the statistics of an individual's language experience. The present study reports on a series of experiments designed to determine whether second language learners of English are able to develop sensitivity to distributional statistics of MWS inherent in different (register-specific) input types.

Keywords: life-long learning; multiword sequences; second language processing; statistical learning

Recent theoretical approaches have highlighted the key importance of linguistic experience to the acquisition and processing of language. This broad class of approaches, commonly referred to as 'emergentist' approaches,[1] put the emphasis on usage and/or experience with language and assume a direct and immediate relationship between processing and learning, conceiving of them as inseparable rather than governed by different mechanisms ('two sides of the same coin'). Language acquisition is viewed as learning how to process linguistic input efficiently (e.g., Chang, Dell & Bock, 2006; Chater & Christiansen, 2018). In the emergentist perspective, language learning does not result in the establishment of a static knowledge system. Rather, as long as there is exposure to linguistic input, an individual's knowledge of a language is subject to constant change. Learning about the statistical regularities and distributional patterns inherent in linguistic input is viewed as a continuous process that does not end at some discrete point in time in ontogenetic development but instead takes place across the lifespan (e.g., Armstrong et al., 2017; Saffran & Kirkham, 2018; Seidenberg & MacDonald, 2018). This lifelong process brings about changes in language representations in response to the statistics in linguistic input. These experientially-driven adaptive processes are shown to occur across multiple linguistic levels and apply to the acquisition of new structures, the modification and/or adjustment of already learned representations or changes in accessibility of learned representations.

Moving away from the traditional 'words-and-rules' approach (e.g., Pinker, 1999), emergentist accounts have developed an increasing interest in the role of multiword sequences (MWS), often defined as variably-sized continuous or discontinuous recurring strings of words. This interest stems from an extensive body of evidence demonstrating that children and adults (both native and non-native speakers) are sensitive to the statistics of MWS and rely on knowledge of such statistics to facilitate their language processing and boost their acquisition (e.g. Shaoul & Westbury, 2011; N. Ellis, 2011; see Arnon & Christiansen, 2017, for a recent review). Sensitivity to the statistics of MWS facilitates chunking - required to integrate the greatest possible amount of available information as fast as possible so at to overcome the fleeting nature of linguistic input and the limited nature of our memory for sequences of linguistic input (Now-or-Never bottleneck, see Christiansen & Chater, 2016). Processing a MWS as a chunk will minimize memory load and speed up integration of the MWS with prior context (see, e.g., a chunk-based computational model of early language acquisition presented in a recent study by McCauley & Christiansen, 2019).

Frequency estimates obtained from corpora of actual language use have been shown to be robust predictors of language behavior across different types of experimental designs, as evidenced by higher accuracy rates, faster reaction times, and fewer and faster fixations. These effects have been shown in both child and adult populations as well as second-language learner populations. While earlier studies on the processing of MWS have used a threshold-approach to test whether MWS are stored and processed as holistic units (Biber & Conrad, 1999), more recent studies have incorpo-

[1] Following the literature (see, e.g., Kidd et al. 2018), we use the term 'emergentist' to refer to a broad class of approaches - usage-based (a.k.a. experience-based) models, complex dynamic systems theory, constraint-based approaches, exemplar-based models and connectionist models - that share a number of key tenets, for more details (see, e.g., Beckner et al. 2009; Daelemans & van den Bosch, 2005; McClelland et al. 2010)

rated further methodological improvement by testing these effects across the frequency continuum after controlling for substring frequency (for studies in child language acquisition, see, Bannard and Matthews, 2008; Matthews and Bannard, 2010; for studies on adult – both first and second language – processing see, Arnon, McCauley & Christiansen, 2017; Arnon and Snider, 2010; Hernandez et al., 2016, Kerz & Wiechmann, 2017, Yi et al. 2017).

This line of research has also shown that while being the most robust statistic, frequency is not the only kind of distributional information to which language users are sensitive. For example, in a study of MWS repetition in children, Matthews and Bannard (2010) showed that MWS with a high slot entropy value have increased uncertainty for what word occur in that slot and that such sequences were easier to generalize and hence easier to process for children than MWS with lower slot entropy.

The prior studies reviewed here have made important theoretical and methodological contributions to research on MWS. However, they have primarily focused on examining sensitivity to the frequencies derived from corpora representing spoken language (i.e., spontaneous conversations). In contrast to early child language acquisition (prior to literacy), where children are mainly exposed to the statistics of the spoken linguistic input (i.e., to child-directed speech), the role of written language becomes increasingly more important in later stages of learning which also sees increased demands on literacy. Indirect support for this assumption comes from a growing number of studies indicating that written language constitutes a key input type in the development of linguistic knowledge, as it provides a source of substantial change in the statistics of an individual's language experience (e.g., Montag & MacDonald, 2015; Seidenberg & MacDonald, 2018). Language users are thus faced with the challenge of keeping track of the ever-changing statistics of these two main types of language input. This challenge is exacerbated by considerable variability in the distributional properties of linguistic patterns at multiple levels of linguistic structure *within* these two input types (Roland, Dick & Elman, 2007; see also work on register/genre[2] variation by Biber and colleagues, e.g. Biber et al. 1999, Biber & Conrad, 2009).

In light of the lifelong nature of language learning highlighted in emergentist accounts, there is an apparent need not only to characterize the statistical learning processes in early stages of child language development, but also to understand how language users develop sensitivity in later stages of learning to the multiple kinds of statistics found in written language. This issue is of particular importance for second language (L2) learners, who are likely to get a lot of their language from written sources. Using a within-subject design, the present study sets out to investigate whether and to what extent language users can develop sensitivity towards the multiple statistics of MWS. We perform analyses of large samples of corpus data representing four registers and use the results from these analyses to make predictions about language users' performance in a MWS decision task. We predict faster response latencies for more frequent MWS (after controlling for all part frequencies) across the registers/genres investigated here. In addition to determining the effects of frequency ('more simple' distributional statistics), the study also investigated whether and to what extent language users are sensitive to 'more complex' distributional statistics (entropy) that captures the variability of MWS. The effects of frequency and entropy were investigated in a L2 learner population by conducting four reaction time experiments where processing latencies of MWS are compared for pairs of MWS that differ in sequence-frequency and entropy of their final slot.

[2]In the present paper, the terms 'registers' and 'genres' are used interchangeably in Biber's sense (2006:11) as referring to "situationally-defined varieties described for their characteristic distributions of linguistic structures and patterns."

Methods

Participants

Sixty advanced learners of English participated as a part of a larger project (34 female and 26 male, M = 23.56 years, SD = 4.52). All participants were college students recruited from the RWTH Aachen University studying either towards an BA or an MA at the time of testing. Participants were asked to fill out the Language Experience and Proficiency Questionnaire (LEAP-Q, see, Lemhofer & Broersma, 2012), a questionnaire used to obtain general demographic information and more specific information on self-rated proficiency for three language areas (reading, understanding and speaking) and self-rated current knowledge of L2 English and exposure to the L2. The data gathered from the LEAP-Q instrument are reported in Table 1, showing means, standard deviations and ranges of our L2 group.

Materials

The current study follows the general methodological approach described in the previous studies reviewed above that used carefully chosen stimuli, controlled for substring frequency. Following these studies, we chose pairs of four-word sequences as stimuli that differed only in the final word and in overall MWS frequency (high vs. low) but were matched for substring frequency (e.g. *to justify the cost* vs. *to justify the effort* from the newspaper register; e.g., *is beyond the scope* vs. *is beyond the boundaries* from the academic register). We constructed a total of 240 experimental items, 60 for each of four registers. The items were constructed using the Corpus Contemporary American English (COCA; Davies, 2008), a 560 million words corpus with approximately equal-sized subcomponents representing the statistics of MWS from the four target registers: (1) spoken (118 million words), (2) fiction: (113 million words), (3) newspaper (114 million words and (4) academic journals (112 million words). In a first step, all COCA text files were preprocessed using the sentence splitting (`ssplit`) and tokenization (`PTNTokenizer`) components from the Stanford CoreNLP toolkit V.3.2.9 (Manning et

al., 2014). In a second step, we extracted frequencies for all n-grams of orders 1 to 4 using Java scripts. N-grams with a frequency of one (so-called 'hapax legomena') were discarded. These two steps were performed on the RWTH Aachen University high-performance computing cluster. In a third step, four-grams that had a function word as their last word were filtered out to ensure that the position at which entropy was measured was filled by a lexical word.[3]. For all remaining four-grams the Shannon entropy H was computed for their final word slot, which is given in (1), where X is the final slot of the MWS, each x is a word that appears in that slot, and $p(x)$ is the probability of seeing each x in that position. All conditional word probabilities needed to compute entropy scores were estimated using second-order Markov models (cf. Willems, Frank, Nijhof, Hagoort, and van den Bosch, 2015).

$$H(X) = -\sum_{x} p(x) \log p(x) \quad (1)$$

We next identified all sequences of four words that began with the same first three words (i.e. shared the same pattern). Within each set of these sequences, a frequency difference score (FDS) was computed for a given sequence in relation to the most frequent sequence in that set.[4] We then ordered the sequences according to their FDS and explored how FDS scores related to entropy using a moving window approach/technique. A window with a size that corresponded to a predefined FDS was moved over the entire candidate-item pool to bin all four-gram into groups with similar FDS (see Figure 2 for a visualization). Inspection of these data indicated that four-grams with small differences in FDS tended to exhibit low entropy scores. Based on these observations, we restricted our candidate pool to four-grams that had entropy scores between 0 and 3 and a difference in log normalized frequency between 6.5 and 30. From this candidate pool, we randomly sampled, from each register, a total of 60 experimental item pairs: 20 pairs from each of three entropy ranges ('low': H(X) between 0 and 1, 'mid': H(X) between 1 and 2, 'high': H(X) between 1 and 2). Applying these filters meant that the log frequencies of our items ranged between 0.69 and 6.85 (spoken $0.69-6.07$, fiction: $0.69-6.85$; news $0.69-5.97$, academic $0.69-5.87$).

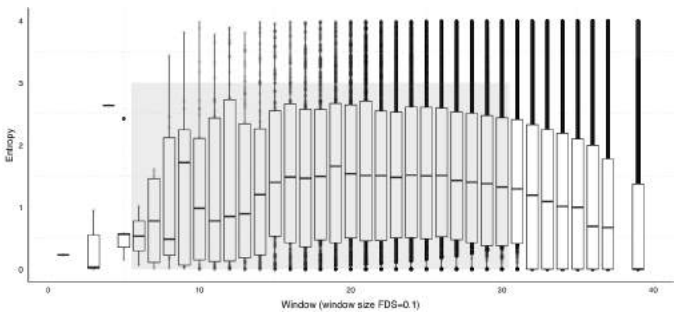

Figure 1: Distribution of entropy scores across the 'frequency difference score' (FDS) range for the academic subcomponent of COCA. The shaded area represents the range from which experimental items were sampled.

Procedure

Four separate MWS experiments, one for each register, were conducted as part of a larger project at two different days with two registers tested per day (day 1: academic and fiction; day 2: news and spoken). Each experiment was divided into two blocks of about 7 minutes each, which were separated by intervening tasks assessing individual differences in L2 experience and another task assessing a cognitive individual differences variable (not investigated here). The 120 MWS from a given register were distributed across two lists that each contained one of the two variants of a given pair, so that in a given experimental run participants would never see both variants of a pair. In addition to the experimental items, the lists also contained 60 ungrammatical items, which were incorrect due to scrambled word order. The order of presentation of the blocks was counterbalanced between participants. Participants were asked to judge if a four-word sequence that appeared on the screen was a possible sequence in English or not. They were given no information about the fact that MWS were extracted from different registers. Each trial began with the presentation of a fixation point for 500 ms. Phrases appeared at once in the middle of the screen and participants were instructed to respond as quickly and accurately as possible using the keyboard. The MWS was then presented and stayed visible on the screen until participants responded or

[3]The stop-list for function words was derived from the 'Essential Word List' https://www.edu.uwo.ca/faculty-profiles/docs/other/webb/essential-word-list.pdf

[4]FDS were expressed in terms of as the absolute of the $log10$ of the normalized frequency of a four-gram minus the $log10$ of the normalized frequency of the most frequent four-gram sharing the first trigram.

until 3000 ms had passed. The task was run using PsychoPy v3.0 (Peirce, 2007).

Results

Responses under 200 ms and over two standard deviations from the mean were excluded. This resulted in loss of small percentage of data for each register ($< 9\%$). Accuracy for target items was near ceiling ($> 92\%$ correct) for all registers. On average, participants were faster in responding to MWS from the spoken and fiction registers (mean response latencies spoken and fiction = 1.44 seconds, $SD = 0.5$) than in responding to MWS from the academic and news registers (mean response latencies: academic = 1.55 seconds, $SD = 0.51$; news = 1.57 seconds, $SD = 0.5$). The results were analyzed using mixed-effect linear regression models. To determine to what extent L2 learners can develop sensitivity to the two distributional statistics of MWS (log MWS frequency, slot entropy) inherent in the four registers investigated in the study, separate models were fitted to the data from each of the four experiments.[5] All analyses were carried out using the `lme4` package (v 1.1-17, Bates et al., 2015) in `R` (version 3.5.0; R Core Team, 2017). Log response times were used as the predicted variable to reduce the skewness in the distribution of response times. In a first step, we fitted models containing all control variables, i.e. LENGTH (in number of characters), two substring frequency measures (LOG FREQUENCY OF THE FINAL UNIGRAM and LOG FREQUENCY OF THE FINAL BIGRAM)[6], BLOCK ORDER (first vs. second), and PAIR VARIANT (high-low frequency variant of a pair). All continuous predictors were mean centered prior to analysis. We then added our key predictors, LOG PHRASE FREQUENCY and SLOT ENTROPY (high, mid, low), to examine their predictive value over and above our controls, using likelihood ratio tests to compare nested models. In all models, we used the maximal random effect structure justified by the data, which included random intercepts for participants and items and by-subject random slopes for log MWS frequency and entropy. To compare the effects of (log) MWS frequency on (log) reaction times across the four registers, standardized coefficients as well as marginal and conditional pseudo-R2 were computed (cf. Nakagawa and Schielzeth, 2013).[7]

In a next step, we tested for a potential interaction between our two key predictors. To this end, we conducted model comparisons between a model containing only the main effects and a corresponding model that also included the two-way interaction between MWS frequency and slot-entropy using Akaike's Information Criterion (AIC). The results of the final best-fitting model for each register are presented in Table 2 below. Likelihood ratio tests comparing models including LOG MWS FREQUENCY with a model that included only the control variables revealed that – after statistically controlling for the effects of length and frequency-related control variables – MWS frequency exerted a significant effect on (log) reaction times for all registers except fiction (spoken: $\chi(1) = 18.53$, $p < .0001$; fiction: $\chi(1) = 2.28$, $p = 0.51$; academic: $\chi(1) = 13.31$, $p = 0.004$; news: $\chi(1) = 59.46$, $p < .0001$). The frequency effect was found to be strongest in the spoken and news registers (both standardized $\beta = -0.13$), followed by academic language (standardized $\beta = -0.11$). A significant main effect of slot entropy was observed for the spoken and academic register (spoken: $\chi(1) = 40.03$, $p < 0.001$; fiction: $\chi(1) = 5.77$, $p = 0.58$; academic: $\chi(1) = 14.23$, $p = 0.047$; news: $\chi(1) = 12.42$, $p = 0.061$), such that that mean response times were significantly faster for MWS with higher slot entropy. There was also a significant interaction effect between MWS frequency and entropy in the spoken register ($\beta = -0.046$, $SE = 0.016$, $t = -2.79$), indicating that the frequency effect was more pronounced in high-entropy MWS (see Figure 2). The effects of the length and frequency related control variables were in the predicted directions - with longer MWS being read more slowly on average and more frequent final words leading to faster response times - but these effects were significant in only some of the registers. Significant effects of block order were observed for two of the four registers (see Table 3 for details).

Discussion and Conclusions

In this paper we reported a series of experiments with English L2 learners designed to determine to what extent the multiple distributional statistics of MWS inherent in register/genre-specific linguistic input (as estimated using a large corpus of actual language use) would affect the processing latencies of the MWS. We found the MWS frequency effect in three out of four registers investigated (all with the exception of fiction), i.e. our participants responded faster to higher frequency MWS, even after controlling for the effects of substring frequency. The finding that our participants showed MWS frequency effects in the spoken register is in line with the results of previous studies on adult native speakers and non-native speakers (e.g., Arnon & Snider, 2010; Tremblay et al., 2012; Hernandez et al. 2016). Importantly, our findings extend this

[5] Two anonymous reviewers recommended to pool the data from the four experiments and report on the interaction effects between our key predictors (log MWS frequency, slot entropy) and a 'register' variable. We have computed such a 'global' using orthogonal contrasts for the 'register' variable. This model revealed a significant effect of log MWS frequency ($= -0.026$, $SE = 0.006$, $t = -4.169$) but no significant interactions between log MWS frequency and register. Since we aimed to test whether our participants can detect and adapt to the changing statistics of multiple input types, we decided to report on four separate models in the study.

[6] To avoid overfitting resulting from multiple substring frequency control variables, we followed the procedure used in Arnon & Snider (2010) and first ran a model with all substring frequency controls and then removed the variables whose standard error was greater than the value of their coefficient in the model. All reported models had low collinearity (all $VIFs < 1.8$).

[7] Standardized beta coefficients indicate how many standard deviations a dependent variable will change, per standard deviation increase in the predictor variable. Pseudo-R2 for generalized mixed-effect models (GLMM) can be categorized into two types: Marginal R^2 represents the variance explained by fixed factors. Conditional R^2 is interpreted as variance explained by both fixed and random factors (i.e. the entire model).

prior research by demonstrating that language users' ability to track the statistics in the input is not limited to the spoken conversational language but it can be observed in written registers/genres. In addition to the MWS frequency effects, the significant main effect of entropy found in the register of academic writing indicated that our participants were able to develop sensitivity to more complex distributional statistics, i.e. they showed faster response latencies with higher slot entropy. The direction of the entropy effect is consistent with the finding of Matthews & Bannard's (2010) study demonstrating that 2-3 years old children were more accurate in repeating MWS with higher slot entropy. Additional support for the facilitatory effect of more complex distributional statistics on the processing of MWS comes from the significant interaction between frequency and entropy indicating that the effect of MWS frequency increased with increasing degrees of MWS entropy.

To our knowledge, this is the first study to show that language users (whether native or non-native speakers) are able to tune to the multiple distributional statistics inherent in register-specific input types within a single language. The findings from this study provide a key contribution to a growing body of research that explore statistical learning through the lens of multilingual acquisition. This research has explored the consequences of accruing statistics in multilanguage input and has typically been conducted using artificial stimulus-sequences (cf., Bulgarelli, Lebkuecher & Weiss, 2018, for a recent overview). Our study has demonstrated how the acquisition of multiple statistics can be investigated on the basis of stimuli constructed from large corpora of au-

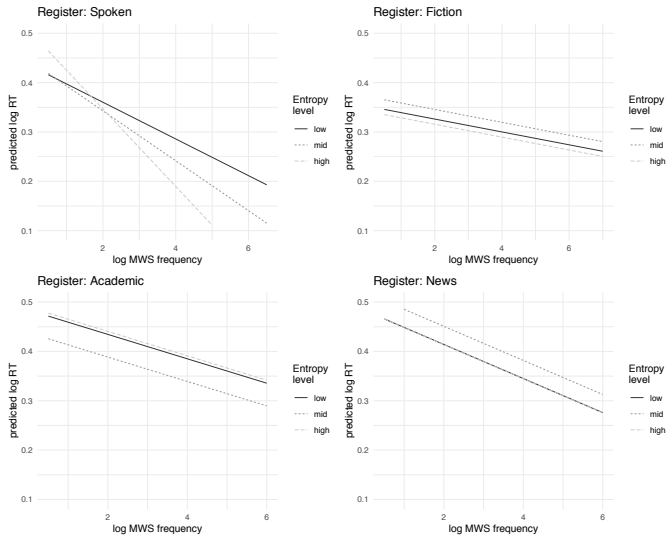

Figure 2: Effects of log MWS frequency by entropy level (high, mid, low) across registers.

thentic language data.

Some of the questions left open by the current study may provide interesting avenues for future work. First, we investigated sensitivity to the register-specific multiple statistics in adult second language learners. The question arises whether similar results could be obtained for adult native speakers. Second, in the light of the lifelong nature of language learning, it is of special importance important to track the developmental progression in response to the changes in the distributional properties of the linguistic input across the lifespan. This involves understanding not only the developmental progression during early stages of child language acquisition (prior to literacy) but also understanding the nature of such progression during later stages of language development, which is strongly driven by the distributional statistics of written input (Seidenberg & MacDonald, 2018). And, third, it would be important to determine whether the ability to tune to multiple statistics is subject to individual variability, and if so, to what extent this variability is linked to other cognitive, affective and environmental factors.

Abstract

Methodological advances have made it possible to generate fMRI predictions for cognitive architectures, such as ACT-R, thus expanding the range of model predictions and making it possible to distinguish between alternative models that produce otherwise identical behavioral patterns. However, for tasks associated with relatively brief response times, fMRI predictions are often not sufficient to compare alternative models. In this paper, we outline a method based on *effective connectivity*, which significantly augments the amount of information that can be extracted from fMRI data to distinguish between models. We show the application of this method in the case of two competing ACT-R models of the Stroop task. Although the models make, predictably, identical behavioral and BOLD time-course predictions, patterns of functional connectivity favor one model over the other. Finally, we show that the same data suggests directions in which both models should be revised.

Keywords: ACT-R, Dynamic Causal Modeling, Cognitive Science

Introduction

One of the traditional problems in the field of cognitive modeling is deciding which of two alternative models provides best explains a phenomenon. Traditionally, the most common approach has been to compare models using null-hypothesis testing procedures. In essence, conditions are identified in which the two models make qualitatively different predictions, and the hypothesized pattern is tested using classical statistical testing techniques. While more sophisticated approaches have been proposed (Pitt, Kim, Navarro, & Myung, 2006), this approach remains the *de facto* standard of the field.

The search for conditions in which two models differ is sometimes strenuous, as the same external behavior can occasionally be obtained through different possible internal processes and model parameters. By shedding light on more direct correlates of cognitive processes, neuroimaging data provides a potential way to distinguish between otherwise behaviorally identical results (Sohn et al., 2004). For this reason, procedures have been devised to derive neuroimaging predictions from computational models, most commonly in the domain of fMRI (Anderson, Fincham, Qin, & Stocco, 2008; Borst, Nijboer, Taatgen, van Rijn, & Anderson, 2015).

While the use of fMRI has greatly expanded upon the possible predictions that can distinguish between the two models, a number of limitations still exist. A main limitation arises from poor temporal resolution of fMRI. The BOLD signal that is recorded in MRI scanners is extremely sluggish, and peaks approximately five seconds after an event. This poses a problem for resolving cognitive processes that occur quickly in time.

Other neuroimaging methods, such as EEG and MEG, offer much greater temporal resolution, but they trade off this advantage with much lower spatial resolution. Furthermore, the oscillatory nature of EEG and MEG signals further complicates the process of deriving predictions from models, as changes in raw signals can occur at different frequency bands (van Vugt, 2014).

Even if these technical issues could be solved, a deeper problem is that the most common methods devised to compare models against neuroimaging data focus on accounting for the common time course of brain activity and model computations. But models, by their very nature, usually make richer predictions about the internal dynamics that lead to either brain activity or behavioral responses. For example, models often make specific assumptions about the *directionality* of an effect, or about how different model components interact with each other. These predictions cannot be tested by simply correlating neuroimaging time series with the order of computations.

In this paper, we describe and demonstrate an alternative and novel method to test models using neuroimaging data. This method is based on patterns of *effective connectivity* between brain regions. "Effective connectivity" is an umbrella term to characterize the functional exchange of information between two brain regions, based on the analysis of their respective time series. Because effective connectivity provides measures of directional communication between two regions, it can be used to examine the internal dynamics of a computational model. Furthermore, because effective connectivity can be estimated from either fMRI or EEG data, it expands the dimensions across which models can be compared with-

out requiring collecting additional data.

In the remainder of this paper, we will outline our method and apply it to a specific, and exquisitely cognitive case, namely, determining which of two prominent computational explanations for the Stroop interference best explains the data.

ACT-R

Although our method could be applied to any computational model, for convenience, it will be demonstrated with two models developed in the Adaptive Control of Thought–Rational (ACT-R) cognitive architecture (Anderson et al., 2004). This choice was made for three reasons. First, ACT-R is the most successful and widespread architecture, having been used in hundreds of publications since its inception, and by far the most popular in the field of cognitive research (Kotseruba & Tsotsos, 2018); Thus, it provides an excellent domain in which to demonstrate the procedure. Second, ACT-R already provides well-tested mappings between architectural components and brain regions with established procedures to predict fMRI activity from model simulations. Therefore, these assumptions can be adopted without the need to provide additional justifications. Finally, the assumptions of ACT-R provide a reasonable mechanism to translate model activity into effective connectivity. As it will be shown, this is based on the functional requirements of the procedural module, which have been examined and discussed in the past.

ACT-R represents knowledge in two formats, *declarative* and *procedural*. Declarative knowledge is made of record-like structures, called *chunks*, which capture semantic memories, perceptual inputs, and motor commands. Procedural knowledge consists of production rules (or simply "productions"), state-action pairs that encode the specific policy to perform a task. In summary, chunks represent information, and productions act upon them.

Chunks are processed by functionally specialized modules. For instance, perceptual modules create new chunks to represent the contents of the outside world, and a memory module maintains chunks in long-term memory. Each module contains one or more buffers, limited-capacity stores that contain at most one chunk. Buffers are the only mechanisms through which chunks and productions interact: Chunks can be inspected, copied, and modified by productions when exposed into buffers.

As noted above, much work has been dedicated to map ACT-R modules to corresponding neural circuits. This work has yielded a number of reliable functional mappings, including the association between anterior cingulate cortex and the goal buffer in the goal module, between the lateral prefrontal cortex and the retrieval buffer of the long-term memory module, between posterior parietal cortex and the imaginal buffer of working memory, between the fusiform gyrus and the visual buffer in the visual module, and between the primary motor cortex and the manual buffer in the motor module (Fincham & Anderson, 2006; Sohn, Albert, Jung, Carter, & Anderson, 2007; Danker, Gunn, & Anderson, 2008; Anderson et al., 2004, 2008). These five modules will be the focus of this paper.

Dynamic Causal Modeling

To estimate effective connectivity, we adopted a framework known as Dynamic Causal Modeling (DCM) (Friston, Harrison, & Penny, 2003). In essence, DCM is procedure to model the time-course of in brain activity in a set of brain regions through a dynamical system of other brain regions and event vectors. Specifically, the time course of activity of a region i is expressed as a bilinear state equation:

$$\dot{\boldsymbol{y}} = \boldsymbol{A}\boldsymbol{y} + \sum_i x_i \boldsymbol{B}(i)\boldsymbol{y} + \boldsymbol{C}\boldsymbol{x} \tag{1}$$

where $\boldsymbol{y}$ are the time series of neuronal activities and $\boldsymbol{x}$ are the time series of the events. $\boldsymbol{A}$ defines intrinsic connectivity between different regions (fixed connectivity), $\boldsymbol{C}$ defines effects by task inputs, and $\boldsymbol{B}$ defines the modular effects that task conditions have on the connectivity between regions (modulation of connectivity).

ACT-R Predictions for Effective Connectivity

Because effective connectivity can be interpreted as directional effects between cortical regions, a direct link can be made between this measure and the nature of ACT-R computations. As discussed above, ACT-R works by firing one production at a time during its cognitive cycle; this production, in turn, changes the state of the system by modifying or copying information from one buffer to the other. For example, in what is perhaps the most common operation in ACT-R models, a production rule extracts values from the slots of chunks placed in either the imaginal or the visual buffer (to extract contextual task information) and places them in the retrieval buffer, so that they function as cues for retrieving relevant information from long-term memory. In fact, production rules are the only way information is exchanged between modules.

Given their role in coordinating module-to-module communication, we made the assumption that patterns of effective connectivity can be derived by the analysis of information transferred carried by out in the sequence of production rules firing.

On the surface, this idea runs against the established identification between production rules (and their associated procedural module) and the activity of the basal ganglia (Anderson et al., 2004; Anderson, 2007). The two interpretations, however, are not incompatible with each other. Anderson et al. (2008) had previously suggested that common functional connectivity patterns in the brain reflect the ubiquity of common operations that exchange information between different buffers; the example production given above is one of those put forward by the authors. It has also been noted before that the function of the basal ganglia is to direct inputs to cortical regions, a role that is both compatible with the procedural module and with the proposed interpretation of effective connectivity (Stocco, Lebiere, & Anderson, 2010). Finally, a recent study that combined ACT-R modeling and Transcranial

Magnetic Stimulation (Rice & Stocco, 2019) has provided evidence that production rules do not only reflect the activity of the basal ganglia but also, more generally, the direct exchange of information between cortical regions. Thus, we believe that the hypothesis that production rules could be used to estimate effective connective is a plausible one.

In this study, the relationship between production rules and effective connectivity was operationalized in the following, simple algorithm. First, an $N \times N$ squared matrix $\boldsymbol{E}$, with N being the number of buffers examined, is generated and initialized to zeros. Then, the target model is run and its trace is segmented into epochs of interest (e.g., all the trials of the same conditions). The structure of each production rule firing within that epoch is then examined. For each variable in the production rule, the *source* buffer S at which the variable is introduced (or, technically, bound to a value) in the left-hand side and the *target* buffer T in which the bound value is placed are recorded. The value of the matrix cell $\boldsymbol{E}_{S,T}$ is then incremented by one. If a variable appears in multiple source buffers $S_1, S_2 \ldots S_N$ or target buffers $T_1, T_2 \ldots T_N$, then all the cells $\boldsymbol{E}_{i \in N, j \in N}$ are updated. When all the productions have been examined, $\boldsymbol{E}$ is taken to represent the predicted effective connectivity for that particular condition.

An Application of the Method: ACT-R Models of the Stroop Task

This method was demonstrated using two competing models of the Stroop task. In the Stroop task, participants are shown a colored character string and asked to report the color of the character string. The character string can either be congruent with the color ("RED" printed in red), incongruent ("BLUE" printed in green), or neutral ("CHAIR" printed in blue). The typical finding is that reaction times in each condition are significantly different from one another, with congruent trials being the fastest, incongruent trials being the slowest, and neutral trials in between (Bugg, McDaniel, Scullin, & Braver, 2011). This difference in reaction times between trial types is referred to as Stroop interference.

The two models were adapted versions of two previously proposed models of the Stroop task, authored by Lovett (2005) and by Altmann and Davidson (2001), respectively. Since both models were published before ACT-R was modified to account for neuroimaging data, they had to be re-implemented in the most recent version of ACT-R (version 7.6). This processes also ensured that the two models interacted with the task using the same sensorimotor mechanisms, i.e. visual objects and responses were given in the same way. From now on, we will refer to these two models as the Altmann-like model and the Lovett-like model.

The re-implemented models maintained the underlying assumptions of their original versions. Specifically, the two models provide different explanations about the nature of Stroop interference. In the Altmann model (Figure 1A), Stroop interference is driven by interference at the lemma layer. When a word is processed, it has direct access to its' lemma, or conceptual representation. Access to the lemma of a color is indirect, requiring an extra retrieval not seen with words. The model assumes that the word dimension of the Stroop stimulus is automatically processed first, therefore activating the lemma attached to the word dimension of the stimulus. As it tries to process the color dimension of the stimulus, the word-lemma is active and can either facilitate or inhibit retrieval of the correct color-lemma. In cases of facilitation, activation from the word-lemma spreads to the coinciding color-lemma, increasing the likelihood of correct retrieval on congruent trials. Oppositely, on incongruent trials, this activation spreads to the incorrect color-lemma, creating increased competition between color-lemmas and introducing ambiguity. For neutral trials, the word-lemma has no corresponding color-lemma, resulting in neither facilitation nor inhibition. The color-lemma is compared to visual cues and re-selected if inconsistent or otherwise used in further processing. A manual response is then retrieved using the color-lemma, and used to press a key on the keyboard.

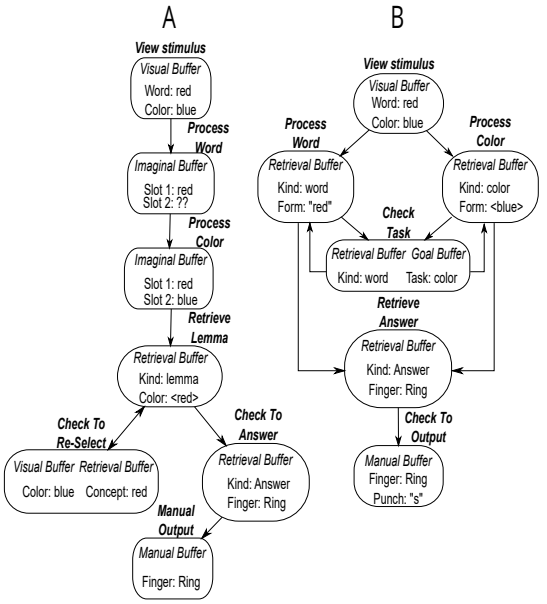

Figure 1: Flow-chart representation of the strategies used by the Altmann model ("A", left) and the Lovett model ("B", right) when processing Stroop trials.

In the Lovett model (Figure 1B), Stroop interference is driven by the competition between alternative *word-association chunks*, linking a word to its' conceptual representation, and *color-association chunks*, linking a color to its' conceptual representation. The idea is similar to lemmas from the Altmann model, but in this case both types of dimension-associated chunks need to be retrieved. The Lovett model accounts for individual differences by supporting various strategies to complete the task. In contrast to the Altmann model, this model allows for processing of either stimulus dimension first, but is highly biased towards the word dimension. From either path, chunks associated with the processed dimension

are retrieved. Processing can maintain with the retrieval of an answer directly, or the task is checked. Answering directly allows for incorrect answers on incongruent trials and fast responses on congruent trials. When the task is checked, the model compares the dimension of the processed chunk to the goal, which for our purpose is to always respond according to the color of the stimulus. If there is a mismatch, processing continues with the alternative stimulus dimension. Now when retrieving the alternative dimension-associated chunk, the previously retrieved chunk has the same effect as in the Altmann model, facilitating retrieval on congruent trials, having no effect on neutral trials, and inhibiting retrieval on incongruent trials. Notably, this does not necessarily happen on every trial, as there are alternate pathways and strategies, and the model will not retrieve the wrong answer at this point. The base-level activations are set in such a way that incongruent chunks slow retrieval of the correct chunk, and congruent chunks facilitate retrieval of the correct chunk. Once the correct dimension-associated chunk is retrieved, a manual answer is retrieved using the matching chunk, and used to press a key on the keyboard.

The two models offer an ideal comparison for several reasons. First, they deal with an experimental paradigm that is representative of research in cognitive neuroscience. Second, although they embody different and opposing views about the nature of Stroop interference, they are equally successful at predicting the canonical response time effects in the Stroop task (Lovett, 2005; Altmann & Davidson, 2001). Most importantly, these two models exemplify the limits of model identification using behavioral and fMRI data. The two models make use of the same five buffers (visual, motor, goal, imaginal, retrieval). When considering the time needed for perceptual and visual processes (identical in the two models), the difference between the two models is concentrated in a 300 ms window in which different interactions between imaginal, goal, and retrieval buffers are posited. Because the BOLD responses recorded in fMRI are much more sluggish and extend for multiple seconds after a point event, it is reasonable to assume that the two models would make almost identical neuroimaging predictions.

To confirm this suspicion, ACT-R's canonical BOLD-response prediction tools were used to simulate the neuroimaging responses for the the various experimental conditions in the two models. Fig 2 illustrate the case for incongruent trials. For the sake of illustration, the amplitudes of the BOLD curves were fit so that they would have the same height[1]. It is immediately apparent that the different inter-module dynamics of the two models are lost in the neuroimaging data; all the BOLD curves for all modules are largely overlapping within and between models.

Crucially, although these different interactions produce indistinguishable BOLD traces, they *do* produce different *effective connectivity* matrices. And, as the next sections will show, these matrices *do* provide evidence in favor of one model over the other.

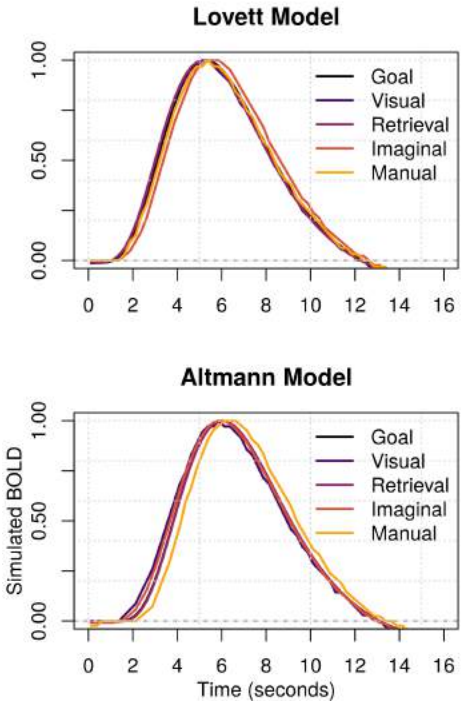

Figure 2: Normalized BOLD-response predictions for incongruent Stroop trials across five different modules in the Lovett (top) and Altmann (bottom) models (See Fig. 1)

Materials and Methods

Experimental Dataset

In this analysis, we used fMRI data publicly available from an open repository[2]. The original data was collected at Carnegie Mellon University and published by Verstynen (2014).

Participants

The dataset contained data from $N = 30$ participants (10 female), aged 21–45 (mean 31). The recruitment procedures can be found in the original publication (Verstynen, 2014).

Experimental Task

Participants performed a manual-response version of the Stroop task (Stroop, 1935), during which the subjects were asked to indicate the color of a written word presented in the center of the screen. Stimuli could be congruent ("RED" printed in red), incongruent ("RED" printed in green), or neutral ("CHAIR" printed in red). Participants responded by indicating the colors red, green, and blue using the right index, middle, and ring fingers, respectively. Each session consisted

[1]The amplitude of the BOLD response is a free parameter that can be separately fit for every module; thus, our procedure does not lose generality

[2]The data is available on OpenNeuro at the following URL: https://openneuro.org/datasets/ds000164/versions/00001

of 120 trials (42 congruent, 42 neutral, 36 incongruent) in randomized order.

Image Acquisition and Preprocessing

As described in Verstynen (2014), the original raw data was acquired using a Siemens Verio 3T system in the Scientific Imaging and Brain Research (SIBR) Center at Carnegie Mellon University with a 32-channel head coil. Functional images were collected using gradient echoplanar pulse sequence with TR = 1,500 ms, TE = 20 ms, and a 90 flip angle. Each volume acquisition consisted of 30 axial slices, each of which was 4 mm thick with 0-mm gap and an in-plane resolution of 3.2 $\times$ 3.2 mm. A T1-weighted structural image was also acquired for each participant in the same space as the functional images, but consisting of 176 1-mm slice with with an in-plane resolution of 1 $\times$ 1 mm.

For the purpose of our analysis, the original raw data was processed in SPM12 (Wellcome Department of Imaging Neuroscience, `www.fil.ion.ucl.ac.uk/spm`) following the exactly same preprocessing pipeline as the one indicated in the original publication. Images were corrected for differences in slice acquisition time, spatially realigned to the first image in the series, normalized to the Montreal Neurological Institute (MNI) ICBM 152 template, resampled to 2 $\times$ 2 $\times$ 2 mm voxels, and finally smoothed with a 8 $\times$ 8 $\times$ 8-mm full-width-at-half-maximum Gaussian kernel to decrease spatial noise and to accommodate individual differences in anatomy.

Regions of Interest

DCM analysis is performed on fMRI time-series extracted from specific ROIs. In our case, the ROIs correspond to the specific brain regions that have been previously identified as corresponding to ACT-R buffers. The Talairach coordinates used for each module in the brain followed the convention used by Anderson et al. (2008). The algorithms described in Lacadie, Fulbright, Rajeevan, Constable, and Papademetris (2008) were used to convert Talairach coordinates to Montreal Neurological Imaging Institute (MNI) coordinates. The ROI mask files were created through FSL (Woolrich et al., 2009) of size 16 mm (125 voxels in total) then used to extract fMRI time series from each voxel in each ROI. Principal Component Analysis was then applied on all the extracted time series to identify the time series that best characterized each ROI. The largest principle component was used to project the original data to the new space with more than 75% of the variance explained in each module.

Dynamic Causal Modeling Analysis

Because DCM is a model-based technique, estimates of connectivity can only derived from parameters corresponding to the specified connectivity between ROIs. To gather complete estimates of connectivity, an unconstrained, fully connected model was generated, in which any ROI was bidirectionally connected to all the others. Furthermore, to identify different patterns of connectivity between conditions, both matrices B and C were used. Specifically, matrix C was used to specify the onset and offset of stimuli, and drive the activity of the "visual" ROI, thus initiating trial-specific activity in the network. In addition, we used the modulatory matrix B to specify modulatory effects of condition-specific trials (congruent, neutral, and incongruent) and the ROI connectivity parameters $\boldsymbol{A}$. Thus, the effective connectivity matrix E_k specific to task condition k can be expressed as the element-wise product of $\boldsymbol{A}$ and the modulatory effects of condition k $\boldsymbol{B}_k$, namely:

$$\boldsymbol{E}_k = \boldsymbol{A} + \boldsymbol{A} \odot \boldsymbol{B}_k \tag{2}$$

As it is common in DCM, all the parameters were identified using an Expectation-Maximization procedure.

Results

Figure 3 illustrates the results of the effective connectivity analysis of the fMRI data and the corresponding model predictions. In the figure, columns correspond to the three experimental conditions of the Stroop task (congruent, incongruent, and neutral trials), while the rows correspond to either the predictions of the models (Lovett model, top row; Altmann model, middle row) or the empirical data (bottom row). The reported values of effective connectivity were generated by performing a Bayesian parameter averaging procedure (Kasess et al., 2010) over the individual connectivity matrices generated for each individual participant. Because, in DCM, self-connectivity values need to be set to negative values to ensure the stability of the dynamic state equation (1), the corresponding values were ignored in the analysis and set to zero in Figure 3. Note that the reason we chose Frobenius norm instead of correlation as the metric is that we are interested in the **absolute** measurement of the effective connectivity, not the relative scale between modules. For example, two connectivity vectors of $[1,1,1,2,1]$ and $[-2,-2,-2,-1,-2]$ would have perfect correlation ($r = 1$), yet they represent opposite connectivity effects (excitatory vs. inhibitory) in all modules. The scale of the values between real fMRI data and ACT-R models may be different, but since all ACT-R models are on the same scale, the differences are still comparable across models.

In general, the connectivity patterns predicted by the two models are much less rich and interconnected than what was measured in the data (Figure 3). This is not unexpected, given the high level of neural abstraction that characterizes ACT-R models (Figure 1). Critically, and as expected, the two models do make different predictions in terms of effective connectivity. To compare the degree of similarity between each model's predictions and the data, we calculated the Frobenius distance of the difference between the predicted ($\boldsymbol{P}$) and the empirical data matrix ($\boldsymbol{D}$) for each condition k, i.e. $||\boldsymbol{P}_k - \boldsymbol{D}_k||_F$. This measure can be interpreted as a dissimilarity metric; the smaller the difference between two matrices, the smaller the norm. The results of these comparisons are shown in Figure 4. As shown, the Lovett model yields consistently smaller norm values, and is therefore more similar to the data, across all three conditions.

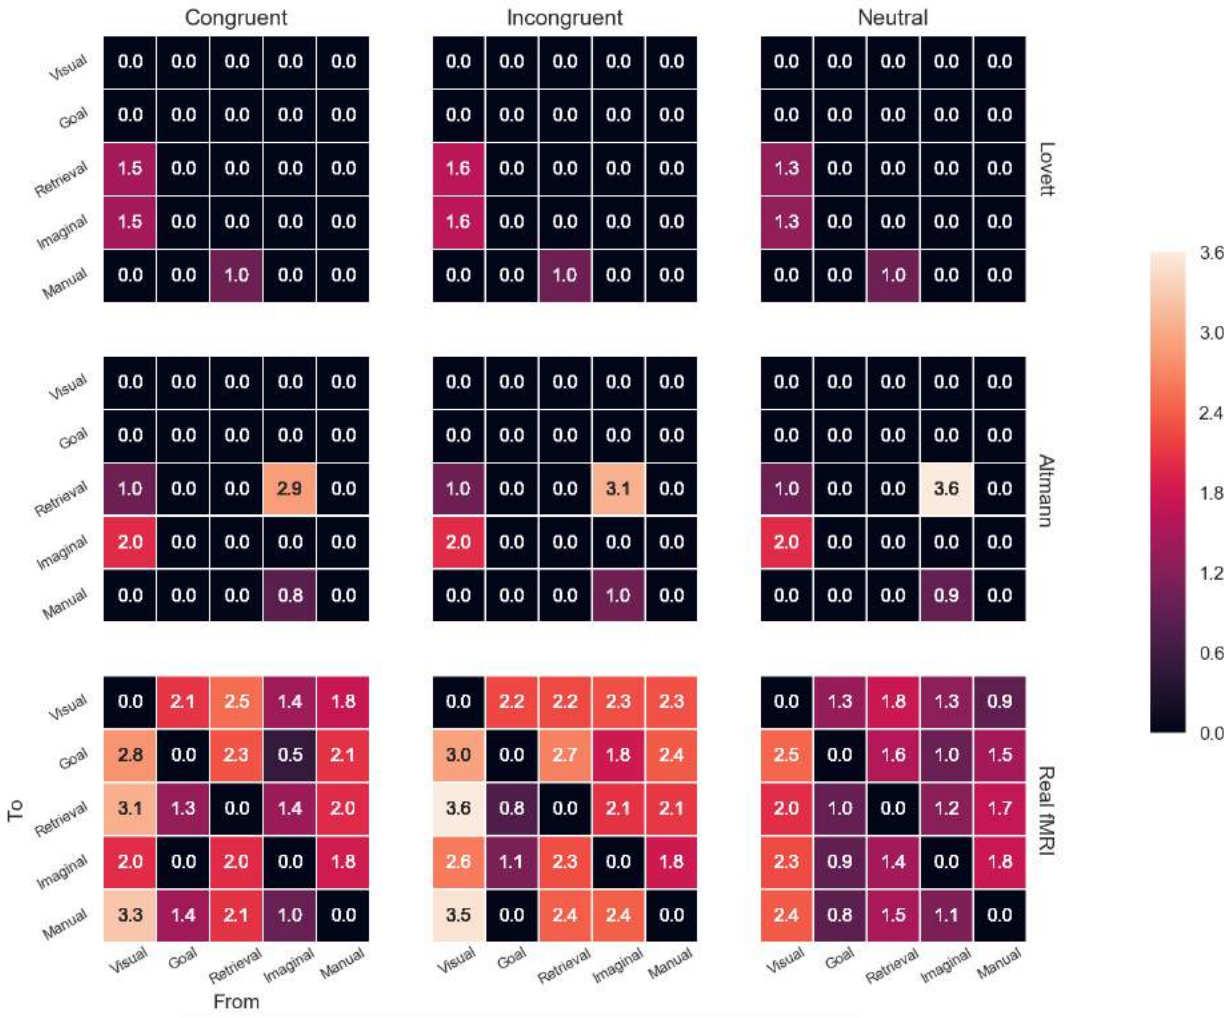

Figure 3: Effective connectivity analysis of the fMRI data and corresponding model predictions (rows), divided by experimental condition (columns).

Discussion

This paper has provided a proof of concept of how analysis of effective connectivity can be used to supplement traditional, GLM-based analysis of neuroimaging data in distinguishing between alternative models. While effective connectivity analysis has been used in cognitive neuroscience for more than a decade, this is the first time, to the best of our knowledge, that this method is used in conjunction with a cognitive modeling approach, and with cognitive architectures in particular. In outlining our method, we choose ACT-R as a modeling paradigm and DCM as a technique to estimate effective connectivity. Neither of these choices, however, are absolute requirements. Connectivity estimates can be gathered from many types of models; the procedure described in this paper certainly applies to other production system-based architecture, like Soar and EPIC, as well. Similarly, although connectivity was estimated with DCM, other methods could be possibly used. For example, Granger Causality. Thus, although we made specific implementation choices, our methods could be instatiated in multiple ways.

Despite encouraging results, a number of limitations need to be acknowledged. First, our method for deriving effective connectivity predictions from ACT-R models is still preliminary. While we believe that it is reasonable, other procedures could be envisioned. For example, operations such as buffer status checks and buffer harvesting could be included in generating our matrices. It is plausible that richer prediction schemes could lead to more realistic connectivity matrices that the ones in Figure 3. It is also plausible that better similarity metrics than Frobenius distance could be used to compare predictions.

These limitations notwithstanding, we see our method as having potential for future modeling research. In particular, we believe that the connectivity matrices obtained from the data can be used to inform model development as well as for model comparison. It is apparent that neither the Lovett nor the Altmann model provide good fits to the data. Because the differences correspond to variables in production rules, the

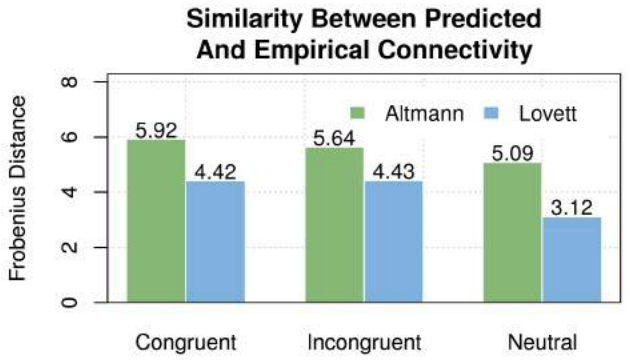

Figure 4: Similarity (Frobenius distance) bewteen predicted and empirical effective connectivity for the Altmann and the Lovett models.

comparison suggests which other production rules or variable bindings could be taking place in the model. In theory, and provided reasonable task constraints, an analysis of the effective connectivity matrices might be used to automatically generate production rules that would match the data. We see this an exciting opportunity for future research.

Abstract

What mechanisms underlie people's ability to use cross-situational statistics to learn the meanings of words? Here we present a large-scale evaluation of two major models of cross-situational learning: associative (Kachergis, Yu, & Shiffrin, 2012a) and hypothesis testing (Trueswell, Medina, Hafri, & Gleitman, 2013). We fit each model individually to over 1500 participants across seven experiments with a wide range of conditions. We find that the associative model better captures the full range of individual differences and conditions when learning is cross-situational, although the hypothesis testing approach outperforms it when there is no referential ambiguity during training.

Keywords: Cross-situational word learning; language acquisition; Zipfian distributions

Introduction

The ability to acquire language is not only a fundamental part of what makes us human, but a mystery: how do we accomplish it given the complexity of the learning task? Even in an apparently simple task like word learning, many real-world contexts involve multiple possible referents for any one label (Pinker, 1984). How can a learner figure out which referent corresponds to which label? One suggestion is that people can leverage the statistics that come from observing multiple ambiguous presentations of words and objects. This sort of cross-situational word learning has been demonstrated in both children and adults (Yu & Smith, 2007; L. Smith & Yu, 2008). However, there is still considerable debate about what mechanisms underlie cross-situational word learning and what representations are learned (Kachergis & Yu, 2018).

One major theory of cross-situational learning, known as the associative framework, proposes that people track detailed word-object co-occurrence statistics across many presentations (Vouloumanos, 2008; Yu & Smith, 2007). By contrast, the hypothesis testing framework suggests that people track at most one word-object pair theory for each word (or object) and update these hypotheses during learning (Medina, Snedeker, Trueswell, & Gleitman, 2011). A number of computational models have been developed based on both frameworks but no consensus has emerged about which account better describes people's learning. We argue that this has occurred, at least in part, because of a focus on modeling aggregate rather than individual data, and because existing experiments have not varied the range and variety of learning conditions sufficiently to differentiate the models.

Here we present and analyze data from seven different experiments with over 1500 participants that vary on a number of factors including vocabulary size, level of ambiguity, length of training, distributional structure, and task. We fit each person's data to both the associative and hypothesis testing models described in the following sections. Our results suggest that associative accounts provide the best fit in almost all cases, unless there is no ambiguity during learning and the learning is thus no longer strictly cross-situational.

Associative framework

Associative models propose that people learn word meanings by tracking the frequency with which words and objects co-occur across multiple ambiguous presentations. The representation is a large word-object matrix in which each cell contains the associative strength between one word and one object (Vouloumanos, 2008; Yu & Smith, 2007). This basic framework has been applied widely, and the model we implement here is one of the most widely used (Kachergis et al., 2012a). It provides a compelling account of human behavior across studies that vary the number of late repetitions (Kachergis et al., 2012a) and if learning is passive or active (Kachergis, Yu, & Shiffrin, 2012b; Kachergis & Yu, 2018).

Formally, the goal of the model is to update the association strength between a word (w) and object (o) within an association matrix ($M_{w,o}$). It incorporates several psychologically-motivated parameters that specify the total amount of updating on each trial (χ), memory fidelity (α), and the bias towards updating the association strength of uncertain versus already familiar words and objects (λ) with uncertainly of an item quantified as the entropy across all association strengths for that item.

Hypothesis testing framework

As an alternative to the memory-intensive associative framework, Medina et al. (2011) outlined a more minimalistic approach based on storing only a single hypothesis for each word. The hypothesis represents a guess about the referent of the word, and is replaced if it is inconsistent with new training trials or fails to be recalled when the word is present.

Table 1: **Overview of experimental structure**. This table describes all of the experiments whose data we fit. *Vocabulary* indicates the number of unique word-object pairs to be learned (which also corresponds to the number of objects present during the test phase). *Ambiguity* indicates the number of objects present on each training screen. *Guessing* indicates whether learning was passive (just watching) or active (if participants were required to submit a guess after each word during training). *Presentations* indicates the total number of training trials. *Distribution* indicates the frequency distribution of the words and objects across the experiment. *Length Relationship* indicates the relationship between the length of words and their frequency during training, with more frequent words being shorter in the *Correlated condition*. *N* indicates number of complete participants. *Source* indicates the source of the data set: H&P (2018) denotes Hendrickson and Perfors (2018).

We evaluate the Propose-but-Verify hypothesis testing model (Trueswell et al., 2013), a popular extension of the original Medina et al. (2011) formulation, which captures children's word learning behavior well (Woodard, Gleitman, & Trueswell, 2016; Aravind et al., 2018). The model involves a two-stage process. Upon initially being exposed to a word, the model chooses an object from the as-yet-unmapped objects in that trial and maps it to that word to form a word-object hypothesis. The initial probability of later recalling that mapping is denoted by a free parameter $\alpha_{initial}$. On each subsequent exposure to the word, if the model recalls the hypothesis and the corresponding object is present, the probability is updated to a different memory strength indicated by another free parameter, $\alpha_{confirmed}$. If the hypothesis fails to be recalled or the corresponding object is not present, a new hypothesis is established with an unmapped object.

Model comparisons

Many previous papers have compared these two modeling approaches in terms of how well they fit experimental data (e.g., K. Smith, Smith, & Blythe, 2009; Kachergis et al., 2012b; Rasilo & Räsänen, 2015; Kachergis & Yu, 2018; Aussems & Vogt, 2018; Stevens, Gleitman, Trueswell, & Yang, 2017). Despite this effort, no consensus has emerged. One reason may be the focus on modeling aggregate performance using one optimal set of parameter values per model for all learners, which ignores individual differences. This approach may favor highly stochastic models that can fit different people's responses with a single parameter, rather than models that can fit the behavior of more people using individual parameter values. Moreover, comparison studies commonly fit these models to experiments that involve relatively few learners, and have a small number of conditions which do not capture the variation across conditions in the literature. Finally, such studies tend to use uniform word frequencies that do not reflect the highly-skewed distribution of words in natural language, which limits the generalizability to real-world word learning (Hendrickson & Perfors, 2018).

In this paper we address these issues by evaluating a hypothesis testing model and an associative learning model against experimental data involving over 1500 participants and spanning the broad range of conditions shown in Table 1. We varied the distribution of the words and objects, the size of the vocabulary to be learned, whether the task was passive or active, the number of presentations during training, the level of ambiguity during learning, and the relationship between the length of the word and word frequency. We fit parameter values for each learner by optimizing the log-likelihood of model response probability for each of the word-object test trials. When comparing models, we penalize for additional parameters by converting the log likelihood to AIC values (Akaike, 1974).

Experiments

The empirical data that we use for model evaluation includes data from the eight conditions from Hendrickson and Perfors (2018) in addition to eight additional new conditions. We describe each in turn.

Hendrickson and Perfors (2018)

The goal of the work in Hendrickson and Perfors (2018) was to explore cross-situational learning when the words followed either a ZIPFIAN or a UNIFORM distribution. The first experiment involved presenting participants with a small vocabulary of words in one of the two distributions. The second increased the vocabulary and ambiguity level, while adding a condition in which the length of the word was negatively correlated with word frequency (shorter words were more frequent). The third evaluated the effect of removing ambiguity during training.

Procedure. Each experiment consisted of a training phase and a test phase, though Experiment 1 repeated these phases multiple times. During training, participants viewed either 3, 4, or 1 objects on the screen at once while they heard the words for each object presented one at a time in random order. In experiments with ambiguity during training, participants were asked to guess which object each word matched. At test, people were shown all of the items at once and asked to select the matching object for each word. They were not given feedback during training or test.

Conditions. In the UNIFORM conditions the words and objects all occurred with the same frequency, while in the ZIPFIAN conditions a few words and objects occurred very frequently and many words occurred very infrequently or only once across training. The pairing of words and objects and trial order was randomized across participants.

Materials. Words varied in length from one to three syllables and were designed to sound English-like as well as be maximally distinct from each other. They were generated by the AT&T Natural Voices Text-to-Speech tool (Crystal voice). The objects were selected from the NOUNS image corpus (Horst & Hout, 2015) and each image was 150x150 pixels displayed against a white background. Hendrickson and Perfors (2018) contains the full set of stimuli.

Participants. Their 597 participants were recruited from Amazon Mechanical Turk (AMT). Our four additional experiments (with 974 participants) were also run on AMT, paying US$3.25 for the $\sim$20 minute task.

Experiment 1

Experiment 1 provides a near replication of Experiment 2 of Hendrickson and Perfors (2018), a design aimed to approximate learning conditions when the meaning of words is ambiguous. There were two minor differences. First, their experiment included four single-presentation items in order to check for participant cheating; we omitted those in order to ensure that the UNIFORM distribution contained no low-frequency items. As a result, we had 240 rather than 244 total presentations and 28 rather than 32 test items. Second, we did not include their second ZIPFIAN condition, in which the length of the word and word frequency was correlated. 337 individuals provided complete data, half in the UNIFORM condition and half in the ZIPFIAN condition.

Experiment 2

A number of simulation studies have suggested that increasing the number of items to be learned should be particularly challenging for learners in Zipfian environments (Vogt, 2012; Reisenauer, Smith, & Blythe, 2013). In Experiment 2 we therefore replicated the design of Experiment 1 but with 40 unique word-object pairs instead of 28. We presented each word slightly less frequently in order to match the total number of word-object presentations in Experiment 1. In the test phase 40 rather than 28 objects were displayed, resulting in a more difficult test. Complete data was collected from 161 individuals, with roughly half assigned randomly to the UNIFORM and ZIPFIAN conditions.

Experiment 3

In all of the experiments so far, participants have been required to respond by selecting a best-guess object after each word was presented during training. However, recent work has suggested that forcing people to guess may influence the representation that they learn (Aussems & Vogt, 2018). We address this possibility in Experiment 3, which is identical to Experiment 1 but removes the obligation to guess during training. Instead of waiting for a guess after each word, the next word is played automatically after 2000 ms.

The other difference from Experiment 1 is that the length of each word was correlated with its frequency in the ZIPFIAN condition, as is found in natural language and Hendrickson and Perfors (2018). Complete data was collected from 166 individuals, with roughly half assigned randomly to the UNIFORM and ZIPFIAN conditions.

Experiment 4

Experiment 4 provides a near replication of Experiment 3 of Hendrickson and Perfors (2018), whose goal was to approximate learning when the meaning of words was unambiguous. The only differences, as in Experiment 1, were that we removed the four "cheating check" items and thus had 240 presentations and 28 test items, and we had only one ZIPFIAN condition in which word length was correlated with frequency. Additionally, since there was no ambiguity during training, participants were not required to guess. Instead, the timing of item presentation matched Experiment 3. Complete data was collected from 310 individuals, with roughly half assigned to the UNIFORM and ZIPFIAN conditions.

Model Fitting

Both models were fit to the individual data of each person independently by minimizing the negative log likelihood across all responses in the test phase. Every person participated in exactly one condition and thus parameters were not constrained across conditions in any way. For the associative model, the likelihood of a correct answer was determined for each word by dividing the associative mass on the correct object by the total associative mass across all objects. For

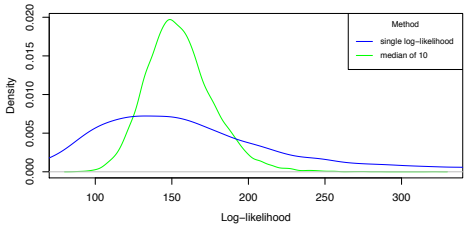

Figure 1: **Distribution of log-likelihood vs. median log-likelihood values for the hypothesis testing model.** The density plot shows the different distributions of 10,000 simulations produced by the hypothesis testing model for one individual participant with a constant set of parameters when using either a single log-likelihood value or the median of 10 such values. Using the median of 10 values results in a substantial increase in stability.

the hypothesis testing model, the likelihood was given by the stored probability value for a correct pairing, smoothing zero probability values to 0.0001.

Interestingly, the models differed widely from each other in the variability of the responses probabilities predicted at test. Given a fixed training trial order and a single set of parameter values, the associative model has no stochastic aspect to how the representation is formed. Therefore, the likelihood of a set of responses given a set of parameters is stable and parameter estimation was straightforward.[1]

In contrast, the hypothesis testing model is decidedly random about which words are paired with objects when forming hypotheses. This results in the production of markedly different representations and thus likelihoods from one simulation to the next, even when the training trials and parameter values are constant across runs. In order to address this issue, we performed ten simulations for each set of parameters during the optimization process and used the median log likelihood across the simulations. This required the use of a particle swarm optimization algorithm to determine the optimal parameters, which is more robust to less smooth optimization problems.[2] It was notable that across the range of 10 likelihood values for a set of parameters, the best value was markedly better than the median likelihood value, suggesting that optimization routines that rely on the best likelihood given a set of parameters can overestimate the expected fit to data of a set of parameters, especially for the hypothesis testing model. In addition, the median likelihood from 10 simulations of the hypothesis testing model produces considerably more stable estimates relative to a single simulation (Figure 1).

The number of parameters differ between the two models, with the associative model containing three (α, χ and λ) and the hypothesis testing model containing only two ($\alpha_{initial}$ and $\alpha_{confirmed}$). We therefore penalized for model complexity by converting the log likelihood scores to AIC values; lower AIC scores indicate a better fit to the data after taking the number of free parameters into account.

[1]The optimal parameter values were derived using the default settings for the optimize function in the SciPy package in Python 3.

[2]Fitting was done using the PSO package in Python 3 using a swarm size of 1,000 and a maximum of 50 iterations.

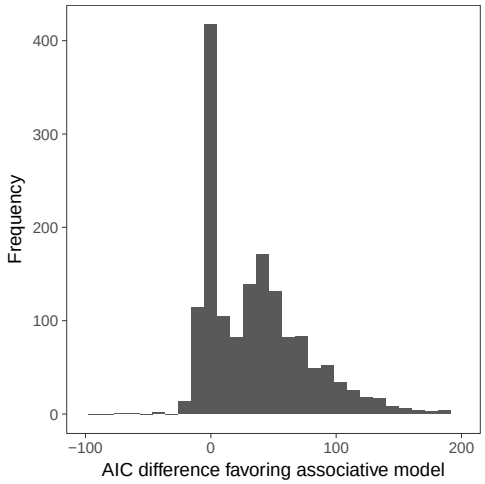

Figure 2: **Overall model performance.** The histogram shows the difference between the AIC score for the hypothesis testing model and the AIC score for the associative model for each person across all datasets. Positive scores (which made up 74% of the data) indicate that the associative model had a lower AIC score than the hypothesis testing model and thus accounted for the data better.

Results

Figure 2 shows the overall performance of the two models across all individuals. The AIC scores of the associative model are lower than the hypothesis testing model for 74% of participants. Since a lower AIC indicates better fit, this suggests that for most people the associative model provides a better account of their performance. Next, we turn to exploring exactly when and where each model does best.

Ambiguity. As the top row of Figure 3 illustrates, the performance of the two models strongly depends on the degree of ambiguity during training. In conditions with any degree of ambiguity during training (by presenting three or four items on each training screen, rather than individually), the associative model is a better fit in virtually all cases (97% of participants). However, the opposite is true when there is no ambiguity: when only one item was shown at a time, the hypothesis testing model was favored for 68% of participants.

Word frequency. The near unanimous advantage for the associative model in ambiguous learning conditions suggests that the only differences in model performance due to word frequency might occur in the conditions without ambiguity. In the conditions with only one item per screen (top left panel of Figure 3), the hypothesis testing model (red points) is highly preferred (96% of the time) when the distribution is UNIFORM. When the word frequency distribution is ZIPFIAN (blue points), the two models are roughly even (52% of participants are better fit by the associative model).

Vocabulary size. The impact of vocabulary size on model performance differs based on the ambiguity of word meaning during training (bottom row, left and center panels in Figure 3). When word meaning is ambiguous during training, the hypothesis testing model does particularly poorly as the vocabulary size increases. (Note that we do not show the 3-item

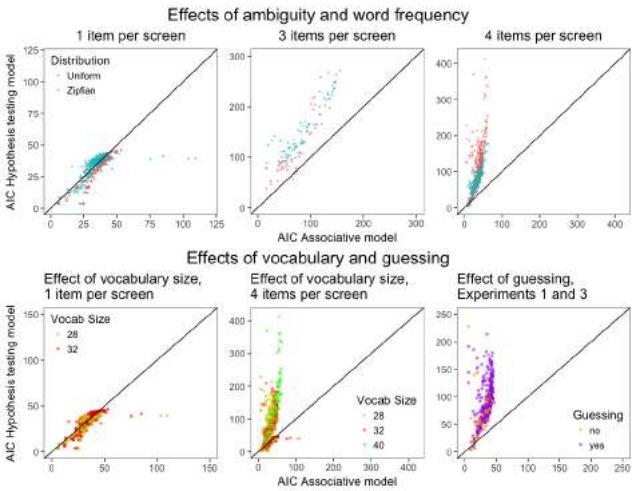

Figure 3: **Model comparisons for different effects.** All panels show the AIC scores for the hypothesis testing model (y axis) plotted against the AIC scores of the associative model (x axis). Values above the identity line indicate that the AIC score of the associative model is better (lower). *Top:* A comparison of the effects of ambiguity and word frequency. Each red dot shows a participant in the UNIFORM condition; blue dots represent people from the ZIPFIAN condition. Each panel shows a different level of ambiguity during training (1, 3, or 4 items on screen at once). The associative model does much better whenever there is ambiguity (and regardless of distribution), while the hypothesis testing model does slightly better when there is only one item on screen during learning. *Bottom left and center:* Evaluation of the effects of vocabulary size, broken down by degree of ambiguity. When training is unambiguous, there is no consistent effect of vocabulary size on performance; when it is ambiguous, the hypothesis training model appears to perform especially poorly when there are more words to be learned. *Bottom right:* Regardless of whether participants were passive or active learners, the AIC favored the associative model.

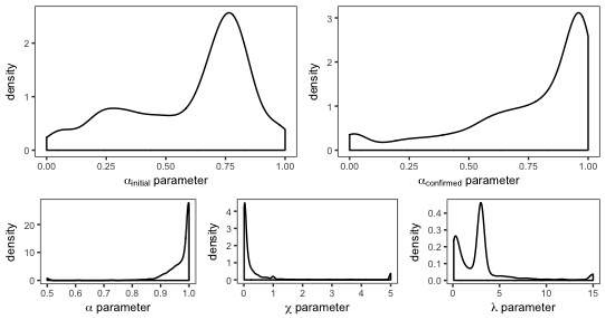

Figure 4: **Distribution of best fitting parameters across all participants**. *Top row*: Hypothesis testing model parameters $\alpha_{initial}$ (initial probability of recalling a mapping) and $\alpha_{confirmed}$ (later probability of recalling a mapping). *Bottom row*: Associative model parameters α (memory decay rate), χ (amount of updating for each trial), and λ (bias towards updating uncertain words and objects).

ambiguous case because vocabulary size in those conditions was constant at 12 items). Within the unambiguous training conditions there does not appear to be any consistent effect of vocabulary size on model performance.

Guessing. In order to evaluate the prediction that forcing participants to guess during training can bias participants to adopt hypothesis testing representations (Aussems & Vogt, 2018), the bottom right panel of Figure 3 shows the performance of both models as a function of whether participants had to guess or not. Here we include only data from Experiments 1 and 3, similar experiments that differ in whether guessing occurs. Both have a vocabulary size of 28 and ambiguous training (although the relationship between word length and word frequency differs between the two ZIPFIAN conditions). Across all conditions the associative model consistently outperforms the hypothesis testing model.

Fitted Parameters

In addition to being useful for model comparison, the best-fitting parameters across all participants (shown in Figure 4) provide us with several deeper insights. First, the distribution of parameter values can tell us something about the distribution of individual differences across the population. For example, the distributions of α and χ for the associative model are highly skewed and show ceiling and floor effects, which suggest these parameters might not capture meaningful variation across individuals. By contrast, the distributions of the memory strength parameters for the hypothesis testing model both display a unimodal peak around relatively high values with a long tail of low values for some participants. This suggests a high level of population variance or reflects the inherent stochasticity of the hypothesis testing model.

It is also useful to compare our best-fit parameters to the reported values from other studies, which generally fit aggregate data or use other fitting metrics. The distribution of our fitted values for the two hypothesis testing model parameters are generally higher than those reported by Trueswell et al. (2013) in their two experiments: $\alpha_{initial}$ values of 0.26 and 0.60, and $\alpha_{confirmed}$ values of 0.71 and 0.81. On average, our best-fit parameter values were higher and show less difference between the initial and confirmed memory strength. It remains an open question if this difference is due to modeling individual and aggregate performance or a shift in strategy due to experimental conditions.

In contrast to the hypothesis testing model, the values reported for the associative model by Kachergis et al. (2012b) are largely consistent with our results. Their optimized values, fit to aggregate data, are $\alpha = 0.97$, $\chi = 0.05$, and $\lambda = 1.74$; values quite similar to the peaks of our distributions.

Finally, some model parameters strongly depend on the experimental condition. For example, the multimodal distribution of λ values (bottom right panel of Figure 4) suggests a mixture of different strategies across participants. We investigate this in Figure 5, which separates the best-fit λ values according to the ambiguity during training. It is evident that as learning conditions are more ambiguous, the λ value decreases. Since λ affects the weight assigned to novel words relative to familiar words, one interpretation of this is that the level of ambiguity during training has a strong impact on the extent to which novel items are emphasized during learning.

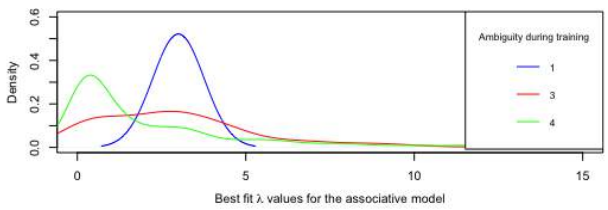

Figure 5: **Distribution of λ by ambiguity.** The best-fit λ values for the associative model (x axis) are plotted as a function of the level of ambiguity during training. The distribution of λ when there is no ambiguity (blue) has higher average values. As ambiguity increases (red, then green) the estimated λ values get smaller.

Discussion

In this work we investigated which of two computational models of cross-situational word learning offers a better account of word learning by individual participants across a wide range of conditions. For most people, the associative model (Kachergis et al., 2012a) outperforms the hypothesis testing model (Trueswell et al., 2013).

The advantage for the associative model is most pronounced in conditions in which the meaning of words is ambiguous during training, where it provides a better account for nearly all people. However, in conditions without ambiguity of word meaning, the hypothesis testing model outperformed the associative model for over 60% of participants. This advantage for the hypothesis testing model in unambiguous training conditions occurred for nearly every participant who experienced a uniform frequency distribution of words, but for participants in conditions with a Zipfian word frequency distribution the associative and hypothesis testing models provide the best account equally often.

The impact of other aspects of the learning environment on the relative performance of the two models was less striking. The total number of unique words present did not seem to influence which model was preferred, though there was some suggestion that the participants whose AIC was worst for the hypothesis testing model were in the conditions with the largest vocabulary size. Finally, manipulating if participants were required to guess during training had no effect on model preference as all relevant conditions were ambiguous during training and thus nearly all participants were best fit by the associative model.

Why the hypothesis testing model, despite multiple studies showing support for the model, performed consistently worse in the ambiguous learning contexts that require cross-situational learning is perhaps the biggest open question raised by these results. One possibility is that the hypothesis testing model, though designed to account for individual learning behavior, is not sufficiently flexible to account for the variation across participants. Restricting the memory strength to two possible values might provide a good account of aggregate data but be too rigid for matching individual behavior.

Another possible explanation for the worse performance of the hypothesis testing model is that even if people do form hypotheses about word-object pairs, they are also incorporating some co-occurrence information to shape their representations. This class of hybrid learning mechanisms, which incorporate both hypothesis testing and associative learning mechanisms (Yurovsky & Frank, 2015), provide a suggestion of additional types of models that might better capture the range of learning behavior in the ambiguous conditions. Similarly, Pursuit (Stevens et al., 2017), a recent variant of the Propose-but-Verify model that retains disconfirmed meanings and counts of referential success, might also improve on the performance of the earlier hypothesis testing model by finding a balance between testing hypotheses and gathering some co-occurrence information.

A final explanation of this effect may be due to specific aspects of the model fitting in this study. These choices include how the hypothesis testing model was extended to produce probability distributions across responses, the 10-fold simulation of parameter values to compute the median log likelihood, or the choice of AIC for model comparison instead of measures that have higher penalties for model complexity (e.g. BIC) or flexibility (Navarro, Pitt, & Myung, 2004).

Despite the clear advantage across many conditions for one model in this comparison, further work is clearly needed to fully understand the learning mechanisms and representations that underlie word learning. These include evaluating alternative models (e.g. Yu & Smith, 2012; Yurovsky & Frank, 2015; Stevens et al., 2017), expanding the range of evaluation techniques, and constraining models with additional data (e.g. Kachergis & Yu, 2018) or conditions (e.g. Hendrickson & Perfors, 2018).

Abstract

Capturing the effects of fatigue and, more generally, the effects of physical and mental states on human performance has been a topic of research for many years. Recent models, especially those developed in a cognitive architecture, have shown great promise in capturing these effects by providing insight into the specific cognitive and other components involved in task performance (like perception and motor movement). In particular, separate models have been developed to account for both time-of-day and time-on-task effects related to fatigue. In this paper, we present a novel unified model, developed in the ACT-R cognitive architecture, that captures both time-of-day and time-on-task effects with a single set of mechanisms and parameters. We demonstrate how this unified model accounts for quantitative and qualitative aspects of fatigued performance from two experiments, one focused on time-on-task effects under conditions of moderate fatigue, the other focusing on time-of-day effects under conditions of severe fatigue in a study of long-term (88-hour) sleep deprivation.

Keywords: Fatigue; sleep deprivation; cognitive architectures

Introduction

One of the most significant physiological states that affects human cognition is fatigue. Decades of research have investigated the effects of fatigue, sleep deprivation, and time-on-task in a number of important areas, including industrial disasters (e.g. Mitler et al.,1988), transportation accidents (e.g. Lauber & Kayten, 1988; Dinges, 1995), and motor vehicle crashes (e.g. Horne & Reyner, 1999; Pack et al., 1995). These studies have explored in depth the question of how fatigue modulates cognition and performance, and how we might quantify the effects of fatigue using mathematical or computational models and formalisms.

Of the many aspects of cognitive fatigue, there are two main factors that affect sustained attention and task performance: (1) sleep-related factors which are a function of sleep history and the time of the day when the task is being performed (circadian rhythm); and (2) task-related factors which are a function of the type of the task and how long the person has been doing the task, or *time-on-task* (Figure 1). Fatigue can also vary widely in its level of intensity: mild to moderate time-of-day or time-on-task effects may affect performance significantly (e.g., Pattyn et al, 2008; Bakan, 1955; Mackworth, 1948; Parasuraman, 1979), but severe fatigue that occur with long-term sleep deprivation can have even more drastic impacts on performance (e.g., Doran, Van Dongen, Dinges, 2001; Dorrian, Rogers, & Dinges, 2005).

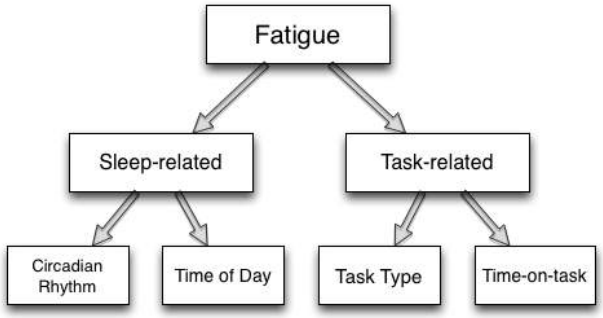

Figure 1: Main factors contributing to fatigue in sustained-attention tasks.

Mathematical models of fatigue come in various forms, and can provide very good insight into the fluctuations in overall performance, accounting for moderate time-of-day and time-on-task effects (e.g. Fisk & Schneider, 1981; Giambra & Quilter, 1987; Mackworth, 1964) as well as effects of long-term sleep deprivation (e.g., Achermann, 2004; Borb & Achermann, 1999; Hursh et al., 2004; Jewett & Kronauer, 1999; McCauley et al., 2013). Such mathematical models aim to model the overall level of fatigue

at different points in time, but do not provide a detailed account of cognitive (and other) processes involved. Building on this work, recent models have focused on modeling fatigue within a computational cognitive architecture (e.g. French & Morris, 2003; Jones, Laird, & Neville, 1998; Gunzelmann, Gross, Gluck, & Dinges, 2009; Gunzelmann, Moore, Salvucci, & Gluck, 2011; Walsh, Gunzelmann, & Van Dongen, 2017; Veksler & Gunzelmann, 2018) to offer deeper insight into relationship between fatigue and the basic information processing mechanisms inherent to a task.

In this paper, we present a new unified model of fatigue that accounts for both sleep-related and task-related factors, and accounts for performance under both moderate and severe fatigue. In particular, we extend the work of Veksler and Gunzelmann (2018) and Walsh et al. (2017) by first examining the underlying theoretical foundations of both types of fatigue based on recent empirical work. We then utilize these ideas to propose an updated formulation of fatigue within the ACT-R cognitive architecture, testing its predictions against two data sets that demonstrate the benefits of a unified model.

Theoretical Foundations

The central idea of our modeling work is the concept of *microlapses*, introduced by Gunzelmann et al. (2009) to account for changes in behavioral performance related to fatigue. Microlapses can be viewed as an implementation of the "state instability" hypothesis (Doran et al., 2001): that a person's fatigue may be characterized as the switching between sleep and awake states, which may fluctuate second by second and can eventually progress to a physiological sleep state. Microlapses, however, incorporate the idea that switches between sleep and awake states may be more rapid (i.e., tens of ms), with transitions into, and remaining within, a "sleep" state becoming more likely as fatigue increases.

The concept of microlapses relies on the computational mechanisms of a procedural system in a cognitive architecture. A procedural system implemented as a production system is the central core of most well-established cognitive architectures like ACT-R (Anderson, 2007). ACT-R's production system implements a serial bottleneck in cognitive processing, representing cognition as a sequence of recognize-decide-act cycles that require about 50 ms each to execute. Under fatigue, microlapses cause the execution phase of the cycle to fail, leading to delays in completing, or even failure to complete, a task. As we will see, this theoretical foundation allows for an elegant model of fatigue that can account for both sleep- and task-related factors, and for performance across a range of degrees of fatigue.

Modeling Time-of-Day Effects

The first building block for our unified model is the model of sleep-related fatigue described in Walsh et al. (2017). Their model relied on ACT-R's concept of *utility*, namely that each production rule (effectively a 50-ms unit of action) has an associated utility that determines its usefulness in being activated, and this utility can be compared to those of other rules to determine the next action. By manipulating the utility of the productions and the utility threshold, the system is able to produce microlapses: if the utility U_i of the selected production is less than a set utility threshold UT, a microlapse occurs. Because U_i values are noisy, changes in U_i and UT thus influence the probability of microlapses occurring.

To account for sleep-related factors, Walsh et al. (2017) used a biomathematical model to quantify the overall impact of time awake and circadian rhythms. First, let us assume that we have a biomathematical model value $B^S(t)$ that, given a sleep schedule S (i.e., the prior hours for which the person was asleep and awake), provides the level of fatigue at a given time of day t. As mentioned earlier, several such models have been developed in the past; Gunzelmann et al. use the formulation provided by McCauley et al. (2013), which we include here as well. Using this value, we can specify a fatigue scale factor $F_{bio}(t)$ that will scale a production's overall utility proportionally based on the biomathematical model's predictions:[1]

$$F_{bio}(t) = 1 - c_{bio} * B^S(t)$$

We also include a fatigue constant c_{bio} to scale the biomathematical value, and we will consider this constant as one parameter to estimate in our model fitting later.

The next component of the model represents the accumulated effect of microlapses, and incorporates the fact that when a microlapse occurs, another microlapse is more likely to occur immediately after. This component is formulated as follows:

$$F_{dec}(n) = (c_{dec})^n$$

Here, n is the number of consecutive microlapses that have occurred—thus, $n = 0$ after a normal production has fired, but would increase by 1 for each consecutive microlapse thereafter until another normal production firing. c_{dec} is assumed to be a constant between 0 and 1, and thus the value $F_{dec}(n)$ is also a value between 0 and 1 that decreases with larger values of n. As described by Walsh et al. (2017), $F_{dec}(n)$ can quickly decay to the point that will be too low to fire any production; however, there is a counterbalancing effect that resets $F_{dec}(n)$ by setting $n = 0$ (akin to awakening the model) when a stimulus is presented.

Integrating these factors together, following Gunzelmann et al. (2009), Walsh et al. (2017) defined a fatigued utility $FU_i(t,n)$ as a modified value of production i's base utility $U_i(t)$ scaled by both $F_{bio}(t)$ and $F_{dec}(n)$:

$$FU_i(t,n) = F_{bio}(t) * F_{dec}(n) * U_i(t) + \epsilon$$

The final term ϵ adds noise to the final fatigued utility, where the noise is sampled from a logistic distribution. This component is carried over from the standard utility function

[1] The names of some variables and constants have been changed from the original formulation for increased clarity.

in ACT-R, which includes this parameter to generate stochasticity in model behavior. Once this fatigued utility is computed, its value is compared to a utility threshold $UT(t)$, computed using the biomathematical model and a specified initial utility threshold UT_0:

$$UT_{bio}(t) = 1 - d_{bio} * B^S(t)$$

$$UT(t) = UT_{bio}(t) * UT_0$$

These equations introduce another constant, d_{bio}, that scales the biomathematical model value.

Modeling Time-on-Task Effects

As an extension to the above model of time-of-day effects, Veksler and Gunzelmann (2018) developed a model to capture the effects of time-on-task. Using the same core mechanisms as Walsh et al. (2017) described earlier, they replaced the biomathematical factor $F_{bio}(t)$ with a time-on-task factor $F_{\text{tot}}(T)$ defined as follows:

$$F_{tot}(T) = (1 + T)^{c_{tot}}$$

$$FU_i(t, T, n) = F_{tot}(T) * F_{dec}(n) * U_i(t) + \epsilon$$

Here, T represents the total time-on-task, or time spent performing the same task. Veksler et al. used a similar formulation to revise the computation of the utility threshold:

$$UT_{tot}(T) = (1 + T)^{d_{tot}}$$

$$UT(T) = UT_{tot}(T) * UT_0$$

The constants c_{tot} and d_{tot} are assumed to be between –1 and 0, and thus their respective functions decrease as the time-on-task T increases.

A Unified Model of Fatigue

The foundational components above provide the basis for our own unified model, and at first glance, one might expect that we could simply combine the equations and have a unified account directly. Unfortunately, a simple combination does not work well either theoretically or experimentally. We thus explore how we might combine these accounts and then proceed with a specification of the final unified model.

Developing a Unified Model

Examining the formulations for the time-of-day and time-on-task models above, the most straightforward approach to a unified model would be to simply multiple the respective factors together—that is, computing fatigued utility as:

$$FU_i(t, T, n) = F_{bio}(t) * F_{tot}(T) * F_{dec}(n) * U_i(t) + \epsilon$$

This approach multiples the biomathematical component $F_{bio}(t)$ with the time-on-task component $F_{tot}(T)$ to derive the total fatigued utility. In fact, this formulation has been tried with limited success in earlier work: Khosroshahi et al. (2016) used it to account for time-of-day effects on performance in psychomotor vigilance and driving.

Unfortunately, however, we have attempted to use this formulation to account for a broader set of time-of-day and time-on-task effects (discussed more later), and found this approach lacking for several reasons. Using this formulation, it was impossible to find a set of parameter values that produces acceptable results simultaneously for both time-on-task and time-of-day effects—especially when the latter is drawn out to long periods of sleep deprivation. For example, consider how the model might account for lapses in the psychomotor vigilance task (PVT), where participants simply see a visual stimulus and press a button in response, and where a *lapse* is defined as a response time greater than 500 ms. Using the formulation above, the model can nicely fit the number of lapses in the early stages of fatigue, namely during the first day or two without sleep; however, this produces a model that rarely suffers the sleep attacks (response times greater than 30 s) suffered by humans after 48-88 hours of sleep deprivation. On the flip side, if the model parameters were fitted to produce a human-like frequency of sleep attacks, the lapses under moderate fatigue would be much too large.

In summary, this was not an issue of parameter fitting—the model formulation itself was fundamentally flawed. Closer analysis of the model revealed its theoretical flaw: increasing values of the biomathematical model $B^S(t)$ over time would actually scale down the time-on-task effect—effectively making the time-on-task effects *smaller* as the model became more fatigued. This effect is counterintuitive, and indeed, we did not find any evidence to support it in our available data or in the literature. In addition, in their study of time-on-task effects, Veksler et al. (2018) found no correlation between either prior night's sleep or wake-up time and the difference in response times between the first and last blocks of a 35-minute task—indicating an additive, not multiplicative, relationship between time-of-day and time-on-task (see Kribbs & Dinges, 1994; Gunzelmann et al., 2010).

Yet another observation about the naïve combined model, and about the earlier time-on-task model, relates to the model's $F_{dec}(n)$ equation. Recall that this factor incorporates the idea of cascading microsleeps, such that when a microsleep occurs, another is more likely to happen in the subsequent cycle. In the original formulation, because $F_{dec}(n) = (c_{dec})^n$ and $0 < c_{dec} < 1$, there is a rapid initial drop for small n followed by a leveling off to an asymptote near zero. Instead, based on our observations of sleep attacks, a better formulation would allow for only a slight drop for small n, but as n gets larger, the microsleeps would rapidly deteriorate into a sleep attack.

The Unified Model

Given the reasoning above, we created our unified model based on the earlier models of time-of-day and time-on-task while reflecting the evidence above. In particular, we modified the formulations of several equations as follows. First, we changed the decrement factor to a negated exponential function to introduce a steep drop in fatigue as microsleeps accumulate:

$$F_{dec}(t,n) = -(e)^{c_{dec}*n} + 2$$

Next, we modified the biomathematical factor to eliminate the initial 1 in a way that forces it to reduce the overall utility:

$$F_{bio}(t) = -c_{bio} * B^S(t)$$

We then introduced the additive effect between time-of-day and time-on-task into the computation of fatigued utility:

$$F_{tot}(T) = (1+T)^{c_{tot}}$$

$$FU_i(t,T,n) = F_{dec}(t,n) * [F_{bio}(t) + F_{tot}(T) + U_i(t) + \epsilon]$$

Analogous changes were applied to the utility threshold:

$$UT_{bio}(t) = -d_{bio} * B^S(t)$$

$$UT_{tot}(T) = (1+T)^{d_{tot}}$$

$$UT(t,T) = UT_{bio}(t) + UT_{tot}(T) + UT_0$$

These changes all together represent our unified model that accounts for both time-of-day and time-on-task effects. The next section aims to validate this model across two experimental data sets.

Model Evaluation

To validate our model, we rely on two studies that employ arguably the most common task in fatigue-related studies, namely the psychomotor vigilance task (PVT: Dinges and Powell, 1985). As mentioned, the PVT involves an extremely simple stimulus-response. PVT has been used extensively in sleep-related studies because of its sensitivity to sleep and circadian-based fatigue and its procedural simplicity and the consistency of individual performance (e.g., Gunzelmann, Moore, Gluck, Van Dongen, Dinges, 2008; Dorrian et al., 2005). PVT is thus a highly sensitive sustained attention task which can be an independent measure of fatigue (Van Dongen et al., 2011).

A typical PVT trial lasts 10 minutes and requires a button response every 2-10 seconds. The visual stimulus is a millisecond counter displayed on the screen, which starts at 0 at stimulus onset and counts forward as time passes; when the person presses the response key, the counter stops, thus providing feedback for performance. The main dependent measure in the PVT is the number of *lapses*, where a lapse is defined as a reaction time of more than 500 ms. Researchers have also measured the *median response time* (RT) of alert responses (reaction times between 150 and 500 ms), *false starts* (incorrect keypresses or reaction times less than 150 ms), and *sleep attacks* where the participant does not respond for 30 seconds or more.

It is worth noting that we used a single set of parameter values for the models in both studies. Our unified model contains 7 free parameters in total (see Table 1). Another parameter that was treated as a free parameter in previous models is *cycle time*, which controls the amount of time to evaluate and select a production during each cognitive cycle.

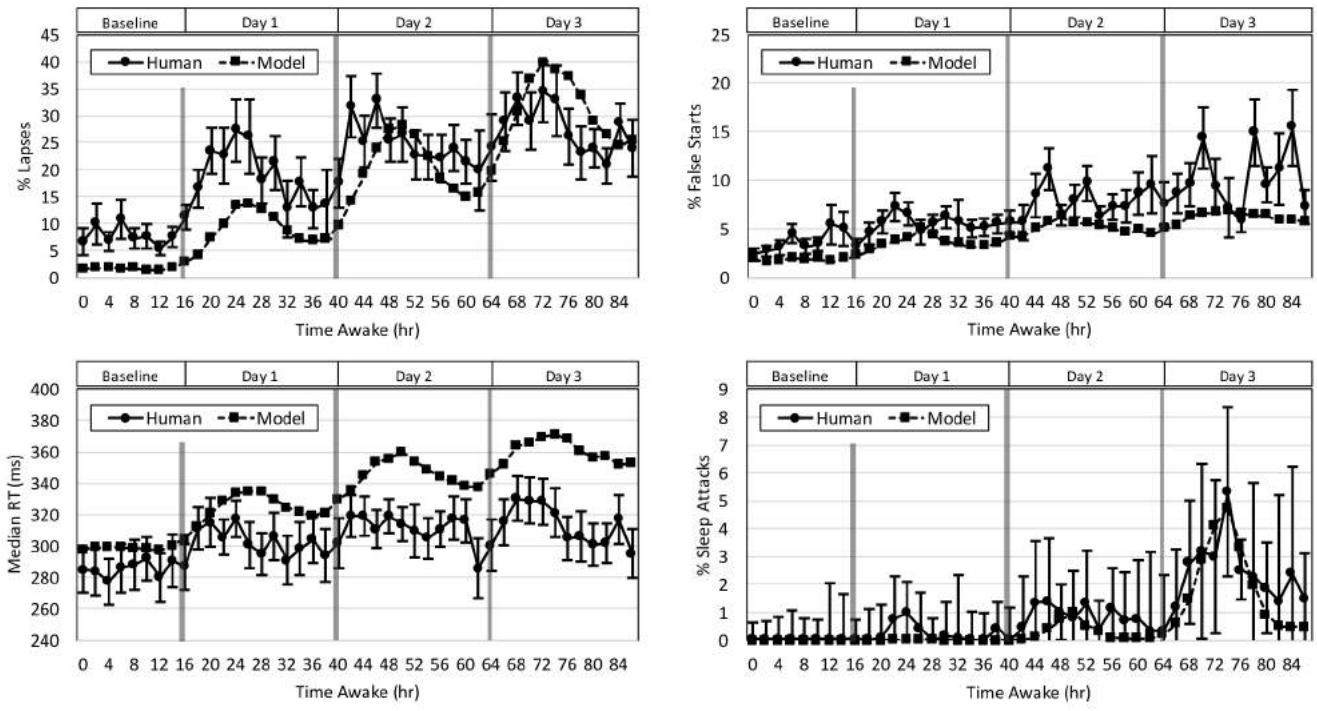

Figure 2: Human and model results for the PVT across 88 hours of sleep deprivation (Study 1).

We used the default value of 50 ms (Anderson, 2007) to keep the consistency with ACT-R theory. To reduce the chance of overfitting, we searched the parameter values to first fit parameters related to the time-on-task effect and then used the same values to fit parameters related to the time-of-day effect. Table 1 shows the list of free parameters and our best estimates for each parameter.

Table 1: ACT-R unified fatigue model free parameters and their estimations.

Parameter	Definition	Estimates
c_{dec}	Utility decrement factor	.006
c_{bio}	Utility biomathematical factor	.028
c_{tot}	Time-on-task decrement factor	.12
U_i	Base utility[2]	1.56
d_{bio}	Threshold biomathematical factor	.01
d_{tot}	Threshold time-on-task decrement factor	.04
UT_0	The initial threshold	1.15

PVT Model

Because the fatigue mechanisms described here are general to any production system or task, we require a model specifically of the PVT to test the fatigue mechanisms. For this purpose, we developed an ACT-R model that performs the PVT in as straightforward a manner as possible, with three main production rules, following the original model by Walsh et al. (2017):

1. *Attend*: shift visual attention to the stimulus
2. *Encode-and-Respond*: completes the visual encoding of the stimulus and initiates the response keypress
3. *Wait*: wait for the next stimulus

To capture the false starts in the PVT model, Walsh et al. (2017) used procedural partial matching: when enabled, productions whose conditions do not perfectly match the current state get a chance to be selected with a similarity difference (a negative value) added to their utility:

$$U_i' = U_i + SD_i + \epsilon$$

SD_i is the similarity difference which is added to the utility value when the conditions for the production are not met. At each cycle, the production with the greatest value U_i is selected when its utility exceeds the utility threshold. By enabling the procedural partial matching, Walsh et al. (2017) eliminated the need of a separate production (false-response); encode-and-respond can be selected at any time and when it is selected before the stimulus appears, false starts occur (which happens rarely because of the similarity difference added to it).

In the design of PVT in Walsh et al. (2017), U_i' was treated as a single free parameter meaning that one value was estimated and used for all the productions. The ACT-R's procedural learning (Anderson, 2007) was also disabled due to the nature of PVT and similar sustained attention tasks (Van Dongen et al., 2003) and the similarity difference was set to negative value of the production utility to simplify matters. Here we follow a similar design to stay consistent with earlier studies.

Study 1: Time-of-Day Experiment and Results

The first study for our model evaluation is a study of long-term sleep deprivation conducted by Doran et al. (2001). The study included 13 healthy participants who experienced 88 hours of total sleep deprivation. During periods of wakefulness for the duration of the study, participants

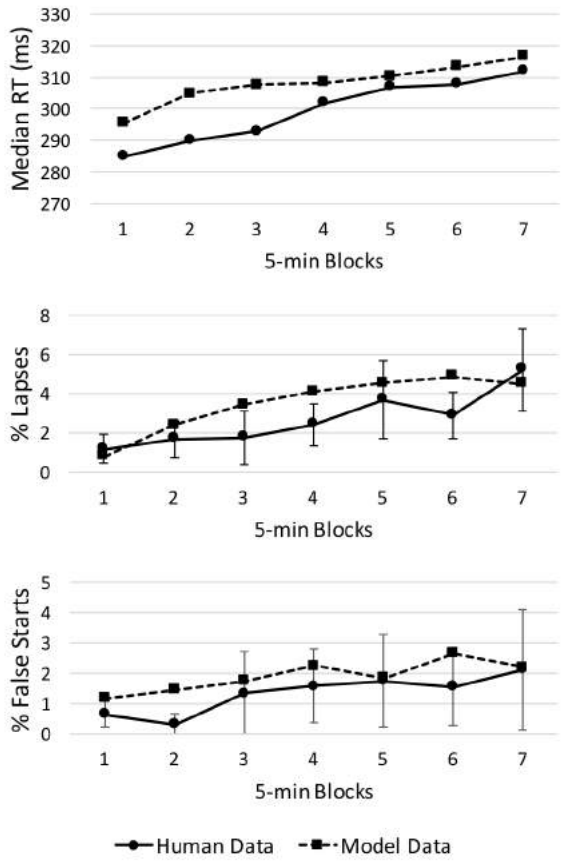

Figure 3: Human and model PVT results across the 5-min blocks of the 35-min experiment (Study 2).

[2] Base utility is defined as the standard utility value for all productions.

completed a battery of performance evaluation tasks every 2 hours, including a 10-minute PVT. Although Gunzelmann et al. (2009) modeled the same experiment, our effort here is different in two ways: (1) the older model used different parameter values for each day, whereas we are constraining our model to a single set of parameters; and (2) the older model did not include the time-on-task factor; although time-on-task was not a focus of the study, it is important for us to know that the model can produce a good fit while incorporating this factor (see also Gunzelmann et al. 2011).

To model this study, we ran iterations of the PVT model for 10-minute periods and matched the sleep schedule of the model to the 88-hour sleep deprivation experimental protocol. Parameters were estimated to produce the best fit across the four PVT measures; a single set of parameter values was used across the entire experiment. Figure 2 shows the human data and model's performance for all four measures: lapses ($R^2 = 0.68$, $RMSE = 7.92$), median reaction times ($R^2 = 0.55$, $RMSE = 34.41$), false starts ($R^2 = 0.56$, $RMSE = 3.42$), and sleep attacks ($R^2 = 0.77$, $RMSE = 0.64$). Overall, the model accounted for all the major aspects of the data; it slightly underpredicted lapses in days 1-2, and slightly overpredicted RT in days 4-5, but in general, the model captured most of the fluctuations in performance across all four measures.

Study 2: Time-on-Task Experiment and Results

The second study for our model evaluation is a study examining time-on-task effects conducted by Veksler and Gunzelmann (2018). In the study, 20 participants performed a 35-minute PVT instead of the usual 10 minutes; by extending the typical PVT duration, they were able to draw out how the effects of time-on-task on PVT are similar to those of sleep loss. As mentioned earlier, Veksler and Gunzelmann modeled the time-on-task effects in this experiment, but at the time did not incorporate the biomathematical model, and used a different set of parameters than earlier models. To include biomathematical modeling in our simulations, we assumed 8 hours the night before the experiment, waking at 7:30am and performing the experiment at 10:00am.

The results of the model compared to the human data are shown in Figure 3. For this evaluation, we compared the performance of the model with the experimental results across seven 5-minute blocks of PVT. The model was able to capture the changes across the blocks for median reaction times ($R^2 = 0.85$, $RMSE = 9.67$), lapses ($R^2 = 0.53$, $RMSE = 1.27$), and false starts ($R^2 = 0.55$, $RMSE = 0.69$). The model shows a slight overprediction of lapses in the middle blocks, but in general, the model performs well for these three measures, especially considering that this is the same model with the same parameters as the previous study.

General Discussion

In this paper, we introduce a unified computational model that accounts for two of the most important aspect of fatigue, namely time-of-day and time-on-task effects on behavior and performance. Our result once again accounts for the microlapse hypothesis (Gunzelmann et al. 2009) and the fact that microlapses could account for both sleep loss and time-on-task effects in sustained attention (following Veksler et al., 2018). We were also able to capture both the time-of-day and time-on-task effects with the same parameters; going forward, we are interested in understanding how these parameters might generalize to other tasks, and how they might vary across individuals. It is also notable that the mechanisms here are complex, with a number of free parameters that are sensitive to changes in setting. Nevertheless, we believe that as we continue to fit additional experiments with this unified model, we can reduce the space of free parameters and can find parameter values that cut across a variety of task domains, providing an even more general model with easier estimation of parameters.

In conclusion, by validating that the unified model can account for the negative consequences in behavioral performance of both time-of-day and time-on-task effects, we have demonstrated that both phenomena have similar natures and as a result could be modeled with a single set of mechanisms. Although PVT as a testbed for our modeling seems to be a simple task, this research will give us a strong foundation to expand the model to more complex domains. We are also interested in extending this model beyond the sleep-loss and time-on-task to moderate levels of fatigue (e.g., sequential sleep limitation), which would further bolster the model's generalizability to complex real-world task domains.

Abstract

Locke argued that persons born blind do not possess true knowledge about color. While prior studies find some knowledge of color among blind individuals, questions remain about the depth of this knowledge. Do blind individuals merely learn inferentially shallow verbal associations (e.g., bananayellow)? We hypothesized instead that blind individuals are more likely to acquire causally-relevant color information. Blind (n=20) and sighted adults (n=20) reported colors of natural kinds (e.g. banana) and artifacts (e.g. car) and judged the likelihood that two instances of a type have the same color. Relative to the sighted, blind participants were less likely to know specific object colors (e.g. banana-yellow), but made identical inferences about color consistency (more consistent colors for natural kinds). Inferences were similar across groups even for novel objects. Further, blind individuals gave detailed and coherent causal explanations of color origins. Inferentially rich knowledge of sensory categories can develop without first-person experience.

I know what you did last summer (and how often). Epistemic states and statistical normality in causal judgements

Abstract

When several causes contributed to an outcome, we often single out one causal factor as being "more of a cause" than others. What explains this selection? Existing research suggests that people's judgements of actual causation can be influenced by the degree to which they regard certain events as norm-deviant, or "abnormal" (Hart & Honoré, 1963; Kahneman & Miller, 1986; Hitchcock & Knobe, 2009; Halpern & Hitchcock 2015). In this paper, we argue that statistical abnormality influences causal judgements about human agents by changing the agents' epistemic states (*Epistemic Hypothesis*). In Experiment 1, we replicate previous findings that people assign more causal strength to a statistically abnormally acting agent, but show that they also assign them more knowledge about the behaviour of their peers. In Experiment 2, we show that in case of equal epistemic uncertainty, people do not differentiate between statistically abnormal and normal causal agents. In Experiment 3, we explore the difference between type and token abnormality, and find that a token abnormal, but type normal behaviour still influences causal judgments, with people's epistemic judgments mirroring these causal judgments. We discuss the implications of this research for current norm-frameworks in causal cognition.

Keywords: statistical norms, normality, causal judgment, counterfactual reasoning, epistemic states

Our ability to form causal judgements plays a fundamental role in human cognition. In everyday life, we encounter situations that demand an explanation of why something happened, how it happened, or how it could have been prevented. Fortunately, our environment is rich in statistical information. Statistical patterns have been shown to be a reliable cue in guiding people's causal inferences and judgements (Cheng, 1997). The co-variation of cue and outcome, their proximity in space and time or the temporal order in which events occur have been shown to inform assumptions about *causal structure*, i.e. the existence of a causal relation between cue and outcome, as well as *causal strength*, i.e. the degree of a causal relation between cue and outcome (Lagnado, Waldmann, Hagmayer & Sloman, 2007).

Recent research suggests that the influence of statistical information on causal cognition goes even further. The *statistical normality* of a causal factor, i.e. how likely, typical or frequent it is perceived, can make a difference to people's causal judgement about this factor over and beyond its actual causal contribution (Cheng & Novick, 1991; Hitchcock & Knobe, 2009; Samland & Waldman, 2016; Kominsky, Phillips, Gerstenberg, Lagnado & Knobe, 2015; Icard, Kominsky, Knobe, 2017). In a range of empirical studies, people have been shown to differentiate between causal factors according to their statistical features, even when both factors are necessary for the outcome to occur (Hitchcock & Knobe, 2009; Icard et al., 2017; Gerstenberg & Icard, n.d.).

Most prominently, this research suggests that deviations from statistical normality increases the causal strength assigned to a cause. Specifically, people are more inclined to judge that *C* causes *E* when *C* is perceived to be statistically "abnormal", i.e. unlikely, infrequent or atypical manner, rather than when C is perceived to be statistically normal. This holds even when in both cases, *C* is known to have the same actual causal contribution to the effect. These findings raise the question of why people take statistical features into account even when these features do not function as supplementary cues to causal structure or strength. What makes people prefer abnormal causal candidates?

Normality matters – but why?

A prominent line of research argues that norms or normality influence causal judgments by changing the relevance or propensity to consider counterfactual possibilities (Kahneman & Miller, 1986; Hitchcock & Knobe, 2009, Icard et al., 2017). A statistical norm violation increases the likelihood of thinking about an alternative scenario in which the norm-violation is replaced by norm-conforming behaviour. A typical test case in this research is causation in a conjunctive causal structure, where two causes are each necessary to produce an outcome. When both C_{normal} and $C_{abnormal}$ together bring about outcome E, people will be more likely to envisage a counterfactual scenario in which $C_{abnormal}$ is absent, rather than a counterfactual in which C_{normal} is absent. According to the counterfactual account, imagining a counterfactual alternative in which normality, or norm-conformity, is restored highlights the causal role of the abnormal causal factor for the outcome, compared to that of the normal causal factor (Kahneman & Miller, 1986; Hitchcock & Knobe, 2009, Icard et al., 2017).

Counterfactual accounts of norm effects in causal cognition have gained increasing popularity. On the one hand, they have integrated norms into formal causal frameworks that can explain a variety of norm effects on causal judgments, such as "causal superseding" (Kominsky

et al., 2017) or "abnormal deflation" (Icard et al., 2017; 2018). On the other hand, they not only predict the influence of statistical norms on people's causal judgements, but also the impact of other kind of norms, such as prescriptive norms (Hitchock & Knobe, 2008) or norms of proper functioning (Phillips & Kominsky, 2018). Recently, it has been suggested that the influence of both prescriptive and statistical norms on causal judgements can be explained by a single normality concept (Bear & Knobe, 2017).

Knowing me, knowing you

The majority of studies supporting the counterfactual account has been conducted using vignette stories in which participants rate the causal impact of human agents who differ in certain aspects of normality. This has led some to argue that the influence of moral abnormality on causal judgements in the context of human agents reveals something about people's blame responses, rather than a difference in counterfactual and causal reasoning (Samland & Waldman, 2016, Alicke, Rose & Bloom, 2012). However, most research argues that statistical norms influence the underlying process of causal judgement. When it comes to statistical norms, it is the abnormality itself that leads people to judge a causal difference between an abnormally and a normally acting causal agent.

In this paper, we propose an alternative hypothesis. While we agree that statistical likelihoods can have an impact on people's causal judgements about events or objects, we think that in the context of human agents, there is another important factor to consider. Epistemic states, i.e. the knowledge an agent has about their environment, have been shown to influence how we evaluate the causality of their actions (Lagnado & Channon, 2008). Whether an agent engages in a frequent of typical action, or an infrequent or atypical action, will likely change their epistemic states about the consequences of this action. In particular, in the case of conjunctive causal structures, an abnormally acting agent seems to have an epistemic advantage over the normally acting agent in knowing or expecting the outcome to happen. We believe it is the epistemic advantage that arises from a statistically abnormal action, rather than the abnormality per se, that drives the main difference in people's judgements about causal agents. We call this the *Epistemic Hypothesis* (EP). We conducted three experiments to investigate this hypothesis. In Experiment 1, we replicate previous literature by showing that people assign more causal strength to a statistically abnormally acting agent. In Experiment 2, we show that in case of equal epistemic uncertainty, people do not make a causal difference between abnormal and normal causal agents. In Experiment 3, we find that a token abnormal, but type normal behaviour still influences causal judgments, with people's epistemic judgments mirroring these causal judgments. We discuss the implications of this research for current norm-frameworks in causal cognition.

Experiment 1

The term "statistical abnormality" has been used broadly in the causal cognition literature, referring to actions or events that are unlikely, rare or atypical. In our experiments we have concentrated on statistical normality in the sense of the frequency of an action. We follow the current paradigm of assessing causal ratings of two causal agents in a conjunctive causal structure, while varying the statistical normality of their actions. In order to focus our investigation, we deviate from the current experimental paradigms in two aspects. Instead of descriptive vignettes ("Agent X frequently does action Y"), we use sequential animated video scenes in order to represent action frequencies more naturalistically. Furthermore, previous literature has suggested that the co-variation between cause and effect influences causal considerations (Harinen, 2017, Cheng 1997, Kirfel & Lagnado, 2018). Current experimental studies are ambiguous about the statistical normality of the effect, which is why we decided to employ a causal structure which allows us to control the frequency of the outcome.

Participants[1]

176 participants were recruited for this online study via Amazon Mechanical Turk. 10 participants were excluded for answering more than one check question wrong, leaving a final sample of 166 (M_{age} = 37.19, SD_{age}=11.24, *age range*= [20-77]; 101 male, 64 female, 1 N.A.) They were paid £0.70 upon completion of the study (Ø 8.06min).

Design

We manipulated two factors in a two-agent-scenario: the statistical normality of an action (*frequent* vs. *infrequent action*) and the type of scenario (*microwave* vs. *coffee machine*). Statistical normality, i.e. frequency of actions was manipulated for one agent (Agent 2: *varied agent*) while holding the frequency of actions fixed on the second agent (Agent 1: *fixed agent*). The scenario type was manipulated between-participant, while the statistical normality was manipulated within-participant. Participant saw two video clips ("*frequent", "infrequent"*) from one of the two scenario types, presented in randomized order. Names of the agents were varied across all conditions.

Material

The frame story consists of two co-workers in a shared office. Depending on the scenario type, the office has either two coffee machines or two microwaves that the employees can use. For energy saving purposes, the company introduces the "Green Friday" on which the building is switched into a power-saving mode. As a result, the use of more than one coffee machine (microwave) on Fridays will lead to a power failure in the building. All workers are aware of the Green Friday.

[1] The material and data for all experiments are available under: https://osf.io/zhvsb/

Figure 1. Scenario "Coffee Machine" with Fixed Agent ("Henry") and varied Agent ("James").

Response Measures

Causal Rating. After each video clip participants were asked to express their agreement with statements about the causal contribution of each agent to the outcome ["Agent 1 (2) has caused the power failure."] on a 7-point Likert scale [1 – 'Strongly disagree' to 7 – 'strongly agree']. Questions were presented in randomized order.

Manipulation Checks. In two subsequent manipulation check questions, participants were asked about their understanding of the action frequency in the scenario ["Who used a coffee machine frequently (rather than infrequently) this week?" – 'Agent 1', 'Agent 2'; multiple answers possible] and the causal structure ["The use of how many coffee machines does it take to produce a power failure on Friday? – 'One coffee machine', 'Two coffee machines']. At the end of the survey, i.e. after watching both videos and answering the causal rating questions, participants were asked to express their opinion about the epistemic states of the agents in both videos ["Agent 1 (2) knew that Agent 2 (1) would use a microwave on Friday."] on a 7-point Likert scale [1 – 'strongly disagree' to 7 – 'strongly agree']. By this, we wanted to check for people's assumptions of the agent's epistemic states.

Results

A Mixed ANOVA for participant's agreement ratings about the causal statements revealed a significant interaction for Frequency × Agent, $F_{(1,164)} = 29.05$, $p < .001$, $\eta_p^2 = .15$. While people judge no difference between the causal contribution of the agents when both of them have frequently performed the action, an agent whose action is rare is seen as more causal ($M = 5.52$, $SD = 1.63$, 95% CI [5.27, 5.78]) then a frequently acting agent ($M = 4.54$, $SD = 1.97$, 95% CI [4.24, 4.84]).

There was no effect for scenario type ($p = .653$). A Mixed ANOVA for agreement ratings about the agent's epistemic states revealed a significant interaction for Frequency × Agent $F_{(1,164)} = 291.60$, $p < .001$, $\eta_p^2 = .64$. When the two agents differ in the frequency of their actions, people express more agreement with the proposition that the agent acting for the first time on Friday knows that their (frequently acting) coworker would act ($M = 5.83$, $SD = 1.74$, 95% CI [5.54, 6.07]), than vice versa ($M = 2.37$, $SD = 1.54$, 95% CI [2.11, 2.64]).

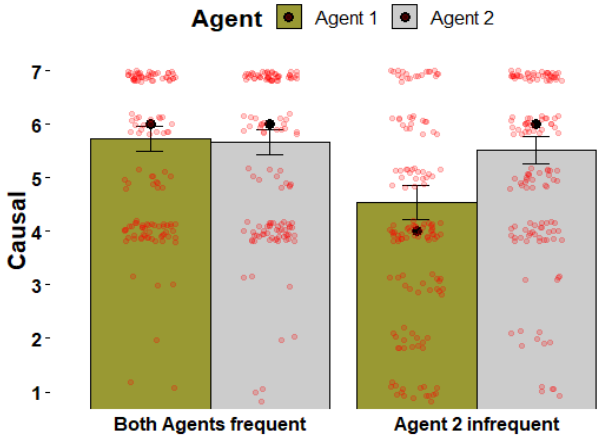

Figure 2. Mean agreement ratings (scale 1-7) for causal statement. Error bars represent ±1 SE mean, black points represent the median.

Discussion

In this experiment we found that when a frequently and infrequently acting agent together cause an outcome, people judge the agent who has acted infrequently to be of greater causal strength than the frequently acting agent. Our findings are in line with the literature in causal cognition showing that people tend to assign more causal strength to abnormal causes (Hitchcock & Knobe, 2009, Icard et al., 2017). In our study, we manipulated the statistical normality among agents' actions. However, in a two-agent conjunctive structure, acting abnormally gives the agent a better chance of foreseeing the consequences of their action. This is because the infrequent worker has witnessed the frequent worker acting on multiple occasions, whereas the frequent worker has never seen the infrequent worker act. In accordance with this prediction, we found that people assigned more knowledge about the co-worker's behaviour to the abnormally acting agent. This leaves open the question whether it was the epistemic advantage of the abnormally acting agent, or the abnormality of their action, that led people to make a causal difference. For our second experiment, we therefore examined whether abnormality still influences causal judgements when there is no such epistemic advantage.

Experiment 2

In the second experiment, we aimed to investigate the effect of statistical normality on causal judgments when neither agent knows about the frequency of the other's actions.

Participants

171 participants were recruited for this online study via MTurk; 19 were excluded for answering more than one check question wrong (N=152, M_{age} = 38.22, SD_{age} =11.25, *age*

range= [19-71]; 81 male, 79 female,). They were paid £0.70 upon completion of the study (Ø 8.61min).

Design & Material

The experiment was designed as Experiment 1, with the difference that the two agents are shown as working in separate offices on different floors. The agents are introduced as co-workers who "[despite] working for the same company, do not know each other and have never met or seen each other." (https://youtu.be/dYaXueuGOoA).

Response Measures

We used the same Causal Rating Measures and Manipulation Checks as in in Experiment 1.

Figure 3. Scenario "Coffee Machine" with fixed Agent 1 ("Henry") and varied Agent 2 ("James").

Results

A Mixed ANOVA for participant's agreement ratings about the causal statements revealed a main effect for Frequency $F(1,150) = 9.96$, $p = .002$, $\eta_p^2 = .06$. Higher causal ratings are given when both agents act frequently ($M = 5.07$, $SD = 1.87$, 95% *CI* [4.87, 5.28]), compared to the case in which only one has acted frequently ($M = 4.72$, $SD = 2.06$, 95% *CI* [4.60, 4.93]).

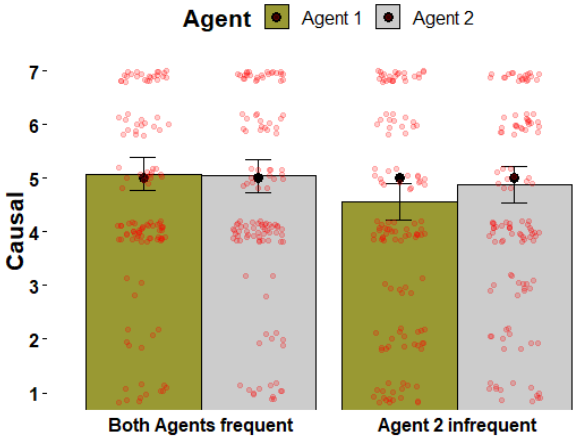

Figure 4. Mean agreement ratings (scale 1-7) for causal statement. Error bars represent ±1 SE mean, black points represent the median.

There was no interaction effect of Frequency × Agent ($p = .118$), and no effect of scenario type ($p = .441$).

A Mixed ANOVA for agreement ratings about the agent's epistemic states revealed a significant interaction for Frequency × Agent $F_{(1,150)} = 4.83$, $p = .029$, $\eta_p^2 = .03$.

Discussion

In our second experiment, we investigated whether statistical normality influences causal judgments when neither agent knows about the other's behaviour. We found that people do not differentiate between a frequently and rarely agent when neither agent knows or observes the other's behaviour. When both agents operate out of sight from each other, people do not judge the abnormally acting agent as contributing more to the joint outcome of their actions. However, the epistemic manipulation check questions revealed that our manipulation of epistemic uncertainty was only partly successful. Although both agents were introduced as working from different offices and not knowing each other, participants still assumed a very small epistemic difference when they differ in their action frequency. Compared to Experiment 1, however, the epistemic difference is negligible ($MD_{EXP1} = 3.36$, $MD_{EXP2} = 0.16$) and rated at the bottom of the 7 point Likert scale [1 – 'strongly disagree' to 7 – 'strongly agree'] (*Frequent Agent*: $M = 1.24$, *infrequent Agent* $M = 1.40$).

As a result, people overall disagreed with the statement that the agents had knowledge of each other. Our experiment shows that the general reduction in the agents' knowledge about each other led to an absence of influence of statistical normality. If an agent has not secured knowledge about the behaviour of their peers, people do not take into account the statistical normality of the agent's behaviour when making causal judgements. Our second experiment therefore shows that in case of epistemic uncertainty, i.e. when acting abnormally does not generate an epistemic advantage, statistical normality does not affect causal judgement.

Type and Token Normality

Our two experiments so far confirm the hypothesis that statistical normality influences causal judgments by giving an epistemic advantage. However, there is another interesting case to consider. Statistical abnormality does not necessarily need to lead to an epistemic advantage when agents, despite differing in their action frequency, can still predict the general outcome-causing behaviour. This case might be hard to experience naturally, because it is exactly the unpredictability of abnormal behaviour that makes it difficult for other agents to foresee it, leading to an epistemic asymmetry. However, when the agent acts for the first time, but their specific action has been performed frequently before by someone else, the agent's behaviour is still abnormal, but others might have been able to foresee the occurrence of this type of action. Strictly speaking, in such a case the abnormality of the behaviour is abnormal only in a limited sense. The agent is abnormal on an "agent-token" level, i.e. *this* particular agent performing action φ, but normal on an "agent-type" level, i.e. *an agent* performing action φ. In their

paper "Two types of typicality", Sytsma, Livengood and Rose (2015) reassess the role of statistical normality by distinguishing between agent-level and population-level statistical norms. They find that agent-level statistical normality has an influence on causal attributions, while deviating from a populational-level norm does not affect people's causal judgements.

For our third experiment, we adopted a similar paradigm as used by Sytsma et al. (2015). We introduced a third 'auxiliary' agent who uses one of the outcome triggering devices regularly during the week before the abnormally acting agent uses it on Friday. By this, we were interested whether an action that is token abnormal, but type normal, still influences causal judgment. Crucially, we assumed that introducing type normality might also make a difference to the agents' epistemic states. That is, in contrast to Experiment 1, here we would expect the token normally acting agent to have certain foreseeability that *someone* performs the causally relevant action on Friday (even though on that day, this happens to be a different agent than expected). The manipulation of epistemic states in Experiment 3 however is much noisy and occurs indirectly through the manipulation of type normality. In line with EP, we predict that if people continue to judge the token abnormal agent to be more causal for the outcome, this would again be tracked by a perceived epistemic asymmetry between these agents.

Experiment 3

In the third experiment, we aimed to investigate the effect of statistical normality on causal judgments when an agent acts statistically abnormal, but their action has been performed before by others.

Participants

180 participants were recruited for this online study via Amazon Mechanical Turk; 26 were excluded for answering more than manipulation wrong (N=154, M_{age} = 38.47, SD_{age} =12.16, *age range* = [19-72]; 90 male, 62 female, 1 2.A). They were paid £0.70 upon completion of the study (Ø 8.64min).

Design & Material

We used the same scenarios as in Experiment 1, but added a third causally irrelevant agent, Agent 3. The statistical normality of the agents who are causing the final outcome was manipulated as before, i.e. varied for one agent and held fixed for the other (*Agent 1*: fixed agent; *Agent 2*: varied agent). In the condition in which both Agent 1 and Agent 2 behave statistically normal, both of them use a coffee machine (microwave) from Monday to Friday, with Agent 3 simply being present and not acting (https://youtu.be/Tsxt1peUA74). In the condition in which Agent 2 acts abnormally, Agent 2 uses the coffee machine (microwave) on Friday, but Agent 3 uses that exact same coffee machine (microwave) the days before, i.e. from Monday to Thursday (https://youtu.be/k2wE52iZPKY).

Response Measures

We used the same Causal Rating Measures as in Experiment 1, but for the sake of completeness, added a Causal Rating for Agent 3 which we did not include in our analysis. We added a Manipulation Check Question to test whether people correctly perceived who had acted on the final day of the outcome ["Who used a microwave on Friday?" 'Agent 1', 'Agent 2', 'Agent 3', multiple answers possible]. We changed our Epistemic Question into a question about i) the type of behaviour "Agent 1 (2) knew that the other coffee machine (microwave) would be used by someone on Friday", and ii) the behaviour of the specific agent "Agent 1 (2) knew that Agent 2 (1) would use the other coffee machine (microwave) on Friday" [1 – 'strongly disagree' to 7 – 'strongly agree'].

Figure 5. Scenario "Coffee Machine" with fixed Agent 1 ("Dan"), varied Agent 2 ("Eddie") and 'auxiliary' Agent 3 ("Sam").

Results

A Mixed ANOVA for participant's agreement ratings about the causal statements about Agent 1 (fixed) and Agent 2 (varied) revealed an interaction effect for Frequency × Agent $F_{(1,152)} = 9.89$, $p = .002$, $\eta_p^2 = .06$.

When Agent 1 and 2 differ in the frequency of the actions that they perform on Friday, people agree more with the statement that the infrequently acting Agent 2 caused the outcome (M = 5.05, SD = 1.99, 95% CI [4.73, 5.36]), than that the frequently acting Agent 1 (M = 4.48, SD = 2.11, 95% CI [4.15, 4.82]).

A Mixed ANOVA for agreement ratings about agent's epistemic states for the type of behaviour revealed a significant interaction for Frequency × Agent $F_{(1,152)} = 10.82$, $p = .001$, $\eta_p^2 = .07$. The infrequently acting agent is judged to have more certainty that *someone* would use the other device on Friday (M = 4.73, SD = 2.01, 95% CI [4.41, 5.05]), than the frequently acting agent (M = 4.23, SD = 2.12, 95% CI [3.89, 4.56]). A Mixed ANOVA for ratings on the agent's assumptions about the *specific agent* using the other device also revealed a significant interaction for Frequency × Agent $F_{(1,152)} = 110.01$, $p < .001$, $\eta_p^2 = .42$. Participants agreed substantially more with the statement that the infrequently acting agent knows that the frequently acting agent would be

using the other relevant device on Friday (M = 4.61, SD = 2.01, 95% CI [4.29, 4.93]), than vice versa (M = 2.53, SD = 1.83, 95% CI [2.24, 2.82]).

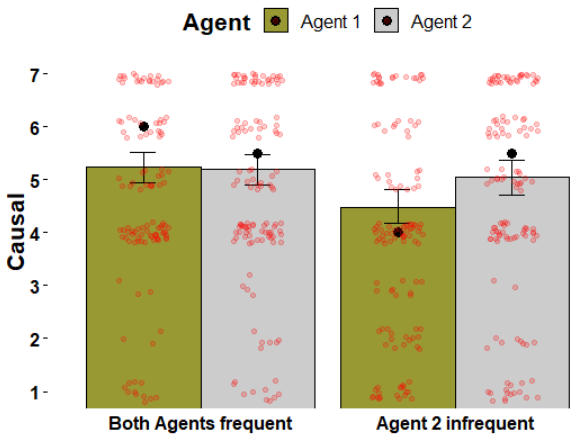

Figure 4. Mean agreement ratings (scale 1-7) for causal statements. Error bars represent ±1 SE mean, black points represent the median.

Subgroup Analysis. We conducted an additional analysis for the causal agreement ratings of the subgroup of people who rated the type behaviour expectations of normal and abnormal agent as equal (n=98). Here, we found no significant interaction for Frequency × Agent ($F_{(1,96)}$ = 1.6, p = .147) ($MD_{\text{Abnormal-Normal}}$=0.29, SD_{MD}=2.0).

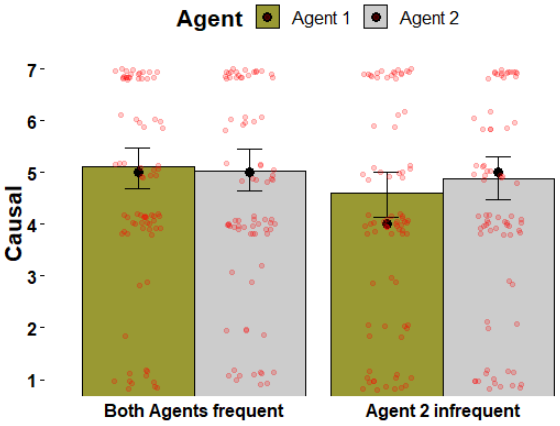

Figure 5. Mean agreement ratings (scale 1-7) for causal statements. Error bars represent ±1 SE mean, black points represent the median.

Discussion

In our third experiment, we found that an action that is token abnormal, but type normal, still influences causal judgments,. However, the judged difference between token normal and abnormal agent is significantly smaller than in Experiment 1. In addition, we found that people thought that the normally acting is less certain that the abnormally acting agent would act, but also less certain that *someone else* would act. This result comes as a surprise, given that both focal agents should have been able to expect *an agent* to act in the final scenario. While we assessed the focal agents' expectations towards the general type and each other's token behaviour, we did not assess their predictions about the behaviour of the third 'auxiliary' agent. It is therefore likely that some people might have assumed Agent 1 (and/or Agent 2) to have expected Agent's 3 omission. In consequence, it might be that the difference in action type expectations comes about as a difference in expectations about who *in fact* acted on Friday. This, again, leaves the normal agent with an epistemic disadvantage. However, a subgroup analysis showed that participants who assumed that both agents had equal behaviour type knowledge, i.e. that both agents were equally expecting that someone would act on Friday, did not judge a significant causal difference between abnormal and normal agent.

General Discussion

In three experiments, we investigated what we call the *Epistemic Hypothesis* (EP), the hypothesis that statistical abnormality will influence causal judgments via generating an epistemic asymmetry. In our first experiment, we showed that an abnormally acting agent is seen as more causally effective for an outcome, but also as more knowing about the behaviour of their normal counterpart. In accordance with EP, we found that in the case of mutual ignorance about each other, statistical abnormality does not influence causal judgements. Finally, we found that token abnormal, but type normal behaviour still influences causal judgments. At the same time, people's epistemic judgments about type and token behaviour mirror these causal judgments.

What role do epistemic states play in the influence of normality on causal judgements? Samland and Waldmann (2016) have shown that the mental states of agents can affect whether people's judgements about their causal contribution are influenced by prescriptive abnormality. They found that people do not take prescriptive norms into account for their causal judgments when the norm-violating agent is unaware of their norm transgression. Counterfactual accounts leave open under which circumstances people start to perceive a behaviour as "abnormal" (Phillips & Kominsky, 2018). Therefore, an agent's lack of knowledge or awareness of existing norms might determine whether the behaviour is perceived as norm-violating or abnormal in the first place. However, we think that in case of statistical normality, an agent can assess the normality status of their behaviour relative to their own action history, their agent-level normality. In consequence, the assessment of statistical normality is not necessarily conditional on the knowledge about external factors, such as rules or laws, or the behaviour of other people. In this paper, we aim to make different claim. We argue that it is the epistemic state that occurs qua the normality or abnormality of an action that drives the difference in people's causal judgements (Kirfel & Lagnado, 2017; Kirfel & Lagnado, 2018). Our experiments support this hypothesis. Hence, we argue that current norm incorporating causal frameworks are in need of a firm theory of epistemic states in order to explain their influence on norm-based causal cognition.

Abstract

We show that computational reinforcement learning can model human decision making in the Iowa Gambling Task (IGT). The IGT is a card game, which tests decision making under uncertainty. In our experiments, we found that modulating learning rate decay in Q-learning, enables the approximation of both the behaviour of normal subjects and those who are emotionally impaired by ventromedial prefrontal lesions. Outcomes observed in impaired subjects are modeled by high learning rate decay, while low learning rate decay replicates healthy subjects under otherwise identical conditions. The ventromedial prefrontal cortex has been associated with emotion based reward valuation, and, the value function in reinforcement learning provides an analogous assessment mechanism. Thus reinforcement learning can provide a good model for the role of emotional reward as a modulator of the learning rate.

Keywords: reinforcement learning; Q-learning; learning rate decay; Iowa Gambling Task; ventromedial prefrontal impairment

Introduction

According to psycho-evolutionary theorists, emotions assist the organism in maintaining homeostasis relative to its behavioural and survival goals (Plutchik, 2003). The emotion feedback mechanism solves problems without the need for higher cognitive analysis (Damasio, 2006).[1] Rolls (2013, Ch. 4) proposes that emotions regulate instrumental learning and influence contingent outcome-action selection.

The pre-frontal cortex and its regions play a key role in goal directed learning and behaviour (Miller & Cohen, 2001). Ventromedial prefrontal cortex (VMF) lesions produce a characteristic learning deficit, where the subject, while retaining good intellectual function and understanding, is no longer able to learn from real life mistakes. Wallis (2007) has argued that the VMF provides emotion valuation input critical for good decision making.

The Iowa Gambling Task (IGT) was the first clinical test, which identified VMF impairment in human trials (Bechara, Damasio, Damasio, & Anderson, 1994). In the IGT, subjects need to choose a card from one of four decks. There are two 'good,' and two 'bad' decks, but the 'bad' decks start with positive rewards. Once penalties set in on the bad decks, subjects should adjust the choice of decks accordingly. Fellows and Farah (2005, 2004) present a re-shuffled variation of the original IGT, where penalties start earlier in the bad decks. While VMF impaired subjects fail the original IGT, they pass the re-shuffled variant. On the basis of these differing test results, Fellows and Farah (2005, 2004) link VMF impairment to reversal learning deficit.

[1] First published in 1994 by G.P. Putnam's Sons, New York, USA.

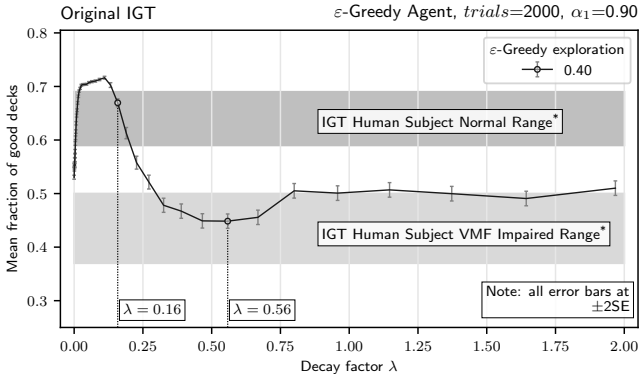

Figure 1: The ε-Greedy agent applied to the original IGT data with different learning rate decay values. A low decay rate yields normal behaviour, whereas a high decay rate reproduces VMF impairment. *See text and Table 4 for details.

Computational reinforcement learning methods approximate an optimal decision policy by iteratively aggregating time-contingent reward values (Sutton & Barto, 2018). For example, reinforcement learning techniques may be used to calculate a suitable path for escaping a maze (Osmankovic & Konjicija, 2011).

Watkins (1989) developed, the Q-learning framework, a reinforcement learning model, which, in addition to the discount rate, uses a single novel parameter denoted by α, known as the learning rate. The learning rate determines the relative contribution of current yield to accumulated value. We add to the Q-learning model a decay factor parameter λ, which produces exponential decay of the learning rate (Powell, 2011, pp. 427). We show that Q-learning, with the addition of learning rate decay, reproduces the clinical results of the original and re-shuffled IGT variants.

Figure 1 presents our key result for the original IGT variant. For low learning rate decay, the ε-Greedy agent performs in the range of normal human subjects. As learning rate decay increases, agent performance reduces to the range of VMF impaired subjects. The dark and light gray zones mark the mean fraction of cards chosen from the good decks, reported in the literature for normal and VMF impaired subjects respectively.

In the remainder of this paper, we first review related literature. Then we discuss the IGT in detail, develop the computational treatment, and summarize the experimental design and the results. These are followed by the discussion and conclusion.

Literature Review

According to Dalgleish (2004), the prefrontal cortex constitutes a primary anatomical locus for animal and human behaviour attributed to emotion. Dalgleish's prefrontal cortex includes the areas (Krawczyk, 2002, pp. 633-635) others have called the VMF (Bechara, 2004) or OFC (Rolls, 2000; Wallis, 2007). This paper uses the term VMF to refer to the area of the prefrontal cortex involved in valuation by emotion. However, some studies prefer the term orbitofrontal cortex, or OFC. This section retains the respective authors' original use of the terms OFC or VMF.

VMF impaired patients, can recognise poor decisions and describe good decision making strategies, but exhibit a distinctive inability to learn from their mistakes (Bechara et al., 1994). In IGT studies, this inability applies to negative (Bechara et al., 1994) and positive rewards (Bechara, Tranel, & Damasio, 2000).

To explain VMF impaired deficits, Damasio (1998) proposes the Somatic Marker Hypothesis: an involuntary feedback mechanism where a physical or virtual body sensation is associated with a particular emotion. VMF impairment disrupts somatic marker pathways, and the affected individual remains in a slow, logic based decision making paradigm (Bechara, 2004; Damasio, 1998, 2006). Others have instead advanced the view that VMF impairment leads to loss of reversal learning ability (Dunn, Dalgleish, & Lawrence, 2006; Maia & McClelland, 2005; Fellows & Farah, 2003, 2005, 2004). Reversal learning ability is the facility to unlearn a stimulus-response-association, which had previously produced favourable emotion-valued outcomes.

The VMF is also associated with emotion (Krawczyk, 2002; Hornak et al., 2003; Rolls, 2000). Modelling emotion in learning and decision making has been challenging (Volz & Hertwig, 2016). Without using emotion, the Rescorla-Wagner classical conditioning model presents a learning rule for assessing the pre and post trial associative strength of a new stimulus (Rescorla & Wagner, 1972). TD(λ) reinforcement learning methods extend the Rescorla-Wagner model and enable intra-trial assessment of an associative stimulus (Sutton & Barto, 2018, pp. 350-357). Contingent stimulus-response animal studies also inspired Q-learning. However, unlike Rescorla-Wagner, Q-learning does not explain the conditioning mechanism, but instead develops a decision theoretic learning framework (Watkins, 1989). Q-learning remains one of the most successful machine learning algorithms, especially as the feedback stage for deep neural networks (Mnih et al., 2015).

Puviani and Rama (2016) propose a complex, neurologically motivated emotion learning framework, which models both the OFC and the Amygdala. However, typically computational emotion synthesis employs more abstract, behaviourally driven approaches based on varied psychological views. Recently, reinforcement learning approaches incorporating emotion have been receiving increased attention. Reinforcement learning can produce lightweight models, has close ties to optimal control, and provides an intuitive approach for aggregating contingent values (Powell, 2011; Sutton & Barto, 2018).

Moerland, Broekens, and Jonker (2018; 2017) identify and survey 52 papers published from 1998 to 2016 relating to emotion and reinforcement learning. They report four common methods for eliciting emotion: homeostatic targets, introspective appraisal, value function or reward modulation, and, sensor or sense driven. Emotions influence rewards, contingencies, modulate the exploitation versus exploration trade-off, and sometimes directly act on action selection. Typically, the value function itself aggregates emotion modulated inputs into an action selection mapping. We believe that emotion modulated reinforcement learning thus aims to encapsulate the functionality of the VMF.

While developing our model, the Moerland et al. (2018; 2017) survey had not yet come out. However, we had considered Broekens, Jacobs, and Jonker (2015), where joy, distress, hope, and fear act as value inputs into TD(0) computational reinforcement learning. In contrast to Moerland et al. (2018; 2017) and Broekens et al. (2015), our model does not need an emotion generation layer. In the context of the discussed models, our model re-interprets the Q-value function as a single aggregated emotion signal. While our learning rate is modulated by another hyper-parameter, the decay factor, we do not synthesize emotions to modulate these hyper-parameters. Instead, we use an external search grid to assess the end-effect of learning rate changes, which we hypothesize might result from VMF impairment.

Our learning rate decay law does not satisfy the well-known statistical convergence requirement that the sum of the learning weights must be infinite (Robbins & Monro, 1951; Spall, 2003). In practice, fully proving theoretical statistical convergence is difficult (Spall, 2003, p. 122), and proof of theoretical convergence does not automatically ascertain good model performance (Powell, 2011, p. 450). Moreover, an individual organism and its decision making mechanisms possess a finite lifespan. Therefore we think it is valid to investigate finite term, periodic decisions with tools where statistical convergence is not theoretically guaranteed. We propose that our method of simulating human behaviour with

learning rate decay could form a useful baseline for generalised reinforcement learning solutions. We focus here on the empirical effect of learning rate decay on decision quality and learning.

The Iowa Gambling Task

The original (Bechara et al., 1994) and re-shuffled (Fellows & Farah, 2005, 2004) Iowa Gambling Task (IGT) variants form the basis of this paper and we explain them here in more detail.

Description

The IGT is a card game where the participant receives a loan, and should maximize profit including repayment of any loans. The card game consists of four decks: A, B, C, and D. The participants are told that "some decks are worse than others." (Bechara et al., 2000, p. 2192) In each turn, the participant draws one card from any deck. For each draw, the participant then receives a fixed reward, and occasionally has to pay a fine. Decks C and D, known as the 'good' decks, give low fixed rewards, low fines, and, on average, yield net gains. The remaining two 'bad' decks, A and B, produce high rewards, but even higher losses, and, on average, produce a net loss.

The game stops after 100 turns, when the dealer announces the end. However, the participant does not know when the game will end. If the participant runs out of money, additional loans are available. The hypothesis is that the participants discover the 'good,' low risk decks and choose accordingly. A score of more than 50 draws from the good decks is defined as a normative pass by Fellows and Farah (2005, 2004).

While the original IGT lasts 100 turns, Bechara et al. (1994) only predefine a 40-draw sequence for each deck. They do not discuss whether any participants drew more than 40 cards from the same deck, and in the provided example draws, human participants do not draw more than 40 cards from the same deck. In our implementation, we use the published 40-draw predefined sequences. However, to ensure that a software agent could potentially draw more than 40 consecutive cards from the same deck, we loop at the end of each deck to the beginning of the deck.

Original and Re-shuffled Card Deck Differences

In the original IGT, the 'bad' decks, A and B, each start with an eight card long 'special' sequence, where the player receives positive net gains. Consequently, at the beginning of the task, the 'bad' decks appear 'good.' However, in each bad deck, the 'special sequence' is immediately followed by one or more high fines, causing the player, on subsequent selections, to lose all gains and move into debt.

In the re-shuffled variant, Fellows and Farah (2005, 2004) move the first 8 cards in each original deck to the end. This removes the initial confounding conditioning sequence, and players experience, across all decks, fines relatively quickly.

The full details of the original and re-shuffled decks can be found in Bechara et al. (1994, p. 9) and Fellows and Farah (2005, 2004, p. 59) respectively.

ε-Greedy Q-Learning with Learning Rate Decay

This section motivates and develops our Q-learning model with learning rate decay.

Computational Background

The IGT constitutes a version of the n-armed bandit problem (Ross, 1983, pp. 131-151): there are four processes, of which only one can be operated at any one time. The software agent devises a policy for gaining information (exploring), for assessing (scoring), and then choosing the most advantageous process (exploiting). Kuleshov and Precup (2000) present various classic computational techniques for scoring, and for balancing exploration versus exploitation. We employ Q-learning because it is simple and permits investigation of learning rates which vary from $1/n$ and its derivatives.

Single State Q-learning

We model the IGT as a single state environment with four card decks and four actions. We do not fully implement Q-learning as proposed by Watkins (1989) where the current contribution to the Q-factors uses off-policy updating. Instead, we apply on-policy value function updates as suggested by Sutton and Barto (2018, p. 32).

Given an action a, let $Q(a)$ be an unknown value function, and let $Q_n(a)$ denote the n^{th} iterative approximation. Then we write the computational estimation problem as:

$$Q_n(a) = \alpha_n r_n^a + (1-\alpha_n)\gamma Q_{n-1}(a) \tag{1}$$

where $r_n^a = reward_n^a - fine_n^a$ is the net reward for action a at iteration n , γ is the discount rate, and α_n is the learning rate at iteration n. The discount rate γ, when set to less than 1, is used to devalue future yields r_n^a. We assume that the length of the card game, although unknown, is not long enough to create a preference for present rewards. Consequently, we set $\gamma = 1$.

Learning Rate Decay

A rapidly decaying learning rate sequence, $\{\alpha_n\}$, can get close to 0 prior to some final period T and effectively curtail learning. We consider a geometric-decay learning rate sequence of the form (Powell, 2011, pp. 427):

$$\alpha_n = \Lambda\alpha_{n-1} \tag{2a}$$

$$\Lambda = 2^{-\lambda/ln2} \tag{2b}$$

where $\lambda \in [0,\infty)$ is the *decay factor*, and $ln2$ is a normalizing constant used to rescale to natural logarithms in the computations.

Given equation (2b), $\{\alpha\}_n$ only satisfies the theoretical statistical convergence requirement $\sum_n \alpha_n = \infty$ (Powell, 2011, pp. 274-285), when $\lambda = 0$.

However, equations (2a) and (2b) always guarantee, in a finite number of iterations, computational convergence in the sense of $|Q_n - Q_{n-1}| < \varepsilon$ for some $n \ll \infty$ and $\varepsilon > 0$. In practice, our approach produces good approximations to normal as well as VMF impaired behaviour.

Table 1: Methodology, Simulation Parameter Summary

Trials, N	2000
Initial Learning Rate, α_1	0.05 to 1 by 0.05 steps
*Decay Factor, λ	$\lambda_i = \lambda_{max} 2^{-ir/ln2}$
ε-Greediness, ε	0.00 to 0.50 by 0.10 steps

*With $\lambda_{max} = 3.3765$, $r = 0.012$, $i = 0, 1, 2, ...$

Table 2: Original IGT Test, Pixel Match Computed Means $\pm$ SE for Fraction of Cards Chosen from the Good Decks reported in the IGT Literature

Subjects	Study	N	Mean fraction of good decks
Controls	Bechara et al. (1994)	44	0.69 ± 0.015
	Bechara et al. (1998)	21	0.62 ± 0.032
	Bechara et al. (2000)*	20	0.59 ± 0.019
	Farah et al. (2004)	14	0.63 ± 0.023
VMF Impaired	Bechara et al. (1994)	6	0.37 ± 0.055
	Bechara et al. (1998)	9	0.40 ± 0.035

	Farah et al. (2004)	9	0.50 ± 0.020

*Results reported in 20 draw blocks. Calculation of 100 draw values assume no inter-block covariance.

The ε-Greedy Agent

For most of the time, the ε-Greedy agent exhibits unconstrained maximizing behaviour, and at any iteration n, picks the deck with the highest attributed value:

$$Q_n^* = \max_a Q_n(a),\ a \in \{A, B, C, D\} \tag{3}$$

To ensure exploration, occasionally the ε-Greedy agent chooses an action randomly. Consequently, the agent's decision making rule is:

$$Q_{n,\varepsilon}^* = \begin{cases} Q_n^*, & \text{with probability } 1-\varepsilon, \\ \text{choose } a \text{ randomly} & \text{with probability } \varepsilon \end{cases} \tag{4}$$

where $\varepsilon \in [0, 1]$ indicates the probability of exploration.

Experimental Design and Results

Simulations consist of multiple trials of 100 draws. All cross-section comparisons are conducted at the 100^{th} draw, which corresponds to the duration of the clinical tasks. Table 1 summarizes the parameter values used in this paper. We assess the parameter space with brute-force, grid-based searches.

As the original test data (Bechara et al., 1994, 2000; Fellows & Farah, 2005, 2004; Bechara, Damasio, Tranel, & Anderson, 1998) was not available, we converted the graphical presentations into numerical format using pixel matching. For each study, Tables 2 and 3 summarize, for normal and VMF impaired subjects, the pixel match calculated original and re-shuffled IGT test results respectively, reported in terms of the fraction of cards chosen from the good decks.

Table 3: Re-shuffled IGT Test, Pixel Match Computed Means $\pm$ SE for Fraction of Cards Chosen from the Good Decks reported in the IGT Literature

Subjects	Study	N	Mean fraction of good decks
Controls	Farah et al. (2004)	17	0.72 ± 0.038
VMF Impaired	Farah et al. (2004)	9	0.67 ± 0.078

Table 4: Original and Re-shuffled IGT Mean Fraction Good Deck Ranges Used for Comparing ε-Greedy Agent and Literature Results

IGT Variant	Original	Re-shuffled
Pixel matched studies Comparison Rule	4 Table 2 Minimum and Maximum	1 Table 3 $\pm$ 2 SEs
Normal Match Range	0.59 to 0.69	0.64 to 0.80
VMF Impaired Match Range	0.37 to 0.50	0.51 to 0.83

Table 4 shows the pixel matched ranges of fraction of good decks we derived from IGT literature results and use to compare to the ε-Greedy agent results.

Results

We found that, given appropriate standard values for initial learning rate and exploration, learning rate decay λ proves to be the key variable, which determines the ε-Greedy agent's degree of success. We first present the results obtained from learning rate decay and exploration variations, and then discuss the effects of the initial learning rate.

The Effects of Learning Rate Decay and Exploration Fig. 2 shows, given exploration, the strong effect of learning rate decay on mean fraction of good decks. For the original IGT, as the decay factor increases, the mean fraction good decks achieved by the agent decreases; and, eventually approaches a value close to or below 0.5, the IGT fail criterion. But for the re-shuffled IGT, as the decay factor increases, mean fraction of good decks scores remain above 0.5.

Figure 2 also shows that for the original and re-shuffled decks, at $\varepsilon = 0.40$, the ε-Greedy agent matches actual IGT test subject behaviours: control subject behaviour is matched at a learning rate decay factor of $\lambda = 0.16$ (15% per period learning rate decay), and VMF impaired subject behaviour is matched at $\lambda = 0.56$ (43% decay).

$\varepsilon = 0.40$ constitutes the first exploration value at which we obtain a match for healthy and VMF impaired human performance zones. Further match candidates exist for $\varepsilon =$

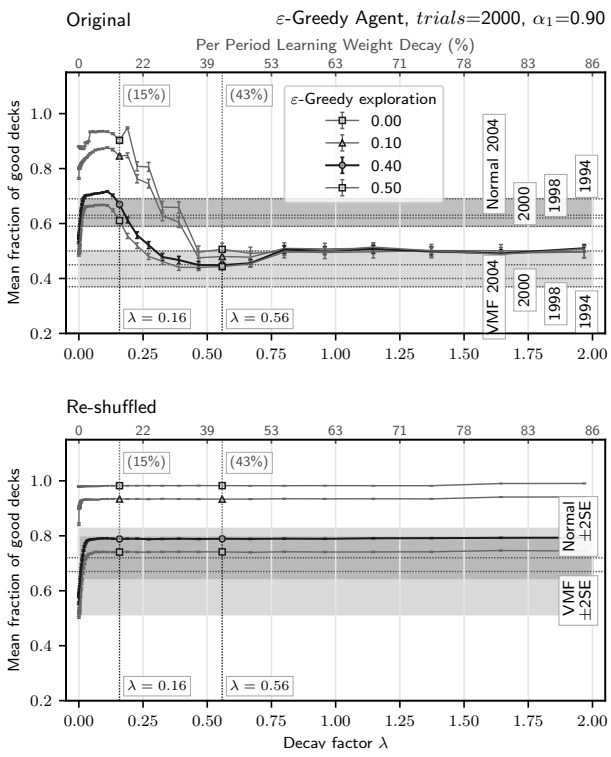

Figure 2: Learning rate decay and ε-Greedy agent IGT performance. Dark lines approximate human IGT behaviour. With high exploration, for the Original IGT, at the lower decay factor, the agent matches control subject performance; and, at the higher decay factor, the agent matches VMF impaired subject results. With high exploration, for the re-shuffled IGT, at the lower and higher decay factors, the agent matches human subject performance.

$0.40 - 0.50$, where the values of the agent's mean fraction of good decks are inside the match ranges for the corresponding values reported in the literature for human subjects.

At $\varepsilon = 0.50$, the agent explores 50% of the time. 50% exploration seems high. However, it constitutes a targeted strategy, for example, compared to always choosing lottery numbers randomly. We can also see that agents, which do not explore at all ($\varepsilon = 0.0$), or explore just a little ($\varepsilon = 0.10$), substantially exceed human performance. We discuss this result later.

Table 3 shows that the re-shuffled deck VMF impaired match range is derived from a single study with 9 participants. In Fellows and Farah (2005, 2004, p. 60, Figure 4), VMF impaired subject performance includes a high performace cluster of 3 subjects with a pixel matched cluster mean of 0.95. These 3 VMF impaired subjects achieve a re-shuffled deck test result approximated by the performance of our ε=0.10 agent, which achieves across all decay factors a mean fraction of good decks score of 0.92.

Having only a single re-shuffled deck study makes interpreting the statistical context of this high performance cluster difficult. Therefore in Table 4, we construct re-shuffled deck VMF performance match ranges using ± 2 standard errors, which produces approximately a 92% confidence interval (two-sided p-value: 0.080516). Our match range can be interpreted as the smallest match range based on the availability of a single study.

With re-shuffled decks, the decay factor λ influences the mean fraction of good decks by very little. This result appears to be driven by card sequencing. To test the effect of card sequencing, we created a new deck environment, where cards are drawn randomly, without replacement, from the original IGT decks. This new random draw card environment produces plots, which display a pattern similar to that of the original decks in Figure 2, except that as the decay factor increases, mean fraction of good decks decreases towards but remains above 0.5. Therefore relative to randomly ordered decks, both the original and re-shuffled decks create sequencing biases, which put different demands on learning: the original decks tax re-learning, while the re-shuffled decks teach via 'early punishment.' It would be interesting to test whether both normal and VMF impaired subjects pass the random draw version of the IGT as predicted by our simulation.

Finally, increasing exploration leads to a steady downward shift of the mean fraction of good decks plots with little effect on contour shaping. In contrast, learning rate decay λ appears key for determining agent behaviour; and increasing learning rate decay approximates the behaviour of normal and VMF impaired IGT participants.

The Effects of the Initial Learning Rate Unlike learning rate decay, the initial learning rate α_1, like exploration, only has a mild effect on the mean fraction of good decks.

Figure 3 shows the effect of the initial learning rate α_1 on mean fraction good decks at the 100th draw for the ε-Greedy agent with $\varepsilon = 0.40$. For the the original and re-shuffled decks, mean fraction of good decks scores vary little along the initial learning rate axis. In contrast, increasing learning rate decay leads to normative IGT fail (i.e., mean fraction of good decks ≤ 0.50) for the original decks; but not for the re-shuffled decks, thereby inducing agent behaviour to match human trial performance.

Discussion

In our Q-learning IGT simulations, learning rate decay λ constitutes a critical parameter. Increasing learning rate decay generates the observed behaviour of human IGT participants. For low learning decay factors, the ε-Greedy agent passes both the original and re-shuffled IGT. As we increase the learning decay factor, the agent fails the original test, while continuing to pass the re-shuffled variant. Therefore, increasing the decay factor leads to the learning behaviour of VMF impaired IGT participants.

In reinforcement learning, the software agent's internal valuation produces action selection. Rolls and others have ar-

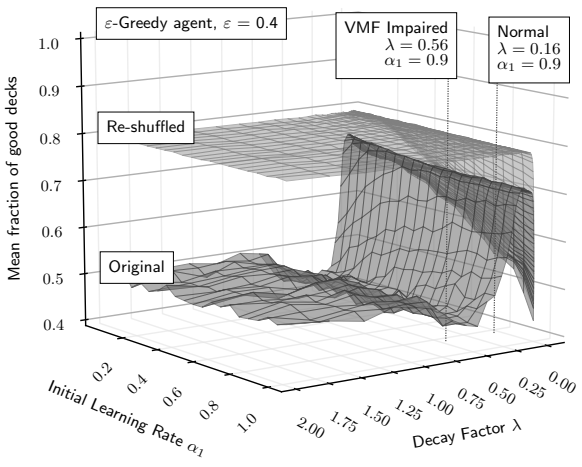

Figure 3: ε-Greedy agent with $\varepsilon = 0.40$: fraction of good decks by initial learning rate α_1, and decay factor λ. Initial learning rate α_1 variations exert a mild influence, while learning rate decay λ variations exert a strong influence on mean fraction of good decks. Normal and VMF impaired match values are marked accordingly for $\varepsilon = 0.40$.

gued that emotions result from reward assessment in the VMF (Krawczyk, 2002; Hornak et al., 2003; Rolls, 2000, 2013). We draw parallels between VMF provided reward values and the reinforcement learning process. The Q-value function encapsulates reward information. Learning rate decay λ can elicit progressive decay in current reward contribution. If learning rate decay is very high, then current reward value contribution decreases rapidly, and this leads to quick computational convergence. This effect produces two impediments, which may mimic VMF impairment: the value function not only 'finalises' too quickly, but also is itself dominated disproportionately by initial experiences.

Consequently with high learning rate decay, early and high 'bad' deck payoffs in the original IGT produce an incorrectly learned policy response: the 'bad' decks appear to be good. The ε-Greedy agent's beliefs, once established, even when presented with current information to the contrary, can no longer be modified. If emotion impairment due to VMF lesions removes the ability to unlearn previously learned responses, then in reinforcement learning, this behavioural effect can be achieved via high learning rate decay.

Conclusion

Bechara et al. (1994, in title) state that VMF impaired patients suffer from an "insensitivity to future consequences." Our simulated VMF impaired original IGT results suggest that this insensitivity comes from remaining mired in the past, and appears consistent with loss of the ability to reverse learning.

Interestingly, at lower exploration values, the ε-Greedy agent achieves mean fractions of good decks that are better than those achieved by human subjects. To match actual test subject behaviours, exploration has to be set at a high level.

It is not clear why agent behaviour, while qualitatively mirroring human behaviour, achieves better than human results. A number of possibilities could explain this finding. A reformulated model with decaying ε-Greediness may provide additional insight into the exploration versus exploitation tradeoff. Human behaviour may initially have higher exploration, which then progressively decreases with learning. In this paper, to keep the parameter count low, to avoid over-fitting, and to focus on the decay factor λ, we have not added any additional parameters for modelling variable exploration.

Alternatively, given the lack of full-knowledge, human behaviour may be more cautious. Human level learning has evolved for a wide variety of tasks, and therefore may perform optimally at other tasks for which Q-learning is less well suited. In contrast, grid search allows the searcher to become all-knowing with respect to the parameter space. For humans with incomplete information, keeping exploration high may make sense, just in case a deck would produce some unexpected yields later in the task.

Finally, it is also possible that the calculations performed by reinforcement learning agents are too hard for mental arithmetic and that the lack of precise calculations leads to sub-optimal decisions.

In a psycho-evolutionary context, emotions provide a flexible mechanism for establishing homoeostatis under environmental uncertainty (Plutchik, 2003; Rolls, 2013). If this environmental uncertainty fulfils certain regularity conditions, such as distributional full, or bounded, time-invariance, existence of the mean, or high-yield state correlation, then there could be high survival value to speculative learning; that is, deriving a working decision policy from just a few samples. From short learning bursts, the organism, or agent, could converge, to a long-term optimal decision rule. Emotions (via learning rate decay) could be responsible for opening and closing a short learning window. It is possible that the VMF driven emotion mechanism has evolved to produce the ability for organisms to learn efficiently from just a few samples.

Humans have evolved as generalised decision learners. In many machine learning tasks, only a narrow range of hyperparameter values produce a coherent result. Therefore the addition of a learning decay factor, which mimics human learning could provide an ideal starting point over a number of tasks for computational learning. Overall, our results indicate that computational reinforcement learning may be used as the basis for modelling emotion based learning. The results are encouraging for further investigation into more complex forms of learning and emotions.

Abstract

The adoption of conversational agents is growing at a rapid pace. Agents however, are not optimised to simulate key social aspects of situated human conversational environments. Humans are intellectually biased towards social activity when facing more anthropomorphic agents or when presented with subtle social cues. In this work, we explore the effects of simulating anthropomorphism and social eye-gaze in three conversational agents. We tested whether subjects' visual attention would be similar to agents in different forms of embodiment and social eye-gaze. In a within-subject situated interaction study (N=30), we asked subjects to engage in task-oriented dialogue with a smart speaker and two variations of a social robot. We observed shifting of interactive behaviour by human users, as shown in differences in behavioural and objective measures. With a trade-off in task performance, social facilitation is higher with more anthropomorphic social agents when performing the same task.

Keywords: human-computer interaction, social agents, conversational artificial intelligence, smart speakers, social robots

Introduction

With conversational AI and domestic technology on the rise, several questions remain open on how humans engage with interactive agents when in different forms of embodiment and social behaviour. A wide range of interaction modalities has been researched for agents, that come in various forms such as smart speakers (Alam, Reaz, & Ali, 2012), and social robots (Breazeal, Dautenhahn, & Kanda, 2016). However, by design, social robots provide additional modes of pragmatic communication. Social robots can express their internal state using not only speech but also non-verbal behaviour. By generating multimodal communicative behaviours (Breazeal & Fitzpatrick, 2000; Mizoguchi, Sato, Takagi, Nakao, & Hatamura, 1997), social robots enable different manifestations of interaction similar to how humans interact with each other (Shibata, Tashima, & Tanie, 1999).

In the fields of human-computer interaction and human-robot interaction, anthropomorphism is often leveraged as a way to make machines more comfortable to use. The additional comfort comes from ascribing human features to machines with the aim to simplify the complexity of technology (Marakas, Johnson, & Palmer, 2000; Moon & Nass, 1996). While interactions between humans include many subtle social cues that we take for granted, 'face-to-face' interactions are still considered to be the gold standard of communication when interacting with either humans or conversational agents (Adalgeirsson & Breazeal, 2010). Therefore, agents need to employ anthropomorphic designs and a rich set of social behaviours to be considered as socially intelligent partners in interactions.

Figure 1: Situated interaction with a human-like social robot.

Many social robots do employ these elements, especially the ones with a human-like design, and provide the possibility of generating non-verbal social behaviours in their interactions with humans (Fong, Nourbakhsh, & Dautenhahn, 2003). Many of these behavioural elements are subtle social cues (e.g. gaze shifts and facial expressions), that are highly important for situated human conversational environments. One reason why face-to-face interaction is preferred is that a lot of familiar information is encoded in the non-verbal cues that are being exchanged. However, generating and interpreting these cues, induces higher levels of cognitive load (Torta, Oberzaucher, Werner, Cuijpers, & Juola, 2013) and may therefore increase interaction time. This suggests that human-like conversational agents that can express patterned non-verbal behaviours can cause social facilitation in users, but may be less efficient in task performance.

In this paper we contribute to this emerging field with a two-fold empirical evaluation of the elements of: 1) *anthropomorphic design* and 2) *non-verbal social behaviour* in conversational agents. We study whether a human-like face (i.e. a social robot), capable of displaying non-verbal cues, shifts interactive behaviour in comparison to a voice-only conversational agent (i.e. a smart speaker), that does not employ these multimodal features. Our contribution consists of a user study that was conducted with participants interacting with a smart speaker and a social robot collaborating in dialogue. To comprehend the effects of the comparison further, we test whether it is the anthropomorphic face or the social eye-gaze features that contribute to the perceived differences and remove the non-verbal behaviour of the social robot in a third condition.

The aim of the study was therefore to investigate the following research question:

- What are the effects in human behaviour when simulating anthropomorphism and social eye-gaze in conversational agents?

Related work

Conversational agents have become ubiquitous, and they are embedded in various forms and embodiments, from smart phones to voice-based smart speakers such as Amazon Echo and Google Home. There seems to be an interest in literature on how different representations of physical embodiment and anthropomorphic features affect the perception of social presence and facilitation in agents. Studies have compared agents in digital screens to social robots (Torta et al., 2013; Kidd & Breazeal, 2008) and have shown that anthropomorphic agents that are physically co-located are generally preferred and perceived to be more socially present than their virtually embodied versions (Kennedy, Baxter, & Belpaeme, 2015; Lee, Jung, Kim, & Kim, 2006; Kidd & Breazeal, 2004; Bainbridge, Hart, Kim, & Scassellati, 2008; Koda & Ishioh, 2018; Jung & Lee, 2004; Thellman, Silvervarg, Gulz, & Ziemke, 2016), or remote video representations of the same agents (Powers, Kiesler, Fussell, Fussell, & Torrey, 2007; Wainer, Feil-Seifer, Shell, & Mataric, 2006). Other studies have shown that social robots' perceived situation awareness is higher (Luria, Hoffman, & Zuckerman, 2017), and by adding non-verbal cues, the same agent is perceived more socially present (Pereira, Prada, & Paiva, 2014; Goble & Edwards, 2018).

Anthropomorphic agents take advantage of design elements afforded in their shape and movements (Gomez, Szapiro, Galindo, & Nakamura, 2018). Social robots in particular, raise expectations on how sophisticated they are in their actions and how socially intelligent they are perceived. A very human-like agent will make humans expect a higher degree of interaction and *social facilitation*, which is essential when designing the physical appearance of a social agent. However, it is not just the physical embodiment of the robot that has implications on its perceived social presence, but the behaviour and actions of the robot as well (Straub, 2016).

Socially interactive agents that make use of social behaviour features promise an opportunity to bring social values into computing and help coordination between humans and machines by taking advantage of their social cues and intentions (Dourish, 2004). While conversational interfaces manifest intent recognition using language and dialogue, social robots as embodied interfaces, communicate intentions with the use of multimodal cues, and additionally encourage users to anticipate joint actions and shared intent in the same physical space (Luria et al., 2017).

Non-verbal behaviour is used for communication and social coordination. The more human-like the agents' responses, the more they are attributed as social actors (Nass & Steuer, 1993). Social eye-gaze in particular, refers to the communicative cues of eye contact between humans and is classified to 4 main archetypes (Admoni & Scassellati, 2017): 1) *Mutual gaze* where interlocutors attention is directed at each other, 2) *Joint attention* where interlocutor's focus their attention on the same object, 3) *Referential gaze* which is directed to an object and often comes with referring language, and 4) *Gaze aversions* that typically avert from the main direction of gaze -i.e. the interlocutors face.

(a) Smart Speaker (b) Social Robot

Figure 2: The conversational agents used in the study.

The current work differs and in part extends the discussed studies. First, we simulate both anthropomorphism and non-verbal behaviour in the same study, and second we apply the comparison in only physically present voice-based agents, where we discuss the implications of *social eye-gaze* against *task performance*. Is a human-like face sufficient to cause social facilitation or is non-verbal social behaviour also needed when interacting with conversational agents?

Method

In order to investigate the impact of anthropomorphism and social eye-gaze in this study, we chose three conversational agents and a human trial. All agents engaged in human-agent interaction using the same dialogue policy and simulated situation awareness of human actions (Figure 1).

Experimental conditions

1. The *Human Agent (H)*. In order to avoid any misunderstandings on the task and the subjects' role, we began the interactions with a control trial with a human instructor. That way, subjects got familiar with the task and we were able to reduce the learning curve.

2. The *Smart Speaker (SS)* is an embodied conversational agent (Figure 2a) that can only interact with speech. We used a first generation Amazon Echo smart speaker, which was connected via Bluetooth and a Text-to-speech (TTS) service similar to the default Echo TTS was selected to send pre-scripted voice commands.

3. The *AnthropoMorphic Robot (AMR)* is an embodied conversational agent (Figure 2b) in the form of a robotic head with a human-like face, that as the SS uses only speech to interact and no other modalities. We used a back-projected human-like robotic head with three degrees of freedom called

Furhat. The robot was stationary and did not use any head movements, but statically looked at the subject. The robot had a TTS of equivalent quality to Echo, speaking the same pre-scripted utterances. The reason for choosing a robotic head instead of a full-body embodied robot is that it limits the modalities of communication, making it easier to control for comparison to a smart speaker.

4. The *AnthropoMorphic Social Robot (AMSR)* is the same robotic head as AMR that also uses voice for interaction and additionally generates a set of social eye-gaze behaviours using head movement. These included task-based functional behaviours such as gazing to the ingredient during a referring expression and a turn-taking gaze mechanism.

Hypotheses

Towards answering the research question defined above, we posed the following hypotheses:

- ☐ **H1.** We expected that a robot with non-verbal social behaviour will be perceived to be more socially present (Pereira et al., 2014). *The AMSR will cause more social facilitation with human users than the SS and the AMR.*
- ☐ **H2.** While non-vebal behaviour should cause more social facilitation, a human-like design without non-verbal cues should not induce the same differences. *Differences in social facilitation will not apply between the SS and AMR.*
- ☐ **H3.** *There will not be any difference in task performance across the agents.*
- ☐ **H4.** As a conversational partner, *the AMSR will generally be preferred for the task.*

Experimental design

A within-subject design was used in a study (Kontogiorgos, Pereira, Andersson, et al., 2019) where participants interacted with all four agents. To test our hypotheses, we manipulated two independent variables [*embodiment* and *social eye-gaze*], in three conditions [*Smart Speaker (SS)*, *AntropoMorphic Robot (AMR)*, *AntropoMorphic Social Robot (AMSR)*], presented in different orders to participants using a Latin Square, and a *human trial* that was always first.

Task

We asked subjects to cook 4 variations of fresh spring rolls without providing the recipes; they had to find out the recipes while interacting with the agents. Different varieties of ingredients and amounts were used. The setup also included ingredients not used in any of the recipes, encouraging participants to interact with the agents to find out the correct ingredients for each recipe. The task was the same in each condition, but different recipes were used (varied across conditions).

To ensure participants would engage with the agents more, they were told that if they followed the recipe with the correct ingredients and amounts, they would take the food with them at the end of the experiment. Counting the time participants took to cook the recipe served as a measure of the time they spent engaging with each agent. We had a total of 20 ingredients and a recipe typically included 7 ingredients to prepare.

All agents used a combination of nouns, adjectives and spatial indexicals as linguistic indicators to identify ingredients on the table, "The *cucumber* is the *green* thing *on the right*". AMSR however, also gazed at the referent ingredients (typically 0.5s prior to the reference). The agent's role in the task was therefore to instruct and the subject's role was to assemble the ingredients together.

Dialogue policy

All agents followed the same dialogue policy and interaction protocol, which was defined upon a set of *dialogue acts* within the action space of the interaction (Kontogiorgos, Pereira, & Gustafson, 2019). Given a human action or utterance, an appropriate response was selected from the dialogue policy. Driven by the possible set of actions, agent utterances are aggregated to higher level *dialogue acts* that describe the current state of the conversation. The dialogue acts model user actions, user utterances and any changes in the environment. An example dialogue:

USER : [FINISHED ACTION] What's next?
AGENT : [INSTRUCTION] Next, take three pieces of lettuce and put it in the spring roll.
USER : [CLARIFICATION-Q] Where is the lettuce?
AGENT : [CLARIFICATION-A] The lettuce is the green thing in the middle.
USER : [STARTED ACTION] Uh, yes!

To dismiss potential problems in speech recognition and language understanding, we used a human wizard (WoZ) to control the behaviours of the agents in timings and decision making. The social behaviours were designed to maintain a socially contingent interaction with the subjects, and in order to keep the dialogues between the subjects and the agents consistent for comparison across conditions. The human wizard had to select the appropriate agent response, triggered only by the state of the environment and user actions. The wizard application and dialogue acts were the same across all conditions. For every dialogue act, a set of predefined utterances was available, that the system would choose at random to generate, given the current dialogue act. The wizard therefore indicated only the current dialogue act in conversation.

Gaze for facilitating turn-taking

Gaze has been shown to be important for regulating conversational turn-taking, as people look towards the listener at the end of their utterances to indicate they have finished their turn (Kendon, 1967). Employing such a behaviour in agents, leads to human-like conversational turn-taking where each participant waits for the speaker's utterance before taking an action (Skantze, Hjalmarsson, & Oertel, 2014). In order to facilitate natural turn-taking mechanisms from the agent, we defined a heuristic gaze model on timings for turn-taking gaze and referential gaze to objects.

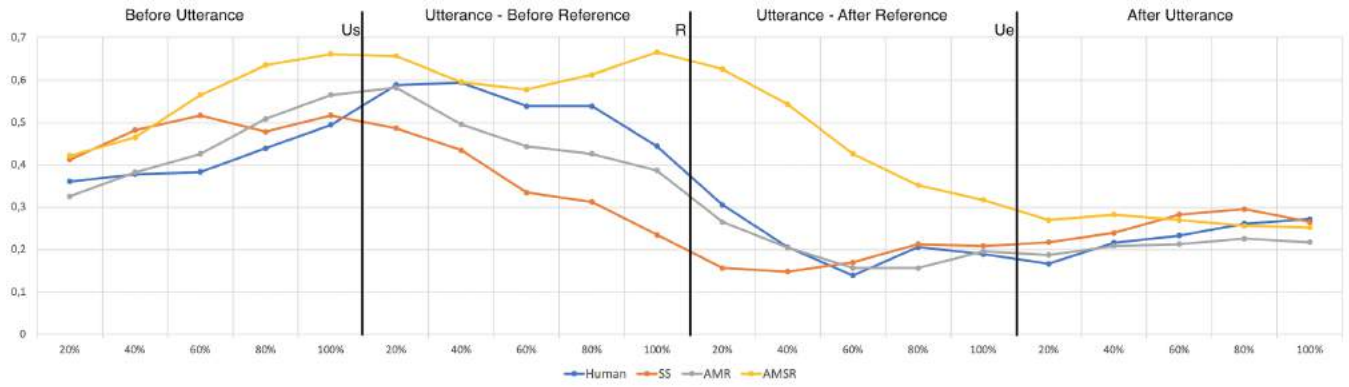

Figure 3: Gaze proportion to the agent during an agent instruction. Each phase of the instruction is normalised in time: Before the utterance - During the Utterance and before the reference - During the utterance and after the reference - After the utterance. The x axis shows the relative time of the instruction and the y axis the eye-gaze proportion across all participants per condition.

The AMSR agent engaged in *mutual gaze* and *joint attention* with the subjects during the interactions. Before an utterance, the agent made a gaze shift to the subject to establish attention, followed by deictic gaze to a referent object indicating it is keeping the floor, and at the end of the utterance a gaze shift back at the subject to establish the end of the turn and pass the floor to the subject. The agent gazed at referent objects right before they were mentioned (500ms before).

Experimental procedure

Participation in the study was individual and the experiment was divided in 3 phases. First, participants filled a demographics questionnaire and then cooked the first recipe with a human instructor. In the second phase, they cooked a recipe with the help of an agent. They repeated that phase 3 times with a new agent every time (counter-balanced). In the third phase, participants filled an exit questionnaire. During the agent trials, participants were alone in the room, and a human wizard was monitoring their actions using a ceiling camera with a live feed of the room (Figure 1). Participants were not told that the agents were controlled by a human wizard.

The human instructor throughout the trial was kept the same for all subjects, and followed the same behaviour and dialogue policy as the agents. The subjects stood in front of a table, with a cutting board and ingredients prepared and laid out in front of them. The agents were situated on the sides of the table, with only the agent relevant to the task visible.

Participants

Participants were compensated with a cinema ticket and the food they cooked during the study. We recruited 30 participants (18 female and 12 male) with ages in range 19-42 and mean 24.2 (stdev=5). The experiment was in English, and all participants were fluent (mean 5.8, stdev=0.7). 17 had interacted with a robot before and 20 had interacted with smart speaker. 13 had interacted with both a smart speaker and a robot before, while 6 with none of the two. Overall, their experience with digital technology was 4.8 (stdev=1.6) and their cooking skills were 5.0 (stdev=1.2). 24 had never cooked spring rolls recipes before. All scales above are 1-7.

Results

We present the main findings along two main themes: a) *visual attention*, and b) *interaction time*. Repeated measures analyses of variance (ANOVA) and post-hoc tests with Bonferroni corrections were carried out to test statistical differences across conditions. We report the behavioural and objective measures on visual attention during the agent utterances, interaction times (Table 2), and finally, notable insights from qualitative data.

Visual attention

Using motion capture, we detected subjects' head pose over time and measuring their visual angle (Kontogiorgos et al., 2018), we extracted proportional eye-gaze to the agent and the task table during different phases of the robot's utterances: a) before the robot speaks an utterance, b) during the utterance right before a reference to an object is uttered, c) during an utterance right after the reference has occured, and d) after the utterance. The four phases of proportional eye-gaze to the agent are presented in figure 3. Before and after the utterance phases are in 2 second intervals.

Each phase is first normalised per subject to reduce subject variability and then, each phase interval mean is used for comparison (Table 1). It is important to note that while agent conditions were counter-balanced in order, the human trial was always first to get familiar with the task.

Eye-gaze to the agent before the utterance. A repeated measures ANOVA to test the effect of gaze before the robot instruction showed a significant main effect, Wilks' Lambda = .674, $F(3,27) = 4.35$, $p = .013$). Post-hoc tests with a Bonferroni correction, and p value adjusted for multiple comparisons, revealed that gaze towards AMSR is statistically different than gaze to the AMR condition (p=.022) and to the Human trial (p=.029). No other statistical differences were found in pairwise comparisons.

	Human Trial		SS		AMR		AMSR	
	Mean	*SD*	*Mean*	*SD*	*Mean*	*SD*	*Mean*	*SD*
Before Utterance	.4008	.1822	.4740	.2083	.4476	.2083	**.5472**	.2028
During Utterance (Before Reference)	.5402	.2131	**.3609**	.2321	.4659	.2057	**.6239**	.2114
During Utterance (After Reference)	.2119	.1749	.1836	.1605	.2006	.1320	**.4514**	.1851
After Utterance	.2273	.1570	.2524	.1372	.2072	.1301	.2599	.1633

Table 1: Mean eye-gaze to agent in different phases of the agent utterances. Each phase is normalised per subject and each phase interval mean is used for comparison.

	SS	AMR	AMSR
Task time (sec)	212.6 ± 7.93	217.2 ± 7.75	232.9 ± 8.52

Table 2: Interaction time in seconds: Each cell shows mean and standard error of the mean.

Eye-gaze to the agent during utterance (before the reference). A repeated measures ANOVA on the gaze before the reference showed a significant main effect, Wilks' Lambda = .483, F(3,27) = 9.65, $p < .001$). Post-hoc tests with a Bonferroni correction and p value adjusted for multiple comparisons revealed that gaze towards AMSR is statistically different than gaze to SS ($p<.001$) and AMR (p=.001). SS was also different than the Human trial (p=.022). No other statistical differences were found in pairwise comparisons between the rest of the conditions.

Eye-gaze to the agent during utterance (after the reference). A repeated measures ANOVA on the gaze after the reference revealed a significant main effect, Wilks' Lambda = .316, F(3,27) = 19.49, $p < .001$). Post-hoc tests with a Bonferroni correction and p value adjusted for multiple comparisons showed that gaze towards AMSR is statistically different than gaze to all other conditions ($p<.001$) and to the Human trial ($p<.001$). Here as well, no other statistical differences were found in pairwise comparisons between the rest of the conditions.

Eye-gaze to the agent after the utterance. A repeated measures ANOVA on the gaze after the robot instruction showed no statistically significant difference across conditions, Wilks' Lambda = .859, F(3,27) = 1.47, p = .244).

Interaction time

As indicators to task performance we measured *task time* (time from first to last agent action). We tested for comparison in time within the sequence of the conditions, and no statistical difference was found, meaning the condition sequence did not affect task performance (subjects were not significantly faster in the last trial). When compared across conditions however, a repeated measures ANOVA revealed a significant main effect, Wilks' Lambda = .739, F(2,28) = 4.94, p = .014). Post-hoc tests with a Bonferroni correction and p value adjusted for multiple comparisons showed a significant effect between AMSR to SS (p=.041) and AMR (p=.023) but there was no evidence of a difference between SS and AMR (Table 2).

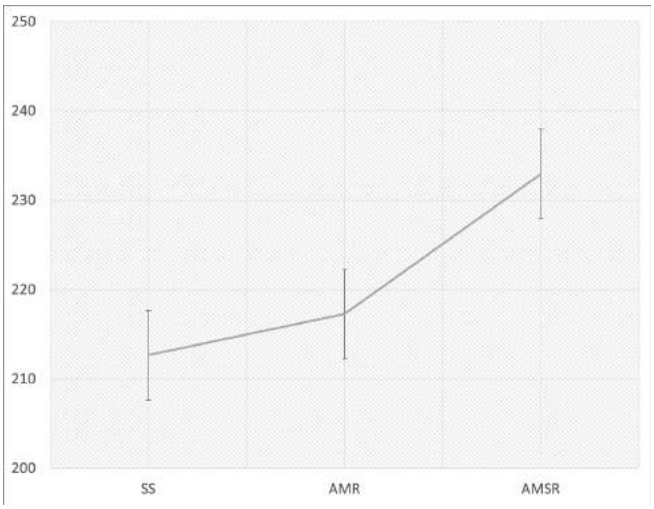

Figure 4: Mean *interaction time* per condition. Error bars indicate standard error of the mean (n = 30).

Qualitative data

The post-experimental questionnaire included asking participants to choose their preferred agent for the task and questions to elaborate on the preference. Participants were also asked to identify the differences of the three agents to understand if they are aware of what is tested in the experiment.

Perceived differences between agents. Out of the 30 participants, 18 replied this question. While the differences in the agent embodiment were obvious between [SS] and [AMR/AMSR], 66% of the participants did not notice a difference between [AMR] and [AMSR]. Asking participants further, we found they identified that there was head movement from the social robots, but were not aware that only one of them [AMSR] employed that behaviour.

Preferred agent. 69% of the participants preferred AMSR, while 24% preferred AMR and 7% preferred SS (χ^2 = 17.862, $p < .001$). Looking further at the participants who did not notice a difference between AMR and AMSR, 2/3 chose AMSR as the preferred robot for the task. However, from 1/3 of the participants who identified the difference in gaze, therefore less sensitive to our manipulation, all preferred AMSR.

Discussion

In an experiment with human subjects, we found a lack of positive effects in task performance on interactions with anthropomorphic social agents. Nonetheless, our findings show a higher degree of social facilitation in conversation with AMSR, as determined by subjects' visual attention and agent preference. Our strongest finding therefore is a trade-off between interaction time and social facilitation.

Anthropomorphism

The agents we compared represent different levels of embodiment in conversational agents. The most preferred agent for

the task had an anthropomorphic embodiment and a set of social eye-gaze behaviours. While AMSR was preferred, task time was increased by 10% with this agent in comparison to the less anthropomorphic in physical embodiment SS. We saw that participants looked at AMSR longer after the referent word was uttered and started following up on the agent's instruction close to the end of its turn. Intuitively, a turn-taking gaze mechanism invokes subjects a greater feeling of social facilitation, assuming they attribute that agent the role of a more socially present partner in conversation.

Non-verbal social behaviour

AMSR has joint attention afforded as an embodied phenomenon in its actions. Eye-gaze here is attributed as a social function where it regulates turn-taking, closer to how humans do when they interact with each other. AMSR therefore gave the impression that it is aware of the situatedness of the task.

In cases, it is possible the user may be distracted from the task through agent social behaviour because more attention is required to the agent's behaviour. While face-to-face collaboration is favourable due to its natural mediated channels of communication, interpreting social cues and maintaining attention is a timely and cognitively demanding process.

Social behaviour and task performance

Social behaviour is timely and counter-intuitive to task performance with more attentive agents. Nevertheless, task performance is certainly dependent on the nature of the task; in more task-oriented domains, such as emergency management, interactions may be more efficiency-prone. A human user may want to get the task done as quickly as possible, and get frustrated when having to interact longer than necessary. However, other tasks such as in the home-care domain are very dependent on social cues and interaction value.

As mentioned, referring expressions to objects did not contain any ambiguities in language (i.e. "this one here"). Therefore gaze from AMSR did not add value to task success but was attributed to a social function, as humans typically gaze at objects before mentioning them in language. Our purpose in the gaze condition (AMSR) was therefore not to increase task performance but to observe the social functions of gaze behaviour across agents.

We were able to verify hypothesis **[H1]**, that AMSR will cause social facilitation, as shown in the visual attention and preference dimensions, however with the cost of task performance. We did verify **[H2]** in the assumption that SS and AMR will not be different in social facilitation. In fact, a human-like design is not enough to establish rapport with human users; human-like behaviour may be expected too, when more anthropomorphic designs are manifested. The results also suggest that smart speakers, while embodied, do not facilitate the same turn-taking mechanisms as social robots do, likely due to the lack of non-verbal behaviours.

The results support **[H4]** reflecting that AMSR would be preferred for the task. We saw a wide difference between AMSR and SS, however AMR was also rated higher than SS, which may align with the fact that there is a relation to anthropomorphic agents with human-like designs, in terms of natural means of communication.

Most participants were more familiar with smart speakers than with social robots, which may indicate a novelty effect in the agent preference. Social robots are at time of writing emerging platforms and not as common and commercially available as smart speakers. However, we found that 2/3 of the participants were not able to identify the difference between AMR and AMSR, while they still preferred AMSR for the task. This indicates that the non-verbal behaviours used were subtle and asserted familiarity with the device.

Finally, we reject hypothesis **[H3]** reflecting that no differences would be found in task performance. Our assumption is that anthropomorphic facial features, without non-verbal behaviours is not enough to create more socially contingent interactions than SS: it is a combination of the two features that creates social facilitation to users.

Conclusion

In this paper, we presented a trade-off between task performance and social behaviour with conversational agents. Our contribution lies on an empirical evaluation of the anthropomorphic and non-verbal behaviour parameters of agents in task-oriented dialogues. This is particularly important to applications in which agents engage in a variety of tasks, and depending on the nature of the task, may need more or less social facilitation versus the value of task performance.

Not every agent needs to be anthropomorphised or to communicate with nonverbal behaviour; teasing out these variables and how they affect interaction time and social behaviour is the focus of this paper. To fully address the aspect of a potential novelty effect, longitudinal studies need to be designed where users' experiences are tested in long-term interactions with social robots and smart speakers. Potentially, increased familiarity with AMSR could decrease gaze time to levels similar to a more familiar social agent (i.e. another human).

To understand which of the independent variables contributed to the general preference of the robot, we concluded that while an anthropomorphic physical embodiment affects social behaviour, a set of non-verbal behaviours also increase the interaction time with the agent. Further research should be conducted in a variety of HRI scenarios, to investigate variability in the nature of the task and its relation to social facilitation between human users and agents. In sum, despite the task performance shortcomings of social and situation aware robots, they do hold a good interaction paradigm for enabling social facilitation with users.

Abstract

The Rubber Hand Illusion (RHI) is an illusion of body ownership. This study investigates the RHI in *furries*: people who manifest interest in anthropomorphic animals through various combinations of costuming, roleplay, identification with a *fursona*, and unusual bodily experiences. Furry culture suggests two ways furries could differ from non-furries in their RHI experience: (1) furries' malleable perception of bodily self and identity may result in stronger feelings of illusory experience; alternatively, (2) furries' identification with non-human animals may result in weaker feelings of self-ownership for a human prosthetic. Results support the latter hypothesis; furries felt less subjective embodiment compared to non-furries. Moreover, proprioceptive drift was predicted by the extent individual furries valued humanity and their human bodies. The less esteem furries had for humanity and their human form, the less drift toward the human rubber hand was observed. These findings suggest how embodiment is related to subjectivity, identity, and practice.

Keywords: Rubber Hand Illusion; Embodiment; Body Perception; Culture; Identity

Introduction

Embodiment has been defined as the subjective awareness of, and self-coincidence with, one's own body (Longo et al., 2008). Research suggests that this pre-reflexive, bodily self-consciousness is constituted and undergirded by complex processes of bottom-up and top-down modulation of multisensory integration (Tsakiris, 2010). Previous studies have investigated the influences of these processes by using the Rubber Hand Illusion (RHI), a bodily illusion in which participants experience a sense of ownership for a prosthetic human hand (Botvinick & Cohen, 1998). To perform the RHI, a prosthetic hand is placed inside the participant's peripersonal space in a position congruent with their real hand. Participants are then instructed to look at the rubber hand while it and the real hand are stroked synchronously with a paintbrush. When these incongruous visual and tactile stimuli are integrated, participants report experiencing the rubber hand as their own. Additionally, when the illusion of ownership of the rubber hand is successfully induced, participants exhibit proprioceptive drift, a tendency to perceive the location of their real hand as closer to the rubber hand than it actually is. Longo et al.'s (2008) principal component analysis of RHI questionnaire data found evidence for three dissociable subcomponents influencing the experience of embodiment of the rubber hand: "ownership"; "location"; and "agency". The two subcomponents of "ownership" and "location" were significantly correlated with increased levels of proprioceptive drift in the RHI, suggesting that both top-down "body-representation" and

bottom-up "body schema" influences converged to structure the experience of embodiment of the rubber hand.

Further experimental research on the RHI has supported the dissociation of these influences by either highlighting significant group differences in experience of the RHI or manipulating the RHI procedure itself. Findings supporting the influence of "body-representation" on RHI experience have found that incongruent positioning, shape, texture (Haans et. al, 2008; Tsakiris & Haggard, 2005) and skin color (Lira et al., 2017) of the rubber hand attenuate RHI experience. Findings supporting the influence of "body schema" on RHI experience have found that asynchronous stimulation of the rubber hand attenuates the strength of the illusion significantly more than incongruence with body-representation (Armel & Ramachandran, 2003) and that populations with increased body-schema plasticity or flexibility such as individuals who are diagnosed with anorexia nervosa (Keizer et al., 2014), susceptible to out-of-body experiences (Braithewaite et al., 2017), hemiparetic (Llorens et al., 2017), psychosis-prone (Germine et al., 2012), or under the influence of dexamphetamine (Albrecht et al., 2011) demonstrate higher susceptibility to the RHI.

If previous research suggests (1) decreased illusory effects when individuals identify less with the form of the rubber hand and (2) increased illusory effects for individuals with greater body-schema flexibility, could the RHI be used to test hypotheses that interrogate the nature of body perception and experience in a unique population? *Furries* are self-identified fans of media featuring non-human animal characters who have been imbued with human-like traits (e.g., speech and bipedal walking; Gerbasi et al., 2008). As is typical with other media-based fandoms (e.g., science fiction; Jenkins, 1992), furries are both avid consumers and creators of fan-made artwork, animation, and writing (Plante, Roberts, Reysen, & Gerbasi, 2016a). They often share this interest with other fans, congregating primarily online, but also in-person at local meet-ups and at large-scale fan conventions (Mock, Plante, Reysen & Gerbasi, 2013). Illustrating the scope of these meetups, conventions such as Anthrocon, one of the world's largest furry conventions, regularly attract more than 5,000 furries.

A subset of the furry fandom (approximately 20%) also expresses their interest through *fursuiting*, the wearing of elaborate, mascot-style foam-and-fabric costumes of furry-themed characters (Plante, et al., 2016b). Fursuiting is somewhat analogous to the practice of cosplaying among anime fans, who invest considerable time and effort into dressing up and interacting with other fans as their favorite character from a show (Reysen, et al., 2018). Unlike cosplay, however, fursuiting tends to involve characters of furries' own creation.

One of the most universal activities in the furry fandom is the creation of a *fursona* – a non-human animal avatar imbued with human traits. Fursonas are used by furries as a representation of themselves within fandom spaces. Virtually all furries have a fursona, usually consisting of one or more non-human species, a name, and physical and personality traits (Plante et al., 2016b). Furries spend a great deal of time creating, thinking about, and interacting with others in the fandom through their fursonas, with which they strongly identify (Plante et al., 2016b). This suggests the possibility that many furries may have a relatively malleable perception of self and body. For example, a furry may spend an hour or two per day interacting with other furries as their fursona, whose species differs from their own (i.e., not human), whose personality may differ from their own (e.g., more gregarious), and whose appearance, gender, and age may differ from their own. Given that prior research has shown that furries have fairly active imaginations and spend a great deal of time engaging in fantasy-themed activities (e.g., role-playing games and online roleplaying; Plante et al., 2016b), furries' perception of bodily self and identity may be influenced by spending time engaged in furry-themed activities.

Speaking to this possibility, research suggests that some furries are likely to think of themselves as less than fully human and identify, at least in part, with non-human animals (Roberts et al., 2015). Furry conventions are also often attended by *therians* and *Otherkin,* those who have human bodies but experience themselves as something other than human (Gerbasi, Fein, Reysen, Plante, & Roberts, 2017). In contrast to non-therian furries, who may identify *with* a non-human species but usually understand themselves to be fundamentally human, therians identify *as* a non-human animal that exists or has existed on earth, such as a bear or a mammoth, while Otherkin identify *as* a creature usually considered to be mythological or fantasy-based, such as a fairy or unicorn. (*Note*: Although there are many therians and Otherkin who do not identify as furries, all therians and Otherkin in the current study also identified as furries.) Therians and Otherkin often report experiencing unusual bodily experiences, such as feeling phantom limbs belonging to the creature they identify as (such as claws, tails, or wings), and/or "shifts" into a mental state that they associate with their identified species. Many therians and Otherkin report experiences of deep discomfort with their human bodies and/or a desire to be in the body of the species with which they identify (Grivell, Clegg, & Roxburgh, 2014).

Presently, the RHI allows for testing between two competing hypotheses. If furries identify less with the human form of the rubber hand as compared to a control population then they should exhibit decreased RHI experience as a group. However, if furries have relatively greater body-schema flexibility, they should exhibit increased RHI experience. Results can inform our general understanding for how embodiment relates to identity, subjectivity, and practice.

Methods

Participants

All participants were recruited and tested at Anthrocon 2018 in a quiet, private room. Of the 57 participants tested, two early participants' data were not analyzed because they were recorded as having worn a ring or band-aid during the

procedure; one participant dropped out before completion; four other participants did not self-identify as furries in the subsequent survey. This left 50 furries for analyses (M_{age}=26.77; 11 female/36 male/3 NA; $M_{education\ years}$=15.55). For a comparison group of non-furries, we used raw data from 131 participants previously published in Longo et al. (2008).

Procedure

Rubber Hand Illusion We used the procedure described in Longo et al. (2008) as a model to carry out the RHI in the current study but using only a right rubber hand (there was no effect of handedness in the original study) and an occluder box described by the JoVE Science Education Database (2019). (In this version, the participant can view the experimenter.) Participants sat across from the experimenter with their hand hidden inside the occluder and the rubber hand placed congruently in view. There were two blocks. At the beginning of each block, participants estimated the location of the tip of their occluded right index finger by reporting the corresponding number on a ruler with a variable random offset (to prevent participants from using a remembered numeric label rather than a perceived location on subsequent trials). Following the pre-test location judgment, a 60s induction phase consisted of the visible rubber hand and occluded real hand being stroked with 2 identical paint brushes. In the *synchronous* block, individual fingers on each hand were brushed simultaneously; in the *asynchronous* block they were brushed 180° out of phase. (The asynchronous condition is frequently conceptualized as a kind of control or placebo, although subjective *deafference* scores have been observed to be higher in this condition.) Block order was randomized. After the induction phase in each block, participants were again asked to estimate the location of their index finger. Upon completion of the post-induction location judgement, participants filled out a

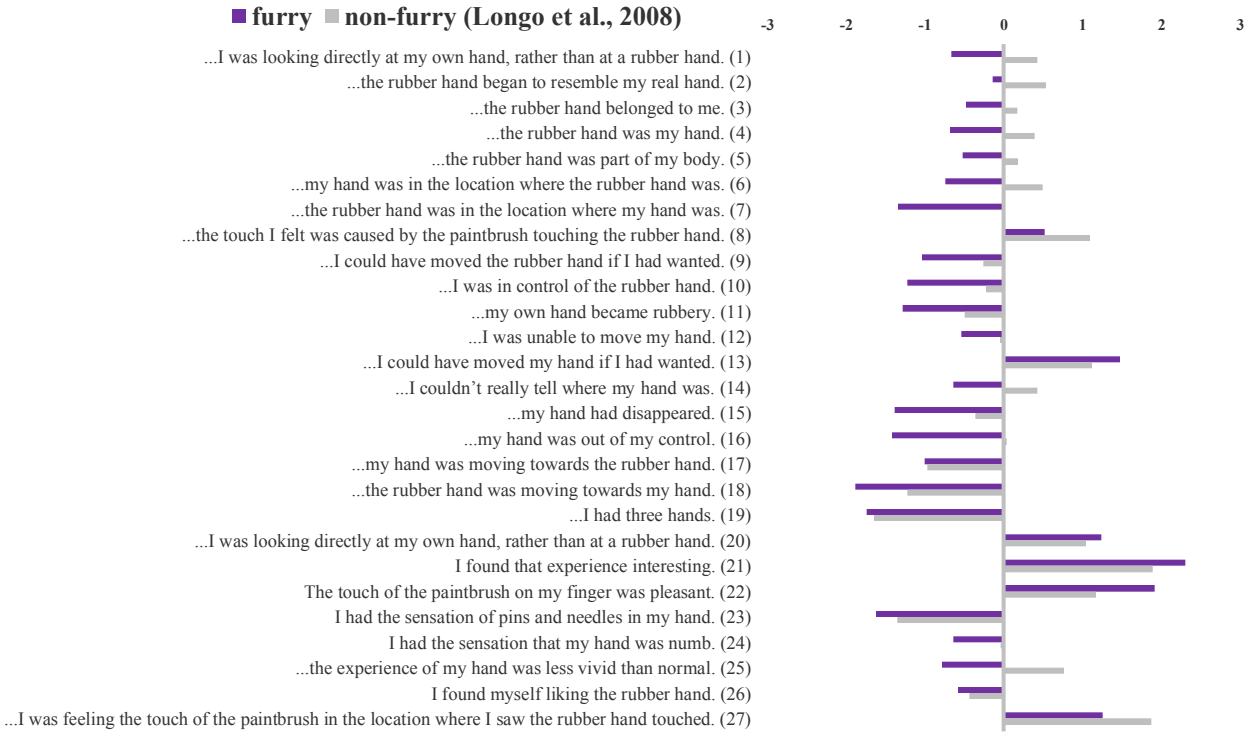

Figure 1. RHI embodiment survey items and response means. 7-point agreement scale; -3=strongly disagree; 0=neither agree or disagree; 3=strongly agree. (From Longo et al., 2008)

questionnaire assessing their subjective experience of the illusion (see Figure 1). This questionnaire, developed by Longo et al. (2008), measures 5 principal components (*embodiment of rubber hand, loss of own hand, movement, affect and deafference*) and three subcomponents of embodiment (*ownership, location, and agency*).

Experiential Survey After completion of both Rubber Hand Illusion blocks, participants filled out a survey with items designed to measure a number of variables related to their identity, experience, and attitudes, including questions about sexual identity, time since identifying as a furry and/or therian, and beliefs about being other than 100% human. The survey also asked systematic questions about the Duration ("How long ago did you start …"), Frequency ("How often do you have…"), and Intensity ("How intense are…") of relevant experiences and practices including: *Fursuiting*, *Role-Playing*, and *Online Interaction* with other furries. Two attitude scales were included as well (below).

Humanity-esteem version of the Rosenberg Self-Esteem Scale (Luke & Maio, 2009). This scale measures the extent to which participants think humanity is bad or good ("Human Value"). Example questions include, "I feel that the human species is very valuable, at least on an equal plane with other species in the universe;" "I feel that human beings have a number of very good qualities;" "All in all, I am inclined to regard the human species as a failure."

Identity version of the Transgender Congruence Scale. We modified a previously validated gender congruence scale (Kozee, Tylka, & Bauerband, 2012) to measure the extent to which furry participants feel comfortable with the match between their identity and human body ("Human Body Image"). Example questions include, "My outward appearance represents my identity;" "I experience a sense of unity between my identity and my body;" "My physical appearance adequately expresses my identity."

Results

Subjective Results Between Groups (Figure 2A.) Compared to the non-furry population reported in Longo et al. (2008), furries appear to experience several critical principal components of the RHI to a lesser extent when asked identical questions [MANOVA: $F(5, 175) = 9.72$, $p < .0005$; Wilk's $\Lambda = 0.783$].

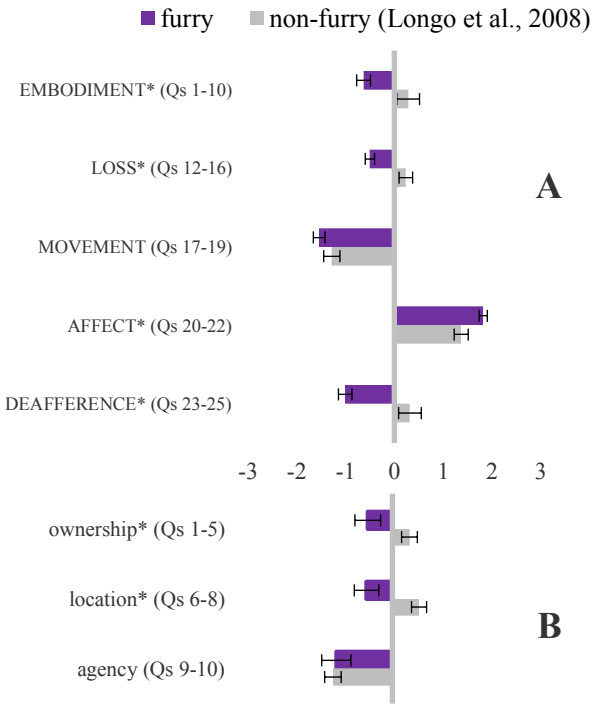

Figure 2. **(A)** Mean scores for Rubber Hand Survey principal components and **(B)** Mean scores for Embodiment item subcomponents. (*) Indicates significant differences between furry and non-furry groups. All survey scores shown were recorded after synchronous condition except deafference scores which indicate responses recorded after asynchronous condition.

Post-test ANOVAs indicate that furries reported significantly weaker experiences associated with the principal components of *embodiment* [$F(1, 179) = 11.22$, $p < .001$] and *loss* [$F(1, 179) = 16.94$, $p < .0005$], (during synchronous condition) and *deafference* [$F(1, 179) = 24.16$, $p < .0005$] (during asynchronous condition; See Longo et al., 2008 for more detailed explanation). Furries exhibited higher scores for *affect* [$F(1, 179) = 7.69$, $p < .01$] (regardless of condition; i.e., in synchronous and asynchronous blocks) suggesting furry participants enjoyed the experience of being brushed irrespective of any illusory effects. There was no significant difference for *movement* (as non-furries also reported negative scores). (Figure 2B.) Furries indicated weaker subjective feelings for the critical embodiment subcomponents [$F(3, 177) = 6.45$, $p < .0005$; Wilk's $\Lambda = 0.901$.] of *ownership* [$F(1, 179) = 7.71$, $p < .0005$] and *location* [$F(1, 179) = 13.38$, $p < .01$], but no difference for *agency*.

Proprioceptive Results Between Groups Proprioceptive drift is the tendency for participants to perceive the location of their real hand as closer to the rubber hand than it actually is. It is calculated by subtracting post-induction index finger location judgments from pre-induction location judgments in the synchronous block. Despite numerically smaller numerical averages for furries vs. non-furries, proprioceptive drift did not differ significantly for either condition.

Table 1. Proprioceptive Drift (cm) Between Groups and Conditions

Condition		Synchronous		Asynchronous	
	N	*M*	*SD*	*M*	*SD*
Furry	**50**	**0.76**	**3.73**	**0.05**	**3.57**
Non-furry	120	1.34	3.22	0.30	2.69

Between Group Results Summary Negative average values on relevant components, significantly lower than a large control sample, indicated lower subjective embodiment, loss, and deafference scores for furries. This suggests that identifying or role-playing as somewhat less, or other than human may be mitigating the strength of the RHI. That is, furries may experience the illusion to a lesser extent because they identify less with the human rubber hand.

These results simultaneously appear to argue against the alternative hypothesis; that furry participants who actively move between human and non-human roles in terms of distinct individual identities and practices, might have a more plastic body schema as compared to non-furries. This hypothesis predicts larger RHI effects in furries when compared to a typical population. This was not the result.

Analyses focused on variability within the furry sample could sharpen our explanation. If furries are experiencing the illusion to a lesser extent because they identify less with the human rubber hand, then we should expect that the strength of the illusion for furries could be predicted by the extent to which individual participants value humanity and feel comfort in their human bodies

Table 2. Correlations (**R**) 2-tailed significance values (*p*) and sample sizes (N) for relations between **Proprioceptive Effects** (Prop Drift), **Human Value and Body Image Questionnaires**, and **Furry Experience Data**. Furry Experience Data includes (1) Frequency in terms of hours per day (Freq) (2) Intensity of Experience (Intens) and (3) Time in Months since beginning a particular kind of practice, including (A) Fursuiting (Wear), (B) Role-Playing (Role) and (C) Online Interaction with other furries (Online). Also shown are correlations for time in months since first identifying as a furry (Furry Time) and the relative extent in percentage terms that participants identify as Human/Non-human (Human %). * Indicates correlation is significant at the 0.05 level; ** correlation is significant at the 0.01 level.

Proprioceptive Results Within Group In furry participants, the extent of drift toward the rubber hand was positively correlated with individual scores on the **Humanity-esteem version of the Rosenberg Self-Esteem scale** ("Human Value") and the **Identity version of the Transgender Congruence Scale** ("Body Image"), which were highly correlated with each other. This suggests that among furries, lower esteem for humanity and feelings of incongruence between one's identity and human body is predictive of less proprioceptive drift towards the rubber hand (see Table 2 and Figure 3).

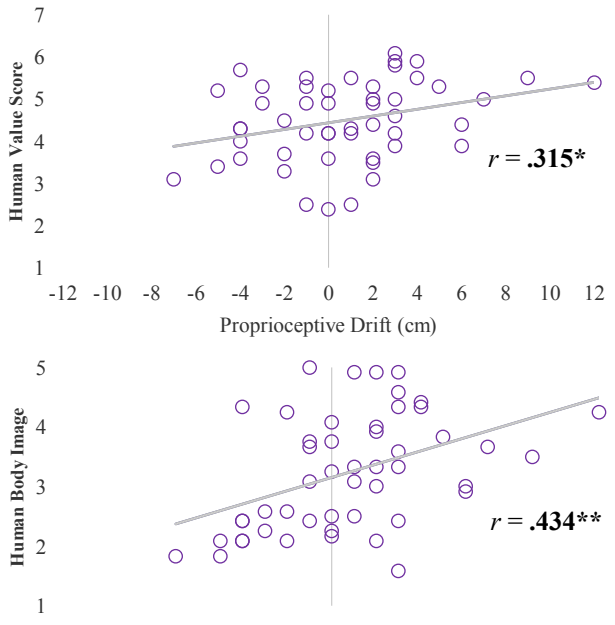

Figure 3. Correlations between individual proprioceptive drift scores (cm) and Human Value (7pt. scale, top) and Human Body Image (5pt. scale, bottom) scores. See Table 2.

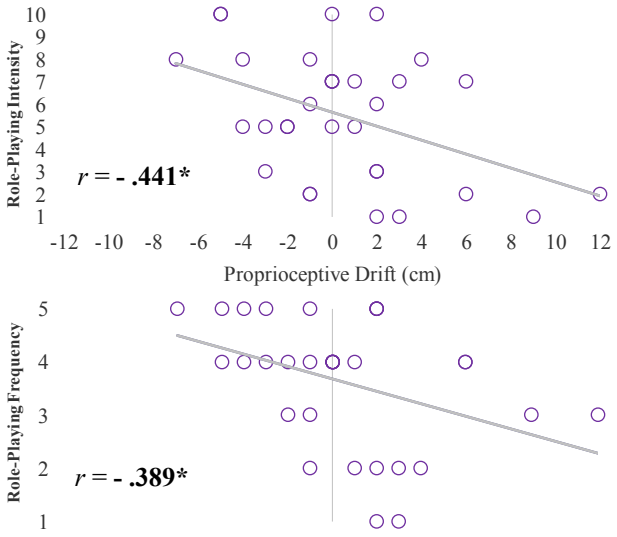

Figure 4. Correlations between individual proprioceptive drift scores (cm) and Role-Playing Intensity (10pt. scale, top) and Frequency (5pt. scale, bottom). See Table 2.

There were significant negative correlations between individual proprioceptive drift scores and Role-Playing Intensity and Frequency Scores from the **Experiential Survey**. This suggests that among furries, more frequent and intense role-playing in a fursona is predictive of less proprioceptive drift towards the rubber hand (see Table 2 and Figure 4).

Therian or Otherkin vs. Non-Therian Furries (Table 3.) There were significant differences (MANOVA and post-test ANOVAs) between non-therian and therian/Otherkin participants and survey scores (Human Value and Body Image) predictive of Proprioceptive drift (which showed a marginal difference between these groups). Therians had lower Human Value and Body Image scores and predictably self-identified as less human than non-therian furries.

Table 3. Non-Therian Furries vs. **Therian Furries**.

	Human %**	Prop Drift	Human Value*	Body Image*
Non-therian (*N*=38)	98.19	1.32	4.71	3.43
Therian (*N*=12)	**61.50**	**-1.00**	**3.83**	**2.64**
p	*<.0001*	*=.06*	*<.01*	*<.05*

General Results Summary The overall pattern of results supports the hypothesis that furries are experiencing a mitigated RHI because they identify less with the human rubber hand. **(1)** Compared to a control sample, furries exhibit lower average and subjectively negative scores for relevant principal components of a validated RHI survey. **(2)** The extent of proprioceptive drift, which can be regarded as a more objective illusion index, is predicted by Human Value, Body Image, and Role-Playing scores in furries. **(3)** Therians and Otherkin, i.e., furries who identify *as* non-human, exhibit lower survey scores associated with human esteem and marginally lower scores for proprioceptive drift as compared to non-therian furries.

Discussion & Conclusion

The present study suggests ways that illusions of body ownership can be used to test distinct hypotheses - that make opposite predictions - within unique populations. Lira et al. (2017) found that individual differences in implicit racial bias modulated proprioceptive drift (and other measures of RHI magnitude). That is, higher racial bias in white participants mitigated drift toward a black rubber hand, suggesting that within-subject attitudinal differences can reduce proprioceptive effects. Elsewhere it has been suggested (Dempsey-Jones & Kirikos, 2014) that proprioceptive effects are relatively impervious to top-down modulation, suggesting that neurocognitive group differences in body-perception may be driving results in other groups (e.g., in autism) that show reduced RHI effects. While the results of this study suggest that furries are less likely to identify with a human hand, they cannot determine if, broadly speaking, top-down or bottom up processes better describe why this is the case.

Despite these limitations (based principally on using a comparison data set from a previous study and correlational methods) the present study seeks to broaden the range of salient identity categories to studies of cognitive difference, joining the growing body of literature that explores the implications of variability in particular populations. We investigated a subculture whose membership is defined through a powerful and often embodied experience of affinity with a particular symbolic form – in this case, anthropomorphic animals. Our findings suggest that the kind of cultural differences that may not be visible to the eye or reportable on a typical demographic questionnaire, but manifest instead in self-identification with a particular community, subjective experience of difference, and ongoing participation in patterned cultural practices (Roepstorff, Niewöner, & Beck, 2010), may be profoundly related to body perception. These findings argue for a broader conceptualization of cultural and identity difference than is often found in cross-cultural cognitive research – one deeply grounded in both subjectivity and practice.

Implicit Evaluations Reflect Causal Information

Abstract

Evaluations along a positivenegative dimension can be measured either explicitly (via self-report) or implicitly (via response interference tasks). Whether implicit evaluations encode relational information (e.g., A causes B) or only co-occurrence information (AB) has been debated extensively. 1,082 participants observed a machine being activated by causally responsible stimuli and dispensing rewards in the presence of merely associated, but not causal, stimuli. Evaluations of causally responsible vs. associated stimuli were measured implicitly and explicitly. Explicit and implicit evaluations of causally responsible stimuli were more positive than those of associated stimuli, both in the presence (Study 1) and absence (Study 2) of verbal instructions about the operation of the machine. Study 3 eliminated temporal primacy and overshadowing as explanations of the effect. Supporting propositional theories, these findings suggest that implicit evaluations are sensitive not only to co-occurrence but also to relational information, whether conveyed verbally or learned solely from experience.

Unexpectedness makes a sociolinguistic variant easier to learn: An alien-language-learning experiment

Abstract

We report two artificial-language-learning experiments investigating if the acquisition of sociolinguistic associations is facilitated by two kinds of expectation violation: encountering a variant (a) for the first time or (b) in an ungrammatical context. Participants learned an artificial language with two dialects, each spoken by one of two alien species: *Gulus* and *Norls*. The two dialects differed with regard to a plural suffix: Gulus mostly used *-dup*, and Norls mostly used *-nup*. In the first learning phase, participants learned the language without aliens; in the second learning phase, they were exposed to it with alien interlocutors. In Experiment 1 we manipulated whether *-nup* occurred in the first learning phase; in Experiment 2 we manipulated linguistic constraints on its occurrence. The acquisition of sociolinguistic association was evaluated by asking participants to select suffixes given aliens and vice versa. We found that sociolinguistic acquisition was facilitated in Experiment 1, but not Experiment 2. In Experiment 2, however, a post hoc analysis revealed that participants who had learned the grammatical context of the linguistic conditioning did experience facilitation, while those who had not did not. Our results provide laboratory evidence that unexpectedness facilitates the learning of sociolinguistic variation.

Keywords: artificial-language learning; social meaning; sociolinguistics; salience; surprisal

Introduction

The role of *salience* in the acquisition and propagation of linguistic variants has long been documented in classic sociolinguistic research (Labov, 1972). Variants with higher salience are encoded with more attention and higher meta-linguistic awareness, leading them to be more easily recognized and retained than other variants with equal frequency, resulting in an acquisition bias that cannot be explained by frequency of exposure alone (Jaeger & Weatherholtz, 2016).

In this study we investigated the role of salience in facilitating the learning of sociolinguistic meaning (i.e., the association of particular linguistic variants with particular social groups). We focused in particular on the effect of previous experience on salience. Previous work has paid much attention to the role of certain kinds of *non-linguistic* experience such as social and developmental experience (Foulkes & Docherty, 2006) or social stereotypes (Levy, 2008), but *linguistic* experience is relatively understudied. In particular, there is very little work on how the perceived salience of a sociolinguistic variant is affected by prior experience of that variant in other contexts. Jaeger and Weatherholtz (2016, p. 1) proposed that salience related to language experience can be understood in terms of expectation violation, analogous to the well-attested novelty bias effect: Novel items and events that we do not expect tend to stand out. Jaeger and Weatherholtz (2016) argued that this might occur for linguistic variants that a listener has not encountered before and might thus lead to surprisal. The salience generated by surprisal may facilitate learning the variant and its socioindexical meaning.

Although Jaeger and Weatherholtz's (2016) approach to experience-based salience seems appealing for its operationalization of expectation-related salience in an information-theoretic framework (Shannon, 1948; Hale, 2001; Levy, 2008), it is not yet supported by linguistic data. Several experimental studies on language processing show that less expected words and structures take longer to process and at greater cost (McRae, Spivey-Knowlton, & Tanenhaus, 1998; McDonald & Shillcock, 2003), with similar effects observed in comprehension tasks (Kaschak & Glenberg, 2004; Squires, 2014; Fraundorf & Jaeger, 2016). However, additional processing for novel variants in comprehension does not necessarily result in better performance in noticing or memorizing these variants or in associating them with the right social group.

The present study

The present study investigates the hypothesis that experience-dependent salience can arise from expectation violation, and cause a sociolinguistic variant to be more learnable. We used an "alien language" learning paradigm in which participants first learned a miniature artificial language and were then exposed to it in a simple social context with "alien interlocutors". We investigated two kinds of expectation violation, hypothesizing that participants would be more likely to learn a sociolinguistic association if (Experiment 1) they had not encountered it before and (Experiment 2) they had encountered it before, but subject to grammatical constraints that now appear to be violated.

As an example of the first kind of violation, one might imagine an American English speaker visiting Liverpool and hearing, for the first time, *book* pronounced with a final velar fricative [x] (as in German *Buch*) instead of the expected velar stop [k]. As an example of the second kind of violation, consider a speaker who has heard *-th* pronounced as [f], but only at the end of syllables (as in [boʊf] for *both* or [ˈɛfnɪk] for *ethnic*). For a speaker who had acquired syllable-finality as a constraint on this variant, hearing [fɪnk] for *think* would likely be relatively salient.

In both our experiments a certain variant of the alien language was associated predominately (but not necessarily exclusively) with a particular species of alien. We evaluated whether participants had learned this sociolinguistic association pattern by asking them at the end of the experiment to (a) select the variant that a given alien would most likely produce, and (b) select the alien most likely to produce a given variant. We predicted that increased salience, via expectation violation, would lead participants to do better at both tasks (though, because we did not make the sociolinguistic relationship categorical, we did not expect that the response to the two tasks would be identical).

Finally, we predicted that listeners who learned a sociolinguistic association in the experiment could generalize that relationship to new words.

Experiment 1: First encounter

Experiment Overview

In Experiment 1, we investigated whether encountering a linguistic variant for the first time in a social context would facilitate the sociolinguistic learning of that variant (we will term this hypothesized effect "first-encounter facilitation"). Participants were trained on an alien language with two dialects, each used by a different alien species, the *Gulus* or the *Norls* (Fig. 1). The dialects differed with regard to a plural suffix: Gulus used *-dup* as the only form of the plural suffix whereas Norls sometimes used *-dup* but mostly used *-nup*.

The experimental procedure consisted of three phases: Participants were first trained on the language without seeing any aliens, which was intended to establish *prior experience* with the language; then (having been introduced to the two alien species) they were exposed further to the language with alien interlocutors, which allowed them to learn associations between plural suffixes and alien species. In the third and final phase, acquisition of sociolinguistic variants was evaluated on the basis of whether participants could infer which alien might have used a given suffix and, conversely, which suffix a given alien might have used.

Crucially, we manipulated participants' *prior experience* with the variant *-nup* such that half the participants would never be exposed to it in the first phase, encountering only *-dup* (*NoExposure* condition), whereas the other half would see both suffixes in every phase (*Exposure* condition). We predicted that participants with no experience of *-nup* in the first learning phase would find it more salient in the second phase and better learn to associate it with Norls.

Method

Participants 100 participants completed Experiment 1 online within the specified amount of time (1.5 hours). After excluding participants whose duration was below the 2.5% quantile or above the 97.5% quantile of all participants, we used the data of the remaining 93 participants. There were 51 female and 43 male participants, aged 17–73 (mean: 28.9) years. 30 of them were recruited from the University of Pennsylvania subject pool (in return for course credit) and 64 were recruited through the Prolific Academic website (and were paid $5 each). 49 participants were in the *Exposure* condition and 45 in the *NoExposure* condition.

Alien language The artificial language was composed of 14 word stems, as shown in Table 1, and a plural suffix with two variants, *-dup*, *-nup*.

Table 1: 14 Stem Words in the Alien Language

nesel, laniz, firot, hiwen, maqub, jemulok, gequzis
tugan, nuwik, falon, wumos, wukin, sehilod, takoles

The 14 stem words were randomly generated by combining one or two CV syllables with a word-final CVC syllable from a segment pool of five vowels /a e i o u/ and 12 consonants /k g q h m n t s z j l w/.

Aliens The language was used by two alien species: *Gulus* and *Norls*. The stem forms were the same across dialects, but the suffix variants had different distributions: Gulus attached *-dup* to all 14 words to signal plurality, whereas Norls attached *-dup* to only four of the words (*hiwen*, *wukin*, *jemulok* and *wumos*) and *-nup* to the remaining eight words. Put differently, Gulus used the *-dup* variant 100% of the time as their plural suffix whereas Norls used *-dup* and *-nup* at a ratio of 71% to 29%. Within each alien species, six idiosyncratic aliens were designed in order to ensure that the linguistic variation on the group level wouldn't be mistaken for variation on the individual level (See Fig. 1 for examples).

Figure 1: Alien Species: Gulus (left) and Norls (right)

Procedure The experimental task was composed of two learning phases, in which participants were trained on the alien words through passive exposure to word-object[1] pairs and multiple-choice exercises with feedback, and a test

[1]We thank Professor Janet Pierrehumbert for making images of the objects available for use. The artworks are copyrighted to Northwestern University and used with permission.

(a) (b)

Figure 2: Example trials in learning phase 1: (a) a passive exposure trial; (b) a forced-choice trial

(a) (b)

Figure 3: Example trials in learning phase 2: (a) a passive exposure trial; (b) a forced-choice trial

phase that evaluated how well participants had learned the association between plural variants and alien species.

First learning phase: Learning without aliens. The experiment started with a learning phase that exposed participants to the words of the language without any aliens. This was designed to give participants exposure to the language before introducing it in a social context. It consisted of a series of trials, with two kinds of trial, as shown in Fig. 2. In passive exposure trials (Fig. 2a) a word was paired with an image of the object(s) it referred to. Participants were instructed to memorize the word and its meaning before proceeding to the next trial. In forced-choice trials (Fig. 2b) participants had to choose the correct word to go with an image; there were always two options to choose from, one correct and one a foil generated by changing one or two segments in the stem of the correct form. Participants received one point for each correct response and no point for an incorrect one (maximum: 168 points). Feedback on the correct form and the point received for each question was provided immediately afterwards.

Participants were trained on 28 alien words (14 singular, 14 plural), which were divided into seven sets of four words each, with the constraint that each set contained two singular words and two plural words that all had different stems. For each set, a participant would see a passive exposure trial for each word in turn; then they would see a forced-choice trial for each of the same four words. Then they would proceed to the next set. The order of the seven word sets was randomized, as was the order of the four trials within each passive exposure section and within each forced-choice section. The whole process was repeated once participants had completed training on all seven word sets. In total, participants were exposed to 14 words $\times$ 2 forms (singular and plural) $\times$ 2 trial types (exposure, forced choice) $\times$ 2 repetitions = 112 trials.

Alien introduction. After the first learning phase, the aliens were introduced. Participants were first presented with images of Gulus and Norls, each labeled with the species name; then the labels were removed and participants were instructed to drag and drop each alien into one of the the two boxes labeled *Gulu* and *Norl*. Feedback was provided after the drag-and-drop.

Second learning phase: Learning with aliens. After the aliens had been introduced, the second learning phase started. This phase resembled the first phase in its structure, except that each trial (whether passive-exposure or forced-choice trial) included a picture of an *alien interlocutor*, as shown in Fig. 3. Participants saw both the Gulu and the Norl form of every word, so the second learning phase was twice as long as the first learning phase (with each set of trials containing eight words rather than four). In total each participant was exposed to 14 words $\times$ 2 forms (singular, plural) $\times$ 2 species (Gulu, Norl) $\times$ 2 trial types (exposure, forced choice) $\times$ 2 repetitions = 224 trials.

Test phase: Measuring acquisition. After the second learning phase, the test phase began, which evaluated the extent to which participants had established associations between alien groups and plural suffixes. The test phase contained two tasks: a suffix-identification task in which participants had to choose which form might be used based on the presented alien interlocutor, and an alien-identification task in which participants had to choose which alien was most likely to have said a prompt word. Trials in these tasks contained both *old word* stimuli from the learning phase and *new word* stimuli that participants had never seen, in order to evaluate the generalization of sociolinguistic associations to novel items. Trial order was randomized for each participant, and the order of the two options within each trial was counterbalanced. No feedback was provided.

In ***suffix identification***, trials on old words worked like forced-choice trials in the second learning phase (Fig. 3b), except that the optional answers had identical stems and different suffixes (i.e., the reverse of the situation in the learning phases). Participants were instructed to choose the form the pictured alien would likely use. Trials on new words were different: Participants were presented with a singular word, an image of the object it referred to, and an alien interlocutor; they were required to choose between a *dup*-ending word and a *nup*-ending word as the plural form (Fig. 4).

In all, the task included 56 trials on old words (14 words $\times$ 2 species $\times$ 2 repetitions = 56 trials), 24 trials on

Figure 4: Example suffix-identification trial with a new word

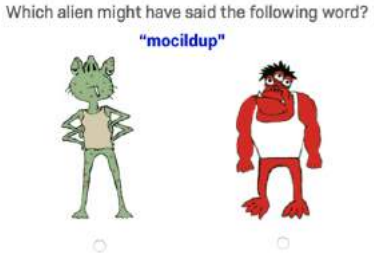

Figure 5: Example alien-identification trial

new words (6 new words × 2 species × 2 repetitions = 24 trials), and 34 filler trials, which tested participants on either singular words or plural words with incorrect stems.

In ***alien identification*** (Fig. 5) participants were given a plural word and had to choose between a Gulu and a Norl as the likely speaker of the word. The idiosyncratic aliens were kept consistent throughout the whole task, but whether they appeared on the left or the right was counterbalanced across questions. The stimulus words were generated by affixing the 14 old words and the six new words once each with *-dup* and once each with *-nup*, so that there were 40 trials (14 old words × 2 suffixes + 6 new words × 2 suffixes) in total.

Experimental conditions. Participants were randomly assigned to two experimental conditions: the *NoExposure* condition and the *Exposure* condition. Fig. 6 shows the distribution of variants in the two learning phases in different experimental conditions.

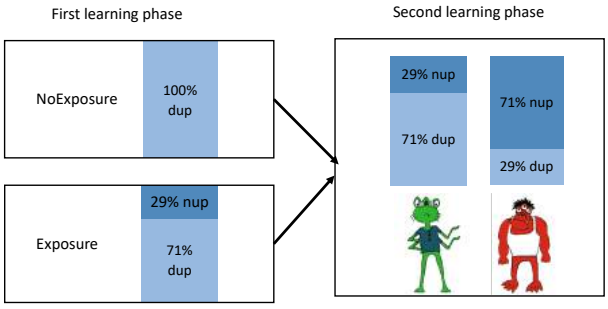

Figure 6: Variant distribution in the learning phases of Experiment 1

The two conditions differed with respect to the presence or absence of the variant *-nup* in the first learning phase: For participants in the *NoExposure* condition, plural words in this phase would always be affixed with *-dup*, whereas participants in the *Exposure* condition would see ten instances of plurals with *-dup* (71%) and four with *-nup* (29%). The two conditions were identical in the second learning phase: Gulus exclusively used *-dup* while Norls used *-nup* 71% of the time and *-dup* 29% of the time.

Results

Analyses were conducted using the R Statistical environment (R Core Team, 2014); linear models were run using the lme4 library (Bates, Mächler, Bolker, & Walker, 2015), and plots were created using ggplot (Wickham, 2016).

On average, it took participants (outliers excluded) 52 minutes (*sd* = 14) to complete the whole experiment. Out of a maximum of 168 points, participants achieved an average score of 153 (*sd* = 13).

Fig. 7 shows the aggregate results for suffix identification (left) and alien identification (right). The left panel shows how often participants selected the *-nup* suffix for a given alien the suffix-identification task. Consistent with our predictions, participants in the *NoExposure* group were more inclined to choose a *-nup* word for a Norl than those in the Exposure condition. Notably, the *-nup* response ratios given a Norl were relatively low in both conditions, nowhere matching the 71% in the input. The right panel shows what proportion of the time participants selected a Norl for a given suffix in the alien-identification task. Again, consistent with the hypothesis, participants in the *NoExposure* condition were more inclined to choose a Norl given a *-nup* word and to choose a Gulu given a *-dup* word, compared with those in the Exposure condition, who chose Norl interlocutors for both *-dup* and *-nup* at chance level.

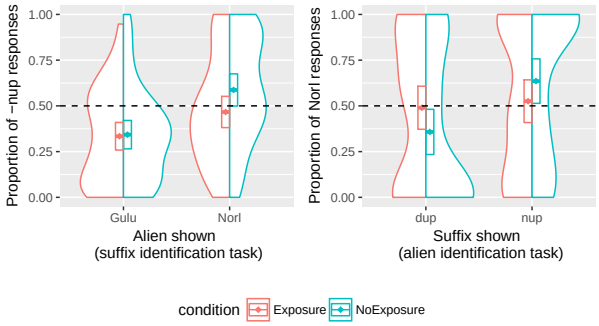

Figure 7: Proportion of *-nup* responses in suffix identification and Norl responses in alien identification (including 95% confidence interval). Dotted line indicates chance level.

Mixed-effects logistic regression models were fit on the two tasks, with Response as the dependent variable, Condition (Exposure as the intercept), Stimulus (Norl as the intercept in suffix identification; *-dup* as the intercept

in alien identification) and their interactions as independent variables, and Participant and Word as random factors. Both models revealed a significant Condition effect ($\beta = 0.57, p = 0.001$ in suffix identification; $\beta = -0.54, p < 0.001$ in alien identification) and its Interaction with Stimulus ($\beta = -0.48$ in suffix identification, $\beta = 1.00$ in alien identification, $p < 0.001$ in both cases). A stimulus effect was found only in suffix identification ($\beta = 0.62, p < 0.001$), not in alien identification ($\beta = 0.14, n.s.$).

Novel Stimuli We hypothesized that participants would apply the sociolinguistic association they had learned in the second training phase to novel words they had never seen before. The results show that identification with old and new words strongly mirrored each other in both conditions and both tasks. A mixed-effects model was fit on each of the two tasks, with Response (Suffix or Alien) as the dependent variable, Participant and Word as random factors, and Condition, Stimuli (either Alien or Suffix) and Novelty as fixed effects. The results showed no significant Novelty effect in suffix identification ($\beta = 0.23, n.s.$) and alien identification ($\beta = 0.10, n.s.$). These results indicate that the acquired sociolinguistic association could be generalized to new lexical items, and that first-encounter facilitation applies to both familiar and unfamiliar words.

Summary Our prediction concerning first-encounter facilitation was supported. That is, participants in the *NoExposure* condition were more likely to acquire the association between *-nup* and the Norl species than participants in the Exposure conditions, suggesting that the first encounter with a novel variant facilitated the acquisition of sociolinguistic variants of that variant. We also found that this effect extended to previously unseen words.

Experiment 2: Constraint violation

Experiment 2 used a similar paradigm to Experiment 1, but we modified the suffixation patterns to investigate a different source of surprisal. Instead of surprisal caused by encountering a variant for the first time, Experiment 2 investigated whether surprisal caused by encountering a linguistic variant in an apparently ungrammatical context (i.e., where it violated a grammatical constraint) would also facilitate the acquisition of sociolinguistic associations. We will term this constraint-violation facilitation.

Method

Participants 103 participants completed Experiment 2 online within 1.5 hours. After excluding participants whose duration was below the 2.5% quantile or above the 97.5% quantile of all participants, there were 97 participants left whose data were used for the final analysis. They were 69 females and 28 males, aged 17–78 (mean: 29.3) years. 28 of them were recruited from the University of Pennsylvania subject pool (and rewarded with course credit), and the remaining 69 were recruited through the Prolific Academic website (and paid $5 each). There were 48 participants in the Conditioned condition and 49 in the Unconditioned condition.

Materials and Procedure The same words and aliens were used in Experiment 2 as in Experiment 1. The procedure was also the same, consisting of two learning phases and a test phase with two tasks.

Experimental Conditions and Predictions There were two between-subjects conditions based on the linguistic environment for the suffix *-nup*, which is shown in Fig. 8.

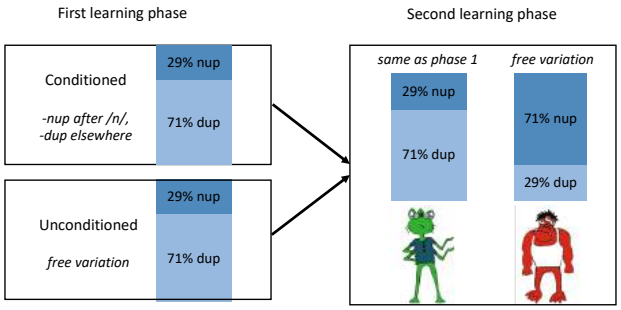

Figure 8: Variant distribution in the learning phases of Experiment 2

In the *Conditioned* condition participants in the first learning phase only ever saw *-nup* attached to the four nasal-ending stems (i.e., *falon*, *hiwen*, *tugan* and *wukin*), while *-dup* was attached to the 10 stems that did not end in a nasal. This implied a grammatical constraint on the distribution of *-nup* (i.e., that it only occurs after nasals). By contrast, participants in the *Unconditioned* condition were exposed to the two suffix variants in free variation (i.e., both *-nup* and *-dup* occurred with both nasal and non-nasal stems), though the variants still occurred at a ratio of ten (*-dup*) to four (*-nup*) – or 71% to 29% – just as in the *Conditioned* condition. In the second learning phase, Gulus exhibited precisely the suffixation pattern of the first phase, whereas Norls used the two suffixes freely across contexts at a ratio of four (*-dup*) to ten (*-nup*).

Similar to Experiment 1, we predicted that participants in the *Conditioned* condition would experience greater surprisal when they saw Norls using the two variants, especially *-nup*, in an ungrammatical way, and would be facilitated by this surprisal in learning the association between *-nup* and the Norl species, compared with those in the *Unconditioned* condition.

Results

On average, participants took 51 minutes (sd = 12) to complete the experiment and achieved a mean score of 152 ($sd = 13$).

Fig. 9 shows the aggregate results for suffix identification (left) and alien identification (right). The results do not appear to exhibit the predicted between-group difference in learning.

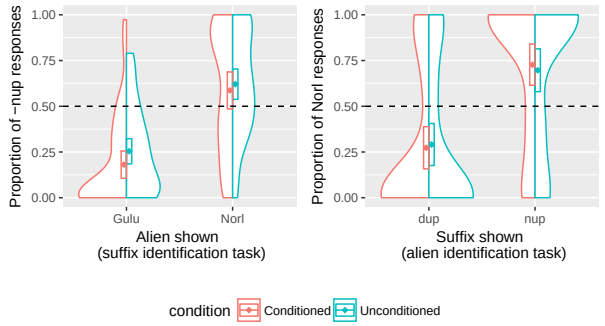

Figure 9: Proportion of *-nup* responses in suffix identification and Norl responses in alien identification (including 95% confidence interval). Dotted line indicates chance level.

A mixed-effects logistic model with Participant and Word as random factors, and Condition, Alien and their Interaction as independent variables revealed a significant Alien effect (Norl as the default, $\beta = -2.08, p < 0.001$) and a significant interaction ($\beta = 0.28, p = 0.012$), but no effect of Condition ($\beta = 0.28, n.s.$). In alien identification, a mixed-effects logistic model showed a significant effect of Suffix (*-nup* as the default, $\beta = 1.96, p < 0.001$), but no effect of Condition ($\beta = 0.06, n.s.$) and the Interaction ($\beta = -0.18, n.s.$).

Learning Proficiency It is possible that the absence of facilitation in Experiment 2 was due to variation in learning performance. The predicted facilitation depends on surprisal due to the apparent violation of a grammatical constraint. It therefore seems *a priori* clear that our predicted effect should occur only if participants learned the grammatical constraint. If they did not, violation of the constraint should not generate surprisal. To evaluate this possibility, we conducted a post hoc analysis in which we took participants' scores in the learning phase as a proxy for their learning performance. In particular, we divided participants into *good learners* and *poor learners* within each condition, according to whether their score was above or below the group mean. We then investigated whether constrain-violation facilitation could be found among good learners but not poor learners.

Fig. 10 shows the results for the 47 *good* and 50 *poor* learners. First, good learners showed a higher *-nup* rate for Norls and a lower *-nup* rate for Gulus in suffix identification, as well as a higher Norl rate for *-nup* and a lower one for *-dup*, compared with poor learners, indicating a better alignment between their responses and the pattern in the input, compared with poor learners. Second, the predicted learning facilitation is exhibited in the results of good learners, in that participants in the *Conditioned* condition exhibited a lower *-nup* rate for Gulus in suffix identification, and exhibited a higher Norl identification rate for *-nup* words and a lower Norl rate for *-dup* words in alien identification, compared with those in the *Unconditioned* condition.

We fit a mixed-effects logistic regression respectively on

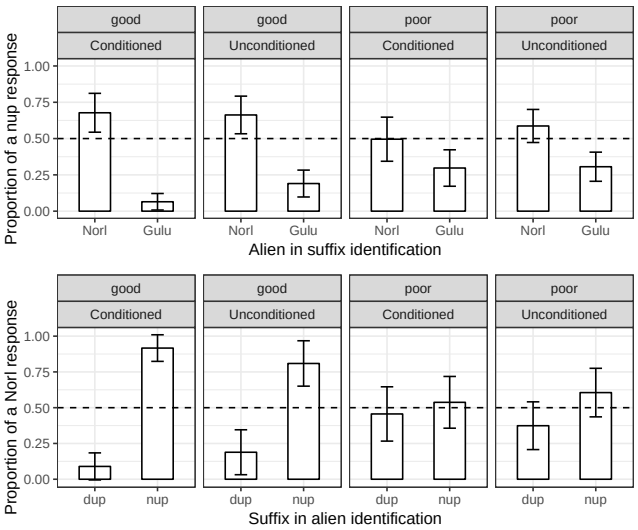

Figure 10: Proportion of *-nup* responses in suffix identification (top) and Norl responses in alien identification (bottom) by *good* and *poor* learners (including 95% confidence interval) Dotted line indicates chance level.

the data of good learners and poor learners. For good learners, the results showed significant effects of Alien ($\beta = 4.5$, $p < 0.001$), Condition ($\beta = 1.9$, $p < 0.001$) and their interaction ($\beta = -1.99$, $p < 0.001$) in suffix identification, as well as significant effects of Suffix ($\beta = 5.28$, $p < 0.001$), Condition ($\beta = 1.16$, $p < 0.001$) and Interaction ($\beta = -2.27$, $p < 0.001$) in alien identification. For poor learners, however, the results of suffix identification showed a main effect of Alien ($\beta = -0.93$, $p < 0.001$) and significant interaction between Alien and Condition ($\beta = -0.38$, $p = 0.008$), but no main effect of Condition ($\beta = 0.42$, $n.s.$). In alien identification, both factors of Suffix ($\beta = 0.33$, $p = 0.012$) and Condition ($\beta = -0.34$, $p = 0.007$) are significant, as is their interaction ($\beta = 0.62$, $p < 0.001$). Interestingly, however, the learning difference associated with the Suffix factor is the opposite of what was predicted: Learners in the *Unconditioned* condition did a better job in associating Norls to *-nup* than those in the *Conditioned* condition.

Novel Stimuli In evaluating whether acquisition effects were generalized to new words, we examined good and poor learners separately given their different patterns in acquisition. The results showed that although learners with different performance showed distinct patterns from each other, the behaviors with seen and unseen stimuli were highly consistent within each of the two learner groups. Good learners showed the correct alien-language association as well as additional facilitation from rule violation with both old and new words. Poor learners also showed consistent behaviors across old and new words, although behavior was mostly near chance level. Two mixed-effects models, one fit on each task, with Response as the dependent variable, Participant and Word as random factors, and Condition,

Stimuli, Novelty and their interactions as mixed effects, showed no significant Novelty effect or Novelty-relevant interactions.

Summary There was no evidence for constraint-violation facilitation in the aggregate results. However, post hoc analysis revealed that there was such an effect among "good learners", participants who performed above the mean in training. This is consistent with the hypothesis, as constraint violation should facilitate learning only among individuals who have learned the constraint. Finally, the results of Experiment 2 replicate those of Experiment 1 in showing an ability to generalize acquired patterns, whether accurate or inaccurate, to new words.

General Discussion

We hypothesized that violation of expectation would cause a linguistic variant to be more salient and, as a result of this, that an association between this variant and a particular social group would be easier to learn. We tested this hypothesis in two experiments, each investigating a different kind of expectation violation.

The first experiment investigated exposure to a previously unencountered variant while the second investigated exposure to a variant that had previously occurred within a narrower grammatical context. In the first experiment the expectation violation had the predicted effect: Participants were more likely to associate the new suffix with the correct alien species (and the correct alien species with the new suffix) when the suffix had not been encountered in the initial learning phase. We also found that this effect extended to previously unseen words.

In the second experiment, we found the predicted effect, but only for *good learners*. While the division of Experiment 2 participants into good and poor learners was not planned and should therefore be taken with caution, the distinction has a clear precedent in earlier work (Rácz, Hay, & Pierrehumbert, 2017) and makes good theoretical sense. We should not expect violation of a grammatical rule to be salient to participants who have not learned that rule. Indeed, it would have been inconsistent with our hypothesis if we had found such an effect for participants who had not learned the rule.

Taken together, our results suggest that unexpectedness increases the salience of variants and makes their social distribution easier to learn, deepening our understanding of the role of individual language experience in the acquisition of sociolinguistic meaning.

Human few-shot learning of compositional instructions

Abstract

People learn in fast and flexible ways that have not been emulated by machines. Once a person learns a new verb "dax," he or she can effortlessly understand how to "dax twice," "walk and dax," or "dax vigorously." There have been striking recent improvements in machine learning for natural language processing, yet the best algorithms require vast amounts of experience and struggle to generalize new concepts in compositional ways. To better understand these distinctively human abilities, we study the compositional skills of people through language-like instruction learning tasks. Our results show that people can learn and use novel functional concepts from very few examples (few-shot learning), successfully applying familiar functions to novel inputs. People can also compose concepts in complex ways that go beyond the provided demonstrations. Two additional experiments examined the assumptions and inductive biases that people make when solving these tasks, revealing three biases: mutual exclusivity, one-to-one mappings, and iconic concatenation. We discuss the implications for cognitive modeling and the potential for building machines with more human-like language learning capabilities.

Keywords: concept learning; compositionality; word learning; neural networks

People use their compositional skills to make critical generalizations in language, thought, and action. Once a person learns a new concept "photobombing", she or he immediately understands how to "photobomb twice", "jump and photobomb", or "photobomb vigorously." This example illustrates systematic compositionality, the algebraic capacity to understand and produce an infinite number of utterances from known components (Chomsky, 1957; Montague, 1970; Fodor, 1975). This ability is central to how people can learn from limited amounts of experience (Lake, Ullman, Tenenbaum, & Gershman, 2017), and uncovering its computational basis is an important open challenge.

There have been dramatic advances in machine language capabilities, yet the best algorithms require tremendous amounts of training data and struggle with generalization. These advances have been largely driven by neural networks, a class of models that has been long criticized for lacking systematic compositionality (Fodor & Pylyshyn, 1988; Marcus, 1998; Fodor & Lepore, 2002; Marcus, 2003; Calvo & Symons, 2014). Neural networks have developed substantially since these classic critiques, yet recent work evaluated contemporary neural networks and found they still fail tests of compositionality (Lake & Baroni, 2018; Bastings, Baroni, Weston, Cho, & Kiela, 2018; Loula, Baroni, & Lake, 2018). To evaluate compositional learning, Lake and Baroni (2018) introduced the SCAN dataset for learning instructions such as "walk twice and jump around right," which were built compositionally from a set of primitive instructions (e.g., "run" and "walk"), modifiers ("twice" or "around right"), and conjunctions ("and" or "after"). The authors found that modern recurrent neural networks can learn how to "run" and to "run twice" when both of these instructions occur in the training phase, yet fail to generalize to the meaning of "jump twice" when "jump" but not "jump twice" is included in the training data.

Classic arguments about the human ability to generalize have mostly rested on thought experiments. The latter, however, might underestimate facilitating factors, such as our knowledge of English, on which we are undoubtedly relying when interpreting "photobombing twice". In this paper, we study the scope and nature of people's compositional learning abilities through artificial instruction learning tasks that minimize reliance on knowledge of a specific language. The tasks require mapping instructions to responses, where an instruction is a sequence of pseudowords and a response is a sequence of colored circles. These tasks follow the popular sequence-to-sequence (seq2seq) framework and studied in Lake and Baroni (2018) and used to great effect in recent machine learning (e.g., machine translation; Sutskever, Vinyals, & Le, 2014). Seq2seq tasks require a learner to first read a sequence of input symbols, and then produce a sequence of output symbols (Fig. 1), whereby the input and output sequences can have different lengths. This framework allows us to directly compare humans and recent recurrent neural network architectures, while providing enough flexibility and richness to study key aspects of compositional learning. Moreover, the seq2seq problems investigated here present a novel challenge for both human and machine learners: unlike standard seq2seq benchmarks, which provide the learner with thousands of paired input and output examples, our "few-shot learning" paradigm provides the learner with only a handful of training examples.

Our tasks differ from the artificial grammar learning (Reber, 1967; Fitch & Friederici, 2012), rule learning (Marcus, Vijayan, Bandi Rao, & Vishton, 1999), and program learning (Stuhlmuller, Tenenbaum, & Goodman, 2010) paradigms in that we do not ask participants to implicitly or explicitly determine if items are grammatical. Instead, we ask them to process input sequences in a pseudo-language in order to generate output sequences ("meanings"). Asking participants to associate new words or sentences with visual referents is a standard practice in psycholinguistics (e.g., Bloom, 2000; Wonnacott, Boyd, Thomson, & Goldberg, 2012, and references there). Some of this work is particularly close to ours in that it studies the biases underlying linguistic generalization (e.g., Hudson Kam & Newport, 2009; Fedzechkina, Newport, & Jaeger, 2016). However, we are not aware of other studies that adopted the sequence-to-sequence language-to-meaning paradigm we are proposing here. Moreover, the biases studied in the earlier miniature language literature are more specific to grammatical phenomena attested in

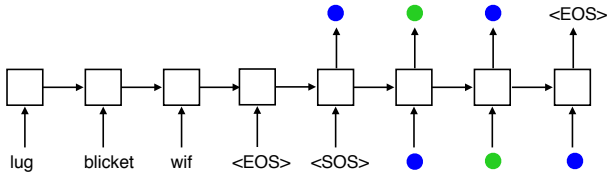

Figure 1: A sequence-to-sequence (seq2seq) recurrent neural network applied to few-shot instruction learning. Instructions are provided in a novel language of pseudowords and processed with an encoder network (in this case, the instruction is "lug blicket wif"), in order to generate an output sequence using a decoder network ("BLUE GREEN BLUE"). The symbols <EOS> and <SOS> denote end-of-sentence and start-of-sentence, respectively. The encoder (left) ends with the first <EOS> symbol, and the decoder (right) begins with <SOS>.

language (e.g., pertaining to linguistic syntax and morphology) than the basic generalization preferences we are exploring here.

Experiment 1: Few-shot instruction learning

Participants were asked to learn novel instructions from limited demonstrations. The task was inspired by the SCAN dataset for evaluating compositional learning in machines (Lake & Baroni, 2018), adapted to be novel and tractable for human learners in the lab. Instead of following instructions in English, participants learned to interpret and execute instructions in a novel language of pseudowords (e.g., "zup blicket lug") by producing a sequence of abstract outputs (a sequence of colored circles; Fig. 2). Some pseudowords were primitive instructions that correspond to a single output symbol, while other pseudowords are interpreted as functions that need to be applied to arguments to construct the output. As in SCAN, one primitive ("zup") is only presented in isolation during study but is evaluated compositionally during test, appearing in each test instruction. To perform well, participants must learn the meaning of each function from just a small number of demonstrations, and then generalize to new primitives and more complex compositions than previously observed.

Stimuli. The instructions consisted of seven possible pseudowords and the output sequences consisted of four possible response symbols (Fig. 2). Four primitive pseudowords are direct mappings from one input word to one output symbol (e.g., "dax" is "RED" and "wif" is "GREEN"), and the other pseudowords are functional terms that take arguments. To discourage a strategy based on word-to-word translation into English, the functional terms could not be easily expressed by single-word modifiers in English; they also formed phrases whose order would be unnatural in English.

The meanings of the functions were as follows. Function 1 ("fep" in Fig. 2) takes the preceding primitive as an argument and repeats its output three times ("dax fep" is "RED RED RED"). Function 2 ("blicket") takes both the preceding primitive and following primitive as arguments, producing their outputs in a specific alternating sequence ("wif blicket dax" is "GREEN RED GREEN"). Last, Function 3 ("kiki") takes both the preceding and following strings as input, processes them, and concatenates their outputs in reverse order ("dax kiki lug" is "BLUE RED"). We also tested Function 3 in cases where its arguments were generated by the other functions, exploring function composition ("wif blicket dax kiki lug" is "BLUE GREEN RED GREEN"). During the study phase (see Methods below), participants saw examples that disambiguated the order of function application for the tested compositions (Function 3 takes scope over the other functions).

Methods. Thirty participants in the United States were recruited using Amazon Mechanical Turk and the psiTurk platform (Gureckis et al., 2015). Participants were informed that the study investigated how people learn input-output associations, and that they would be asked to learn a set of commands and their corresponding outputs. Learning proceeded in a curriculum with four stages, with each stage featuring both a study phase and a test phase. In the first three stages, during the study phase participants learned individual functions from just two demonstrations each (Functions 1 through 3; Fig. 2). In the final stage, participants learned to interpret complex instructions by combining these functions (Function compositions; Fig. 2).

Each study phase presented participants with a set of example input-output mappings. For the first three stages, the study instructions always included the four primitives and two examples of the relevant function, presented together on the screen. For the last stage, the entire set of study instructions was provided together in order to probe composition. During the study phases, the output sequence for one of the study items was covered and participants were asked to reproduce it, given their memory and the other items on the screen. Corrective feedback was provided, and participants cycled through all non-primitive study items until all were produced correctly or three cycles were completed. The test phase asked participants to produce the outputs for novel instructions, with no feedback provided. The study items remained on the screen for reference, so that performance would reflect generalization in the absence of memory limitations. The study and test items always differed from one another by more than one primitive substitution (except in the Function 1 stage, where a single primitive was presented as novel argument to Function 1). Some test items also required reasoning beyond substituting variables, and in particular understanding longer compositions of functions than were seen in the study phase.

The response interface had a pool of possible output symbols which could be clicked or dragged to the response array. The circles could be rearranged within the array or cleared with a reset button. The study and test set only used four output symbols, but the pool provided six possibilities (that is, there were two extra colors that were not associated to pseudowords), to discourage reasoning by exclusion. The assignment of nonsense words to colors and functions was randomized for each participant (drawn from nine possible nonsense words and six colors), and the first three stages were

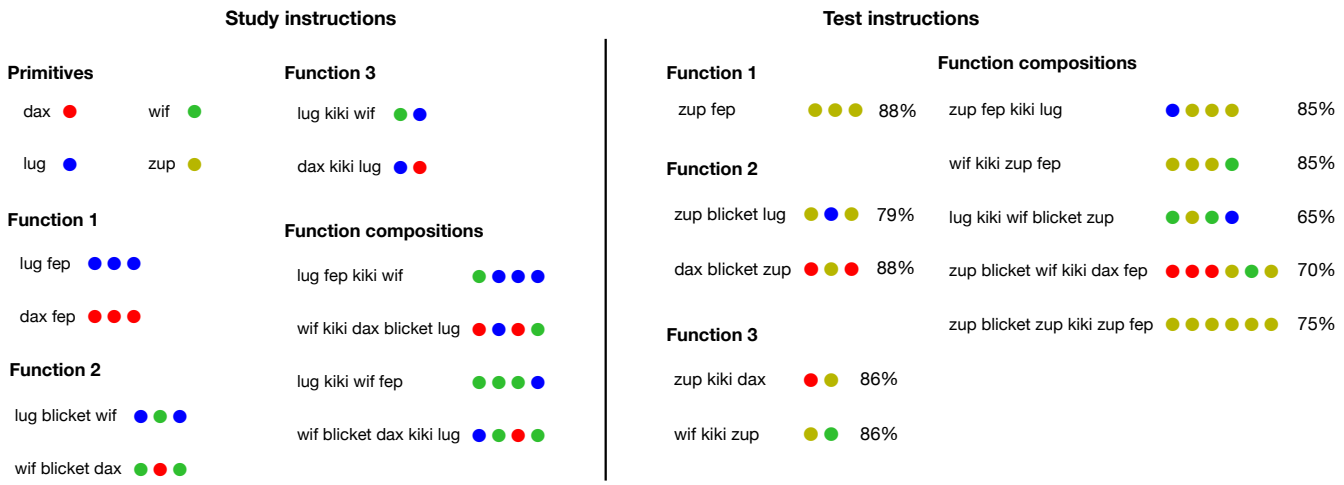

Figure 2: Few-shot learning of instructions in Exp. 1. Participants learned to execute instructions in a novel language of pseudowords by producing sequences of colored circles. Generalization performance is shown next to each test instruction, as the percent correct across participants. The pseudowords and colors were randomized for each participant; the figure illustrates an example of such an assignment.

presented in random order.

We used several strategies to ensure that our participants were paying attention. First, before the experiment, participants practiced using the response interface and had to pass an instructions quiz; they cycled through the quiz until they passed it. Second, catch trials were included during the test phases, probing the study items rather than new items, with the answers clearly presented on the screen above. There was one catch trial per stage (except the last stage had two); a participants' test data was excluded if the participant missed two or more catch trials ($n = 5$). Finally, test phases were also excluded if the corresponding study phases were not passed in the allotted time (13% of remaining data).

Recurrent neural networks. Standard sequence-to-sequence recurrent neural networks (RNNs; Fig. 1) failed to generalize from the study set to the test set. RNNs were trained using supervised learning on the 14 study instructions and evaluated on the test instructions (Fig. 2), using the best overall architecture from Lake and Baroni (2018) on the related SCAN benchmark (2-layer LSTM encoder and decoder, 200 hidden units per layer, a dropout probability of 0.5, no attention). This network (Fig. 1) consists of two neural networks working together: an encoder RNN that processes the instruction and embeds it as a vector, and a decoder RNN that decodes this vector as a sequence of output symbols. Another top architecture from Lake and Baroni was also evaluated (1-layer LSTM encoder and decoder, 100 hidden units per layer, dropout 0.1, with attention). The training setup mimicked Lake and Baroni but with 10,000 instruction presentations, corresponding to about 700 passes through the training data (epochs). Several variants of the architectures were also trained, repeatedly reducing the number of hidden units by half until there were only three hidden units per layer. Averaged across five random seeds, no architecture generalized better than 2.5% correct on the test instructions, confirming Lake and Baroni's conclusion that seq2seq RNNs struggle with few-shot learning and systematic generalization.

Results. Human participants showed an impressive ability to learn functions from limited experience and generalize to novel inputs, as summarized in Fig. 2. In the first three stages, performance was measured separately for each functional term after exclusions through the above attention criteria. Average performance across participants was 84.3% correct ($n = 25$), counting sequences as correct only if every output symbol was correct. Measured for individual functions, accuracy was 88.0% ($n = 25$) for Function 1, 83.3% ($n = 24$) for Function 2, and 86.4% ($n = 22$) for Function 3.[1]

Participants were also able to compose functions together to interpret novel sequences of instructions. In the final stage, accuracy on complex instructions was 76.0% ($n = 20$). People could generalize to longer and more complex instructions than previously observed, an ability that seq2seq neural networks particularly struggle with (Lake & Baroni, 2018). During the study phase, the most complex instruction consisted of five input pseudowords requiring two function compositions, producing four output symbols. At test, most participants could successfully go beyond this, correctly processing six input pseudowords requiring three function compositions, producing six output symbols (72.5% correct).

The pattern of errors showcases intriguing alternative hypotheses that participants adopted. Some errors were suggestive of inductive biases and assumptions that people bring to the learning task—principles that are reasonable a priori and consistent with some but not all of the provided demonstrations. For instance, many errors can be characterized by a bias we term "one-to-one," the assumption that each input

[1]The number of participants varies since data was included on the basis of passing the study phase. For comparison, the overall accuracy with no exclusions at all was 72.0%.

symbol corresponds to exactly one output symbol, and that inputs can be translated one-by-one to outputs without applying complex functional transformations. This characterized 24.4% of all errors.[2] Other errors involved misapplication of Function 3, which required concatenating its arguments in reverse order. When participants made an error, they often concatenated but did not reverse the argument (23.3% of errors for instructions using Function 3), a bias we term "iconic concatenation," referring to a preference for maintaining the order of the input symbols in the order of the output symbols. Forms of iconic concatenation are widely attested in natural language, and constitute important biases in language learning (Haiman, 1980; Goldin-Meadow, So, Özyürek, & Mylander, 2008; de Ruiter, Theakston, Brandt, & Lieven, 2018).

In sum, people learn in several ways that go beyond powerful seq2seq neural networks. People can learn novel functions from as few as two examples and generalize in systematic ways, appropriately applying the functions to previously unused input variables. People can also compose these novel functions together in ways not observed during training. Finally, people appear to bring strong inductive biases to this learning challenge, which may contribute to both their learning successes and failures.

Experiment 2: Inductive biases in instruction learning

This experiment investigated the inductive biases that appeared to influence the previous task. We devised a new set of seq2seq problems that were intentionally ambiguous and compatible with a number of possible generalizations, related to the "poverty of the stimulus" paradigm in experimental linguistics (Wilson, 2006; McCoy, Frank, & Linzen, 2018). These problems provide a more direct window into people's inductive biases because the information provided is insufficient for deducing the correct answer. The design also parametrically varied the context under which the biases were evaluated to better understand their structure and scope.

This experiment studies the one-to-one and iconic concatenation biases identified above, as well as the mutual exclusivity (ME) bias that has been studied extensively in the developmental literature. Classic studies of ME present children with a familiar and an unfamiliar object (e.g., a ball and a spatula; Markman & Wachtel, 1988), or two unfamiliar objects in which one is familiarized during the experiment (Diesendruck & Markson, 2001). When given the instruction "show me the zup," children typically understand "zup" to refer to the novel object rather than acting as a second name for the familiar object. In our instruction learning paradigm, ME is operationalized as the inference that if "dax" means "RED", then "zup" is likely another response besides "RED." Although Exp. 1 did not naturally lend itself to probing the effect of the ME bias, we conjecture that it is because of the latter that participants rapidly eliminated many degenerate solutions (such as all strings referring to the same output item) in virtually any word learning experiment. We thus want to study the impact of ME more explicitly.

Methods. Twenty-eight participants in the United States were recruited using Mechanical Turk and psiTurk. The instructions were as similar as possible to the previous experiment. In contrast, the curriculum of related stages in the previous experiment was replaced by 14 independent trials that evaluated biases under different circumstances. Each trial provided a set of study instructions (input-output mappings) and asked participants to make a judgment about a single new test instruction. To highlight the independence between trials, the pseudoword and colors were re-randomized for each trial from a larger set of 20 possible pseudowords and 8 colors. To emphasize the inductive nature of the task, participants were told that there were multiple reasonable answers for a given trial and were instructed to provide a reasonable guess.

The trials were structured as follows. Six trials pertain to ME and whether participants are sensitive to counterevidence and the number of options in the response pool (e.g., Fig 3A left and middle columns). Three trials pertain to iconic concatenation and how participants concatenate instructions together in the absence of demonstrations (e.g., Fig 3A right column). Three additional trials pertain to how people weigh ME versus one-to-one in judgments that necessarily violate one of these biases (not shown in figure). Finally, two catch trials queried a test instruction that was identical to a study instruction. The design minimized the risk that the biases could be learned from the stimuli themselves. None of the study instructions demonstrated how to concatenate, facilitating a pure evaluation of concatenation preferences. In the novel test trials, 6 instructions supported ME and 6 violated it, although both catch trials also supported ME. We did not explicitly control for the one-to-one bias. Missing a catch trial was the only criterion for exclusion ($n = 6$). There was no memory quiz for the study items since each contained just a few instructions.

Results. There was strong evidence for each of the three inductive biases. The classic mutual exclusivity (ME) effect was replicated within our seq2seq learning paradigm. If "dax" means "RED", what is a "zup"? As shown in the top-left cell of Fig 3A, most participants (18 of 22; 81.8%) chose a single "BLUE" symbol as their response if the pool provided only "RED" and "BLUE" as options, and a larger fraction (20 of 22; 90.9%) followed ME by choosing a (possibly multi-element) meaning different from "RED."

While the ME effect was robust, it was sensitive to context and was not rigidly applied. The other ME trials examined the influence of two additional factors (Fig 3A left and middle columns): the number of contradictory examples provided (0–2; Fig 3A rows) and the number of output symbols available in the response pool (2 vs. 6; Fig 3A columns). With these two variables as fixed effects, we fit a logistic

[2]These errors are defined as responses such that the input and output sequence have the same length, and each input primitive is replaced with its provided output symbol. Function words are replaced with an arbitrary output symbol.

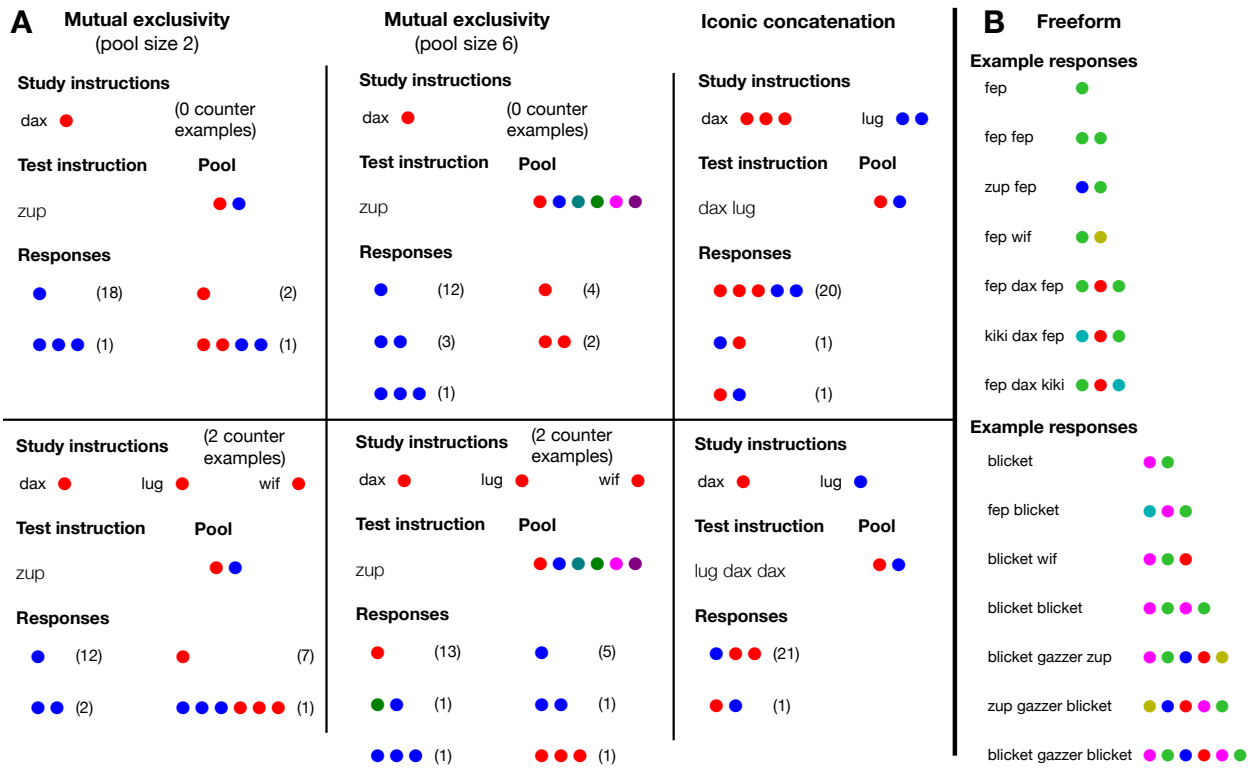

Figure 3: Inductive biases in seq2seq word learning from Exp. 2 and 3. A: In Exp. 2, Participants were asked to respond to the Test instruction given the Study instructions, using only the symbols in the Pool. Shown are four examples trials (left and middle columns) examining mutual exclusivity with varying counter-evidence (varied across rows) and pool sizes (varied across columns), and two example trials (right column) examining iconic concatenation. All unique participant responses are shown with their frequency in parentheses. A canonical assignment of pseudowords and colors was used to aggregate the data, but it was randomized in the experiment. B: Responses from two participants in the Exp. 3 free-form task. The top participant was consistent with ME, one-to-one, and iconic concatenation, while the bottom participant was missing the one-to-one bias. For part B the words and colors are as-seen in the experiment.

mixed model predicting whether or not a response was consistent with ME. Both the number of contradictory examples ($\beta = 1.76$, $SE = 0.483$, $Z = 3.64$, $p < 0.001$) and pool size ($\beta = 2.05$, $SE = 0.698$, $Z = 2.93$, $p < 0.01$) were significant predictors, indicating that people were willing to override or weaken ME when faced with more ME counter-evidence (or equivalently in our case, positive evidence that "RED" is the right answer), or when more output symbols were available in the pool (Fig. 4). The second effect is intriguing. Although we leave a detailed analysis to future work, we conjecture that it stems from pragmatic reasoning on behalf of the participants: When five yet-to-be-named objects are in the pool, ME is such a weak heuristic that participants might conclude that the experiment is not asking them to rely on it.

There was strong confirmatory evidence for iconic concatenation. Across three trials that examined this bias in various forms, we found that 93.9% ($n = 22$) of responses were consistent with iconic concatenation, even though no examples of concatenation were provided during this experiment (Fig. 3A right column). In three trials where all of the output symbols in the pool were already assigned to unique pseudowords, participants had to choose between violating ME by reassigning an output symbol, or violating one-to-one by choosing a more complex functional or multi-element meaning. Interestingly, the responses were evenly split (50.0%) between following one principle versus the other.

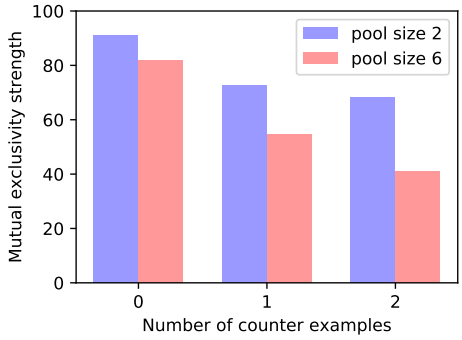

Figure 4: The proportion of responses consistent with mutual exclusivity (y-axis) declines with the number of contradictory examples and the number of output symbols available in the response pool.

Taken together, there was substantial support for three inductive biases in how people approach compositional learning in sequence-to-sequence mapping problem, confirming our hypotheses from Exp. 1. A drawback of this experiment's within-subjects design was the risk of judgments interfering with one another. The experiment used heavy randomization

and mitigated the risk that the biases could be learned from the aggregate statistics of the stimuli, but these controls were not perfect. The next experiment addresses these concerns.

Experiment 3: Inductive biases in free-form response

In this experiment, participants responded to novel instructions without receiving any demonstrations, e.g., making plausible guesses for the outputs of instructions "fep", "fep fep," and "fep wif" and how they relate to one another. This design offers the purest examination of people's assumptions since they have no relevant evidence about how to respond.

Methods. Thirty participants in the United States were recruited using Mechanical Turk and psiTurk. The instructions were similar as possible to the previous experiments, using Exp. 2's wording emphasizing there are multiple reasonable answers and to provide a reasonable guess. Participants produced the output for seven novel instructions utilizing five possible pseudowords (Fig. 3B). Responses were entered on a single page, allowing participants to edit and maintain consistency. Participants also approved a summary view of their responses before submitting. There were six pool options, and the assignment of pseudowords and item order were random. One participant was excluded because she or he reported using an external aid in a post-test survey.

Results. The results provide strong confirmatory evidence for the three key inductive biases: ME, iconic concatenation, and one-to-one. Although the task was highly underdetermined, there was a substantial structure in the responses, unlike an untrained seq2seq recurrent neural network which would respond arbitrarily. The majority of participants (17 of 29; 58.6%) responded in an analogous way to the participant shown at the top of Fig. 3B. This set of responses is perfectly consistent with all three inductive biases, assigning a unique output symbol to each input symbol and concatenating to preserve the input ordering. Other participants produced alternative hypotheses that followed some but not all the inductive biases. Overall, 23 of 29 participants (79.3%) followed iconic concatenation, assigning consistent (but possibly multi-element) output sequences to individual input words (e.g., Fig. 3B bottom). In all but one of these cases, each input word was assigned a unique output sequence, abiding by mutual exclusivity (22 of 23; 95.7%).

Discussion and Conclusions

People learn in fast and flexible ways not captured by today's algorithms. After learning how to "dax", people can immediately understand how to "dax slowly" or "dax like you mean it." These types of inferences are critical to language learning and understanding, yet modern recurrent neural networks struggle to generalize in similarly systematic ways (Lake & Baroni, 2018; Loula et al., 2018). To study these distinctively human abilities, we examined people's compositional skills in novel language-like instruction learning problems. The tasks followed the popular sequence-to-sequence (seq2seq) framework from machine learning, allowing humans and machines to be compared side-by-side. Experiment 1 examined how people learn novel instructions from examples, asking participants to interpret sequences of pseudowords by producing sequences of abstract output symbols. People could learn new functions from just two examples and successfully applied them to new inputs, while standard seq2seq recurrent neural networks (RNNs) failed to generalize. People could also handle longer sequences that require more compositions than previously observed, again surpassing the skills of powerful neural networks. Inspired by the errors participants made, Experiments 2 and 3 investigated inductive biases that constrain human learning, revealing that human learners draw upon mutual exclusivity (ME), iconic concatenation, and one-to-one in seq2seq word learning tasks.

More than a source of error, these biases provide important inductive constraints. If people interpreted the instruction as unanalyzable wholes, they would have no basis for generalization. Instead, people facilitate generalization by favoring hypotheses that assign unique and consistent meanings to individual words and follow certain input/output ordering constraints. As the final experiment shows, participants assume these characteristics before observing any data. The assumptions turn out to be powerful, characterizing most of the word meanings in Exp. 1 and the related SCAN benchmark, even though neither was designed with these biases in mind. Notably, the biases can mislead when learning function words; this was the case in many of the errors made in Exp. 1.

Future work should investigate the origin and scope of these biases through other compositional learning tasks. To the extent that our tasks evoke language learning, they could recruit biases known in the developmental literature such as mutual exclusivity (Markman & Wachtel, 1988). If the outputs are viewed as objects, one-to-one is related to the whole object assumption in word learning (Macnamara, 1982). Alternatively, if the outputs are viewed as events or actions, iconic concatenation could be justified by aligning a description with its content in time (de Ruiter et al., 2018). Another important line of future work should be providing a more explicit account of how the biases, which we observed emerging in participants' errors, are also aiding faster learning of the correct generalizations.

These insights from human learning could be fruitfully incorporated into machine learning. These biases could facilitate learning of seq2seq problems such as machine translation and semantic parsing, or related image2seq problems such as caption generation. Powerful seq2seq models do not have these inductive biases, suggesting a path to building more powerful and human-like learning architectures by incorporating them.

Abstract

Subject of this article is the question whether the potential for automatic defect analysis for symbolic timed ACT-R models as demonstrated in earlier work can be developed into a scalable and comprehensible technique. We present a formal, operational model of an ACT-R architecture and a translation scheme of ACT-R models into timed automata. We have applied this translation to ACT-R models and report on scalability experiments with automatic defect analysis.

Keywords: ACT-R; Cognitive Architecture; Formal Methods; Timed Automata; Modelling

Introduction

ACT-R (Anderson, 1983, 2009) is a cognitive architecture (an implementation of a unified theory of cognition) that is widely used in cognitive modelling to validate psychological theories. A psychological theory is a hypothesis on how a given task is solved by humans. Psychological theories can be validated by constructing an ACT-R model that implements the psychological theory and comparing the model's predictions to experimental data.

The work (Langenfeld, Westphal, Albrecht, & Podelski, 2018) points out that it is critical for this approach that an ACT-R model *correctly* implements the psychological theory because an incorrect ACT-R model (wrt. the psychological theory) may lead to a false rejection or false acceptance of an invalid theory as follows. An incorrect ACT-R model may give predictions that *do not match* experimental data although the theory's predictions would (thus false rejection), or the model may give predictions that *do match* the experimental data although the theory's predictions would not (thus false acceptance).

(Langenfeld et al., 2018) introduce the notion of *model defect* in general, i.e., any kind of programming error in production rules like simple typing errors, forgotten conditions or requests, etc. They formally study the following three model properties that can indicate the presence of errors. The first considered model property is called *deadlock*, a situation where model execution cannot continue although the model is not in a final state. The second property is *correctness of the mental model*, that is, the questions whether it is possible to observe expected chunks (as defined by the psychological theory) during model executions and whether it is impossible to observe unexpected chunks. The third property is *timing feasibility*, that is, whether an ACT-R model is principally able to reproduce timing aspects that are observed in experimental data (e.g. given a model, is it possible to complete the necessary computation steps of the ACT-R model within the time frame observed with human participants). Using an abstract, formal semantics of ACT-R (Albrecht & Westphal, 2014b), it is principally possible, effective, and useful from a modeller's point of view to automatically and exhaustively analyse ACT-R models for the absence of defects (Langenfeld et al., 2018). Spotting such errors by simulation alone is, in contrast, tedious and time consuming in general.

Subject of this article is the question whether the potential for automatic defect analysis for symbolic timed ACT-R models as mentioned above can be developed into a scalable and comprehensible technique. To this end, we present a formal, operational model of an ACT-R architecture and a translation scheme of ACT-R models into the same formalism of timed automata (Alur & Dill, 1994), that allows us to easily model the discrete, timing, and concurrency aspects of ACT-R and that is well supported by existing analysis tools (Behrmann, David, & Larsen, 2004). We have applied this translation to artificial ACT-R models as well as an ACT-R model from the research literature and we have found the analysis of the resulting network of timed automata (using existing tools) to scale well, both in number of chunks and number of production rules. By using the formalism of timed automata, we obtain a comprehensible model including all architecture aspects, hence the potential to analyse theories regarding architectures in addition to psychological theories.

Related Work. Formalisations of the ACT-R semantics appear in (Albrecht & Westphal, 2014b) and later in (Gall & Frühwirth, 2014; Gall & Frühwirth, 2018), and are used towards comparing cognitive architectures (Ragni et al., 2018).

Preliminary results on the formal analysis of ACT-R models for defects have been presented in (Albrecht & Westphal, 2014a) and elaborated in (Langenfeld et al., 2018). The feasibility of such analyses is investigated by encoding simplified fragments of ACT-R architecture and model aspects and selected rules into logical formulae that can effectively be analysed for satisfiability. This work, in contrast, supports a wider range of analysis goals and aims at a comprehensible model of an architecture and a complete ACT-R model.

An analysis procedure for confluence of ACT-R models can be obtained by encoding an ACT-R architecture and models in constraint handling rules and solving the confluence problems in this domain (Gall & Frühwirth, 2017).

Preliminaries

F-ACT-R. The formal description of ACT-R (Albrecht, 2013; Albrecht & Westphal, 2014a) differentiates between a syntactical

description of the ACT-R model and description of the semantics assigned to the constructs of the model by a cognitive architecture.

The abstract syntax of ACT-R defines a model over a set of module signatures. A module signature consists of a finite set of buffers B, a finite set of module queries Q, and a finite set of action symbols A. A production rule r is a pair of a precondition and an action. A precondition is a proposition over buffer slots and module queries. An action is a set of similar propositions together with a buffer and an action symbol. An ACT-R model is a finite set of production rules $R = \{r_1,...r_n\}$ and a finite set of chunks $\{c_0,...,c_n\}$.

An ACT-R architecture consists of a interpretation function for the action symbols of modules and a production rule selection mechanism. A cognitive state is a function γ from buffers to pairs (c,d) where c is a chunk and d is a time delay. A pair in γ thus describes buffer contents (if $d = 0$) and buffer assignments in the future (if $d > 0$). The ACT-R architecture works in cycles of production rule selection and execution. Cognitive states γ,γ' are in a successor relation ($\gamma \xrightarrow{(r,t)} \gamma'$), if the selection mechanism chooses production rule r (consuming time t) whose precondition is fulfilled by the current cognitive state γ and γ' is the result of applying the interpretation of every action symbol of r to γ.

Running Example. The addition model from the ACT-R tutorial (Bothell, 2017b), Unit 1.7.1, models the addition of two numbers by counting up from the first number in as many steps as given by the second number. To implement counting, the model uses rules whose preconditions match the current number and retrieve the corresponding count fact, i.e. a pair of a number and its direct successor, from declarative memory. In our examples we use the production rule *initialize-addition*, which is only applicable at the beginning of the computation. Its precondition requires an empty goal buffer slot `sum`. To start the addition, its action assigns the first number of the addition to goal buffer slot `sum`, and 0 to the `count` slot that tracks counting of the second number. Then a retrieval for the successor of `sum` is started.

Timed Automata. Timed automata (Alur & Dill, 1994) are a formal, operational model of real-time systems, i.e., systems that have to compute outputs within certain time intervals. In the simplest case, a *timed automaton* $\mathcal{A}$ is a tuple $(L,B,\mathbb{X},I,E,\ell_{ini})$ comprising a finite set of *locations* L (including the *initial location* ℓ_{ini}), a set of *channels* B, and a set of *clocks* $\mathbb{X}$. Function I labels each location with a clock constraint (called location *invariant*), and E is a finite set of edges. An edge $(\ell,\alpha,\varphi,\rho,\ell')$ comprises source and destination location ℓ and ℓ', action α (which can be the internal action τ, or an *output* $b!$ or *input* $b?$ on a channel $b \in B$), clock constraint φ as *guard*, and the *update* $\rho \subseteq \mathbb{X}$ that denotes the set of clocks to be reset.

The operational semantics of a *network of timed automata* $\mathcal{N} = \mathcal{A}_1 \| \cdots \| \mathcal{A}_n$ ('$\|$' denoting parallel composition) is a labelled transition system over *configurations* $\langle \vec{\ell}, \nu \rangle$ where $\vec{\ell}_i$ is the *current location* of automaton $\mathcal{A}_i$ and $\nu : \mathbb{X} \to \mathbb{R}_0^+$ is a valuation of the clocks. Two configurations are in transition relation $\langle \vec{\ell},\nu \rangle \xrightarrow{\lambda} \langle \vec{\ell}',\nu' \rangle$ if and only if $\lambda \in \mathbb{R}_0^+$, $\vec{\ell} = \vec{\ell}'$, and $\nu' = \nu + \lambda$ satisfies the invariants of all locations in $\vec{\ell}$ (delay transition), or there is an edge $(\ell,\tau,\varphi,\rho,\ell') \in E_i$ such that $\vec{\ell}_i = \ell$, $\vec{\ell}'_i = \ell'$, φ is satisfied in ν, and ν' is obtained from ν by resetting the clocks in ρ to zero (internal transition), or there are two edges enabled in two different automata in $\mathcal{N}$ with complementary input and output actions (rendezvous transition). A *computation path* of a network of timed automata is a sequence of configurations starting with $\langle \vec{\ell}_0,\nu_0 \rangle$ where $\vec{\ell}_0$ comprises the initial locations, and ν_0 assigns value 0 to all clocks (and satisfies all location invariants), and subsequent configurations are in transition relation.

The modelling, simulation, and model-checking tool Uppaal (Behrmann et al., 2004) extends the simple case by features such as data variables, broadcast channels, and committed locations where no delay is possible. In the remaining article, we use a graphical representation of timed automata (see, e.g., Figure 1) where the double outline location is initial, locations marked by a 'C' are committed locations, and invariants (if any) are shown in purple. Edges are annotated with action (in cyan), guard (in green), and updates (in blue).

TA-ACT-R

In this section, we describe how we represent ACT-R models by networks of timed automata that can then be analysed for ACT-R model defects. Recall that an ACT-R model R is a finite set $\{r_1,...,r_n\}$ of production rules that has computations *on* an architecture A.

Given an ACT-R model R and an architecture A, we construct networks $\mathcal{N}^R$ and $\mathcal{N}^A$ of timed automata such that we can conclude from analysis results of the network $\mathcal{N}^R \| \mathcal{N}^A$ to the presence or absence of model defects in the ACT-R model on architecture A. Constructing the network $\mathcal{N}^A$ can be considered a one-time effort: In the case described below, we consider timed automata that follow the production rule selection mechanism and the behaviour of models in the ACT-R tool. Network $\mathcal{N}^A$ can be composed with any $\mathcal{N}^R$, i.e., with any network of a specific ACT-R model, as long as model R is compatible with the modules offered by A.

In the following paragraphs, we first describe the construction of the timed automata in $\mathcal{N}^A$ that model module behaviour, here on the example of the declarative module. Then we describe the construction of production rule automata to obtain $\mathcal{N}^R$, and conclude with the production rule selection mechanism in $\mathcal{N}^A$. Figure 5 visualises the overall structure and potential communication between the timed automata in $\mathcal{N}^R \| \mathcal{N}^A$ over shared channels.

Chunks and the Declarative Module. The declarative module is responsible for memory management, i.e. to maintain and recall chunks of previously learned information. Actions of production rules can initiate a recall of information, e.g., the successor of a number in the addition model, and the declarative module delivers one (of possibly many) matching chunks or none at all. Recalling information takes time: In ACT-R, the declarative module takes a certain amount of time to recall information (retrieval delay) or considers a recall failed after a time limit (retrieval threshold).

Our TA-ACT-R model of the declarative module is a set of timed automata that realise the behaviour described above. It comprises one timed automaton $\mathcal{A}^D$, and one timed automaton $\mathcal{A}^{ch}$

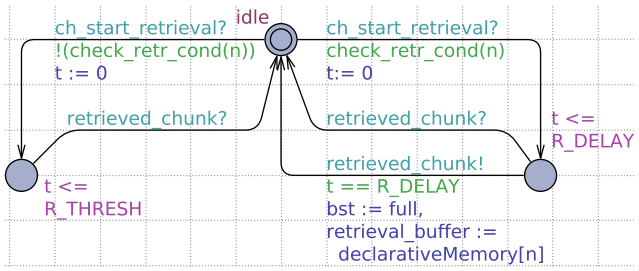

Figure 1: TA-ACT-R chunk automaton $\mathcal{A}^{ch}$.

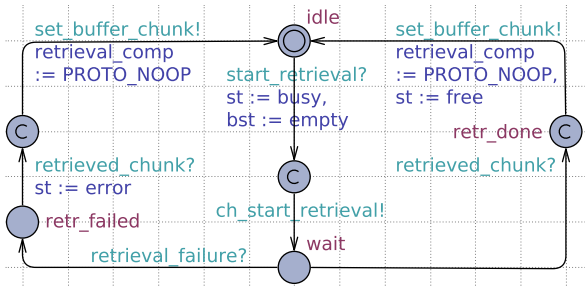

Figure 2: TA-ACT-R automaton $\mathcal{A}^{D}$ (declarative).

for each chunk in memory. The idea of this structure is that, for each recall action, $\mathcal{A}^{D}$ stimulates all chunk automata at once, and each chunk automaton with a chunk matching the current recall action offers its chunk to $\mathcal{A}^{D}$. Selection between matching chunks is non-deterministic (and exhaustively considered in analysis).

Figure 1 shows the TA-ACT-R chunk automaton $\mathcal{A}^{ch}$. From the initial location `idle` there are two possible ways of handling a recall action: Either the chunk managed by $\mathcal{A}^{ch}$ matches the request (continue to the right) or not (continue to the left). The distinction between the two cases is made by function `check_retr_cond()`, which hides the details of comparing the request (as specified by shared variables). Both edges (to the right and to the left of `idle`) reset clock t to 0. By the invariants of the bottom right (or left) locations (shown in purple), either an amount of time units corresponding to retrieval delay or retrieval threshold pass. In case of a match (bottom right location), automaton $\mathcal{A}^{ch}$ can send or receive on the broadcast channel `retrieved_chunk`. If multiple chunks match, exactly one chunk automaton non-deterministically acts as sender and all others receive simultaneously. In any case (including no matching chunk), the synchronisation moves the automaton back to location `idle` and the recall action is completed from the perspective of the chunk automaton. Only the chunk automaton acting as sender writes its chunk into the shared variable `retrieval_buffer` that models the retrieval buffer of the declarative module and sets the buffer flag `bst` to indicate that there is a chunk in the retrieval buffer. This update corresponds to placing the retrieved chunk in the declarative module's retrieval buffer.

That is, the timing behaviour of the declarative module is modelled in the chunk automata. Note that our model can support any number of chunks in memory, yet an upper bound on the number of $\mathcal{A}^{ch}$ automata needs to be fixed before analysing the model. This constraint corresponds to the observation that the majority of ACT-R models considers cognitive tasks that are solved in bounded time, and there is the assumption that only finitely many chunks can be used in bounded time. Yet an analysis of a TA-ACT-R model can detect if a given upper bound is sufficient to support a given ACT-R cognitive model. If not, the upper bound on the number of chunks can be increased and the analysis restarted, which in particular allows us to analyse the maximum number of chunks actually considered in a given ACT-R model. Note, that the specified number of chunks only restricts memory size but not memory content. Chunk content may be set in advance modelling pre-existing declarative knowledge (as in the addition model) and content may be acquired by chunk automata during run time (modelling learning of declarative knowledge).

Checking for matching chunks, retrieving one matching chunk (if any), and reporting the result of the recall action is organised by the timed automaton $\mathcal{A}^{D}$ shown in Figure 2.

In the TA-ACT-R model, the recall action is started by a synchronisation on channel `start_retrieval` with a rule automaton (see below) and taking the edge from location `idle` downwards. Without intermediate delay, the module flags are updated to indicate that the declarative module is busy and then the chunk automata are triggered by sending on channel `ch_start_retrieval` (cf. Figures 2 and 1) and changing to location `wait`. From location `wait`, there are two cases: either at least one chunk matched or none. The first case is handled by the sequence of edges to the right of `wait` (by synchronising with the chunk automata as explained above) and updating some more shared variables of the network, so that other automata in the complete network can access the recalled chunk. The second case (no chunk matched) is handled by the mostly symmetric sequence of edges to the left of `wait`, which sets the module's flags accordingly. In both cases, before returning to location `idle` and being ready for the next recall action, the procedural automaton is notified of completion by synchronisation on channel `set_buffer_chunk`.

Note that Figure 1 shows a simplified chunk automaton for brevity of this presentation. In general, the declarative module is able to learn new chunks. Further note that TA-ACT-R models the purely symbolic variant of ACT-R declarative memory, that is, fulfilling a request is a sufficient condition for a chunk being retrieved from memory. In general, retrieval through the declarative module is affected by an *activation* value that models the effect of frequent usage of a chunk and prevents chunks with an activation value below a given threshold from being retrieved from memory. The analysis of the TA-ACT-R model presented here hence detects model errors like deadlock or (in)correctness of the mental model under the assumption of perfect memory. These errors do not disappear when considering activation hence such errors should be removed before considering more expensive analysis with activation (which is future work).

Production Rules. Given an ACT-R model R consisting of the rules $r_1,\ldots,r_n$, the network $\mathcal{N}^R$ is the parallel composition of n rule automata, i.e. $\mathcal{N}^R = \mathcal{A}^{r_1} \| \cdots \| \mathcal{A}^{r_n}$.

Figure 3 shows a concrete rule automaton to illustrate the principal construction of rule automata. Each rule automaton has two

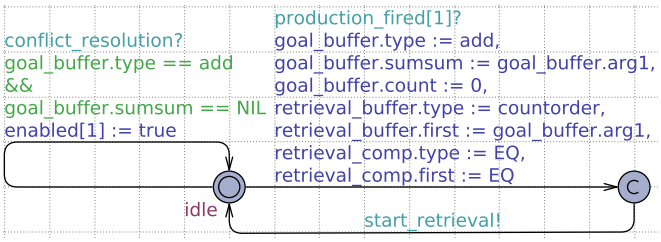

Figure 3: TA-ACT-A automaton $\mathcal{A}^r$ of the production rule *initialize-addition* of the addition model.

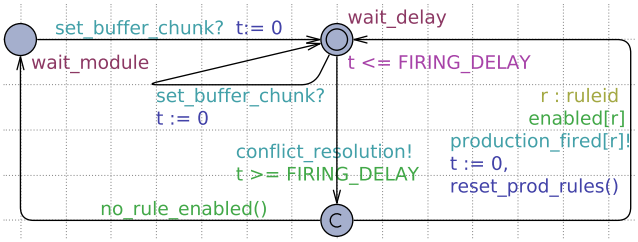

Figure 4: TA-ACT-R automaton $\mathcal{A}^P$ (procedural).

cycles (or phases) starting in the initial location `idle`. To the left is a single edge that synchronises with the procedural module automaton (see below) to determine the currently enabled production rules. The principle is similar to the selection of a matching chunk from the chunk automata by the declarative module automaton $\mathcal{A}^D$ in that it uses a broadcast channel (here `conflict_resolution`).

If the procedural module automaton sends on `conflict_resolution`, all rule automata simultaneously take the left edge from `idle` to `idle` if the guard is satisfied. Automaton $\mathcal{A}^r$ writing a value 1 into their position of the shared array variable `enabled` indicates that it is possible to fire rule r under the current module configuration.

If rule r is selected by the procedural module, the latter sends on the rendezvous channel `production_fired`$[r]$such that the rule automaton takes the sequence of edges to the right of `idle` (cf. Figure 3). The first edge in the sequence has updates according to the actions of the rule, followed by a sequence of edges that trigger activities of modules (in this example, of the declarative module discussed above).

Figure 3 actually shows the rule automaton of the production rule *initialize-addition* (cf. Preliminaries). The precondition of this rule, r_{ia} for short, is satisfied if the goal buffer does not yet hold an intermediate or final result. This precondition has a direct translation to the guard (shown in green) of the left edge in Figure 3. The action of r_{ia} updates the goal buffer and prepares the buffer of the declarative module for a chunk retrieval. This action directly translates to the update (shown in blue) of the right edge in Figure 3.

The general translation of a rule from an ACT-R model uses the structure shown in Figure 3. A translation of the rule's precondition becomes the guard of the left edge and a translation of the rule's action becomes the update of the right edge, followed by a sequence of synchronisations to initiate behaviour of the modules referred to in the rule.

Procedural Module. Figure 4 shows the automaton that realises the behaviour of the procedural module which selects enabled rules for execution. As explained with the rule automaton above, there are two phases. A rule execution cycle starts in location `wait_delay` by sending on channel `conflict_resolution` on the downward edge. Rules whose preconditions are fulfilled receive, and update the shared array `enabled` accordingly. If at least one rule is enabled, the lower location is exited to the right. One enabled rule is selected non-deterministically and sending on the corresponding `production_fired` channel triggers the execution of the action of the selected rule. The shared array `enabled` is also reset on the right edge back to `wait_delay`. In location `wait_delay`, the invariant and the guard of the outgoing edge ensure that the next rule is executed at least `FIRING_DELAY` time units later. In case that no rule is enabled, the procedural module automaton waits for any module to change state, since only a change in the cognitive state makes it necessary to check again for an enabled rule (Anderson, 2009; Bothell, 2017a). The self loop on the location `wait_delay` ensures that the firing delay is observed if the cognitive state changes during the procedural module waiting for the next rule execution cycle to start.

The Rule Execution Cycle. Figure 5 shows everything put together. The network $\mathcal{N}^A$ modelling the (ACT-R model independent) architecture is the parallel composition $\mathcal{A}^P \| \mathcal{A}^D \| \cdots$ of all module automata (as discussed above). The network $\mathcal{N}^R$ representing the behaviour of the considered ACT-R model $R = \{r_1,...,r_n\}$ is the parallel composition $\mathcal{A}^{r_1} \| \cdots \| \mathcal{A}^{r_n} \| \mathcal{A}^{ch}_1 \| \cdots \| \mathcal{A}^{ch}_m$ of the rule automata for R with m chunk automata (memory size).

The cognitive architecture of ACT-R interprets ACT-R models by repetitive application of the following, 3-step rule execution cycle: 1.) wait a fixed time, 2.) check rules' preconditions on the current cognitive state to determine the set of enabled rules, and 3.) executing the action of an enabled rule (if any; otherwise wait for a change of the cognitive state). Modules may work during the waiting time in Step 1. The same execution cycle is directly visible in our TA-ACT-R model where Steps 1 to 3 are driven by automaton $\mathcal{A}^P$ and the steps are conducted in cooperation with the rule automata. The basic rule execution cycle is controlled by $\mathcal{A}^P$ (acting as sender on different channels), yet during its waiting time module automata may work concurrently.

Execution of the TA-ACT-R addition model would start by $\mathcal{A}^P$ waiting for the fixed time in location `wait_delay` (Step 1; cf. Figure 4) and then triggering each rule automaton to update their enabled flag (Step 2; cf. Figure 4 and 3). In our TA-ACT-R addition model, the shared variables are initialised such that the initialisation production rule (as shown in Fig. 3) is enabled. Hence $\mathcal{A}^P$ would then trigger this rule automaton (Step 3; cf. Figure 4 and 3). The rule automaton executes the actions of its rule (possibly in cooperation with module automata) while $\mathcal{A}^P$ is already back in location `wait_delay`, that models Step 1. The retrieval action started by the rule automaton is processed (including the retrieval delay) by the declarative module and

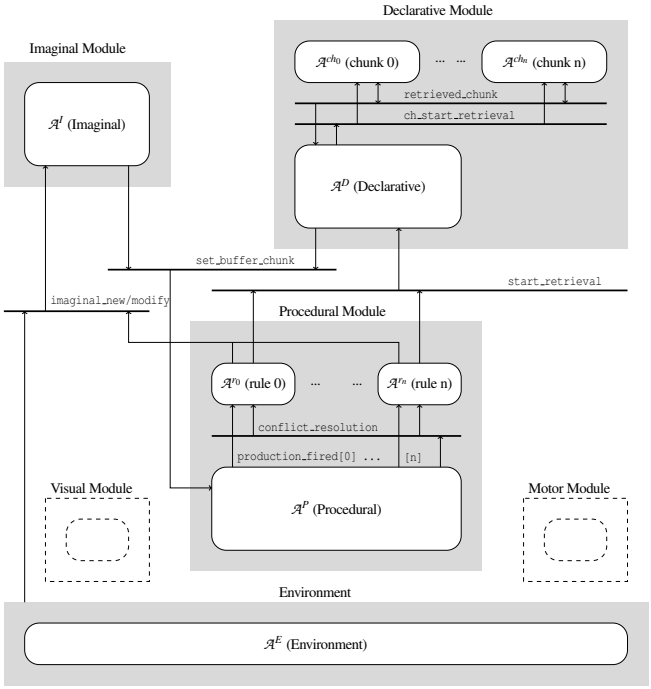

Figure 5: Structure of TA-ACT-R. Each white rectangle represents one timed automaton in the TA-ACT-R model. Arrows show potential synchronisation and are directed from senders to receivers and labelled with the channel name. The grey boxes group together those timed automata that together model an architecture module. Note that the environment does not directly interact with the imaginal module in ACT-R, but through, e.g., the visual module. For our experiments, we have abstracted from this indirection, a timed automaton model of, e.g., the visual module would be placed in the structure as shown by the dashed boxes.

chunk automata (cf. Figure 2 and 1). After completion of this retrieval, $\mathcal{A}^P$ is notified about the changed cognitive state and commences the next rule execution cycle (Step 1).

Formally, we observe sequences of timed automata configurations that are related by delay or synchronisation transitions. In these transition sequences of the TA-ACT-R network, we can clearly identify those configurations that correspond to situations *right before* starting a new rule execution cycle. In the more abstract F-ACT-R semantics, a rule execution cycle basically corresponds to one transition between two cognitive states, namely $\gamma_0 \xrightarrow{(r_1,50)} \gamma_1$ where $\gamma_0 = \{\text{goal} \mapsto (c_0,0), \text{retrieval} \mapsto (\bot,0)\}$ is the initial cognitive state and $\gamma_1 = \{\text{goal} \mapsto (c_0,0), \text{retrieval} \mapsto (c_2,50)\}$ is the cognitive state at the end of the rule execution cycle yet waiting for the retrieval action to complete.

The abstract, F-ACT-R computation paths of a given ACT-R model are hence refined by TA-ACT-R computation paths (one transition in the F-ACT-R model is related to a sequence of transitions in the TA-ACT-R model), which in turn is refined by computations of the ACT-R tool. In all three cases, we can clearly pinpoint the configuration right before the next rule execution and thus conclude from, e.g., an analysis of a TA-ACT-R model to the reachable cognitive states in the more abstract F-ACT-R view.

Discussion. Figures 1 to 4 show an abstract, comprehensible, readable and simulatable *model* of an ACT-R architecture. Using this architecture model, it becomes remarkably easy to evaluate ACT-R models under different architecture assumptions of a much wider range than the parameters of the ACT-R simulator allow. For example, other retrieval delays are obtained by redefining constants in $\mathcal{A}^D$ (cf. Fig.2); counting presentations (to support activation values) can be realised by increasing a counter in the successful case of a chunk automaton; unsuccessful retrieval of chunks in memory (sporadic forgetting) can be realised by removing the left edge from `idle` in the chunk automaton; etc.

By using a formal modelling language like timed automata, we obtain a precisely defined semantics. In contrast to a textual description of ACT-R's behaviour, it is unambiguously determined which delays or edges are possible in each model configuration. The Uppaal tool uses this fact to offer a convenient simulation environment that shows, in each configuration, the enabled edges and allows a user to choose the next one. If a model analysis finds a defect, the simulator can be used to inspect one computation path that exhibits the defect.

From these two aspects, we also envision a use of our TA-ACT-R models in teaching ACT-R: We see our model to fill a gap between a slide presentation of the concepts and principles of ACT-R and the ACT-R tool. Instructors could use the timed automata simulator in order to present the dynamic behaviour of the ACT-R architecture from rule selection to module activities before referring students to the ACT-R tool.

Evaluation

A highly relevant question on model analysis techniques and tools is about scalability. To be practically useful, a tool needs to be able to analyse ACT-R models that are used in cognitive science research.

Our investigation of the scalability of our TA-ACT-R-based approach to model analysis considers the following three research questions: (1) How does the number of chunks in the declarative memory affect the consumption of computational resources? (2) How does the length of the cognitive computation path affect the consumption of computational resources? (3) How does the number of rules in the ACT-R model affect the consumption of computational resources?

Addition Model. We have investigated the scalability of our approach using a parameterised ACT-R model of the addition task. Table 1a reports measurements of the classical addition model with four rules that we apply to a given number of count order chunks in declarative memory. The goal, that is, the number of count steps necessary to complete the addition, is fixed and thereby we isolate the effect on computational resource consumption to the number of chunks. The analysis checks that for each TA-ACT-R computation path, we finally observe the correct result in the goal buffer. Table 1a shows that the analysis of this parameterised addition model easily scales to 1,000 chunks considered for retrieval, while the length of the TA-ACT-R model compu-

Decl.	Time	States	Memory

50	0.7 s	1,431	10.6 MiB
100	2.5 s	2,931	17.8 MiB
500	65.2 s	14,931	177.6 MiB
1,000	254.8 s	29,931	653.9 MiB

(b) Resource consumption with increasing number of chunks (Decl.), with highest possible addend (chunk number minus 1).

Proc.	Time	States	Memory
100	0.8 s	11,806	9.0 MiB
1,000	11.9 s	17,230	58.1 MiB

(c) Resource consumption with increasing number of production rules (Proc.), with highest possible addend.

Table 1: Evaluation results for time and memory consumption of an exhaustive analysis of addition models with `verifyta` 4.1.19 (Behrmann et al., 2004). Column 'States' gives the number of reachable configurations of the network of timed automata (cf. Preliminaries). The figures given above are averaged over ten runs (i7-6500/2.5 GHz, 8 GiB, Windows 10/64bit laptop).

tation path remains constant as expected from the fixed goal. Time consumption increases about linearly because each step of the analysis algorithm needs to check each chunk automaton for whether it offers a matching chunk; the reason for increased memory consumption is that the number of automata in the network uniformly increases the size of each TA-ACT-R configuration.

Table 1b reports measurements from the same model discussed above but with increasing addition goal. The model is supposed to apply the highest number of count steps possible with the given chunks, i.e. the instance with 1,000 chunks is supposed to conduct 999 count steps. The time needed for the analysis in the table scales roughly linearly in both, number of chunks and length of computation; the numbers of reachable TA-ACT-R configurations in the table grow linearly in the length of the computation. Table 1b shows that an exhaustive analysis of the model with a few hundred chunks takes not much more than a minute. With an analysis time in this low order of magnitude, we anticipate that our TA-ACT-R analysis can be effectively used during the process of cognitive modelling, that is, to analyse an ACT-R model for common errors, and, in case errors are found, to fix these errors and re-run the analysis. For large chunk numbers and computation lengths, the time needed to complete the analysis becomes more noticeable. We suggest to value the computation time wrt. the obtained outcome: After (in case of the addition model) about 4 minutes, *all possible computations* of the cognitive model have been considered.

Table 1c reports measurements from a different addition model where each count fact is modelled as its own production rule. That is, in order to, e.g., do 100 count steps, there are 100 different rules. Table 1c shows that the analysis of this parameterised addition model easily scales to 1,000 rules.

Preferred Mental Model Theory. To evaluate the performance of our TA-ACT-R-based approach on a cognitive model from the research literature, we have considered the PMMT[1] model that has been used in (Langenfeld et al., 2018) to illustrate the usefulness of checking models for the absence of deadlocks (a deadlock is a cognitive state where no production rule is able to fire while the end of the modelled behaviour has not been reached).

The considered ACT-R model of the PMMT is technically non-trivial as it makes use of multiple modules (often in the same rule) and depends on complex preconditions including buffer requests and module queries. From its design parameters (about 40 production rules, less than 10 learned chunks), we would have expected an exhaustive analysis of the computational space of the TA-ACT-R model to take at most one second considering the figures in Table 1. In fact, the analysis was much faster: The analysis tool `verifyta` (Behrmann et al., 2004) reported the absence of deadlocks for every possible combination of two premises and a conclusion within 146*ms* (storing 701 TA-ACT-R states in 8.7 MiB of memory). Thus there are complex ACT-R research models that can be very efficiently analysed for the absence of model defects (Langenfeld et al., 2018).

Conclusion and Future Work

As future work we will automate the translation of the production rules of an ACT-R model to the according automata to enable the analysis of models without manual translation. We will also extend TA-ACT-R by hybrid processes like chunk activation and retrieval delays. We will also integrate hybrid processes (e.g. calculation of chunk activation and retrieval delays) into TA-ACT-R to replace the non-deterministic sub symbolic layer for more precise analysis of ACT-R models.

In this article we investigated the potential for automatic defect analysis of ACT-R models. We developed a formal but easy to comprehend model of the ACT-R architecture and a translation scheme for ACT-R models. Benchmark results show, that the analysis of useful properties scales well for high numbers of chunks and production rules so that it can be applied during model development.

Abstract

In this study we investigated the role of conceptually rich explanations and anomalous evidence in children's scientific belief revision. We also explored whether the order in which children experience these two learning opportunities influences their belief revision ability. Five-year-old children were assigned to one of two conditions, where they either first received conceptual explanations about buoyancy and then observed anomalous data in a guided activity (*Explanation-First*), or the reverse (*Anomalies-First*). Results showed that (1) conceptually rich explanations lead to more accurate predictions about which objects sink and which float than anomalous data presentation, and (2) when explanations and anomalous data were combined, children's correct predictions increased significantly from pre-test to post-test when they received the conceptual information before the anomalous evidence (*Explanation-First*), but not in the opposite order condition (*Anomalies-First*). These results suggest that children are more likely to maintain their misconceptions when exposed to anomalies without prior instruction involving conceptually rich explanations.

Keywords: cognitive development; belief revision; scientific reasoning

Supporting Scientific Belief Revision

Scientific beliefs have their foundations in early development. Much of children's early science learning is informal, and the intuitive theories they build through daily observation and cultural learning are frequently at odds with accurate scientific theories (Kuhn, 1989; Vosniadou & Brewer, 1992). Children's naïve misconceptions are often resistant to change (Vosniadou, 2002) and some persist into adulthood (Coley & Tanner, 2012; Pine, Messer, & St. John, 2001; Shtulman & Valcarcel, 2012). Conceptual change is the process of restructuring naive theories to include counter-intuitive concepts, which for some scientific domains can be a lengthy and arduous process (Vosniadou, 2013).

The process of early scientific reasoning has been compared to formal scientific theory change, in which children get to formulate, test, and revise hypotheses based on evidence and observations (Gopnik, 2012; Gopnik & Wellman, 2012). As part of this process, experiencing anomalous evidence that contradicts existing naïve theories is an important driver of belief revision. For example, some existing research suggests that, depending on which type of anomalous data they observe, preschool children either explain away or change their naïve theories about how objects balance (Bonawitz, Van Schijndel, Friel, & Schulz, 2012).

However, anomalous data may not always be sufficient for facilitating belief revision. Research about causal systems has indicated that when children are shown novel causal systems, they can theorize about the causal relation in these systems, and are subsequently resistant to changing these theories, even when immediately presented with new anomalous data (Schauble, 1990; Schulz, Goodman, Tenenbaum, & Jenkins, 2008). This is compounded by the fact that although providing children with anomalous data presents an opportunity for belief revision, children often make errors during the observation, interpretation, generalization, or retention stages of science activities when they encounter anomalous evidence (Chinn & Malhotra, 2002).

In the case of existing misconceptions, children's tendency to hold onto naïve theories may be even more pronounced as these theories are more entrenched. Children's difficulty in making inferences from evidence that is in conflict with their naïve theories may result from the absence of a viable alternative theory (Chinn & Brewer, 1993). If children are provided with alternative explanations, they may be better equipped to interpret the anomalous data they encounter and as a result be more likely to engage in belief revision. Thus, combining anomalous evidence with correct conceptual explanations may be particularly effective for belief revision and science learning more generally (Koslowski, 1996).

Current Study

The goal of the current study was twofold. First, we examined the role of conceptually rich explanations and anomalous evidence in children's ability to revise an existing naïve scientific belief. Second, we explored whether the order in which children experience these two learning opportunities influences their belief revision ability. Five-year-old children were provided with conceptually rich information about buoyancy (during a brief picture book reading session) either before or after they had the opportunity to observe anomalous examples (i.e., heavy objects floating) in a guided play activity. We selected to deliver the conceptually rich explanations in a picture book format not only because picture-book reading is an

enjoyable activity for many young children, but also because research has shown that young children can learn scientific information from picture books, even in cases where they hold misconceptions (Kelemen, Emmons, Seston Schillaci, & Ganea, 2014; Venkadasalam & Ganea, 2018). We presented anomalous evidence through a guided activity, which allowed for active engagement with real, physical objects (Nayfeld, Brenneman, & Gelman, 2011; Peterson & French, 2008). Here, we were interested in how children interpret and generalize from real-life anomalous evidence. In guided activities, adults plan an activity with a learning goal, and scaffold this learning, which allows children to maintain an active role in the process (Weisberg, Hirsh-Pasek, & Golinkoff, 2013). Thus, guided activities provided children with hands on opportunities to interact with anomalous evidence in an engaging way, but also ensured that they were able to produce such evidence with guidance.

We examined belief revision in children's acquisition of a physical science concept (buoyancy), a concept with common misconceptions. Buoyancy is the upward force on objects in a liquid. An object floats if the buoyant force is equal to the force of gravity, and an object sinks when the gravitational force is stronger. Sinking and floating are concepts taught throughout science education (Kallery, 2015; Selley, 1993) and ones for which children often hold misconceptions (Hardy, Jonen, Möller, & Stern, 2006; Yue, Tomita, & Shavelson, 2008). One difficulty young children have is that they often conflate density with weight (Wilkening & Cacchione, 2011), which is problematic when children have to compare the relative densities of the objects and water, often leaving them with the misconception that heavy objects sink and light objects float (Lehrer, Schauble, Strom, & Pligge, 2011; Smith, Carey, & Wiser, 1985). When 5-year-old children notice anomalies to their intuitive theories ("heavy objects sink and light objects float") they sometimes hypothesize about the material of the objects (e.g., wooden objects float). A focus on material is a promising step in children's ability to think about density because some materials are less dense than others and therefore sink at different rates. However, to fully understand what makes objects sink or float, children also have to consider how the mass is distributed and therefore take into account the shape of the object as well. Here we explore the effect of pairing anomalies with conceptually rich explanations to promote children's ability to dissociate the objects' behavior in water from their weight and recognize the role of air-filled cavities and surface tension in explaining why objects sink or float.

The study was designed using a pre-, mid-, and post-test to measure children's belief revision. In each test phase, we examined differences in children's predictions of whether objects would sink or float as a function of the order of instructional methods used (conceptual information or anomalous data). Children's predictions were chosen as an implicit measure of learning. The pre-test allowed us to control for children's previous knowledge. The mid-test allowed us to determine the role of each learning opportunity (explanations or anomalous evidence) on children's belief revision in isolation. Finally, the post-test was used to determine whether the order in which children received the two learning opportunities mattered when they were combined.

We expected that, when compared to pre-test scores, children's predictions at mid-test about which objects float or sink would be significantly higher in the *Explanation-First* condition but not the *Anomalies-First* condition. There is previous research showing that children are able to learn scientific information from conceptually rich explanations (Kelemen et al., 2014; Venkadasalam & Ganea, 2018) and we expected to find the same type of evidence here. However, given the existing research with adults on the use of anomalous evidence indicating that individuals often make errors in the interpretation and generalization of this evidence (Chinn & Malhotra, 2002), we expected that the exposure to anomalies alone will not lead to a change in children's misconceptions.

With respect to the order in which children receive the conceptually rich information and the anomalous evidence, we considered the possibility that children who received the anomalous data first may make comparable gains at post-test after receiving the conceptual information. However, although possible this is not very likely, because without an alternative theory to explain the anomalies, children could appeal to extraneous variables to fit the anomalous evidence into their naïve theory, therefore strengthening it. As a result, the hypothesized difference at mid-test would remain significant at post-test, even after exposure to an alternative theory. The alternative order of presentation (explanations followed by anomalies) might be more effective, because children could rely on the conceptual information provided to interpret the anomalous evidence.

Methods

Participants

Ninety-six 5-year-old children (M = 5.49; range: 5.03- 5.99, 48 males) participated in this study. Equal numbers of children were randomly assigned to one of two conditions: *Explanation-First* (n = 48, M_{age} = 5.50, 24 males, 24 females), and *Anomalies-First* (n = 48, M_{age} = 5.49, 24 males, 24 females). Within these conditions, children were read one book and completed one activity. We developed two books and two guided activities to teach children about buoyancy. This was done to ensure that differences in learning did not arise from the type of book the child read or the activity the child completed. All 16 combinations of the books and activities were included and were counterbalanced, such that 6 children received each possible combination. No differences between the two types of books and activities were expected.

Procedure

There were five phases in this study: a pre-test, a learning phase 1 (depending on the condition, *Explanation-First* or *Anomalies-First*), mid-test phase, learning phase 2 (Explanation/Anomalies, depending on the condition), and the post-test. The session was video-recorded and lasted 40 minutes to 1 hour.

Test Phase. To measure children's belief revision a pre-, mid- and post-test were administered. The procedure for the pre-, mid-, and post-test was identical. The materials for each of the 3 test phases included 4 pairs of objects, for a total of 12 objects pairs. Within each set of 4 pairs, two pairs of objects were the same weight, and two were different weights. Two of the pairs of objects were made of the same material and two were made of different materials. Materials included: metal, plastic, rubber, and glass. For each test phase, children received a different object set, but the order in which children received these sets was counterbalanced across the pre-, mid- and post-tests.

Children were given objects in pairs to inspect. The experimenter told children what each object was made of so there was no ambiguity. Children were then provided with a scale and prompted to weigh the object pairs so they could definitively identify which object was heavier and which was lighter. To avoid differences in response patterns within the sample, within each object set the pairs of objects were presented in the same order to each participant: different weight/different material, same weight/same material, same weight/different material, and different weight/same material.

After children were given time to inspect and feel the objects, weigh them, and were told what they were made of, children were asked the test question: "If I took these two objects and put them into the water, which one would float on the top and which one would sink to the bottom?". Their predictions were recorded. Children received neutral feedback ("Thank you") after answering each question.

Learning Phase. In this phase, we used picture books to deliver the conceptually rich explanations and guided activities to present children with the anomalous evidence. We developed two books and two guided activities to ensure that differences in learning did not arise from the type of book or activity used. For the picture books, we created an informational, non-fiction book, and a narrative, fiction book which contained the same conceptual information about buoyancy. Given previous work reporting no differences in children's learning based on book genre, we did not expect to find differences between these two book types (Venkadasalam & Ganea, 2018).

In the first guided activity, Activity One, children made predictions about whether 12 different objects would sink or float. The objects in this activity varied in weight and material. Children then tested these objects in water to see if their predictions were correct. The second activity, Activity Two, involved children manipulating a piece of clay into shapes that either floated or sank. Children then tested these shapes in water, demonstrating that an object with a constant weight can both sink and float. No differences were expected between activities as children were guided through each activity to ensure the production and observation of anomalous evidence and both activities were designed to demonstrate the same type of anomalies.

Children in the *Explanation-First* condition were read the book prior to the activity, whereas children in the *Anomalies-First* condition were read the book following the activity. During the book reading, the experimenter read either the non-fiction or the fiction book to each child aloud. In the activity, the experimenter guided children through different instances where they could compare objects sinking and floating, either with the 12 objects in Activity One, or the pieces of clay in Activity Two. The books and activities were structured to be analogous in terms of their content. The goal of both learning phases was explicitly identified as teaching children about why objects sink or float. However, no mention of the book was made during the activity, and likewise no mention of the activity was made during the book.

Coding

Children's predictions for which object would sink and which one would float in each pair were scored. Children who correctly identified which object in the pair would sink and which would float received a score of 1. A score of 0 was assigned if children incorrectly identified the sinker and the floater in the object pair or if they said both objects would sink or both objects would float. Two research assistants coded 100% of the children's responses from the video recordings. The coders were blind to the hypotheses of the study, the condition and test phase. There was high interrater reliability determined by Cohen's $\kappa = .91$, $p < .001$, a 95.66% agreement rate. The coders resolved disagreements through discussion.

Results

In preliminary analyses, we ensured there were no differences between the scores at mid- and post-test as a result of the two types of books and activities used. A Mann Whitney U-test found that scores for mid- and post-test were similar for both books (*ps* > .84), and both activities (*ps* > .12). As there were no significant differences between the type of books and activities used in the intervention, these factors were collapsed in the following main analyses. We also examined differences between children's knowledge across the two conditions at pre-test. A Mann Whitney U-test found that the pre-test scores were similar across conditions at baseline, $U = 1017$, $z = -1.02$, $p = .31$ with a mean rank pre-test score of 45.69 for the *Explanation-First* condition and 51.31 for the *Anomalies-First* condition. Additionally, Wilcoxon Signed-ranks tests revealed that the pre-test scores were significantly lower than chance responding, indicating that children held misconceptions at pre-test (*Explanation-First*: $Z = -3.35$, $p =$

.001; *Anomalies-First:* $Z = -2.32$, $p = .021$). Table 1 displays the proportion of correct responses across the three test phases for both conditions.

A generalized estimating equation (GEE) analysis with multinomial distributions and cumulative logit link functions was conducted to investigate whether children correctly predicted which object would sink and which would float. This type of analysis was selected to accommodate the ordinal dependent variable and the presence of a within-subject factor (pre-, mid- and post-test scores) in the data.

Table 1: Percent Correct Responses Across Test Phases by Condition.

Score	Test Phase					
	Pre-Test		Mid-Test		Post-Test	
	Anom-First	Expl-First	Anom-First	Expl-First	Anom-First	Expl-First
0/4	27%	40%	27%	19%	25%	8%
1/4	19%	19%	21%	0%	15%	15%
2/4	33%	19%	27%	27%	25%	8%
3/4	13%	17%	15%	27%	21%	38%
4/4	8%	6%	10%	27%	15%	31%

Notes. Anom-First stands for the *Anomalies-First* condition. Expl-First stands for the *Explanation-First* condition. The percentages are calculated out of 48 total responses for each condition per test phase.

There was no effect of condition, ($p = .31$), nor a difference between pre- and mid-test ($p = .80$), nor pre- and post-test ($p = .10$). However, there was a significant interaction between condition and test phase. From pre- to mid-test children in the *Explanation-First* condition were more likely to answer more test questions correctly, Wald $\chi 2(1) = 19.87$, $p < .001$, $b = 1.51$, $SE = .34$, compared to the *Anomalies-First* condition. Children in the *Explanation-First* condition (Exp(B) = 4.51, 95% CI = [2.33, 8.75]) were approximately four and a half times more likely to answer the test questions correctly at mid-test in comparison to the *Anomalies-First* condition.

Additionally, from pre- to post-test children in the *Explanation-First* condition were more likely to answer more test questions correctly, Wald $\chi 2(1) = 14.66$, $p < .001$, $b = 1.53$, $SE = .40$, compared to the *Anomalies-First* condition. Children in the *Explanation-First* condition (Exp(B) = 4.62, 95% CI = [2.11, 10.09]) were approximately four and a half times more likely to answer the test questions correctly at post-test in comparison to the *Anomalies-First* condition.

Post-hoc Wilcoxon Signed Rank Tests were conducted using a Bonferroni correction to account for multiple comparison (alpha = .008). There was a significant increase in children's score in the *Explanation-First* condition between pre- and mid-test ($z = 4.45$, $p < .001$) and pre- and post-test ($z = 4.86$, $p < .001$), but not between mid- and post-test ($z = 1.63$, $p = .10$). In the *Anomalies-First* condition there was no significant increase in scores for any of the test phases ($ps > .13$); see Figure 1.

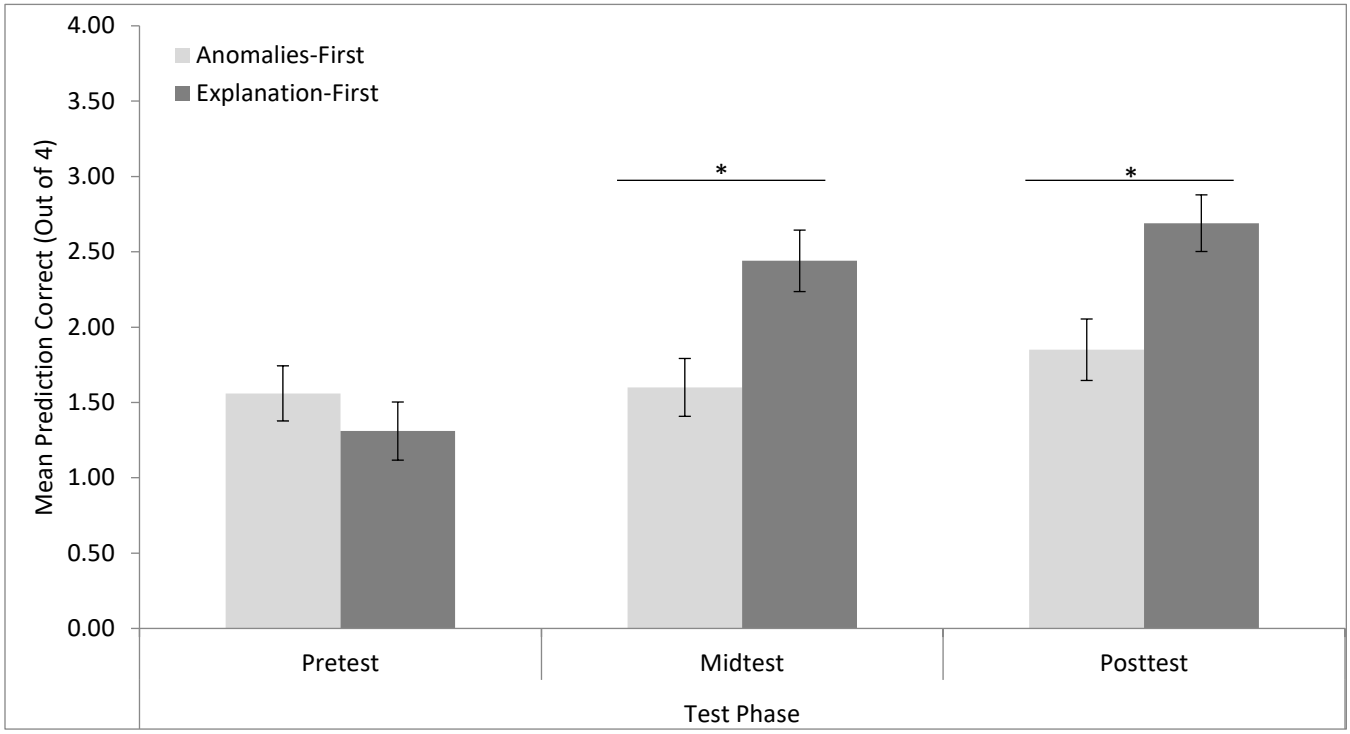

Figure 1: Mean Predictions Correct across Test-Phase by Condition

Discussion

This study investigated the role of conceptually rich explanations and anomalous evidence in children's revision of physical science misconceptions. We first found that children can revise their belief about what makes objects float or sink when provided only with a conceptual explanation but not when only witnessing anomalies. Compared to pre-test scores, children in the *Explanation-First* condition made significantly better predictions at mid-test after they received the conceptual information only. However, the children in the *Anomalies-First* condition did not make significantly better predictions after observing anomalies. This indicates that children maintain their misconceptions when they have exposure to anomalies.

We also found that the order of instructional methods affects children's belief revision in the context of a physical science concept. Children performed better at post-test when presented with rich conceptual explanations *prior to* observing anomalous evidence. The *Explanation-First* condition facilitated greater revision of beliefs than the *Anomalies-First* condition. Of note, even in the *Explanation-First* condition, when children observed anomalous evidence after they received the explanations, the anomalies did not lead to any significant changes. In contrast, results from the *Anomalies-First* condition showed that observing the anomalies first subsequently interfered with children's ability to incorporate and apply the conceptual information they received from the picture book.

Together these findings provide evidence that using anomalous data to promote belief revision can be challenging, as children are biased to rely on their own theories, and resistant to setting aside this prior knowledge when confronted with counter-evidence (Chinn & Brewer, 1993; Kuhn et al., 1988). Despite observing counterexamples, children may ignore them, or even find a way to fit the anomalies within their existing theoretical framework, thereby strengthening their naïve misconceptions. However, when children have access to a viable, alternative explanatory framework, they can then activate this alternative theory to interpret the anomalous evidence. Thus, the present findings indicate that supplementing prior beliefs with an alternative conceptual explanation before anomalous evidence is observed may be particularly effective for promoting knowledge revision.

Further work is needed to determine if the addition of anomalous evidence affects retention after a delay. That is, while we found no positive effects of the anomalous evidence above and beyond what the explanations provided, observing anomalous evidence after receiving the correct explanation, may lead to greater retention of the new theory than receiving only the explanation alone.

Another consideration for future work is that explicit connections were not made between the book and the activity. While these learning phases were built to be highly analogous, and the same content goal was verbally specified for both, no explicit connection was made between them. It is possible that with an explicit connection between the two, children may achieve higher performance across conditions.

Additionally, in the current study the explanations were presented through a picture book. It is an open question whether results would be similar if both the explanations and anomalies are presented in a similar manner. Currently, we are exploring whether pairing live anomalous evidence with verbal explanations will have positive effects on learning. Further work should also explore the applicability of these findings to different scientific concepts. Sinking and floating are complex physical concepts, particularly for young children to grasp. It is possible that presenting children with anomalies only or first may be equally effective for belief revision for simpler concepts.

The current results can inform our theories about the process of conceptual change and optimal science instruction. This study demonstrates the importance of critically examining not just *what* we teach children, but *how* we teach them, and in particular the order in which instruction is delivered. Presenting children with content information before they observe anomalous data prevents children from fitting anomalies into their naïve schema, giving them an alternative viewpoint from which to interpret this evidence. Therefore, this order of presentation better facilitates the revision of children's misconceptions. Providing children with comprehensive explanations of phenomena they observe is a promising educational technique to improve their scientific reasoning and literacy.

Acknowledgments

We are grateful to the children who participated in this research and we thank the families who made this possible. We would like to thank Angela Nyhout, Myrto Grigoroglou and Begum Ozdemir for feedback on a previous draft of this paper. This research was supported by a SSHRC Insight grant to Patricia Ganea.

Abstract

During their first year, infants learn to name objects. To do so, they need to segment speech, extract the label and map it to the correct referent. While children successfully do so in the wild, previous results suggest they struggle to simultaneously learn segmentation and object-label pairings in the lab. Here, we ask if some of children's difficulty is related to the uniform distribution they were exposed to, since it differs from that of natural language, and has high entropy (making it less predictable). Will a low entropy distribution facilitate children's performance in these two tasks? We looked at children's (mean age=10;4 years) simultaneous segmentation and object-label mapping of words in an artificial language task. Low entropy (created by making one word more frequent) facilitated children's performance in both tasks. We discuss the importance of using more ecologic stimuli in the lab, specifically- distributions with lower entropy.

Keywords: Statistical learning; Multi-modal cues; Word segmentation; Word learning; Entropy; Children.

Introduction

During the first year of life, infants make their initial steps in learning language. One ability they acquire is naming objects. To do so, infants need to extract the segmented labels and map them onto the correct object. While infants learn some object-label mappings early on (Bergelson & Swingley, 2012), even older children seem to struggle with simultaneously learning segmentation and object-label pairings in the lab. Previous work examined children's ability to perform both tasks at the same time in a statistical learning paradigm (Lavi-Rotbain & Arnon, 2017). Children were exposed to an unsegmented speech stream where transitional probabilities served as a cue for word boundary (as in Saffran, Aslin, & Newport, 1996). The language had an additional visual cue to segmentation: each word was matched to an image of an object that appeared for the duration of the word (e.g., 'dukame' → blue star). The prediction was that the visual cue will assist segmentation and allow children to learn the object-label pairings, illustrating their ability to integrate multimodal cues. As predicted, the results showed that after a short exposure (under two minutes) 10;6-year-olds managed to learn both aspects (segmentation and object-label mapping). However, while children showed some learning of the object-label pairing (they were above chance, M=34.4%, chance=25%), their learning was relatively poor. Younger children (mean age: 7;8 years) did not learn the pairings at all (M=25.96%%, chance=25%), even though they are clearly capable of relating labels to objects in natural language. Why then do children struggle with this task in the lab? And what can we learn from their difficulty about the factors that impact children's language learning? Here, we ask how the distributional properties of the language may have impeded learning. In particular, we focus on the use of a uniform distribution – where all items are equally frequent. This was the distribution used in the previous study, and one that is used in most statistical learning studies.

A uniform distribution of stimuli, where every element (e.g. word) is presented the same number of times, differs from what is found in natural language. Words in natural language have a Zipfian distribution (Zipf, 1936) with few very frequent words, and most words having low frequency. The Zipfian distribution is a highly skewed distribution, with a narrowed peak for the small number of very frequent words, and a long tail for the rest of the words. Words show a Zipfian distribution across many languages, in both adult-to-adult speech (Zipf, 1936; Piantadosi, 2014) and child directed speech (Hendrickson & Perfors, 2019; Lavi-Rotbain & Arnon, submitted). Other aspects of language, like grammatical categories, also show a Zipfian distribution (Piantadosi, 2014; Lavi-Rotbain & Arnon, submitted). Interestingly, the objects that infants see also show a Zipfian distribution (Clerkin, Hart, Rehg, Yu, & Smith, 2017). That is, using a uniform distribution does not accurately reflect the distribution of words (or objects) that children are exposed to.

Moreover, uniform distributions are also less predictable than non-uniform distributions. One way to quantify the difference between them is to use Shannon's Entropy (Shannon, 1948). Entropy quantifies how unpredictable a distribution is as a whole, with higher entropy assigned to less predictable distributions. The uniform distribution is the least predictable - it is hard to guess which word will appear next when they all have equal probabilities - and consequently has high entropy. Non-uniform distributions, such as Zipfian distributions, are more predictable, and have lower entropies: it is easier to guess the next word when only a few are highly probable.

Here, we ask if children's simultaneous learning of segmentation and object-label pairings will be facilitated when using a distribution with low unigram entropy. Such a finding would have several important implications. First, it would indicate that children are sensitive to entropy, thereby expanding our understanding of the distributional properties

that impact learning. Second, it would highlight the importance of using stimuli that are more ecologically valid in their distributional properties: If children show better learning from a low entropy distribution, then previous conclusions about their ability to use multimodal cues may not be accurate. Under more natural conditions, children may show learning that was not previously detected. To give an example from another domain, children's knowledge of irregular plurals is much better when they are produced in familiar frames, as they are often produced in natural language (e.g. children produce "teeth" more accurately after "brush your---" compared to on its own, Arnon & Clark, 2011). Assessing children's morphological knowledge using single word elicitation under-estimated their true abilities, and could lead to inaccurate conclusions (e.g., that they have not learned the correct irregular form yet). Similarly, performance in artificial language learning studies improves when there are multiple cues to segmentation, as is found in natural language. Visual cues for word boundaries improve segmentation in adults (Cunillera, Camara, Laine, & Rodriguez-Fornells, 2010), as does the use of one-to-one mappings between words and objects (children: Lavi-Rotbain & Arnon, 2017; adults: Thiessen, 2010). Under these conditions, children and adults show better learning.

Will a reduction in entropy have a similar facilitative effect on learning? Looking at another domain, adults' cross-situational learning of novel object-label mappings was facilitated after exposure to a Zipfian distribution (with low entropy) compared to a uniform distribution (with high entropy) (Hendrickson & Perfors, 2019, Experiment 2). This facilitative effect was not found when words and labels were presented one at a time: the authors propose that Zipfian distributions are beneficial only when learners are faced with ambiguity. In such cases, the very frequent word can be learned early on and used to disambiguate later trials. Another reinforcement to the potential advantage of low entropy distributions comes from word segmentation studies: children's and adults' segmentation is facilitated when the input had low entropy (entropy was reduced by making one word more frequent than the other, Lavi-Rotbain & Arnon, 2018, 2019), and when it has a Zipfian distribution (Kurumada, Meylan, & Frank, 2013).

Here, we expand on these findings to look at the effect of reduced entropy on word learning in children: will lower entropy facilitate learning in a task that involves both segmentation and object-label mapping? The segmentation task is inherently ambiguous: since learners are exposed to an unsegmented stream, successfully segmenting one word can help in segmenting the rest. An additional facilitative effect can come from the overall greater predictability of the input: non-uniform distributions are more predictable and have lower entropy. If learners are sensitive to such measures of the environment, then learning may be facilitated even in non-ambiguous situations. Since both factors are relevant for the segmentation task, we hypothesized that segmentation will be better under low entropy. The predictions are less clear about learning the object-label mappings. On the one hand, this task does not involve ambiguity: the same object is always presented with the same label. At the same time, the overall predictability of the mappings is greater in the non-uniform distribution. If there is an effect of reduced entropy regardless of ambiguity, we should see a facilitative effect here as well. We hypothesized that learning the object-label mappings will also be facilitated under low entropy.

The current study

In the current study, we use the same artificial language learning paradigm used previously to examine children's learning of multimodal information (Lavi-Rotbain & Arnon, 2017). Children are exposed to an unsegmented speech stream containing four novel words, with consistent word-object pairings (each word is paired with an object: e.g., 'dukame' with a blue star). We ask if children will show better learning of both segmentation and object-label pairings when exposed to low entropy input compared to high entropy input. We focus our inquiry on words that have lower frequency. Frequency is known to affect word learning during infancy with more frequent words learned earlier (Goodman, Dale, & Li, 2008). Frequency, however, does not account for all the variance in a words' age-of-acquisition. It is easy to find examples of low frequency words among the early acquired ones: for example, the word ' cheek' is learned at 22 months (Frank, Braginsky, Yurovsky, & Marchman, 2017), but appears only 18 per million. Could the low entropy found for words in natural language help children learn low frequency words? Finding such a pattern in our experimental manipulation would open up new avenues for understanding how low frequency words are acquired.

We manipulate entropy by making one word much more frequent: in the high entropy condition, all words appeared an equal number of times (each word appeared 32 times). In the low entropy condition, one word was much more frequent (appearing 214 times), while the other three appeared 19 times (half of the frequency of the words in the high entropy condition). We compare segmentation and word-object pairings for the low frequency words from the low entropy condition (which appeared 19 times) with the words from the high entropy condition (which appeared 32 times). If children are mostly sensitive to frequency, then learning should be better in the high entropy condition. However, if children are sensitive to more than mere frequency, in particular to the entropy of the distribution, than learning of the low frequency words should be better in the low entropy condition. If this happens regardless of ambiguity, then we should see better performance due to entropy reduction for both segmentation and learning the correct object-label pairings.

Method

Participants

61 children took part in this Experiment (age range: from 9;0 to 12;0 years, mean age: 10;4 years; 27 boys, 34 girls). We chose this age range since it matches the one used in the older

group of Lavi-Rotbain & Arnon (2017), where children showed poor learning of the object-label pairings. Participants were visitors at the Bloomfield Science Museum in Jerusalem and were recruited for this study as part of their visit to the Living Lab. Parental consent was obtained for all participants. None of the children had known language or learning difficulties and all were native Hebrew speakers. Each child received a small prize for their participation.

Materials

Auditory stimuli

All participants were exposed to a familiarization stream corresponding to the condition they were assigned to. All streams were composed of the same four unique tri-syllabic synthesized words: "dukame", "nalubi", "kibeto", and "genodi". We used only four words to make the task learnable for children. As the results show, even this number proved challenging for children. The twelve different syllables making up the words were taken from Glicksohn & Cohen (2013). The syllables were created using the PRAAT synthesizer (Boersma & van Heuven, 2001) and were matched on pitch (~76 Hz), volume (~60 dB), and duration (250–350 ms). The four words were created by concatenating the syllables using MATLAB to ensure that there were no co-articulation cues to word boundary. The words were matched for length (average word length- 860ms, range=845-888ms). The words were then concatenated together using MATLAB in a semi-randomized order to create the auditory familiarization streams. Importantly, there were no breaks between words and no prosodic or co-articulation cues in the stream to indicate word boundaries. The only cue for word boundaries was transitional probabilities (TP's): TP's between words were lower compared to TP's within words.

Experimental conditions

We created two auditory sequences, corresponding to two levels of entropy: high and low. In the high entropy level, words followed a uniform distribution with each word appearing 32 times in a semi-randomized order (no word appeared twice in a row). The sequence had 128 tokens and lasted 1:50 minutes. TP's within a word were 1, and TPs between words were 0.333. In the low entropy level, words appeared with a skewed distribution: one word appeared 80% of the time (214 appearances) while each of the other three words appeared only 7% of the time (19 appearances for each word). The sequence had 271 tokens and lasted 3:50 minutes. The identity of the frequent word was counterbalanced across subjects in the low entropy condition to prevent item-specific effects. TP's within a word were 1, but the TP's between words varied depending on the next word (since the frequent word in this condition was more likely to occur). See Table 1 for full details of the experimental conditions.

Visual stimuli

While listening to the audio stream, participants saw shapes on the screen whose appearance was synchronized with word boundaries. Shapes appeared at word onset and remained onscreen for the duration of the word. Each word appeared always with the same shape and vice versa ("dukame": blue star, "nalubi": green hexagon, "kibeto": purple heart, and "genodi": orange diamond). In the low entropy condition, when the same word appeared twice in a row, the shape disappeared briefly (for 200 ms) at the end of the first occurrence and reappeared with the second occurrence onset. The visual stimuli is modelled on the regular condition from Thiessen (2010) and Lavi-Rotbain & Arnon (2017), which was shown to facilitate segmentation in both adults and children. See Fig. 1 for an illustration.

Table 1: Different experimental conditions

	High entropy (Uniform)	**Low entropy**
Exposure length [minutes]	1:50	3:50
Number of tokens	128	271
Tokens per word	32	Frequent: 214 Infrequent: 19
Unigram entropy [bits]	2	1.1
TP's between words	0.33	For the frequent word: 0.75 For infrequent words: 0.08

Segmentation test

This test asked how well children segmented the continuous stream into words using 16 two alternative forced-choice trials. The visual stimuli did not appear on screen during test. Participants heard two words and were asked to decide which belonged to the language they heard. We used non-words as foils ("dunobi", "nabedi", "kilume", and "gekato", average length: 860ms; range 854-868ms), created by taking three syllables from three different words, while keeping their original position. We used non-words (instead of part-words) as foils since these are easier to distinguish from 'real' words. Since children struggle with this task, we chose to focus only on the "easier" non-word vs. word distinction. Each of the four words appeared once with each of the four foils to create 16 trials (in a random order, with the constraint that the same word/foil did not appear in two consecutive trials). The order of words and foils was counter-balanced so that in half the trials, the real word appeared first and in the other half, the foil appeared first.

Fig. 1: Audio-video illustration

Word–shape correspondence test

This test asked how well children learned the correspondence between the words and the shapes. In each trial, children saw the four shapes on the screen and heard one of the four words. Then, they had to choose the shape corresponding to the word. Each word was repeated four times on non-consecutive trials, to create 16 trials that appeared in a random order between subjects.

Procedure

After receiving parental consent, children were seated in front of a computer station with a noise-blocking headset next to an experimenter. The children were told they are about to hear an alien language, and that they need to pay attention to what they will see and hear and try to learn it as best as they can. Each child was randomly assigned to one of the two experimental conditions. After the exposure phase, children completed a segmentation test and a word-shape correspondence test. The instructions were identical in all conditions.

Results

Children were divided as follows between the two conditions: high entropy, N=28; low entropy, N=33. Age did not differ across entropy conditions (F(1)=0.195, p=0.66). In the low entropy condition, the frequent word was counterbalanced across subjects. A one way ANOVA revealed that performance was not impacted by which word was the frequent one in the segmentation test (F(3)=2.326, p=0.1), or in the recognition test (F(3)=0.52, p=0.67). Consequently, in all subsequent analyses we collapsed the data across the different frequent words.

Segmentation analysis

Children showed learning (were above chance) in both conditions (low entropy condition: M=73.9%, t(32)=7.69, p<0.001; high entropy condition: M=65.2%, t(27)=4.83, p<0.001). However, this success rate includes both the frequent and the infrequent word for the low entropy condition. Since the frequent word had much higher frequency (214 appearances) than the other words (19 appearances) in the low entropy condition, it does not make sense to include the frequent word in our analysis. In order to examine the effect of entropy on low frequency words alone, we looked only at trials where the correct answer was a low frequency word (appearing 19 times during exposure). This left 12 trials per participant. In this subset of the segmentation test, children showed learning above chance of the infrequent words (low entropy condition: M=73.0%, t(32)=7.0, p<0.001) (see Fig. 2). We will now compare this mean to the one from the high entropy condition (73.0% versus 65.2% respectively).

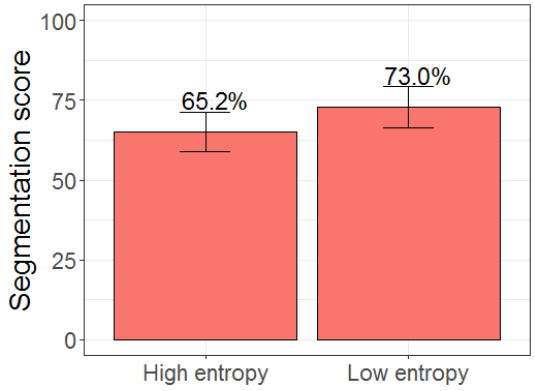

Fig. 2: Mean segmentation score of low frequency words by entropy condition with 95% confidence intervals

We used mixed-effect linear regression model to examine the effect of entropy level on segmentation of infrequent words. Following Barr et al. 2013, the models had the maximal random effect structure justified by the data that would converge. Our dependent binominal variable was success on a single trial of the segmentation test. We had entropy condition (high entropy condition as baseline) as a fixed effect, as well as: age-in months (centered); gender; trial number (centered); and order of appearance in the test (word-first trials vs. foil-first trials). The model had random intercepts for participants and for item (Table 2). To examine the overall effect of entropy, we used model comparisons.

As predicted, entropy level impacted segmentation of low frequency words (chi(1)=3.2, p=0.07). Participants showed better segmentation of low frequency words in the low entropy condition compared to the high entropy condition, despite appearing half the times (β=0.42, SE=0.23, p=0.07). Order of appearance in the test significantly affected segmentation, with better accuracy on trials where the word appeared before the foil (β=0.39, SE=0.16, p<0.05), as has been found in previous studies (Lavi-Rotbain & Arnon, 2017; Raviv & Arnon, 2018). Since the order of presentation of

Table 2: Mixed-effect regression model for segmentation of infrequent words. Variables in bold were significant. Significance obtained using the lmerTest function in R.

	Estimate	**Std. Error**	**z value**	**p-value**
(Intercept)	0.69584	0.21439	3.246	**<.01 ****
Age (centered)	0.23516	0.14220	1.654	=0.098 .
Low entropy condition	0.42079	0.23321	1.804	**=0.07 .**
Gender (male)	-0.03948	0.11747	-0.336	>.1
Trial number (centered)	-0.02390	0.01705	-1.401	>.1
Order of appearance (word)	0.19385	0.07844	2.471	**<.05 ***

words and foils was counter-balanced this could not reflect a preference for pressing 1 or 2, and is in line with the "interval bias" which is often found in 2AFC tests (Yeshurun, Carrasco, & Maloney, 2008). Age almost reached significance: older children were slightly better than younger ones (β=0.24, SE=0.14, *p*=0.098). Trial number and gender did not affect segmentation (trial number: β= -0.02, SE=0.02, *p*>0.1; gender: β= -0.08, SE=0.23, *p*>0.1).

The beneficial effect of low entropy on segmenting low frequency words cannot be attributed to learning only the frequent word, and ruling out foils due to syllables they share with the frequent word. To see if there is a difference between trials in the low entropy condition where the foil shared one syllable with the frequent word (M=72.7%) and trials where it didn't (M=77.3%) we used a linear regression model with success on a single trial as the dependent binominal variable, and "is foil frequent" (assigned '1' for trials in which the foil shared any of its three syllables with the frequent word and '0' when it didn't) as a fixed effect, as well as log frequency (centered), gender, trial number (centered); and order of appearance in the test. The model had random intercepts for subjects and for items. "Is foil frequent" was not a significant predictor of accuracy (β= -0.27, SE=0.25, *p*>0.1), neither all the other fixed effects. That is, children in the low entropy condition indeed learned the low frequency words better.

Recognition analysis

Children showed learning of object-label pairings (were above chance) in the low entropy condition (M=49.3%, chance=25%, t(32)=5.16, *p*<0.001). In contrast, they were not above chance in the high entropy condition (M=32.7%, chance=25%, t(27)=1.66, *p*=0.11). The accuracy in the high entropy condition is similar to that from Lavi-Rotbain & Arnon (2017), using the same task and uniform distribution (M=34.4%). While children did show learning in the previous study (just above chance), their performance was still poor, indicating difficulty in learning the mappings from a uniform distribution. How well did children learn the infrequent words in the low entropy condition? As in the segmentation test, the mean accuracy in the low entropy includes also recognition of the frequent word. In order to look at recognition of low frequency words, we looked only at trials where the correct word was a low frequency word (12 trials per child). Since children learned the frequent word quite well (M=64.6%), we assume that chance level on each trial is not 25% but 33% (since they could rule out the shape corresponding to the frequent word). Note however that this is a quite rigid assumption: children did not show complete learning of the frequent word (they were incorrect 35% of the time), and there was very large variance in accuracy (SD=37.9%), meaning that for some trials they were picking between four options. Nevertheless, we put our prediction to a stringent test and assume that chance is 33% for the low frequency words. As predicted, children learned the infrequent words above chance in the low entropy condition (M=44.0%, chance=33%, t(32)=2.14, p<0.05) (see Fig. 3). This means that while in the uniform condition children did not show learning of the object-label pairings (were not above chance), children in the low entropy condition did show learning even of the infrequent words, despite appearing half the number of times and despite the rigid chance level.

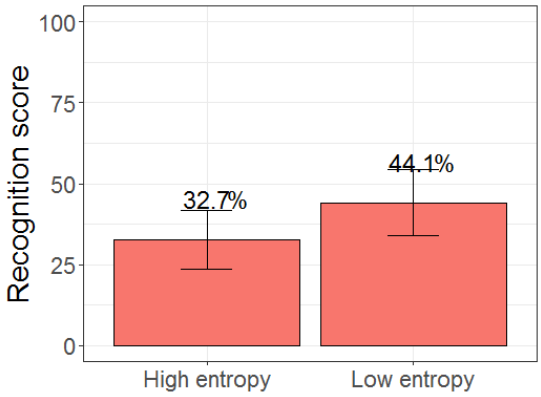

Fig. 3: Mean recognition score of low frequency words by entropy condition with 95% confidence intervals

Is there a correlation between segmentation and recognition scores? Previous results showed positive correlation in adults' performance between these two tasks, indicating that better segmentation went along with better word learning (Lavi-Rotbain & Arnon, 2017; Thiessen, 2010). However, such a correlation was absent in children's performance (Lavi-Rotbain & Arnon, 2017). Here, we found a positive correlation only in the low entropy condition: children who performed well in the segmentation test, were also good at mapping labels to objects (R^2=0.4, t(31)=2.42, *p*<0.05), highlighting the connection between segmentation and word learning found in natural language. Such a correlation was not found in the high entropy condition (R^2=0.21, t(26)=1.12, *p*>0.1).

Discussion

We set to ask whether children's ability to segment and learn object pairings for low frequency words will be better when learning from low entropy input compared to high entropy input. To do so, we examined children's performance in an artificial language across two levels of entropy (high and low), in two tasks: segmentation and object-label pairing. Entropy was reduced by making one word more frequent than the rest, so that it appeared 80% of the time. We focused on children's performance on low frequency words (that appeared only 19 times in the low entropy condition, versus 32 in the high entropy condition). Our results show that entropy reduction is beneficial for children's segmentation, (see also Lavi-Rotbain & Arnon, 2018, 2019), as well as for their learning of object-label mapping. In addition, we found a positive correlation between segmentation and mapping only under the low entropy condition. Based only on findings from the uniform conditions from this study and from Lavi-Rotbain & Arnon (2017), one could conclude that children are not able to simultaneously learn segmentation and object-

label mapping (at least in lab conditions). However, the low entropy condition offers an alternative explanation: when exposed to more predictable and ecological input, children show evidence of learning both tasks at the same time. Importantly, children's object-label accuracy was still not good, raising the need to find ways to make the task easier: we predict that the effect of reduced entropy will be stronger once that is done. We are currently running a similar study with the younger age group (that showed no learning of the object-label mappings in the previous study), to see if entropy reduction will have a similar facilitative effect on this age group and will enable them to learn both the segmentation and object-label pairing.

Why did the low entropy condition facilitate learning? Several inherent properties of low entropy distributions may be facilitative for learning. First, creating a low entropy in the way we did drastically increases the frequency of one or more of the words. These highly frequent words can be learned relatively early on and later serve as an anchor for learning other words, similar to presenting words in isolation prior to presenting the unsegmented stream (Cunillera, Càmara, Laine, & Rodríguez-Fornells, 2010). In addition, TP's between the frequent and infrequent words can be lower and hence be more salient for learning. However, we suggest that there is more to the low entropy condition that facilitates learning than anchoring and lower TP's. Language learners may be sensitive to the overall predictability of the input, and learn better from input with lower entropy. Such an account predicts that entropy reduction will also facilitate learning when there is less ambiguity. Our results provide some support for this, by showing that learning was improved also for the non-ambiguous object-label pairings (contra the prediction made in Hendrickson & Perfors, 2019). This prediction is also supported by findings showing that adults' word segmentation is facilitated in a low entropy condition compared to a medium entropy one, despite both having similar anchoring and TP cues (Lavi-Rotbain & Arnon, 2019). Further work is needed to understand what exactly about low entropy is facilitative and how that relates to the input that children are actually exposed to.

From a methodological perspective, our results highlight the importance of creating experimental stimuli that better reflect the input children hear. In particular, most SL studies use a uniform distribution during exposure, although the distribution itself is not relevant for their research question. However, by doing so, we may be introducing unnecessary difficulties for our participants that may interfere with our assessment of their abilities. For children, who find artificial language learning experiments harder to begin with, such factors may impact performance more, and more easily. Theoretically, the findings point to the importance of studying the impact of entropy on language learning. Entropy has been studied across many domains of language, including language processing, use and structure (e.g., Cohen Priva, 2017; Linzen & Jaeger, n.d.; Piantadosi, Tily, & Gibson, 2011). For example, there is evidence that the entropy of single words is restricted to a small range of values across many languages, suggesting that speakers have similar preferences for how predictable their languages are (Bentz, Alikaniotis, Cysouw, & Ferrer-i-Cancho, 2017). In addition, there is a trade-off between unigram and trigram entropy over time across many languages, indicating that speakers maintain a relatively constant information rate (Cohen Priva & Gleason, 2016). Children also show sensitivity to such measures: two-year-olds show better repetition of unfamiliar four-words sequences when the final word "slot" has higher entropy (Matthews & Bannard, 2010). These studies show that language users are sensitive to entropy and other information-related measures, and suggest that languages are shaped by constrains arising from these measures. However, the role of entropy on language learning is understudied. Our results show that entropy effects are found in children and impact learning of both segmentation and word labels.

Our results may offer a possible explanation for how children acquire low frequency words at a relatively early age. Words in natural language show a Zipfian distribution, in which most of the words have low frequencies. Under a low entropy distribution, such as the Zipfian distribution, the disadvantage of low frequency can turn into an advantage: the few frequent words can serve as an anchor for learning the low frequency ones. We are currently conducting a series of studies to examine the role of entropy in natural language learning, and in predicting variance in age-of-acquisition.

Abstract

The number-line task is a widely used task in diverse fields of study. In the task, a given number that varies every trial is estimated on a continuum flanked with 0 and an upper-bound number. An upper-bound of a number-line is often arbitrarily selected by researchers, although this design variable has been shown to affect the non-linearity in estimates. Examining estimates of varying given numbers (design variable 1) with varying upper-bound numbers (design variable 2) can be costly because adding a new design dimension into a number-line task could drastically increase the number of trials required for examining the underlying representation of number. The present study aims to conduct a number-line task with the given number and the upper-bound being the design variables. A design optimization algorithm, Gaussian Process Active Learning (GPAL), made this new paradigm feasible without increasing the number of trials, by presenting only the most informative combinations of the design variables every trial. Our experimental data showed that the non-linearity of the number-line estimates increases with the upper-bound of the number line. The degree of non-linearity could predict a math skill (i.e., addition proficiency), but only when the upper-bound was relatively large. The observed range-dependency of the number-line estimates would not be fully explored without systematically manipulating the upper-bound as an additional design variable. As in the present number-line task, GPAL would be a useful tool for the research problems that require multidimensional design experiments to be solved.

Who is better? Preschoolers infer relative competence based on efficiency of process and quality of outcome.

Abstract

The ability to reason about our own and others' competence informs our everyday decisions. However, competence is an abstract concept which manifests in the objective properties of the task completed by an agent (i.e., task-based features, such as quality of outcome or task difficulty) as well as the subjective properties of the agent (i.e., agent-based features, such as dexterity, speed, focus). Thus, acquiring an integrated notion of competence may be a nontrivial challenge for young children. Prior work on children's understanding of competence has often used explicit verbal cues to describe the relevant features, or experimental tasks that confounded these features. Here we examine how preschool-aged children evaluate the relative competence of two agents by systematically manipulating task-based and agent-based features without explicit linguistic or gestural support. We find that 4- and 5-year-olds readily use perceptual cues to task-based (i.e., task difficulty) and agent-based (i.e., agent speed) features to infer competence (Exp.1-3) but not when when these perceptual cues are closely matched (Exp.4). These results suggest that a basic understanding of relative competence emerges earlier than previously believed, but an abstract, adult-like concept of competence may continue to develop throughout childhood.

Keywords: Social Cognition, Competence, Ability

Introduction

Beliefs about our own and others' competence are deeply ingrained in our everyday lives; we think about it, talk about it, and use it to guide our daily decisions. Even young children prefer agents who are perceived as more competent (Jara-Ettinger, Tenenbaum, & Schulz, 2015), and consider their own and others' competence to decide how to allocate tasks that vary in difficulty (Magid, DePascale, & Schulz, 2018). More generally, the way we perceive our own competence influences our motivation to learn and to choose challenging goals (Dweck & Leggett, 1988; Nicholls, 1984; Stipek & Iver, 1989; Wentzel & Wigfield, 1998).

However, it is often difficult to generate a clear definition of what it means to be *good* (competent) at something, or what makes some people *better* (more competent) than others. In fact, the meaning of competence seems to change depending on the task domain or the nature of the activity. When we say "Sally is good at math" or "Sally is a good pianist", we are referring to different dimensions on which we evaluate other people - her intellectual abilities in one, and her finesse in playing an instrument in the other. Even within the realm of sports, saying "Sally is good at gymnastics" or "Sally is a good swimmer" refers to physical abilities that vary along several dimensions, such as strength, agility, or speed. Thus, acquiring an integrated concept of competence that incorporates a coherent relationship between these dimensions may be a formidable challenge for young children.

There are broadly two ways in which one's competence can manifest. First, a competent agent might be capable of achieving goals or outcomes that are costlier, or more effortful, than what others can achieve (i.e., more difficult, more complex, or more elaborate). In this case, competence is marked by an objective property of the task or the quality of outcome achieved by the said agent (henceforth task-based features). Second, a competent agent might achieve the same outcome on the same task as others but more efficiently (i.e., spending less time, less physical effort, or less mental effort such as care or attention). In this scenario, competence manifests as a property of the agent who completes the task (henceforth agent-based features). Although there are cases in which we can expect someone to be competent even before observing anything he or she does (e.g., if someone went to Julliard, they presumably can play an instrument quite well), when we are trying to learn about an agent's competence based solely on their actions or outcomes, we usually attend to these task-based and agent-based features.

Prior work suggests that young children readily use explicit task-based features (e.g., clearly good or poor performance; frequency of successes and failures) to infer agents' competence. For instance, 3-year-olds judge that an agent who made a "tastier" cake is better at baking than an agent who made a "yucky" cake (Yang & Frye, 2016). However, a coherent, theory-like understanding of competence that integrates task-based and agent-based features seems to emerge relatively late in childhood. Given a video of two children, one of whom worked diligently on a math problem and the other who "goofed off" and worked only intermittently, children under age 7 say that the one who worked harder is more competent even if they both got the same score (matched outcome, different efficiency; Nicholls, 1978). Strikingly, it was not until age 12 that children showed an adult-like understanding that one's competence is inversely related to the total amount of effort invested when outcome is matched.

One way to interpret these results is that young children consider competence as a globally positive construct, and do not yet understand the specific relationship between task-based and agent-based features in reasoning about an agent's competence. Instead, young children might resort to explicit verbal or perceptual cues, and associate anything positive (e.g., better outcome, higher effort, being more diligent) with higher competence. Consistent with this idea, some studies

suggest that focusing on task-based features such as quality of outcome can lead children astray. Heyman, Gee, & Giles (2003) found that after being told stories about characters that varied in how much they tried and how well they did on schoolwork, children were more likely to remember situations where high effort led to a positive academic outcome than a poor academic outcome. Similarly, 3-4-year-olds only attended to positive task outcome (e.g., who won the race), and not process (e.g., the faster agent tripped on an obstacle), to infer future competence (Yang & Frye, 2016).

However, another possibility is that young children do possess a coherent yet preliminary understanding of competence that manifests only with additional contextual support. For instance, one study used a paradigm similar to Nicholls (1978) but with explicit labeling (e.g. this person is "lazy", this person paints "very well") and found that even 4-year-olds have a mature understanding of the causal relationship between ability, effort, and outcome: They understand that an agent with high ability and a poor outcome probably didn't try hard, whereas an agent with low ability and a good outcome probably did try hard (Wimmer, Wachter, & Perner, 1982). In a similar paradigm, Heyman & Compton (2006) found that 5-year-olds correctly inferred that a faster agent was smarter, but only when primed to focus on difficulty (whether actors thought the test was hard or easy), and not effort (whether the actors tried hard or not).

These two possibilities have been challenging to tease apart particularly because prior work has used different ways of presenting information about competence, making it difficult to compare results across studies. Many studies used narratives that are rather high in verbal or working memory demands, or required extensive domain knowledge about what constitutes better quality or outcome. Thus, studies that are high in verbal or memory demands might have underestimated children's abilities. On the other hand, there are reasons to believe that some of the tasks used in prior work provided ample (and rather generous) behavioral and linguistic cues that are superficially associated with competence. For instance, some prior studies simply required mapping valenced cues of quality (e.g., success vs. failure; good vs. bad outcome) to agents' competence on a similarly valenced scale (e.g., who is smarter?).

However, the quality of outcomes in many real-world activities are usually not clearly marked nor necessarily positive or negative. Therefore, a test of a genuine understanding of competence must ask whether children can integrate information about the expected time or effort required to complete a given task (i.e., difficulty) and the actual time or effort an agent needed to complete the task. For instance, if two people took the same amount of time to build two block towers, one of which clearly looks harder to build than the other (e.g., a tall vs. short tower), a child might simply associate the agent who built the taller tower with higher competence. If, however, the towers are the same height and shape but nonetheless vary in the actual effort required for building (e.g., one is made of many more smaller blocks than the other), judging the competence of agents requires an abstract understanding of competence that goes beyond the use of perceptual cues. Whether children have such an abstract notion of competence remains an open question.

Here, we ask whether 4- and 5-year-olds use task-based features (i.e., difficulty of the completed goal) and agent-based features (i.e., speed) to infer an agent's underlying competence. While competence can be assessed in a variety of domains, our experiments focus on children's inferences about agent competence in building block structures. We choose this domain because 1) previous work has shown that even 4-year-olds can accurately judge the relative difficulty of building different block structures (Gweon, Asaba, & Bennett-Pierre, 2017) and 2) unlike more abstract forms of competence (e.g., mental ability, intelligence), agents' competence on physical tasks often manifests in ways that are more concrete and visually accessible. Thus, we can use simple perceptual features to manipulate task-based and agent-based indicators of competence without relying on explicit verbal cues. Across four experiments, we systematically vary a task-based feature (task difficulty, marked by perceptual properties of the block structures) and an agent-based feature (building speed, marked by duration of total build time) to see if 4- and 5-year-olds can use these features to infer others' relative competence.

Experiment 1

Methods

Participants & Materials We recruited 30 4- to 5-year-old children at a local children's museum (mean: 59.70 months (range: 48 - 70), 47% girls). One additional child was excluded from analyses due to failing the practice question (n = 1, see Procedure). Participants viewed laminated pictures and watched videos on a laptop.

Procedure Children were tested individually in a private testing room. To make sure that children understood the word "better", the experimenter first asked children "Who is better at writing letters - you or your parents?" and then "Who is better at playing on the playground – you or your parents?". If children answered incorrectly (i.e., choosing themselves for writing, their parents for playing), they were corrected. Next, children were given a detailed explanation with visual aids of what would happen in the following videos.

Children first watched a practice video where two agents drew shapes (a star and a flower) and finished at different times (counter-balanced for side; agents throughout were matched on ethnicity and physical build). While the agents were drawing, a screen was lowered to block visual access to their progress. One of the agents indicated she was done drawing (saying "all done" with her hands raised above the screen and then moving to the side of the screen to read a book). A few seconds later, the other agent indicated she was done in the same manner. Then the screen lifted to reveal what they made. Children were asked to indicate which agent

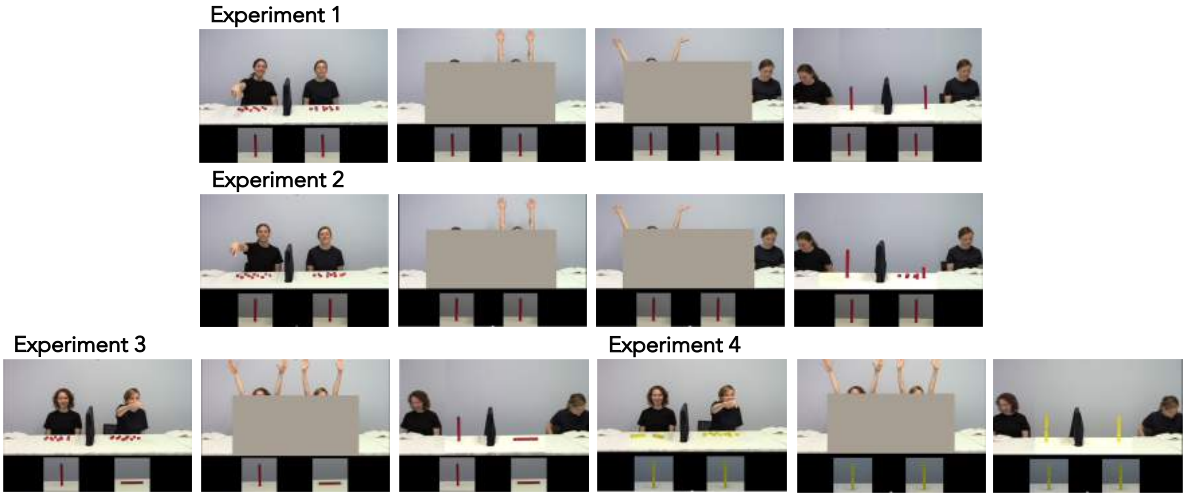

Figure 1: Still images from video stimuli for Experiments 1 through 4. In the first frame of each experiment, agents take turns pointing to the picture below them and saying "I'm going to make this". In the next frame, visual access to their building progress is blocked by an occluder. In Experiments 1 and 2, the agents finish at different times (marked by reaching up their hands, saying "all done", and moving to the side to read a book). In Experiments 3 and 4 agents finish building at the same time. Finally in the last frame, the occluder is lifted to reveal what each agent made.

finished first. If they answered this question incorrectly, they were excluded from analyses.

In the test video, children watched two agents build block structures. Below each agent was a picture of a 10-block vertical tower (see Figure 1, Experiment 1). The agents first indicated that they wanted to build the tower in the picture: One agent first said, pointing to the picture below her, "I'm going to make *this*", then the other agent repeated the same action. Next, the agents said "Ready? Go!" and began to build at the same time. As in the practice video, a screen was lowered to block the child's visual access to the agents' building actions. One agent finished building the tower in 10 seconds, indicating she was done in the same way as in the practice video (raising hands, saying "all done", and moving to the side of the screen to read); 5 seconds later, the other agent indicated she was done in the same manner (building time 15 seconds; side counter balanced). Critically, there were no verbal cues to indicate that one agent was "faster", or "found building easier" - children had to infer the agents' relative competence solely from the perceptual information in the video. The screen then lifted up to reveal what each agent made. At the end children were asked the critical test question, "Who is better at building blocks?"

Results & Discussion

Children's performance on the test question was significantly above chance (binomial test against chance (50%): 86.7% correct, CI = [76.7%, 100%][1], $p < .001$). Thus, children were able to understand that if two agents build the same structure, the agent that completes it earlier is more competent than the one who finishes later. This suggests that, when outcomes were matched (i.e., task-based feature kept constant), children can use differences in building time (an indicator of an agent's speed, an agent-based feature) to infer relative competence. However, another possibility is that children simply associated being faster with being better, without considering outcomes. In Experiment 2, we sought to rule out this alternative. If the agent who finishes first actually does not complete her goal, a simple association would still favor this agent as more competent. However, if children consider speed as an indicator of competence only when the agents have achieved the same goals, they should favor the agent who completed her goal even though she finished later.

Experiment 2

Methods

Participants Using data from Experiment 1, we ran a simulated power analysis using 10,000 binomial tests (bootstrapped samples with replacement) and set the sample size at n = 20 for a simulated power of .96.[2]. We recruited 4- and 5-year-olds at a children's museum (mean: 59.90 months (range: 48 - 71), 50% girls); 5 additional children were excluded from analyses due to failing the practice question (n = 2) or the inclusion criteria question (n = 3, see Procedure).

Procedure The procedure was similar to Experiment 1, except for the final outcome revealed at the end of the test video. While both agents indicated that they'd build a 10-block vertical tower, the agent who finished first (in 10 seconds) actually only built a 3-block tower whereas the agent who finished

[1] All reported CIs are 95% confidence regions estimated through a basic non-parametric bootstrap of the data using 500,000 samples.

[2] Experiments 2 and 3 were pre-registered on Open Science Framework (OSF): https://osf.io/pc945/registrations.

second (in 15 seconds) completed her goal (10-block tower). The test question was the same. To ensure children remembered the key event in the video, we asked: "Which agent didn't finish making her tower?" Children who gave incorrect answers were excluded from analyses.

Results & Discussion

Children's performance on the test question was significantly above chance (binomial test against chance = 50%; 90% correct, CI = [80%, 100%], $p < .001$). These results suggest that children do not indiscriminately use speed or time-to-completion as a cue to competence; when one person did not complete her goal, children resisted saying she was more competent even though the agent claimed to be done before the other agent. This complements our finding from Experiment 1, providing evidence that children's successful use of time-to-completion is not based on a simple heuristic "faster = better".

In Experiment 3, we now ask whether children can use a task-based feature (task difficulty) to infer relative competence when an agent-based feature (time to completion) is held constant. Critically, going beyond prior work that provided children explicit verbal cues to the task difficulty or outcome, we had children simply observe two agents building two different structures–10 blocks stacked vertically vs. lined up horizontally–and use the inferred difficulty of the two tasks to reason about competence. We chose these structures based on findings from (Gweon et al., 2017) showing that 4-year-olds readily judge the 10-block vertical structure as harder to build than the 10-block horizontal structure based on static pictures of the initial states (i.e., scattered blocks) and final states (finished towers), without seeing the building process. Given these results, we predicted that 4- and 5-year-olds would be able to use their understanding of task difficulty to infer the relative competence of two agents, even when total building time is matched.

Experiment 3

Methods

Participants We preregistered this experiment using the same power analysis as in Experiment 2 (see Footnote 2). We recruited 30 4- and 5-year-old children at a local children's museum (mean: 62.25, months (range: 49 - 71) 50% girls); 10 additional children were tested but excluded due to failing the practice question (n = 3, see Procedure) and inclusion criteria question (n = 7, see Procedure).

Procedure The procedure was similar to Experiment 1 with a few changes. To help children understand that the two agents might complete different goals, they were asked to indicate if the agents drew the same or different pictures after watching the practice videos. For the test video, agents had pictures of different block structures below them; one agent had a picture of a 10-block vertical tower and the other had the picture of a 10-block horizontal tower. As in Experiment 1, the agents pointed to the picture and said "I'm going to build this"; however, it was clear that agents were simply pointing to the structure that was depicted below them rather than making an active choice about which one to build. Furthermore, they never explicitly mentioned the physical properties of the structures nor their expected difficulty. Critically, the agents finished building their structures at the same time. Children were asked: "Who is better at building blocks?" followed by the inclusion question "Which tower is better?" Those who answered the inclusion question inaccurately[3] were excluded from analyses.

Results & Discussion

Children's performance on the test question was significantly above chance (95%, CI = [90%, 100%], $p < .001$). This result held even after including the 7 children who failed to answer the inclusion question accurately (74%, CI = [60%, 93%], $p = .02$). Thus, children were able to tell that when two agents take the same amount of time to build block structures, the agent that built the more difficult structure is more skilled. Critically, children were able to do so from their own assessment of the tasks, in the absence of any explicit information about the task difficulty.

While task difficulty was never mentioned explicitly, one might wonder if children still picked up on the fact that the 10-block vertical tower is taller than the 10-block horizontal structure, and simply associated building a"taller" tower with being "better" at building. Prior work provides some evidence against this possibility, showing that simple heuristics such as height or size do not fully explain children's inferences about task difficulty on a range of structures that vary along different dimensions. (Gweon et al., 2017).

However, whether children can infer the relative competence of two agents in the absence of any physical cues for agent-based (Experiment 1) or task-based features (Experiment 3) remains an open question. Experiment 4 provides a test of this ability, by asking children to judge the relative competence of two agents who take equal amounts of time to make towers that look identical in overall shape and height; critically, despite their near identical appearances, the towers differ in their building difficulty because one is made of 10 cubes and the other is made of 2 long blocks (and thus takes fewer steps, and is easier to build; see Figure 1). We chose these structures because Gweon et al. (2017) have shown that 4- and 5-year-olds can reliably identify the 10-block vertical structure as harder to build than the two-block structure given static pictures of the initial and final states, even without seeing the intermediate building process.

Unlike Experiments 1 - 3 where we hypothesized successful performance given explicit perceptual cues, one might entertain different predictions for Experiment 4. To succeed in this task, children must first infer that one tower is harder than the other, and spontaneously use this understanding to reason

[3]While the correct answer was the vertical 10-block tower, the wording of this question was confusing and potentially problematic; we thus also present results that include these children. In Experiment 4, we used a different question.

about the agents' competence; both of these inferences must be made based on the initial and the final states of the towers, without direct visual access to the actual building process. Thus, on the one hand, 4- and 5-year-olds may struggle with this task; prior work suggests that an abstract, coherent understanding of competence does not emerge until later in childhood, and our stimuli provide no superficial perceptual cues that children could use to judge relative competence. On the other hand, given that our task involves minimal verbal and memory demands, children might show an earlier success than previously believed. Thus, we did not preregister this experiment, allowing ourselves to explore a broader age range.

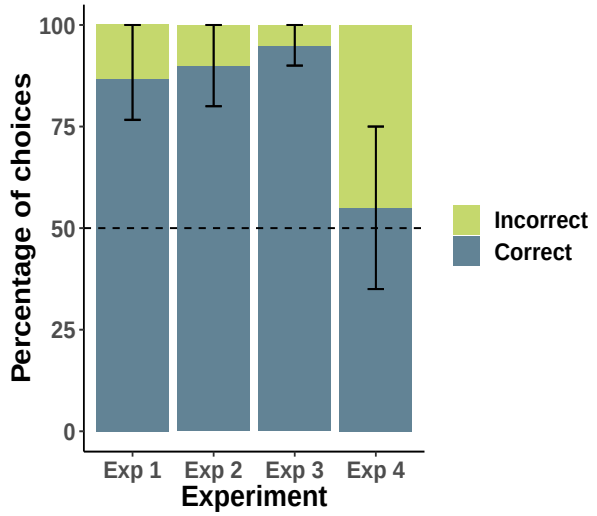

Figure 2: Results from Experiments 1 - 4: The percentage of children who correctly chose the more competent agent Error bars represent bootstrapped 95% confidence intervals. Dashed line indicates chance performance.

Experiment 4

Methods

Participants We used the same sample size as Experiments 2 and 3 (n=20). However, given the more difficult nature of this task, we extended our age range to include 6-year-olds (mean: 62.25 months (range: 48 - 83) 30% girls). Seven additional children were excluded due to failing inclusion criteria question (see Procedure). We also tested 25 adults on Amazon Mechanical Turk.

Procedure The procedure was similar to Experiment 3, with a few changes to minimize task demands. First, we removed the practice trial (more than 93% of children passed in Experiments 1 - 3) because this might bias children to focus on completion time. Additionally, to ensure that children paid attention to the fact that the two agents used different blocks to make similar-looking final structures, children were presented with physical examples of the 10 cubes and 2 long blocks, which were placed next to the side of the screen that matched the tower on the screen. In the test video, one agent had 10 cubes in front of her and pointed to the vertical tower below to indicate that she wants to build that tower; the other agent had 2 long blocks and also pointed to the tower below her (as in other experiments, the pointing was casual and did not indicate any active choice to construct a particular tower). Critically, the agents finished building their structures at the same time. Again, children were asked, "Who is better at building blocks?" followed by a inclusion question, "Which tower is harder to make?" Children were excluded if they incorrectly said that the 2-block tower was harder than the 10-block vertical tower.

Results & Discussion

We first verified that adults can infer relative competence accurately from these videos: 100% of the adults said the agent who built the 10-block tower was more competent than the agent who built the 2-block tower. However, children's performance was not significantly different than chance (55% correct, CI = [35%, 75%], $p = .82$), suggesting that when perceptual markers of difficulty and completion time are matched, children do not distinguish the agent who built the 10-block tower from the agent who built the 2-block tower. However, there was some evidence for a developmental change: Proportionally more 6-year-olds (6/7) than 5-year-olds (3/8) and 4-year-olds (2/5) answered the test question correctly. A logistic regression found a trend for an effect of age in years on children's success on this task ($B = 1.08$, $p = .1$).

General Discussion

Here we asked whether preschool-aged children can use a task-based feature (i.e., difficulty of the task) and an agent-based feature (i.e., agent speed) to infer the relative competence of agents. Critically, these cues were never verbally communicated by the experimenter or the agents in the video. As is the case in many real world situations, children had to spontaneously pick up on these cues and use them to infer relative competence. The difficulty of the tasks had to be inferred from the visual properties of the block structures (such as size or height), and the agents' speed or efficiency had to be inferred from their completion time on a given task. Our results suggest that children not only detect the perceptual cues that signal both types of features, but also readily use them to draw accurate judgments about the relative competence of two agents.

We found near-ceiling performance in 4- and 5-year-old children when one feature was matched and the other clearly varied across agents, marked by explicit perceptual cues. If two agents made the same block tower, the agent who completed her tower first was judged as more competent (Experiment 1), but not when this agent did not complete her goal (Experiment 2). If both agents completed their towers at the same time, the agent who built the more difficult tower was judged as the more competent agent (Experiment 3). However, in a more conservative test where the two agents

spent the same amount of time building towers that varied in difficulty but were matched in their final shape and height, children's accuracy dropped to chance-level (Experiment 4). While there is suggestive evidence that 6-year-olds are able to respond accurately in this scenario, overall children struggled without clear perceptual cues.

What explains children's difficulty with Experiment 4, given their robust success in Experiments 1-3? It is unlikely that children's failure is due to their inability to infer task difficulty; the structures used in the stimuli here have been verified to elicit accurate judgments of difficulty among 4-year-olds in prior work (Gweon et al., 2017). Furthermore, we only included children who were accurately able to tell which tower was "harder". One possibility is that children's success in Exp.1 - 3 simply reflects their use of superficial cues associated with "being better", such as one person finishing the task earlier than the other (Experiment 1) or one tower being larger than the other (Experiment 3). By contrast, Experiment 4 required integrating time and task difficulty in the absence of these cues. Some anecdotal support comes from pilot data for Experiment 4 where children were asked both (1) which tower was "harder" and (2) which tower was "better". While 4- and 5-year-olds correctly judged the 10-block tower as "harder" than the 2-block tower, they did not judge this tower as "better". By contrast, most children in Experiment 3 picked the vertical 10-block tower as "better" than the horizontal 10-block tower, suggesting that children relied primarily on perceptual cues such as relative time or size/height to judge who (or what) is "better".

One way to interpret these results is that children's concept of competence is quite different from that of adults, and that it continues to develop beyond age 5. This interpretation is largely consistent with what previous studies have proposed (Heyman et al., 2003; Nicholls, 1978; Yang & Frye, 2016). However, another possibility is that children's failure on Experiment 4 reflects the developmental change in the semantics of "better", rather than a genuine conceptual change in their understanding of competence. If children strongly associate the word "better" with positive perceptual features of objects or agents, this might bias children's judgments of "who's better at bulding" to whoever finishes first, or whoever builds something larger. When these explicit cues don't differ between the two agents, as in Experiment 4, children are thus at chance.

The current study cannot tease apart these possibilities, as the critical test question involves verbally asking children "who is better". Thus, it still leaves open the possibility that children do have an abstract understanding of competence as a subjective quality that is determined by both task-based and agent-based features. One promising future direction is to try eliciting competence judgments without using the word "better". In addition to non-verbal measures, future work might capitalize on a previous finding that toddlers' friend choice reflects representations of agents' competence (Jara-Ettinger et al., 2015).

Despite the limitation of using a verbal prompt in our outcome measure, our stimuli had lower verbal demands relative to earlier work that involved heavy-handed manipulations of competence with explicit verbal information. The words used in these tasks often implied evaluative judgments (e.g., "lazy", "smart", see Heyman et al., 2003; Heyman & Compton, 2006; Nicholls, 1978), raising the possibility that children in these studies succeeded by matching the valence of these words with "being better", instead of engaging in genuine inference based on the features of the event. On the other hand, while verbal cues may help make these features easier to detect, verbally presented scenarios can also hinder performance by increasing processing demands, taxing verbal knowledge and working memory. This may have led to either underestimation or overestimation of children's understanding of competence depending on the paradigm (Nicholls, 1984; Heyman et al., 2003; Yang & Frye, 2016), producing discrepant findings across studies and age ranges. The fact that children in Experiments 1-3 successfully used task-based and agent-based features suggests that young children are adept at picking up on non-verbal cues embedded in observed events to infer relative competence, in addition to using verbal cues (Wimmer et al., 1982; Heyman & Compton, 2006).

While not quite at the level of adults (note that adults are near-ceiling on Experiment 4), children's robust performance on most of these experiments suggests that some basic notion of competence based on quality and efficiency may emerge early in life. Indeed, infants have a sophisticated understanding of physical events (Stahl & Feigenson, 2015) as well as agent's actions and outcomes (Liu, Ullman, Tenenbaum, & Spelke, 2017). Furthermore, infants can use information about other's effortful actions to inform their own (Leonard, Lee, & Schulz, 2017). In order to employ this sort of social learning about effort, children presumably need some basic understanding of how effort relates to outcomes, scales with difficulty, and is constrained by competence. The ability to go beyond superficial cues to infer who is more competent than others can be especially beneficial for early learning, as the learner can make better decisions about who to learn from or ask for help. Future work could further explore when children begin to use task-based and agent-based features using similar stimuli as the current study with nonverbal dependent measures in a younger age range.

An open question is whether young children's inferences about competence generalize to domains outside of physical ability. One possibility is that children develop a stronger sense of physical competence before mental competence, due to its overt perceptual cues and children's more salient experience in this domain early in life. Furthermore, the paradigms tested here only looked at how task-based and agent-based features relate to inferences about competence, yet many other features are surely involved in this calculation. For example, if someone was unmotivated to play basketball and failed to shoot a 3-pointer, we wouldn't necessarily conclude

that they were unskilled. In other words, we also consider how much people *want* to achieve their goals when inferring their competence. Future work should probe the range of additional features that affect competence judgments broadly.

While we show that preschoolers are fairly accurate at reasoning about other's competence (at least with adequate perceptual cues), a great deal of work has shown that young children are out of touch, and in fact overly optimistic, about their own competence. However, most of these studies looked at how children predict how they would do in the future given their past performance, which might have led to wishful thinking (Schneider, 1998; Parsons & Ruble, 1977; Harter, 2012). Just as children were able to use observed evidence to infer others' competence, they may similarly evaluate their own competence based on observed outcomes. In fact, recent work suggests that children are even sensitive to the discrepancy between their own belief about their actual competence (i.e., the child successfully activates a toy after a few failures) vs. others' beliefs (i.e., an adult only observed the child's failures) and demonstrate their success to others to change these beliefs (Asaba & Gweon, 2018). Collectively these results are consistent with the recent proposal that children's understanding of competence is not "irrationally" optimistic (Cimpian, 2017), and calls for better tasks that tap into their underlying cognitive processes.

More generally, this work highlights the importance of reexamining old topics in a new light. The current work conceptually replicates prior results (including some from the 70's) while also raising new questions about what these results mean. Children's perception of competence in the early years is crucial as it likely informs their achievement beliefs and mindsets, which in turn impacts their academic outcomes (e.g. Dweck, 2006). Thus, understanding the ways in which children conceptualize competence early in life allows us to potentially help set children on the path towards a learning-focused mindset even before they enter formal schooling. We hope a new wave of interest from the broader community will shed more light on this important topic.

Abstract

Observers rapidly extract summary statistics from sets of visually presented items, like the mean size of a set of circles, or the mean expression of a set of faces. Their excellent ability to report summary statistics stands in contrast to near-chance representation of any of the individuals. Here we asked to what extent this 'ensemble perception' signature extends to a more abstract property: *relations* among elements. Participants watched ten unique animations of visually patterned objects (hereafter, 'shapes') colliding with each other and producing a new shape. Collisions conformed to ABA patterns, such that the result shape always matched one of the collider shapes. Recognition tests showed that participants accurately recalled the collisions they saw, but also falsely accepted foils which conformed to the ABA pattern but which were not in fact specifically seen (were rearrangements of the original shapes across collisions). On the other hand, they were much less likely to accept foils which did not conform to the pattern, but were equally distinct rearrangements (e.g., AAB). This suggests that participants represented the overall, common pattern better than the specifics of what they saw; the superior encoding of the summary relative to the individuals thus applies to summaries of relations. However, in contrast to prior findings with visual features, we did not find that recall of individual patterns was entirely at chance. Our paradigm offers a way to pursue future questions such as the pressures and motivations which might govern the trade-off between summarizing evidence vs. retaining individual experiences.

Keywords: ensemble perception; artificial grammar learning; pattern recognition; episodic memory; semantic memory

Introduction

Rather than encoding experiences in perfect detail, the mind naturally uses regularities and summary statistics to compress them. We can keep more items in working memory if items are predictive of each other (Brady, Konkle, & Alvarez, 2009); it becomes faster to find images in search display if they appear in predictable spatial configurations (Chun & Jiang, 1998); and we spontaneously and obligatorily register the mean orientation of sets of gabor patches (Parkes, Lund, Angelucci, Solomon, & Morgan, 2001). Although contingencies and averages are distinct statistics, all of these cases demonstrate that we spontaneously compress experiences, by encoding a summary of what is common across them.

In principle, representational systems can differ in the extent to which they compute summaries and discard individual observations (Dennett, 1991). Curiously, human participants sometimes represent summaries better than the observations composing them. When we see sets—like a series of differently-sized circles—we recall their mean (here, size) substantially better than we can recall any particular individual (Ariely, 2001; Chong & Treisman, 2003; Haberman & Whitney, 2009). This is true even when the number of items is relatively small (4) and when the items are presented sequentially. This suggests that we compute summaries and update them rapidly, discarding the items that went into this computation along the way. This 'ensemble perception' signature is true for visual properties like size, orientation, or facial expression (see Alvarez, 2011 and Whitney & Yamanashi Leib, 2018 for reviews). Here we asked whether this signature also applies to a property which is not a visual feature, but rather an abstract rule.

Algebraic rules (Marcus, 2001) are patterns based on relations among elements, such as *same* and *different*. For example, triplets of syllables can be readily seen as belonging to patterns like ABA— "ga di ga", "ku la ku", or "do re do"—vs AAB—"ga ga di". Learners (adults or infants) can recognize such patterns even with entirely distinct syllable sets and in both auditory and visual modalities (Ferguson, Franconeri, & Waxman, 2018; Marcus, Vijayan, Rao, & Vishton, 1999; Saffran, Pollak, Seibel, & Shkolnik, 2007). Algebraic rules are hallmarks of relational thinking, requiring relatively advanced computational architecture (Marcus, 2001; Overlan, Jacobs, & Piantadosi, 2017). They are also excellent compressions: recognizing that the last element always matches the first reduces the number of bits needed to represent the triplet by 1/3. Thus, despite the possible computational cost, encoding relations among stimuli is adaptive for circumventing limited memory capacity.

Here we asked how a representation of a shared algebraic pattern relates to the representation of the diverse individuals exhibiting the pattern. Specifically, we asked whether we would see the signature of ensemble perception. If so, participants should not only recognize that the set of items tends to follow an ABA pattern, but they should find it easier to recall that abstract pattern than the particular

items they specifically saw (for instance, “ga di ga”, but not “ga ku ga”). Alternatively, due to the computational

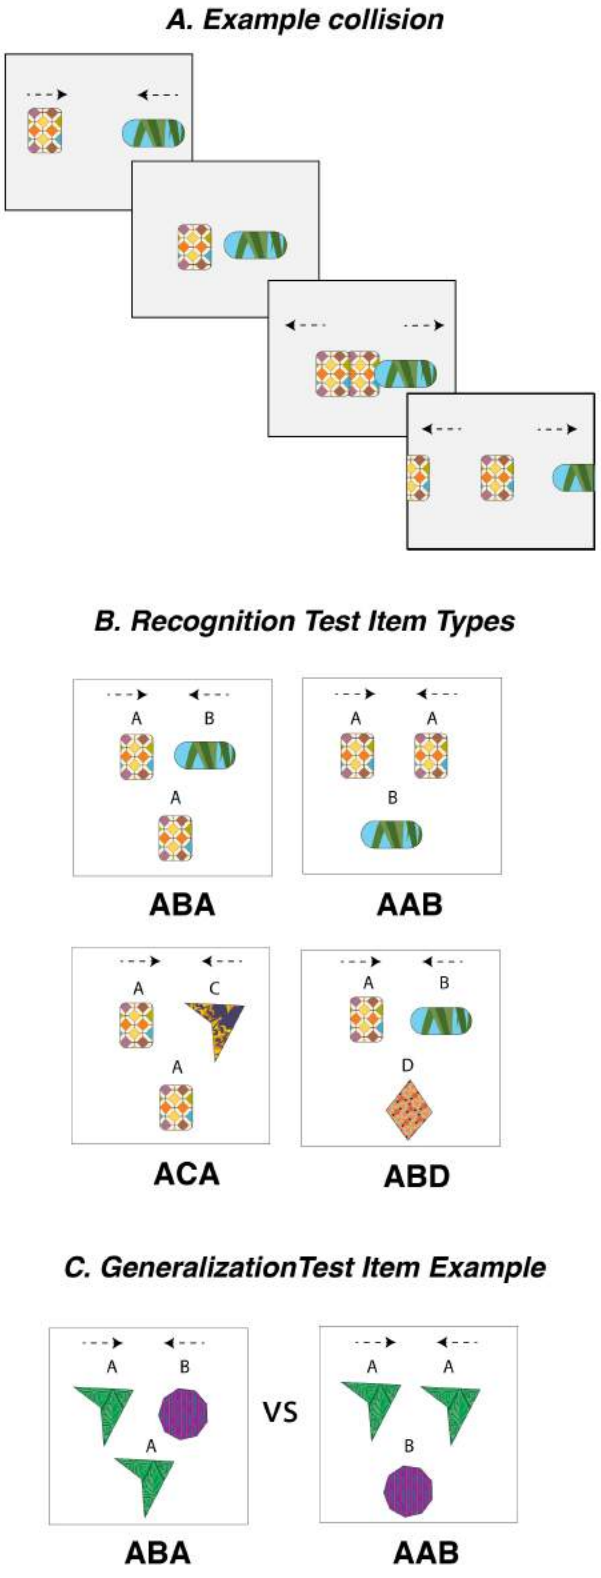

Figure 1. Top: Example of a collision between an A and B shapes and an A shape result. Bottom: Foil types for this collision, represented schematically. C shapes were taken from other collisions presented during the demonstration.

demands of inferring algebraic patterns, participants may be less reliable at recognizing the common ABA pattern across items, failing to summarize the data, and may be better at discerning which individual items they specifically saw.

We used a novel paradigm in which participants watched pairs of novel shapes collide with each other and ‘produce’ a third shape (Figure 1). Participants’ task was to watch the collisions and see how many they could remember. As there was no instruction to look for patterns, the choice to summarize or not had to be intrinsically motivated.

Each collision was in fact governed by an ABA pattern: two distinct shapes, A and B, collided, producing another A. (We use ABA to denote the abstract elements, and lowercase *aba* to denote specific shapes). After watching 10 unique ABA collisions once each, participants performed a recognition test where each test item was either a collision they had seen, or one of three kinds of foils (unseen collisions). ACA foils swapped shapes between collisions: if specific collisions *aba* and *dcd* were shown, foils were *aca* and *dbd*. AAB foils were rearrangements of the same shapes in seen collisions, so that two A’s collided to produce a B.

We reasoned that if participants recalled the common pattern better than the individual items, they should accept ACA foils at a higher rate than AAB foils. This is because ACA is pattern-consistent while AAB is not, though in terms of individual shapes composing the collisions, ACA is in fact more different from the original. ABD foils were also used as these were equal in the number of element-wise changes from ABA as ACA, but were also pattern-inconsistent.

We were also able to ask whether participants recalled *only* the summary pattern, and lost all item representations, by seeing whether they accept ACA foils at the same rate as ABA correct items. In ensemble perception, tests of individual recognition are often at chance (Ariely, 2001; Haberman & Whitney, 2009). Finally, a forced-choice test with new items directly tested whether learners represented the pattern in generalizable form.

Methods

Participants

30 participants were recruited and tested via Amazon Mechanical Turk. Participants provided electronic consent and procedures were approved by the Institutional Review Board of the University of Pennsylvania. Compensation was $2. Three participants were excluded for failing an attention measure, and one for missing data. The included sample had 15 females and 15 males, with age M = 37, range 21 – 64). The task took an average of 15.62 minutes.

Stimuli

Stimuli were animated shape collisions (Figure 1). In each animation, two shapes approached each other from the left and right sides of the screen, met in the middle, and a third

'result' shape appeared between them as they moved away. Individual frames were created in Adobe Illustrator and concatenated into GIFs. Each GIF was composed of 23 frames shown at a 180 ms framerate and 4.14 s duration. GIFs were interspersed with 660 ms of blank screen for a 4.8 s total ISI. The majority of shapes used in the displays is shown in the Appendix.

Procedure

The task was presented to participants using a custom JavaScript webpage. It began with a *demonstration phase.* Participants were shown the following instructions: "You will play a game where you will see pairs of shapes collide with each other and see how many you can remember." They then watched 10 unique demonstration collisions in randomized order (lasting ~ 1 minute). Each of these collisions followed an ABA pattern: the two collider shapes, A and B, were distinct, and the result shape was a duplicate of A. A total of 20 different shapes were used, so that no shapes were repeated across collisions.

They then saw the *specific recognition test*. On each trial, a collision was shown, and participants had to decide whether or not they had seen it in the demonstration phase, by clicking 'yes' or 'no' after it ended. They were allowed to replay the collision. Apart from all 10 demonstration collisions, test items also showed three types of foils, created by rearranging the shapes across or within the demonstration collisions. ACA foils swapped the 'B' shapes between two different collisions, so that if specific shapes *aba* and *dcd* had been shown, foils were *aca* and *dbd*. AAB foils rearranged the shapes within an original collision, so that now two A's collided to produce B. ABD foils produced a result shape taken from another collision. The swaps were selected by pairing the 10 collisions into 5 foil-pairs. One of each of the three foil types was shown for each of the 10 original collisions; thus, there were 10 data points for each participant for each test item type.

We also added three attention check items, which showed previously unseen shapes in which two of the same shape collided, producing another duplicate (i.e., an AAA pattern). Participants had to respond 'no' to all three attention items to be included in the further analyses. Overall, there were 43 specific recognition test trials, shown in randomized order. There was no trial-level feedback, but an overall score was shown at the end of the test.

Participants were then given the *generalization test*. The instructions read, "The collisions you first watched followed certain patterns or rules. Now you will see new collisions and be asked to decide which ones follow similar patterns or rules." A two-alternative forced-choice test asked them to choose between pairs of collisions, shown one at a time, side by side. We used previously unseen shapes to create two new sets of ABA, AAB, and ABD items. Critical questions asked participants to choose between a pattern-consistent collision (ABA) and one of the two foils (AAB or ABD). Filler items showed the two foils, in order to balance the number of times each collision was shown overall. Each question type was shown once for each novel shape set, creating a total of 8 trials.

Finally, we asked participants whether or not they took any notes during the task. No participant reported taking notes.

Results

Specific Recognition Test

We computed the percent acceptance rate ('yes' response) for each type of test item; results are shown in Figure 2. The correct test item (ABA) was identical to the collision previously shown; this was (correctly) accepted at a high rate (M = 85%, SE = 0.05%). The ACA foil item maintained the pattern but its middle shape was swapped across previously seen collisions; this was (falsely) accepted at a high rate (M = 73%, SD = 0.05%). The AAB foil item was accepted at a low rate (M = 15%, SE = 0.06%) as was the ABD foil item (M = 13%, SE = 0.04%).

A 4- way ANOVA indicated a significant effect of item type, $F(75,3) = 59.43$, $p < .001$. Planned t-tests were used to probe these differences pairwise. We found that ACA foils were accepted at a higher rate than AAB foils, $t(25) = 6.77$, $p < .001$, CI [40 75] and ABD foils, $t(25) = 6.16$, $p < .001$, CI [42 86], indicating that participants indeed represented the pattern better than the specifics. Nonetheless, we also found higher acceptance rates for the correct (ABA) items than the ACA foils, $t(25) = 3.30$, $p = .002$, CI [4 19], indicating that item information was not completely lost.

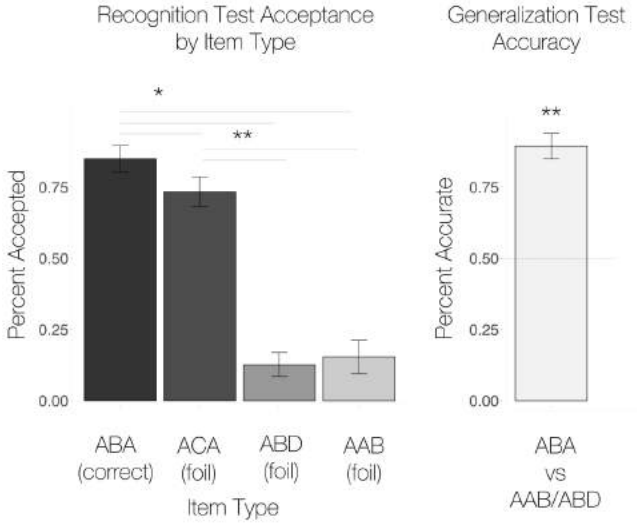

Figure 2. Rate of acceptance on the specific recognition test for each type of test item, and accuracy on the generalization test. Statistical comparisons are shown with * indicating $p < .01$ and ** indicating $p < .001$.

One potential account of these effects is that individual item representations decayed more rapidly or were more susceptible to interference from the question presentations. It should be noted that the majority of test items are also pattern-inconsistent, and so the amount of interference

should be equal for both specific and pattern recall; however, it could still be that the item representations are more susceptible. We thus looked at responses from the first 10 test items only (thus, a random subsample from each participant). The critical effect of greater ACA than AAB acceptance was still significant, $t(25) = 7.10$, $p < .001$, CI [45 82], and the difference between ABA and ACA was marginal, $t(25) = 1.89$, $p = .07$, CI [-1 28].

Generalization Test

Participants were reliably above chance on choosing the pattern-consistent, entirely novel ABA collision relative to both foils; AAB: $M = 89\%$, $SE = 0.05\%$; $t(25) = 7.63$, CI [78 99], $p < .001$; ABD: $M = 90\%$, $SE = 0.05\%$; $t(25) = 8.38$, CI [81 100], $p < .001$ (Figure 2). They were thus highly reliable in learning a generalizable representation of the algebraic rule. As there was no difference between the two foil types ($t < 1$), accuracies for both were collapsed into a composite generalization score ($M = 89\%$). We found that this composite accuracy was not significantly different from the rate at which participants accepted the correct ABA items on the specific recognition test ($t < 1$), indicating that the representation of the abstract pattern was no worse than specific recall. We also found that accuracy on the generalization test was substantially higher than participants' ability to accurately reject the ACA foils (i.e., inverse of their acceptance rate; $t(25) = 7.45$, CI [47 82], $p < .001$. This is in line with the findings from the specific recognition test that the representation of the abstract pattern was superior to specific recall.

Discussion

We investigated the relationship between the ability to recall specific items (unique collisions of three shapes) and to identify and recall the common pattern governing them (here, an ABA algebraic rule). We found that analogously to signatures in ensemble perception, participants recalled the common pattern substantially better than the specifics of the individual items. Nonetheless, some memory of the individuals persisted, in contrast to certain findings with visual feature ensembles.

Our results indicate that the core signature seen in ensemble perception—superior fidelity of summary statistics over individual items—generalizes beyond visual features like size, facial expression, or line orientation (Whitney & Yamanashi Leib, 2018) and similarly applies to relational properties over visual events, like algebraic rules. This substantially extends the repertoire where such ensemble signatures might be found.

Our findings also speak to the question of how much a pattern-based summary relies on the representation of the individuals being summarized. Individual items must of course be processed at *some* level, but showing that their details can be quickly forgotten in spite of near-ceiling summary representations suggests that this level is relatively minimal. Because items were shown sequentially, and were short-lived, learners had to encode the pattern and update the summary with each subsequent representation—otherwise, it would be too late. It could therefore be the case that the item representation is discarded almost immediately after it is perceived.

The literature on episodic memory has similarly investigated whether summary recall is dependent on item recall, and has separated out these representations using delay paradigms and studies of amnesia. With multi-day delays, animals' reliance on the locations of specifically experienced platforms in a water maze declines, and is replaced by a representation of their mean location (Richards et al., 2014). Patients with amnesia (impairment to episodic memory) are as able as controls to extract patterns in artificial grammar learning studies, but unlike them, fail on recognition tasks of individual items from which they learned that grammar (Knowlton, Ramus, & Squire, 1992). Here we offer an elegant way to show this dissociation in healthy participants within a few minutes of testing, and to directly quantify the amount of information preserved about the individual items and the overall patterns. This opens an avenue of research investigating the circumstances and pressures that may motivate our cognitive system to rely on one or the other.

What might such pressures be? If learning is an attempt to infer the underlying model that generates observations, specific experiences serve as evidence towards hypotheses about that model—for example, a mean value or an underlying structure (Tenenbaum, Kemp, Griffiths, & Goodman, 2011). Once their beliefs over relevant models are updated, data points could be discarded (Nagy, Török, & Orbán, 2018). In this light, it has been argued that the choice to update a model vs. keep the data may be informed by factors such as the number of relevant models or how likely the relevant model to update might eventually change (Nagy et al., 2018; Richards & Frankland, 2017). Here, the right model was the ABA pattern, which explained all observations reliably. We might predict that if the pattern sometimes changed, recalling the specifics of all collisions might be enhanced, as this suggests to the learner that the model may not tell the full story or might change. We plan to test this in future work.

Another factor may be the computational cost of that update. Representing items in terms of their relations may be inferentially complex (Frank & Tenenbaum, 2011; Kuehne, Gentner, & Forbus, 2000; Overlan et al., 2017) and appears optional: one could perceive and remember a specific collision without ever representing the relations among its elements. If hypotheses about relations are computationally costly to update, the compression benefit of computing a relation may not outweigh the costs. The qualitative divergence we saw between algebraic patterns here vs. visual features in the past is consistent with this possibility: in the case of algebraic patterns, representations of individuals were not entirely lost, while for visual feature summaries, they often are (Ariely, 2001; Haberman & Whitney, 2009). If visual features require fewer inferential steps to encode than relational patterns, this could be consistent with that idea. Our paradigm offers a way to test some of these questions directly in future work.

Parents Calibrate Speech to Their Children's Vocabulary Knowledge

Abstract

Young children learn language at an incredible rate. While children come prepared with powerful statistical learning mechanisms, the statistics they encounter are also prepared for them: Children learn from caregivers motivated to communicate with them. Do caregivers modify their speech in order to support children's comprehension? We asked children and their parents to play a simple reference game in which the parent's goal was to guide their child to select a target animal from a set of three. We show that parents calibrate their referring expressions to their children's language knowledge, producing more informative references for animals that they thought their children did not know. Further, parents learn about their children's knowledge over the course of the game, and calibrate their referring expressions accordingly. These results underscore the importance of understanding the communicative context in which language learning happens.

Keywords: parent-child interaction; language development; communication

Introduction

Children learn language at astonishing rates, acquiring thousands of words by the time they are toddlers. How do children learn so many words before they know how to dress themselves? One account for children's rapid language acquisition is statistical learning. Young children can attend to the distributional structure of language, learning to discriminate words and identify word order from speech streams (Saffran, 2003; Saffran, Aslin, & Newport, 1996). Statistical learning can be a powerful tool for early language learning, and showcases the ability that children have to harvest information from their surroundings. However, the particular structure of children's language environments may also play a role in supporting language development.

The way we speak to children often differs from the way we speak to adults. Child-directed speech (CDS) exists across cultures, and is characterized by higher pitches and more exaggerated enunciations when compared to adult-directed speech (ADS) (Cooper & Aslin, 1990; Grieser & Kuhl, 1988). Not only do children prefer CDS over ADS, CDS is also a better predictor for language learning than overheard ADS (Shneidman, Arroyo, Levine, & Goldin-Meadow, 2013). CDS does not only differ from ADS in prosodic features- the structural qualities of CDS make speech segmentation and word learning easier (Thiessen, Hill, & Saffran, 2005; Yurovsky, Yu, & Smith, 2012). While children live in the same physical environments as adults, their *language environments* contain specific types of input that facilitate early language learning.

Children's language environments are not only suited for their abilities; they also change across development. Parents play a role in changing their children's language environment, and there is evidence suggesting that these changes aid language development. Parents use simpler, more redundant language when talking to toddlers, and more complex syntactic structures when speaking with school-aged children (Snow, 1972). Importantly, sensitive modification of parent response shapes language learning in children (Hoff-Ginsberg & Shatz, 1982; Tamis-LeMonda, Kuchirko, & Song, 2014).

Why do parents modify the way they speak according to their children? One possible explanation is that parents are actively teaching their children. Indeed, some have posited that CDS is an ostensive cue for social learning, and that infants are born prepared to attend to these cues (Csibra & Gergely, 2009). While it may be true that parents hope to impart knowledge to their children, we argue that effective communication is the proximal goal. The field of linguistics has long established that adults communicate in ways that are efficient. Grice's (1975) maxim of quantity states that speech should be as informative as necessary, and no more. Adults are able to adhere to these maxims, adapting speech according to conversational partners' knowledge as needed for successful communication (Clark & Wilkes-Gibbs, 1986). We argue that the parent's goal to communicate with their child drives the change in language use. Specifically, parents adapt their speech according to their children's language abilities.

Parents modify their language as a *means* to achieve successful communication. Research show that parents use simpler language and are more linguistically aligned with their younger children, and these patterns of speech change as their children develop (Snow, 1972; Yurovsky, Doyle, & Frank, 2016). Parents are also sensitive to children's vocabulary knowledge, and the way they refer to objects change markedly depending on whether they are novel, comprehended, or familiar to their children (Masur, 1997). These changes in parent speech may indicate adaptations that are aimed at fulfilling the goal of effective communication, and that the language necessary to fulfill that goal changes as children develop.

Based on work by Masur (1997), we developed a study to investigate how parents adapt their speech according to

their children's vocabulary knowledge. Masur's study involved parents and children engaging in unstructured free play, and parents reported their children's vocabulary knowledge after the session. Our study uses a structured interactive game that allows us to control for the amount and type of stimuli presented to the parent-child dyads, and parent-reported vocabulary measures are collected before the study. Our paradigm also introduces a communicative goal within a structured game, which also allows parent utterances to be more comparable across dyads.

We designed an interactive iPad game in which parents verbally guide their children to select animals on an iPad. Each animal in the game appeared as a target twice. We predicted that parents would modify their speech based on their beliefs about their children's vocabulary knowledge. Specifically, we predicted: (1) Parents should use shorter referring expressions when describing animals that they believe their children know, and (2) Upon the second appearance of an animal, parents would adapt the length of their referring expression according to whether the child responded accurately on the first appearance of the animal.

Method

Participants

Toddlers (aged 2.0 to 2.5 years) and their parents were recruited from a database of families in the local community or approached on the floor of a local science museum in order to achieve a planned sample of 40 parent-child dyads. A total of 46 parent-child pairs were recruited, but data from six pairs were dropped from analysis due to experimental error or failure to complete the study. The final sample consisted of 40 children aged 2.02 to 2.48 years ($M = 2.17$), 20 of whom were girls.

Stimuli

Eighteen animal images were selected from the Rossion & Pourtois (2004) image set, which is a colored version of the Snodgrass & Vanderwart (1980) object set. Animals were selected based on age of acquisition (AoA), using data from WordBank (Frank, Braginsky, Yurovsky, & Marchman, 2017). The AoA of the selected animals ranged from 12 to 31 months. Half of the animals had lower AoA (12-20 months), and the other half had higher AoA (25-31 months). Each trial featured three animals, all from either the low AoA or high AoA category.

A modified version of the MacArthur-Bates Communicative Development Inventory (CDI; Fenson et al., 2007), a parent-reported measure of children's vocabulary, was administered before the testing session via an online survey. The selected animal words were embedded among the 85 words in the survey. Two of the animal words–one in the early AOA and one in the late AOA category–were accidentally omitted, so trials for those words were not included in analysis.

Figure 1: Example iPad screens for the child (top) and parent (bottom) during the experiment.

Design and Procedure

Each parent-child pair played an interactive game using two iPads. Children were given two warm-up trials to get used to the iPads. The practice and experimental trials began after the warm-up. On each trial, three images of animals were displayed side by side on the child's screen, and a single word appeared on the parent's screen (Figure 1). Parents were instructed to communicate as they normally would with their child, and encourage them to choose the object corresponding to the word on their screen. The child was instructed to listen to their parent for cues. Once an animal was tapped, the trial ended, and a new trial began. There was a total of 36 experimental trials, such that each animal appeared as the target twice. Trials were randomized for each participant, with the constraint that the same animal could not be the target twice in a row. Practice trials followed the same format as experimental trials, with the exception that images of fruit and vegetables were shown. All sessions were videotaped for transcription and coding.

Results

The data of interest in this study were parent utterances used during the interactive game and parents' responses on the adapted CDI. Transcripts of the videos were analyzed for length of referring expressions. We measured the length of parents' referring utterances as a proxy for amount of information given in each utterance. Parent utterances irrelevant to the iPad game (e.g. asking the child to sit down) were not analyzed. Children's utterances were coded when audible, but were not analyzed.

Word difficulty. We first confirm that the animals predicted be later learned were less likely to be marked known by the parents of children in our studies. As predicted, animals in the

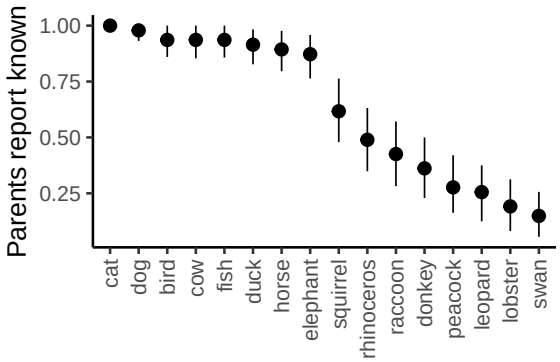

Figure 2: Proportion of parents who reported that their child understood the word for each of our target animals. Error bars indicate 95% confidence intervals computed by non-parametric bootstrap.

early AoA category were judged to be understood by 93% of parents, and items in the late AoA category were judged understood by 35%.

The difference between these groups was confirmed statistically with a logistic mixed effects regression with a fixed effect of AoA type and random effects of participants. The late AoA items were judged known by a significantly smaller proportion of parents (β = -5.49, t = -11.22, $p < .001$). Parents' judgments for each target word are shown in Figure 2.

Length of referring expressions. If parents calibrate their referential expressions to their children's linguistic knowledge, they should provide more information to children for whom a simple bare noun (e.g. "leopard") would be insufficient to identify the target. Parents did this in a number of ways: With one or more adjectives (e.g., "the spotted, yellow leopard"), with similes (e.g., "the one that's like a cat"), and with allusions to familiar animal exemplars of the category. In all of these cases, parents would be required to produce more words. Thus, we analyzed the length of parents' referential expressions as a theory-agnostic proxy for informativeness.

We predicted that parents should produce more informative–and thus longer–referring expressions to refer to animals that they thought their children did not know. We divided every trial of the game into phases: The time before a child selected an animal, and the time following selection until the start of the next trial. Figure 3 shows the number of words that parents produced to refer to animals that they believe their children know versus those they believe their children do not know–both before their children selected an animal and after. In line with our prediction, parents produced significantly longer referring expressions when talking about animals that they believe their children do not know. However, once the child had selected an animal, the expressions that followed did not differ between known and unknown animals.

We confirmed this result statistically, predicting number of words from a mixed effects model with fixed effects of phase and animal knowledge and their interaction, and random effects of participant and item. In this and all future models, we analyzed the number of words on a log scale as that improved model fit, but results are qualitatively similar when raw number of words was the dependent variable. Phase and the interaction of phase and knowledge were significant: Parents produced fewer words after selection (β = -0.51, t = -13.16, $p < .001$), and when the animal was known, (β = -0.21, t = -6, $p = < .001$), but the change was smaller for known animals (β = 0.08, t = 1.61, p = .107). In the remainder of our analyses, we focus on utterances in the pre-selection phase of each trial as the post selection phase did not vary across trial targets.

Although each parent only gave a single bit of information about each animal–whether they thought their child knew it or not–we pooled these judgments across parents to estimate a continuous measure of difficulty (Figure 2). If parents' referring utterances reflect a sensitivity to this continuous difficulty, the length of their referring expressions should vary smoothly with the difficulty of words. Figure 4 shows this relationship, which was confirmed by a mixed effects model predicting length from fixed effects of difficulty and animal knowledge, and random effects of subject and trial target. Referring expressions were reliably longer for more difficult animals (β = 0.2, t = 2.63, p = .012), over and above the increase for unknown animals (β = 0.14, t = 3.05, p = .002)

We then tested our second hypothesis: Parents should modify their productions over the course of the experiment as they obtain evidence about their children's knowledge. Because each animal was the target twice, parents could use their children's selection on the first appearance of the animal to inform their referential expressions on the second appearance. Figure 5 shows the length of parents' referring expressions as a function of their prior belief about their children's knowledge and their children's selection on the first appearance of the target animal. As predicted, parents who thought their children knew an animal, but who observed evidence that

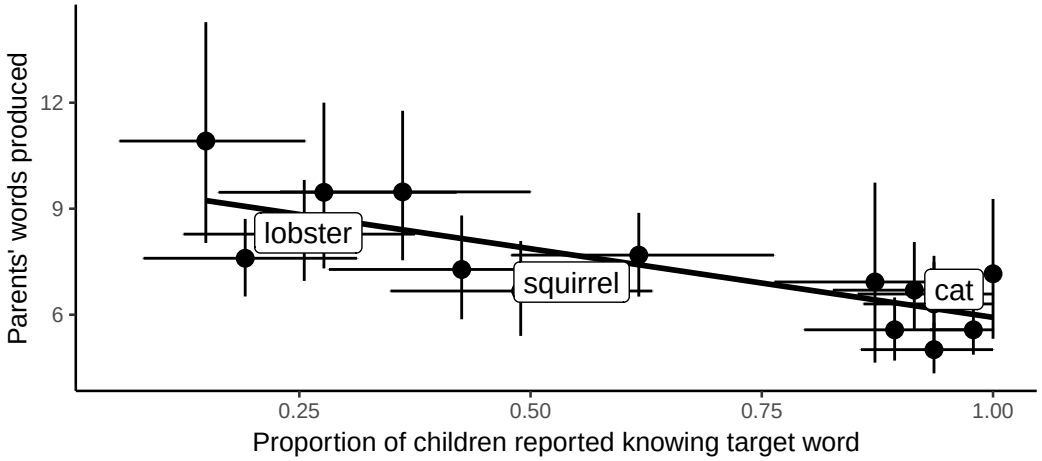

Figure 4: Number of words in parents' referential expressions as a function of the proportion of children reported to know the word for target animal. Points show group averaged proportions, error bars show 95% confidence intervals computed by non-parametric bootstrap.

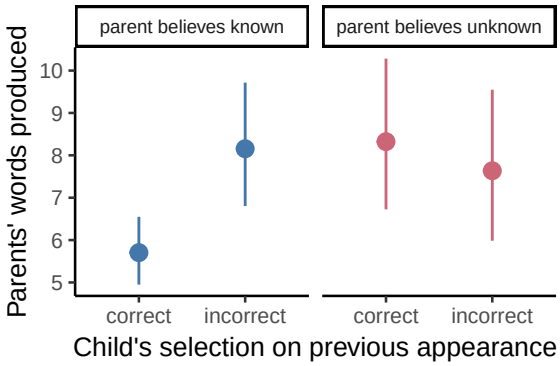

Figure 5: Length of parents' referring expressions on the second appearance of each animal. Points show group averaged proportions; error bars show 95% confidence intervals computed by non-parametric bootstrap.

they didn't (i.e. their children selected the wrong animal), lengthened their referring expressions on its second appearance. Parents who thought their children did not know an animal before the start of the game did not shorten their referring expressions if their children were correct the first time. We cannot say definitively why their referring expressions do not change in length, but one likely explanation is that the references that lead to success the first time were heavily scaffolded and may not even have contained the animal's canonical label (e.g. "the one that looks like a cat" for leopard). We confirmed these results with a mixed effects model predicting length of expressions from parents' prior beliefs, their children's selection on the first trial, and their interaction. We found only the interaction to be significant: References were not reliably longer when parents thought their children did not know the animal ($\beta = 0.28$, $t = 4.14$, $p = < .001$), nor when the children were incorrect on the previous trial ($\beta = 0.27$, $t = 3.82$, $p = < .001$, but only when the parent thought

their children did not know the animal and their children were incorrect on the previous trial ($\beta = -0.44$, $t = -4.29$, $p = < .001$).

Children's selections. Overall, children performed significantly above chance for both low AoA and high AoA trials. In our previous analyses, we showed that parents calibrated the length of their referring expressions to their beliefs about their children's knowledge. They did this both in response to their prior beliefs (Figure 3), and their in-game observations of their children's knowledge (Figure 5). In our final analyses, we asked whether this mattered for children's selections. Are children more likely to succeed in the task when parents provide well calibrated utterances? We asked this question by predicting children's selection trial by trial from a mixed effects logistic regression with fixed effects of parents' prior beliefs about children's knowledge of the target animal, whether the trial was the first or second appearance of the the target animal, the length of parents' referring expressions, and the interaction of parents' prior beliefs and the length of their ex-

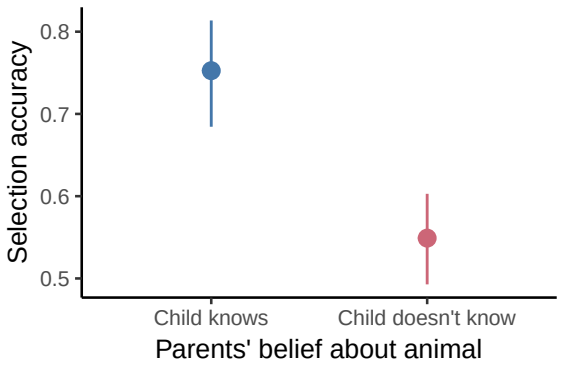

Figure 6: Children's accuracy at selecting both known and unknown animals. Points indicate means, error bars indicate 95% confidence intervals computed by non-parametric bootstrapping.

pressions, as well as random effects of subject and trial target. Children were more likely to be correct when their parents produced longer references, but only for animals that their parents believed that they did not know. Thus, parents' informative references to unknown animals did appear to be supporting successful communication of the target animal. Table 1 shows coefficient estimates for all parameters.

Discussion

Parents have a wealth of knowledge about their kids, including their linguistic development (Fenson et al., 2007). Do they draw on this knowledge when they want to communicate? In a referential communication task, we showed that parents speak differently depending on their beliefs about their children's vocabulary knowledge. Specifically, they produce shorter, less informative expressions to refer to animals that they believe their children know relative to animals that they think their children do not know. Further, parents update their beliefs during the course of the task, producing more informative expressions on the second appearance of an animal they previously thought their children knew if they observed evidence to the contrary (i.e. when children selected the wrong animal). We further found that more informative referring expressions were associated with increased likelihood of successful communication: Children were more likely to correctly select animals whose names they did not know if their parents produced longer utterances to refer to them. We leveraged length as a proxy for informativeness in parents' expressions in the service of quantitative, theory-agnostic predictions. In ongoing work, we are analyzing *how* parents succeed on these trials, and investigating whether different strategies lead to different levels of success.

In general, communicative success was high. Children selected the correct animal at above chance levels, even for targets whose names their parents thought they did not know. Because easy and hard animals appeared on separate trials, children's high accuracy in selecting unfamiliar animals is unlikely to be due to the use of strategies like mutual exclusivity (Markman & Wachtel, 1988). Instead, parents must have produced sufficient information for their children to find the correct target. Taken together with our finding that parents used longer sentences for words they think their children do not know, our results suggest that parents modified their speech as a means to communicate.

Our proposed explanation for these results is that they are produced by a pressure for effective communication: Parents need to produce sufficient information for their children to understand their intended meaning. That is, parents design their utterances for their children's benefit (speaker-design, Jaeger, 2013). It could be instead that these utterances reflect pressure from speaking itself. For example, length of parents' utterances may reflect their difficulty in retrieving certain animal words (MacDonald, 2013). We find this explanation unlikely given that parents were given the target words in written form on their iPad, essentially eliminating retrieval problems (Wingfield, 1968). The fact that parents are using long and short referring expressions depending on their beliefs about children's vocabulary knowledge suggests that they are calibrating to their children.

It is important to note that our current results do not rule out the possibility that parents are engaging in pedagogy. Parents may be using longer referring expressions because they wish to teach their children certain words, and this could potentially explain why parents use longer references for words they believe their children do not know. To understand the motivations behind long and short utterances, we are currently analyzing the content of parents' speech. Preliminary qualitative analysis shows that parents use more adjectives on trials where they believe their children do not know the target word (e.g. "Pick the red lobster" instead of "Pick the lobster"). The use of adjectives on these trials may reflect an intention to teach children about a certain animal, but it could also indicate a pressure to communicate effectively. In the lobster example, the color "red" is likely a helpful cue for children, and parents may be using adjectives as a way to help children select the correct target quickly. While our current findings do not allow us to distinguish between the pedagogical and communicative hypotheses, we hope that further analysis of parents' speech will help us differentiate the two accounts.

Our work contributes to the current literature on parent-child interaction, and forms the basis for further experimental work examining the influences that parent speech has on children's language development. In line with Masur (1997), our findings provide evidence that parents calibrate speech sensitively to their children's vocabulary knowledge. These results are important in light of previous work suggesting that parent responsiveness and sensitivity shape the way young children learn language (Hoff-Ginsberg & Shatz, 1982; Tamis-LeMonda et al., 2014). Furthermore, we propose that parents are modifying their speech as a means to communicate, and that communicative intent shapes the language environ-

ments children experience. Further qualitative analysis of our dataset will shed light onto the characteristics of parent-child communication that are helpful for language acquisition.

Finally, this study highlights the importance of studying the parent-child pair as a unit, rather than viewing children as isolated learners: both parents and children contribute to the process of language development (Brown, 1977; Hoff-Ginsberg & Shatz, 1982). Focusing on the interactive and communicative nature of language captures a more realistic picture of children's language environments: The input that children receive is not random – it is sensitive to their developmental level.

Abstract

The development of self-adaptive systems has attracted lots of attention as they can adapt themselves autonomously to environmental dynamics and maintain user satisfaction. However, there are still tremendous challenges remained. One major challenge is to guarantee the reusability of the system and extend the adaptability with the changing deployment environments. Another challenge is to ensure the adaptability coping with the open and complex environments with the existence of unknown. To solve these problems, we introduce a conceptual self-adaptive model, decoupling the environment with the system. This model is a two-layer structure, based on internal causes and external causes from attribution theory. The first layer, determining how the internal causes affect the adaptation behaviors, is independently designed and reusable; while the second layer, mapping the relationship between external causes with internal causes, is replaceable and dynamically bound to different deployment environments.

Keywords: Self-Adaptation; Attribution Theory; Reusability

Introduction

Current society extensively relies on software systems to achieve specific goals. However, achieving those required goals is a tremendous challenge (Cheng, de Lemos, & et al., 2009) since there are lots of uncertainties that developers have not considered or cannot fully understand during design time, and the changing environment leads to costly reconfiguration and time-consuming maintenance tasks (de Lemos, Giese, & et al., 2010). Therefore, there is a high demand for managing complexity reduction and achieving desired goals within a reasonable cost and timely manner. Self-adaptation is generally considered as one of the most promising approaches to manage the uncertainties of modern software systems since it enables a system to adapt itself autonomously to user requirements or environmental dynamics to continuously achieve system goals including performance, security, fault management, etc (Sawyer, Bencomo, & et al., 2010).

In the existing literatures, most of the adaptation behaviors are triggered by events in the environment (Salehie & Tahvildari, 2009; Shevtsov, Berekmeri, & et al., 2018; Filieri, D'Ippolito, & et al., 2017; Modoni, Trombetta, Veniero, Sacco, & Mourtzis, 2019). That is to say, the main adaptability of a self-adaptive software system is the internal response to the changes in the external environmental factors. Accordingly, the whole lifecycle of the adaptive system, including design time and run-time, is always associated with the environment where the system is deployed. In the design phase, system environment, as well as the mechanisms of perceiving and effecting environment are modeled and implemented. And the set of adaptation policies, tightly binding to this specific environment, are defined and customized. Then at run-time, adaptation behaviors could be achieved by implementing the activities of a well recognized feedback control loop called MAPE-K (Monitoring, Analysis, Planning, and Execution with Knowledge).

One of the disadvantages of current method is that these adaptation policies bound tightly to a specific environment will inevitably limit the adaptivity of the system to various deployment environments. Take a robot system as the example. In a wood floor environment, there could be policies describing how fast the robot should move forward to reach its destination as soon and as safe as possible; or how many angles it shall turn when encountering obstacles. However, the value of speed and angles will be very different in a more slippery tile floor or on a rough cement road. Therefore, for an adaptive system, in addition to being able to adapt in the specific deployment environment, it should have a wide range of applications (i.e., being deployed in a variety of environments). The other disadvantage is that current adaptive systems cannot cope with the increasing complexity and openness of the environment. It is basically impossible to pre customize a complete environment model since the developer cannot fully understand or have considered at design time. Inevitably, new environmental factors might exist and appear at run-time and the system is not reliable to recognize or predict those unforeseen. For example, when designing the adaptive strategies for a robot avoiding obstacles, it is necessary to know in advance what kind of obstacles it might encounter, and then to specify how to deal with obstacle A, obstacle B, etc. Obviously, obstacles in the environment could be infinite. New and unexpected obstacles will emerge constantly in the practical environment, which leads to the inadequate capacity of the existing system.

The fundamental reason for these disadvantages lies in the tight bound between the specific environment and the system. To deal with current challenges, this paper comes up with a novel approach based on attribution theory. Philosophically, the internal causes are the fundamental reasons for the change or the development of things while the external causes are merely the conditions and become operative through internal causes. In other words, it is when the external causes lead to the changes of internal causes that the adaptation behaviors could be triggered. Therefore, the basic idea behind our approach is to decouple the environment with the system both at two stages: independent design and run-time binding. In the design stage, how the adaptation behaviors of the system are determined by the internal causes is focused and emphasized, which makes the design and development of software are independent of the practical environment. In the run-time stage, the relationships between environmental factors (i.e., environmental events as external causes) and state of the system (i.e., internal causes) are dynamically established, thus binding the system to the specific application (i.e., deployment) and realizing the environmental-related adaptability.

The main contributions of our research is summarized as follows:

- We propose a new conceptual model of designing adaptive systems based on the attribution theory;
- We describe a two-layer structure in accordance with the conceptual model. The first layer is the independent design with decisive adaptation policies pertaining the relation between internal causes to adaptation behaviors; while the second layer is the dynamic bound with influential adaptation policies connecting the external causes to internal causes.

Approach Overview

So fundamental is the process of asking and answering "why" questions – trying to figure out what caused something else – that it has been characterized as a basic human activity, and a family of theories has been developed to illumine how and why things happen as they do. This set of theories, collectively called Attribution Theory initiated by Fritz Heider(Heider, 1958) and further advanced by Harold Kelley and Bernard Weiner(Kelley, 1967), attempts to describe and explain the processes involved in everyday explanations, most typical explanations of individual behaviors and events. An interesting example that someone is angry could be attached to the causes of bad-tempered characteristics or something bad happened.

There are a number of definitions for attributions, but a common way to define attributions is as the internal and external process of interpreting and understanding what is behind individual behaviors. External attribution, also called situational attribution, refers to interpreting the causes of behaviors to the situational or environment features outside a person's control. Internal attribution is the process of assigning the causes to some personality traits, rather than to outside forces.

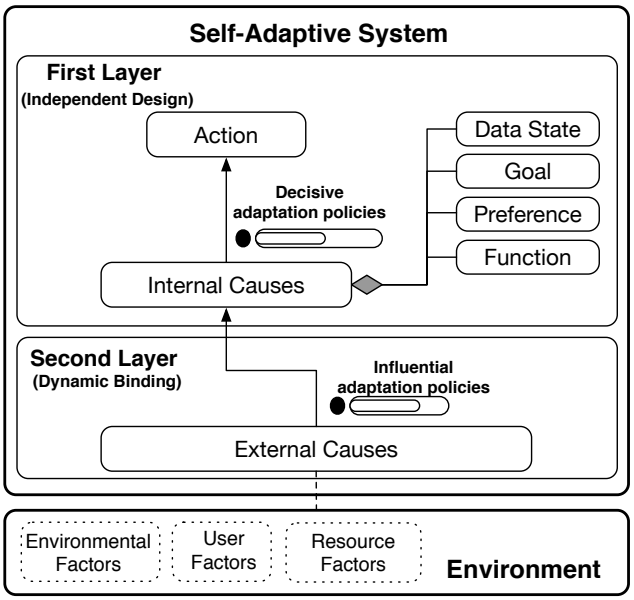

Figure 1: Conceptual Model of Attribution-Based Self-Adaptive System.

Similarly, adaptive behaviors of self-adaptive systems are the reactions to the external causes, i.e., changes. It is important to identify the reason for an adaptation: *why do we have to adapt?*. This is the central question influencing the reaction. In general, the reasons for an adaptation could be i)a change in the technical resources, e.g., the availability of an alternative network connection; ii)a change in the environmental variable, e.g., the workload for a website changed; and iii)a change regarding the user, e.g., a change in the user goal or the user preferences(Krupitzer, Roth, & et al., 2015). Users and operative technical resources could be regarded as a part of the environment and together with the environmental factors form the periphery of adaptive systems (Jiao & Sun, 2016). They are the external conditions of the existences and referred to as external causes.

Factors or events in the environment are not the necessary conditions that systems could execute reactive behaviors. For example, when the number of active users increases, some of the websites may saturate while others may not. In fact, whether an application deployed in the cloud is saturated and then allocated with more resources depends on whether the response latency (the time elapsed from sending the first byte of the request to receiving the last byte of the response) is long, and one will not do so if the latency is within a satisfactory range even if this application is with a huge number of users. In other words, the change of the user number does not determine the adaptive behaviors on an allocation of the resource; instead, the influence could take effect only when the change affects system internal states, which further im-

pair system goals. On the contrary, internal changes on the states of the system itself are the intrinsic reasons for adaptive behaviors.

Figure 1 provides a birds-eye view of our conceptual model of self-adaptive systems. An adaptive system can be divided into two layers, each corresponding to the internal and external attribution process. The first layer is composed of internal causes (including data state, function, preference, and goal) and adaptation behaviors (i.e., actions). Decisive adaptation policies, how to cope with changes in internal causes, determine the relations between internal causes and actions. This layer is independently designed and fixed even with the changing deployment or the extended environment. Note that the changing deployment is the change from one specific environment to another; the extended environment is the open environment with environmental factors from unknown to known. In the second layer, the relationship between external causes and internal causes is denoted in the influential adaptation policies. The second layer is a replaceable component and dynamical bound when the running environment is determined.

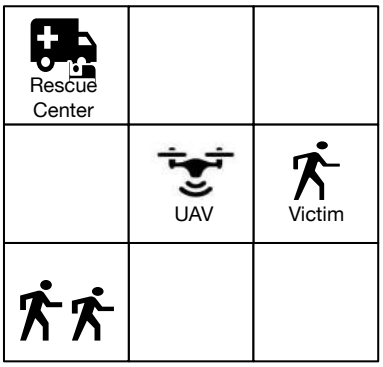

Figure 2: Running Example

Running Example. As a motivating example showcasing our approach, consider a *disaster relief* mission in adaptive system domains (Li, Jiao, & et al., 2018). In such a scenario, communication infrastructure is disabled in a city due to disasters; parts of the city may be unsafe. Figure 2 visualizes a possible configuration of a part of the city (i.e., a district). The rescue center is the safe zone in charge of the district's safety. The district then is divided into several blocks. The victims are spread in different blocks and have no idea of where the rescue center is. The unmanned aerial vehicle(abbr. as UAV) will be arranged to search and guide victims to the rescue center. In the process of searching for the victims, the UAV should not only guarantee the search and rescue task quick and thorough (search and rescue all victims in an acceptable time), but also ensure its own safety (no crash) and energy storage (avoid battery depletion). Furthermore, we expect that this UAV system can participate in missions in various disaster environments, such as fire, floods, earthquakes etc.

Formal Definition of the Conceptual Model

Inspired by the attribution theory, external causes take effects on the system through the internal causes, instead of directly affecting or determining the behaviors of the system. To this end, the conceptual model (M) of a self-adaptive system is defined as a tuple $\mathtt{M} = (\mathtt{IC}, \mathtt{DAP}, \mathtt{IAP})$, where:

- $\mathtt{IC}$ are the internal causes (i.e., intrinsic reasons for adaptation behaviors) which can be further specified as a tuple $\mathtt{IC} = (\mathtt{Data\ State}, \mathtt{Goal}, \mathtt{Preference}, \mathtt{Function})$;
- $\mathtt{DAP}$ are the decisive adaptation policies, which define how the internal causes of the system determine the adaptation behaviors and are generally expressed as rules of "internal causes – actions";
- $\mathtt{IAP}$ are influential adaptation policies, denoting how events in the environment affect the changes of internal causes with the form of "external causes – internal causes".

Internal Causes and System State

Data State The remembered information of the system determined by a set of attribute values. Let $(Attr = a1, ..., an)$ be the attribute set of the system, and $(Dom = dom(a1), ..., dom(an))$ be the set of domains of these attributes. Then the data state of the system is the mapping of these attributes to their values. In the motivation example, UAV system needs to maintain certain data, such as current location, residual power, flight height, searched blocks, unsearched blocks, hazard blocks, status(i.e., cruise or guidance). The data state of UAV is defined by the value of these kinds of information.

Goal the data state that the system expects to achieve or maintain. Generally, goals can be classified into three categories (Filieri et al., 2017). One type of goal is a reference value, called setpoint, to track. In this case, the objective is to keep a measurable quantity as close as possible to the setpoint. The second category of the goals is the variation of the classic setpoint-based goal where the goal resides in a specific range of interest with confidence intervals. The third category of goals concerns the minimization (or maximization) of a measurable quantity of the system. In substance, these goals can be regarded as functions of data states:

$$\mathtt{Goal} = \{\ \mathtt{g} \mid \mathtt{g} \in 2^{\mathtt{Data}} \wedge \mathtt{eval}(\mathtt{g}) = 1\}. \tag{1}$$

In general, the system is considered completely achieving a goal if it enters the target data state; however, in some cases, the system can only (infinitely) get close to the target but not reach. For example, it is impossible to require the UAV's flighting speed "to maintain exactly at 2 meters per second", then the system is said to be achieving the goal to some extent. Therefore, a goal is usually associated with an evaluation function which determines whether the goal has been achieved or how far it has been achieved. For

instance, in this mission scenario, should all the blocks had been searched and rescued, the evaluation result of this goal is one. If it is not, the evaluation function is $\texttt{eval}(\texttt{g}) = \texttt{num}(\texttt{searched blocks}) \div \texttt{num}(\texttt{total blocks})$, and pertains that goal satisfaction is directly proportional to the number of blocks cruised.

Preference The data state that the system is more interested in. Contrary to the goals that the system must be achieved or maintained, the preferences are not necessary must-to-do, but the performance of the system would be better if they are met. For example, the UAV is not only expected to complete the search and rescue goal but also with economical (less electricity consumption) and fast preference (all the victims should be searched as soon as possible). Similar to the goal, the preferences are associated with the utility functions that measure the satisfaction of preferences. For example, a utility function is present: $\texttt{u} = \texttt{residual power} \div \texttt{total energy storage}$, illustrating the tendencies of less energy consuming.

$$\texttt{Preference} = \{\ \texttt{p} \mid \texttt{p} \in 2^{\texttt{Data}} \wedge \texttt{util}(\texttt{p}) \in [0,1]\}. \quad (2)$$

Function The means or methods of achieving the goals. The functions are essentially changing or maintaining system status through manipulating controllable variables. For example, the UAV has the functions of take-off, flying, landing, direction change, etc.

$$\texttt{Function} = \{\texttt{f} \mid \texttt{f} : \texttt{Data} \rightarrow \texttt{Data}\}. \quad (3)$$

System State The state of the system is determined by the internal factors. In other words, data state, the available functions, and the satisfaction of goals and preferences together define the system state. Note that a function is not always valid (sometimes not working); the valid data of the system is the combination of attribute values and functions(i.e., $\texttt{Data} = \{\texttt{s} | \texttt{s} \in (\texttt{Attr} \times \texttt{Dom}) \cup 2^{\texttt{Function}}\}$)

Adaptation Policies

In the complex and uncertain environment, many kinds of environmental factors (discovered and to be discovered) exist, thus resulting in complicated influences on the internal causes. It is not necessarily true that all the changes of environmental factors will affect the system thereupon triggering adaptation behaviors. Only those leading to the changes of internal causes have an impact on the self-adaptive system.

Influential Adaptation Policies The IAP describe how the external causes especially environmental factors affect the internal causes of the system. These external causes directly influence the data state, which will further affect the functions, preferences and goals. In a fire scenario, the environmental factors for the motivation example could be the magnitude of the fire, which inevitably results in different data states for the UAV system. For example, the detection of a serious situation (i.e., high magnitude) for a block would render the UAV marking it as hazard and UAV will try to avoid this block cruise in a certain amount of time for its own safety. However, if in an earthquake scenario, the obstacles from the ground would probably not affect the mark of the block which is stored as an internal data since it is not a threat to high altitude flying UAV.

$$\texttt{IAP} = \{\texttt{p}_\texttt{i} \mid \texttt{p}_\texttt{i} : \texttt{ExtFactors} \rightarrow \texttt{Data State} \times \texttt{Function} \times \texttt{Preference} \times \texttt{Goal}\}. \quad (4)$$

Decisive Adaptation Policies The DAP characterize how the internal causes determine the self-adaptive actions of the system. An action is the operation of a function, which means that taking an action is to perform a function. $\texttt{Action} = \{\texttt{a} | \texttt{f} \in \texttt{Function}, \texttt{a} = \texttt{Do}(\texttt{f})\ \}$. The factors that determine the adaptive actions may involve system states, functions that the system possesses, preferences and goals. For the current location of UAV as shown in Figure 2, without detected victims to be guided to the rescue center, actions of four direction changes (North, South, East, West) are available if all corresponding blocks have not been cruised before and no hazard mark for the time-being.

$$\texttt{DAP} = \{\texttt{p}_\texttt{d} \mid \texttt{p}_\texttt{d} : \texttt{Data State} \times \texttt{Function} \times \texttt{Preference} \times \texttt{Goal} \rightarrow \texttt{Action}\}. \quad (5)$$

Through this conceptual model with a tuple structure, adaptation behaviors are achieved by explicitly defining internal causes and reasoning about the influences of external events on internal causes via IAP, upon which reactive actions are acquired by DAP. Concretely, for the motivation example, the UAV can infer the influences of environmental factors on its internal causes; and then the UAV can reason about its DAP to decide its adaptation behaviors. With the two layer structure, this conceptual model is supposed to be characteristic with applicability and reusability. Applicability entails the appropriateness of our attribution theory based conceptual model to design the self-adaptive systems and to capture dynamics of the environment, triggering IAP and DAP while maintaining satisfaction on system goals. Reusability describes usability of the DAP without modification, especially coordinating with various alterable dynamic binding IAP to different deployment environments and extended environments allowing continuously gaining knowledge.

Implementation Model

This section provides an implementation model of our attribution based approach. Adaptation builds on adaptation policies characterizing casual relationships between external and internal causes of a system, and between internal causes and actions in the knowledge. Adaptation behaviors are achieved by

implementing the activities of the MAPE (Monitoring, Analysis, Planning, Execution) loop (Kephart & Chess, 2003). Analysis and Planning are responsible for identifying possible requirements violations and generating an adaptation strategy, respectively, while Monitoring and Execution are responsible for enacting it at runtime.

Knowledge

To achieve self-adaptation, the system needs to be tailored, mainly regarding to the adaptation policies in the knowledge. This component Knowledge (K) is shared by all MAPE components. Ideally, all of the knowledge should be reusable across the same class of systems, i.e., these systems can adapt to all kinds of deployments and achieve user goals. However, the generality of this component comes at a cost:

- A significant amount of system-specific knowledge needs to be specified and maintained to apply the system to different deployment environments.

- Should the need for changing the K arises with the gain of information from the environment, the whole component shall be revised separately and deployed to aid (correctly) user expectation.

To support the extendability of new information and reusability of adaptation policies across different systems, we separate system-specific knowledge from the environment-specific part, echoing the two-layer structure in the conceptual model. System-specific knowledge, denoted as the DAP and instructing the behaviors to certain states of the system, is fixed and reusable between systems in similar functions. Meanwhile, environment-specific knowledge for defining how events in the deployment environment (external causes) affect system state in the form of IAP, is alterable as the deployment changes or discovery of additional environmental factors impacting system state. This is faithful to the principle of separation of concerns – the principle for separating a design into distinct sections, such that each section addresses a separate concern (Dijkstra & W, 1982).

MAPE Loop

For a specific deployment environment, adaptation behaviors are achieved by following the widely adopted mechanism of MAPE loop, which is shown in the implementation model in Figure 3.

Monitor Events generated in the environment indicating the execution of system actions or natural changes in the external factors are received. Component Monitor (M) gathers or synthesizes particular data through probes (or sensors) from the environment, and saves data in the knowledge in the form of external causes. For our example, events can indicate a serious fire detected by the cruising UAV.

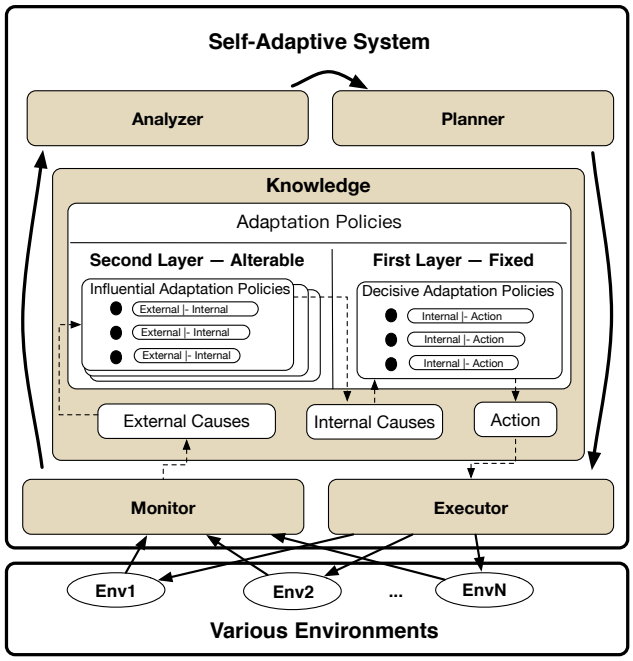

Figure 3: Implementation Model of Attribution-Based Self-Adaptive System.

Analyzer During speculative analysis, conditions of the environment representing violations of goals or better satisfaction of goals which can arise when active entities perform actions are identified. The component Analyzer (A), with the input of external causes from the Monitor, performs analysis by starting adaptation policies engine and reasoning about `IAP` to acquire the data state of the system. On this basis, analyzer further checks whether the goal is fulfilled; preference is satisfied; an adaptation is required. A typical example could be a new mark of hazard blocks resulted from the fire situation which might endanger its own safety.

Planner Component Planner (P) composes a workflow of adaptation actions aiming to counteract violations of system goals or better achieving goals. It consists of one or a set of actions to be enacted inferring from `DAP` in the adaptation policies engine receiving internal causes as input. For each situation, it identifies a policy if one exists, or prompts for a change in the design of the system if the violation cannot be handled and the system goal cannot be satisfied. Direction changing or safe landing could be feasible actions for UAV facing with a dangerous situation.

Executor During execution, the action from the `DAP` is enacted on the system by the component executor (E) through effectors (or actuators). This activity receives as input the current conditions of the environment from the monitoring activity, and identifies if a specific state in the adaptation policy is reached. If that is the case, it enacts specific action indicated in the adaptation strategy.

Discussion

Self-adaptation has been growing increasingly important. Though numerous excellent research efforts have been put into this area, self-adaptation as a field is still in its infancy, and existing knowledge and approaches are not adequate enough to address today's ever-expanding and ever-changing various environments. In this paper, we mainly focus on a novel conceptual model to design self-adaptive systems for various and open environments based on attribution theory, offering reusability engineering by decoupling the environment with the system. Accordingly, the related work will be classified into two categories. First, we look into the mechanisms of reusability in adaptive systems, positioning our work. Then, we discuss cross approaches among different disciplines that play an important role in the construction of self-adaptive systems.

Reusability has always been a concern in adaptive systems field. Generally, research has focused on providing frameworks for adaptation, such as rainbow (Garlan, Cheng, & et al., 2004) monitoring the executing system in the system-layer through an abstract model in the architecture layer which interacts with system layer through a translation layer, and Hogna, a platform for deploying self-managing web applications on cloud (Barna, Ghanbari, & et al., 2015), allowing developers to customize each phase of the feedback loop without having to implement the entire layer themselves. Autonomic Software Product Lines (ASPL) is a strategy for developing self-adaptive software systems with systematic reuse by integrating a domain-independent managing system into a domain-specific software product line (Abbas & Nadeem, 2018). Besides, different patterns that can be reused have been proposed facilitating the development of dynamic adaptive systems (Ramirez & Cheng, 2010); other techniques such as bidirectional transformations, a mechanism of synchronization, have been applied to ensure the correctness of reusability in adaptive systems (Colson, Dupuis, & et al., 2016). Though our approach divides the system framework into two levels like most of the reusable approaches, the basis for this division is the attribution to either environment or system itself facilitating the reusability in various deployment environments, not the structure to be reused in different systems with similar functions.

Adaptive system is an interdisciplinary research field. The concept of self-adaptation, derived from biology, is the characteristics of a creature changing its habits to adapt to a new environment (Longman, 1994). Biological approaches in computer science have emerged with the study of collective behavior in natural multi-agent systems by Parunak (Parunak, 1997). Other mechanisms in biology, such as flocking, nest building, molding (Mamei, Menezes, & et al., 2006) and human immune system (Hart, McEwan, & et al., 2011) has been adopted in self-organizing systems and can be transferred to self-adaptive systems. Besides that, it is important to learn and borrow from other fields of knowledge that are working or have been working in the development and study of similar systems, or have already contributed solutions that fit for the purpose of self-adaptive systems. Researches from chemical have been gradually applied. Viroli et al. propose a coordination model for self-organizing systems based on biochemical tuple spaces and chemical reactions (Viroli, Mirko, & et al., 2009). In the physical field, Weyns et al. employ field-based mechanisms for adaptive task assignment in multi-agent systems. Social area concentrates on market and auction mechanisms and as an example, coordination in multi-agent systems is based on social conventions (Salazar, Rodríguez-Aguilar, & et al., 2010). To the end, our approach is inspired by the research findings from psychology, emphasizing that the influence on adaptation behaviors comes from two aspects, the external environment and the internal system. It decouples the system with a specific environment and brings a new perspective in the construction of self-adaptive systems.

In our future research, we plan to further elaborate on the work presented in this paper by applying the method to practical scenarios to strengthen the applicability. In addition, the mapping relations between external factors and internal causes are complicated and changeable due to open and various environments. More efforts would be put into investigating the automatic acquisition of influential adaptation policies, such as machine learning in response to uncertain environmental changes and reinforcement learning method constantly adjusting to new environments.

Inquiry, Theory-Formation, and the Phenomenology of Explanation

Emily G. Liquin (eliquin@princeton.edu)
Tania Lombrozo (lombrozo@princeton.edu)
Department of Psychology, Princeton University
Princeton, NJ 08540 USA

Abstract

Explanations not only increase understanding; they are often deeply *satisfying*. In the present research, we explore how this phenomenological sense of "explanatory satisfaction" relates to the functional role of explanation within the process of inquiry. In two studies, we address the following questions: 1) Does explanatory satisfaction track the epistemic, learning-directed features of explanation? and 2) How does explanatory satisfaction relate to both antecedent and subsequent curiosity? In answering these questions, we uncover novel determinants of explanatory satisfaction and contribute to the broader literature on explanation and inquiry.

Keywords: explanation; curiosity; theories; inquiry; learning

Humans have an insatiable drive to explain the world around them, and this drive plays an important role in supporting our amazing capacity to learn (Lombrozo, 2012, 2016). In fact, some have suggested that explanation is to theory-building as orgasm is to reproduction (Gopnik, 2000): the phenomenological sense of satisfaction that accompanies an explanation motivates theory-building, just as orgasm motivates reproduction. In the present research, we investigate this hallmark phenomenological component of explanation ("explanatory satisfaction"). What makes an explanation satisfying, and how does this phenomenological sense function to support learning and theory-formation?

Following Gopnik (2000), we assume explanations are comprised of two elements: an epistemic element and a phenomenological element. The epistemic element of an explanation is straightforwardly related to the process of theory-formation and inquiry: broadly, an explanation includes theory-relevant information, which enables learning and facilitates future prediction and intervention. The phenomenological element, on the other hand, is best characterized as an affective response (Gopnik, 2000), and its role in the process of theory-formation and inquiry is less clear. In the present research, we address two questions that situate explanatory satisfaction within this broader process.

First, how does the phenomenological component of explanation relate to the epistemic component of explanation? If explanatory satisfaction plays a functional role in the process of theory-building and inquiry, we might expect explanations to be found more satisfying when they possess features that suggest the epistemic function of explanation has been achieved. We refer to such features as "learning-directed," as they relate to the epistemic role explanation plays in learning. For instance, we might expect explanations to be deemed more satisfying when they identify novel, useful, and generalizable patterns in the environment, or when they possess explanatory virtues (such as simplicity and breadth) that support correspondingly simple and broad theories. Our first research question is whether explanatory satisfaction is indeed influenced by these learning-directed features.

Second, how does explanatory satisfaction relate to *curiosity*, another affective state that often drives explanation-seeking and exploration? Does curiosity about the answer to a given question increase the explanatory satisfaction experienced upon receiving the answer? Do satisfying explanations terminate inquiry by satisfying curiosity, or do they stimulate further inquiry by prompting curiosity about related matters?

In addressing these questions, our studies are among the first to consider explanatory satisfaction within a broader process of inquiry and theory-building, tying the phenomenological component of explanation to its epistemic role ("learning-directed" considerations), and linking it to other affective states that influence learning (namely curiosity). We briefly review prior work on explanatory satisfaction and curiosity before presenting two novel studies.

Prior Work on Explanatory Satisfaction

Research on explanatory preferences and judgments of explanation quality has shown that people prefer explanations that are simple in the sense that they appeal to few unexplained causes (Bonawitz & Lombrozo, 2012; Lombrozo, 2007; Pacer & Lombrozo, 2017; see also Thagard, 1989), and broad in two senses: in that they explain all the relevant features of what's currently being explained (Johnson, Johnston, Toig, & Keil, 2014; Pennington & Hastie, 1992; Thagard, 1989), and in that they explain additional phenomena as well (Preston & Epley, 2005). Other research has found that people prefer explanations with reductive mechanism information (Hopkins, Weisberg, & Taylor, 2016), that appeal to the function of the thing being explained (Kelemen & Rosset, 2009), that have a narrow "latent scope" (Khemlani, Sussman, & Oppenheimer, 2011), and that cite information "inherent" to what is being explained (Cimpian & Salomon, 2014).

There is also evidence that explanations are favored when they are believed to be generalizable and well-suited to future goals. For example, people find functional explanations more acceptable when they appeal to a generalizable causal process (Lombrozo & Carey, 2006). They also judge such explanations better (relative to

category-based or mechanistic explanations) when they anticipate making future inferences on the basis of information about an entity's function as opposed to information about its category membership or the mechanism by which it operates (Vasilyeva, Wilkenfeld, & Lombrozo, 2017). Additionally, it has been proposed that the "explanatory virtues" that have been tied to explanatory satisfaction—simplicity and breadth—are important exactly because they point to the value of an explanation in guiding future inference and action (Lombrozo, 2016; Pacer & Lombrozo, 2017; see also Vasilyeva, Blanchard, & Lombrozo, 2018). Consistent with this idea, research finds that prompts to explain make children and adults more likely to discover simple and broad patterns, improving learning under some conditions (for a review, see Lombrozo, 2016).

Taken together, this work suggests that explanatory satisfaction may be driven in part by features of explanations relevant to learning and theory-formation. Very little work, however, has investigated the relationship between judgments of explanatory satisfaction and learning-directed considerations more directly. In one study, Zemla, Sloman, Bechlivanidis, and Lagnado (2017) presented participants with explanations drawn from an on-line forum, and had them rate the explanations on several dimensions, including what they called novelty ("I learned something new from this explanation"), generality ("This explanation appeals to a general principle [that is, a general rule that applies to many things]"), perceived expertise ("This explanation was written by an expert in this topic"), and quality ("This is a good explanation"). Novelty and generality were moderately correlated with quality, though these correlations were not significant after correcting for multiple comparisons. There was also evidence of a preference for *complexity* over simplicity: participants favored explanations involving multiple causal mechanisms. These findings hint at possible relationships between learning-directed considerations and judgments of explanation quality, but many questions remain open. In particular, which learning-directed features might predict explanatory satisfaction, and when and why is simplicity versus complexity favored? In Studies 1-2, we consider how judgments of learning, utility, simplicity, complexity, expertise, and breadth relate to explanatory satisfaction.

Prior Work on Curiosity and Epistemic Emotions

Recent work on *explanation-seeking curiosity* has investigated what triggers curiosity about why something is the case, motivating a learner to seek an explanation (Liquin & Lombrozo, 2018). In this work, participants received explanation-seeking questions posed in an on-line forum, and rated the questions along a variety of dimensions, including curiosity ("How curious are you about the answer to this question?"). Anticipated learning, generality, and future utility were among the strongest predictors of curiosity. Complexity and expertise were also found to be positive predictors of curiosity. However, it is not known whether curiosity about an explanation affects the perceived quality of or rated satisfaction with that explanation once obtained. In Studies 1-2, we consider whether antecedent curiosity predicts explanatory satisfaction. In Study 2, we additionally consider how explanatory satisfaction affects curiosity for further inquiry.

One reason it is valuable to relate explanation to curiosity is because doing so helps bridge the epistemic role of explanation with the affective and motivational factors that guide (epistemic) behavior. Curiosity is often characterized as an *epistemic feeling* or *emotion* (alternatively referred to as a noetic feeling; Arango-Muñoz, 2014; de Sousa, 2009; Dokic, 2012; Morton, 2010): one of a class of evaluative appraisals of one's own knowledge, which have a distinctive phenomenology and guide epistemic action (de Sousa, 2009). While a full treatment of epistemic emotions is beyond the scope of this paper, linking explanatory satisfaction to curiosity and learning is a step towards a more complete account of how the phenomenological and epistemic roles of explanation function together to support effective learning.

Study 1

In Study 1, we present participants with why-questions and their corresponding answers. In addition to having them indicate the extent to which they find each answer satisfying ("explanatory satisfaction"), we have them rate each answer along a variety of epistemically-relevant dimensions. We also have them rate their curiosity about the answer to each question prior to receiving it. This design allows us to address two related questions.

First, we ask about the role of learning and theory-building considerations in determining explanatory satisfaction. To do so, we have participants indicate the extent to which each explanation teaches them something new, and whether the information it offers is useful and generalizable. We also ask them to evaluate the extent to which each explanation is simple, broad (in the sense of applying beyond what is being explained), and required expertise to produce. We can then evaluate whether and how strongly these factors predict explanatory satisfaction.

Second, we ask how curiosity about an explanation affects explanatory satisfaction. Specifically, are the explanations offered in response to questions that elicit high levels of curiosity judged more satisfying than those offered in response to questions that elicit lower levels of curiosity?

By answering these questions, we shed light on how explanatory satisfaction relates to the epistemic features of explanations and to curiosity, another epistemic emotion that drives inquiry.

Method

Participants Participants in Study 1 were 159 adults (77 male, 78 female, 2 other, and 1 prefer not to specify, ages 19-68) recruited from Amazon Mechanical Turk. Participation was restricted to MTurk workers in the United States, who had completed at least 1000 prior tasks with a

Table 1: Items (each rated on a seven-point scale) for explanatory satisfaction and learning-directed features in Studies 1-2.

Dimension	Full text of item
Satisfaction	How satisfying do you find the answer to this question?
Actual Learning	To what extent has the answer to this question taught you something new?
Learning Potential	Do you think there is something to be learned from the answer to this question (even if you yourself already knew the answer)?
Expertise	Do you think that answering this question required special expertise in some domain?
Simplicity	Do you think the answer to this question is simple or complex?
Breadth	Do you think the answer to this question is narrow (only applies to what is being explained) or broad (also applies to other similar cases)?
Future Utility	To what extent will the answer to this question be useful to you in the future?
Regularity	Do you think the answer to this question helps reveal a genuine pattern, structure, or regularity?

minimum approval rating of 99%. Forty additional participants completed the study but were not included in analyses because they did not pass two attention checks.

Materials Fifty-six questions and answers were selected from the book *1000 Questions & Answers Factfile* (Kerrod, Madgwick, Reed, Collins, & Brooks, 2006). For example, the question "Why do some stars explode?" was answered with the following explanation: "Massive stars explode when they come to the end of their lives. They swell up into huge supergiants. Supergiants are unstable, so they collapse and blast into pieces in an explosion called a supernova. Supernovae are the most intense explosions in the universe, as bright as billions of suns put together."

Procedure Each participant saw four questions randomly selected from the 56 questions described above. Participants first rated their curiosity about each question ("Consider the following: *[question premise]*. How curious are you about why this is the case?"). Participants also rated seven items that are not relevant to the present research and are not reported here. Next, participants completed seven arithmetic problems; those who did not correctly respond to at least five items were excluded.[1] After this task, participants read the answer to each of the four questions, and rated each answer on explanatory satisfaction and several learning-directed features (see Table 1). Finally, participants completed a memory check, which required selecting four of the questions presented during the rating tasks from a list with four distractor questions. Participants were given one point for each correct response (hit or correct rejection), and those who scored fewer than six points were excluded.

Results

Due to the nested structure of the data, all analyses used a mixed-models approach, with random intercepts for participant and item in all models. Standardized regression coefficients are reported; all reported coefficients reached significance at the $p < .05$ level using likelihood ratio tests. In addition to the results reported here, all regression analyses were repeated controlling for the length of the explanation in number of words, as prior work has shown that longer explanations tend to be more satisfying (Weisberg, Taylor, & Hopkins, 2015). Controlling for explanation length had no effect on our results.

Learning-Directed Features First, we tested the role of learning-directed considerations in predicting explanatory satisfaction. To do so we fit a regression model predicting satisfaction with all learning-directed considerations entered simultaneously as fixed effects. Only actual learning, β = 0.26, 95% CI [0.17, 0.34], learning potential, β = 0.18, 95% CI [0.10, 0.26], and future utility, β = 0.12, 95% CI [0.04, 0.21], explained unique variance in satisfaction holding all other measures fixed (see Figure 1). However, as many of the measures were modestly correlated with each other (see Figure 2), potentially affecting the robustness of the coefficient estimates reported above, we also fit a separate regression model for each measure. Actual learning, β = 0.39, 95% CI [0.32, 0.47], learning potential, β = 0.39, 95% CI [0.31, 0.46], expertise, β = 0.31, 95% CI [0.24, 0.39], simplicity, β = -0.23, 95% CI [-0.30, -0.15], breadth, β = 0.13, 95% CI [0.05, 0.20], future utility, β = 0.25, 95% CI [0.17, 0.33], and regularity, β = 0.17, 95% CI [0.10, 0.25], were all significant predictors of explanatory satisfaction (see Figure 1).

Antecedent Curiosity Next, we tested whether curiosity about the anticipated answer to a question predicted explanatory satisfaction. We found that curiosity was a significant (though modest) predictor, β = 0.19, 95% CI [0.11, 0.26], and that the model including curiosity as a fixed effect was a significant improvement upon the null model, $\chi^2(1) = 23.12$, $p < .001$.

[1] This attention check may assess numeracy, which could lead to unnecessary exclusions that are irrelevant to successful completion of our task. However, when the participants who failed this task are included in all analyses (for Studies 1 and 2), all results remain unchanged.

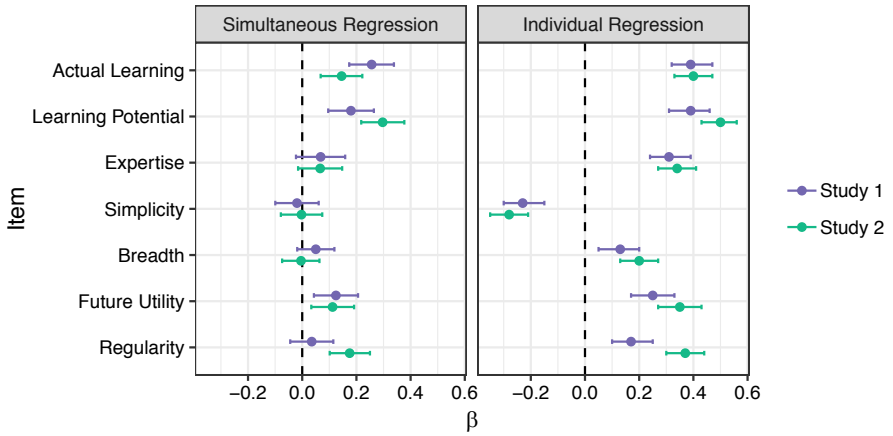

Figure 1: Study 1 and Study 2 standardized regression coefficients for each measure predicting explanatory satisfaction, in a simultaneous regression model (left panel) and in individual regression models (right panel). Study 2 regression coefficients control for interest and knowledge. Error bars = 95% CI.

Discussion

The findings from Study 1 are largely consistent with previous research on the role of breadth (Johnson et al., 2014; Preston & Epley, 2005), future utility (Vasilyeva et al., 2017), and generalizability (Lombrozo & Carey, 2006) in driving explanatory satisfaction. However, one important qualification is that *complexity*, rather than *simplicity*, led to higher ratings of explanatory satisfaction. This is surprising in light of prior work documenting a preference for simpler explanations when using well-controlled stimuli (where, for example, probability is matched; Lombrozo, 2007, Pacer & Lombrozo, 2017), but is consistent with prior work using more naturalistic stimuli, such as those employed here (e.g., Zemla et al., 2017).

Our findings go beyond prior work in identifying an important role for our new learning-directed measures of actual learning, learning potential, and expertise. In fact, these were among the strongest predictors of explanatory satisfaction. We also found a modest role for antecedent curiosity, in that greater curiosity about the answer to a question predicted greater satisfaction with the answer. While this has not (to our knowledge) been tested in prior research, there is evidence that the gap between curiosity about the answer to a trivia question and the satisfaction upon receiving the answer predicts later memory for the answer (Marvin & Shohamy, 2016). This suggests that how much is learned from an explanation could be a function of *both* antecedent curiosity and the explanatory satisfaction experienced from the explanation itself.

These findings highlight the value of approaching the study of explanatory satisfaction through the lens of theory-formation and inquiry. In particular, if achieving explanatory satisfaction effectively motivates learning and theory-formation, then we should expect a close correspondence between explanatory phenomenology and the epistemic functions of explanation. Our findings provide initial support for this correspondence.

Study 2

In Study 2, we replicate the key findings from Study 1, while controlling for two potentially relevant factors: participants' a priori interest in and knowledge about the topics the explanations address. We also investigate how explanatory satisfaction relates to the ongoing process of inquiry (for a discussion, see Danovitch & Mills, 2018) by considering how explanatory satisfaction affects subsequent curiosity. We propose two competing hypotheses: First, it is possible that the receipt of a satisfying explanation will halt further inquiry. Supporting this hypothesis, Frazier, Wellman, and Gelman (2009) found that preschoolers in both naturalistic and experimental settings were less likely to re-ask a question following an explanation (vs. a non-explanation) from an adult, suggesting that the receipt of an explanation stopped further inquiry, at least concerning the topic in question. Relatedly, Mills, Sands, Rowles, and Campbell (2019) found that children were more likely to request additional information in response to explanations that they rated as less-complete answers to the relevant question, relative to more-complete explanations.

However, it is also possible that receiving a satisfying explanation could *promote* further inquiry. Even a satisfying explanation will often highlight new things the learner does not yet know, promoting further exploration and information search. For example, Liquin and Lombrozo (2017) found that generating explanations during learning increased information search in the face of surprising evidence (see also Legare, 2012). Moreover, some theories of curiosity posit that curiosity peaks when there is a modest "gap" between a learner's current and desired knowledge state, resulting in an inverted-U-shaped relationship between prior knowledge and curiosity (Loewenstein, 1994). For learners on the ascending side of the "U," a satisfying explanation could result in *greater* curiosity.

To distinguish between these hypotheses, we ask participants to rate their curiosity about several follow-up questions in response to an explanation, after completing the

same ratings as in Study 1. If explanatory satisfaction halts inquiry, we would expect greater satisfaction to predict lower curiosity about follow-up questions. By contrast, if explanatory satisfaction promotes inquiry, we would expect greater satisfaction to predict greater curiosity about follow-up questions.

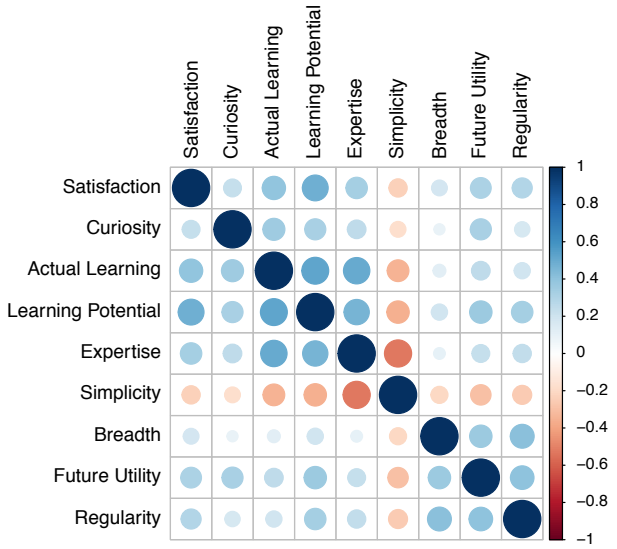

Figure 2: Matrix of pairwise correlation magnitudes for all measures of interest (collapsed across Study 1 and Study 2 data).

Method

Participants One hundred seventy-one adults (96 male and 75 female, ages 21-69) from Amazon Mechanical Turk participated in Study 2. Participation was restricted to MTurk workers in the United States who had completed at least 1000 HITs with a minimum approval rating of 99%. Twenty-nine additional participants completed the study but were excluded from analysis because they did not pass the same attention checks used in Study 1.

Materials Of the 56 questions and answers used in Study 1, twenty were randomly selected for use in this study. An initial sample of 48 MTurk participants read random samples of five question-answer pairs and wrote between 3 and 10 follow-up questions in response to each answer. From this set of follow-up questions, we randomly selected 10 for each question-answer pair. Thus, the materials used in this study were 20 question-answer pairs from *1000 Questions & Answers Factfile* (Kerrod et al., 2006), with 10 follow-up questions in response to each. Additionally, each question was classified into a "topic area," based loosely on the chapter and page topics in the *1000 Questions & Answers Factfile* book. The 20 questions fell into 14 distinct topic areas (e.g., "dinosaurs," "stars," "Ancient Egypt").

Procedure First, each participant rated their interest in and knowledge about each of the 14 topic areas described above. Then, each participant saw four questions randomly selected from the 20 questions. For each question, they completed the initial curiosity rating, followed by the arithmetic distractor/attention task, as in Study 1. Then, two tasks were presented in a randomized order: the answer ratings, as described in Study 1, and the follow-up question task. For the latter task, participants saw a random sample of five of the ten follow-up questions for each of the four questions (presented with answers) that they had seen previously. For each follow-up question, participants rated how curious they were about the answer to that question on a seven-point scale. These five ratings were averaged within each of the four questions, creating a "follow-up curiosity" scale for each question rated by each participant (Cronbach's α = 0.85).

Results

Results were analyzed as in Study 1, using a mixed-models approach. Again, all results remained unchanged when controlling for explanation length.

Replications of Study 1 First, we repeated all analyses from the previous study, but controlling for interest in and knowledge of the topics corresponding to the question-answer pairs. In a simultaneous regression model, actual learning, β = 0.14, 95% CI [0.07, 0.22], learning potential, β = 0.30, 95% CI [0.22, 0.38], future utility, β = 0.12, 95% CI [0.04, 0.20], and regularity, β = 0.18, 95% CI [0.10, 0.25], explained unique variance in satisfaction holding all other measures fixed (see Figure 1). In separate regression models, actual learning, β = 0.40, 95% CI [0.33, 0.47], learning potential, β = 0.50, 95% CI [0.43, 0.56], expertise, β = 0.34, 95% CI [0.27, 0.41], simplicity, β = -0.28, 95% CI [-0.35, -0.21], breadth, β = 0.20, 95% CI [0.13, 0.27], future utility, β = 0.35, 95% CI [0.27, 0.43], and regularity, β = 0.37, 95% CI [0.30, 0.44], were all significant predictors of explanatory satisfaction (see Figure 1). Curiosity was also a significant predictor of explanatory satisfaction, controlling for interest and knowledge, β = 0.19, 95% CI [0.11, 0.26].

Satisfaction and Inquiry Next, we tested the relationship between explanatory satisfaction and subsequent curiosity. To do so, we compared a model predicting average follow-up curiosity with satisfaction as a fixed effect to a null model with no fixed effects. Satisfaction was a significant predictor of follow-up curiosity, $\chi^2(1) = 45.20$, $p < .001$. Critically, the relationship between satisfaction and follow-up curiosity was positive, β = 0.22, 95% CI [0.16, 0.29], indicating that explanatory satisfaction, at least in this context, *encourages* rather than halts ongoing inquiry.

Finally, we repeated this analysis, but controlling for interest in and knowledge of the topics corresponding to the question-answer pairs. Satisfaction remained a significant predictor of follow-up curiosity, β = 0.21, 95% CI [0.14, 0.27], $\chi^2(1) = 40.45$, $p < .001$.

Discussion

In Study 2, we replicated the results of Study 1 while

controlling for topic knowledge and interest, again demonstrating that learning-directed features predict explanatory satisfaction, and that curiosity about an explanation-seeking question predicts satisfaction with the answer.

Study 2 also investigated how explanatory satisfaction relates to subsequent curiosity. We found support for the hypothesis that explanatory satisfaction encourages rather than halts inquiry—that is, the more satisfied a participant was with a given explanation, the more curious they were about several follow-up questions. This is in contrast to past work demonstrating a negative relationship between explanation *completeness* and subsequent information search (Frazier et al., 2009; Mills et al., 2019). This could reflect methodological differences in what was evaluated (explanatory completeness versus satisfaction), or in the opportunities for further inquiry that were offered. For instance, we might expect inquiry concerning the original explanandum to cease after obtaining a satisfying explanation, but for inquiry concerning related matters to be piqued. These questions merit further research.

General Discussion

Explanations play an important role in the process of inquiry: they contribute to learning and theory-building, which in turn support predictions, interventions, and understanding. Explanations also have a unique phenomenology that may motivate this theory-building behavior. However, most research on explanation has not directly addressed how this phenomenology relates to the functional role of explanation within the process of theory-formation and inquiry. In the present research, we addressed two questions: 1) To what extent is explanatory satisfaction driven by features of an explanation that support learning and theory-formation? and 2) How does explanatory satisfaction relate to *curiosity*, another epistemic emotion that motivates inquiry?

In response to the first question, we find that several learning-directed features (such as actual learning, learning potential, future utility, and regularity) are related to explanatory satisfaction, even when controlling for interest in and knowledge of the topics addressed by the explanation. Answering the second question, we find that antecedent curiosity predicts satisfaction with a subsequent explanation to a modest degree, and that explanatory satisfaction in turn predicts curiosity about follow-up questions in response to an explanation, thus encouraging further inquiry.

These studies build upon previous research on explanatory satisfaction and explanation-seeking behavior. In particular, we replicate previous research on the role of breadth, generalizability, and future utility in explanatory satisfaction, and we find several additional predictors of explanatory satisfaction that have not previously been explored—or for the case of learning, that have not previously found strong support (Zemla et al., 2017). Additionally, we add to recent research on curiosity (Liquin & Lombrozo, 2018; Marvin & Shohamy, 2016), demonstrating a systematic relationship to explanatory satisfaction throughout the process of inquiry.

Several limitations of these studies must be noted. First, future work should explore a broader range of materials, including "everyday" questions and explanations from more ecologically-valid settings. Second, the findings we report are all correlational, so it remains to be seen whether (for example) curiosity about an explanation *causes* satisfaction with the later-received explanation. More critically, these studies do not cleanly disentangle the phenomenological component of explanation from the epistemic component. That is, participants' ratings of explanatory satisfaction likely reflected affective responses (perhaps in contrast to ratings of goodness, quality, or completeness, which have often been used in past research; e.g., Mills et al., 2019; Vasilyeva et al., 2018; Zemla et al., 2017), but also evaluation of (epistemic) quality, which may not have been accompanied by any particular phenomenology. For our purposes, the key question is whether and how explanatory satisfaction motivates inquiry, so it is notable that in Study 2, there was a positive relationship between explanatory satisfaction and ongoing curiosity. Future work should explore the relationship between explanatory satisfaction and subsequent epistemic *behaviors*, such as information search, as well as epistemic *consequences*, such as learning.

Another possible limitation of this work is that participants only read a single explanation in response to each question, while previous work on explanatory preferences (e.g., Lombrozo, 2007; Pacer & Lombrozo, 2017) has typically used *comparative* judgments of explanation quality between two competing explanations. As a result, satisfaction judgments in the present research may reflect satisfaction that an explanation *exists*, rather than satisfaction that this explanation fulfills certain explanatory desiderata relative to other possible explanations. Future work should explore whether different criteria are used to evaluate explanations presented simultaneously versus in isolation.

Despite these limitations, these studies are among the first to approach explanatory satisfaction in terms of its functional role within a broader process of inquiry, providing new insights into the determinants of explanatory satisfaction and the importance of this phenomenology in driving ongoing inquiry and theory-building.

Hard choices: Children's understanding of the cost of action selection

Abstract

When predicting or explaining another person's actions, we often appeal to the physical effort they require; a person who works hard for something, for instance, must really like it (Liu, Ullman, Tenenbaum, & Spelke, 2017). But people are not only motivated to avoid physical effort; they also seek to avoid mental effort (Shenhav et al., 2017; Kool & Botvinick, 2018). Here, we ask whether mental effort enters into preschoolers' understanding of other people's actions. Across 4 experiments (N=112), we presented 4- and 5-year-old children with an agent (naive in Exp 1, 2 and 4, and knowledgeable in Exp 3) who can either move through a simple or complex maze environment with a specific goal (in Exp 1-3, to reach a play structure beyond the mazes, and in Exp 4, to practice solving the mazes). We found that children were sensitive to the physical and mental effort associated with more complex mazes, and to the trade-offs between effort and gain in skill. The intuition that choices impose costs on our bodies and minds appears to guide children's understanding of other people.

Keywords: intuitive psychology; cognitive development; decision-making

Introduction

Observing other people try hard tells us something about their desires, beliefs, competence, and what is worth trying for ourselves. All of these abilities rely on the the basic intuition that actions carry cost in the first place. This intuition is an early-emerging component of our human social intelligence: Infants, children, and adults consider the physical effort behind other people's actions as one variable in their plans to maximize utility (Jara-Ettinger, Gweon, Schulz, & Tenenbaum, 2016; Gergely & Csibra, 2003; Baker, Saxe, & Tenenbaum, 2009), and use how hard people try to infer their goals, beliefs, competence, and the value of effort in general (Jara-Ettinger, Tenenbaum, & Schulz, 2015; Baker, Jara-Ettinger, Saxe, & Tenenbaum, 2017; Leonard, Lee, & Schulz, 2017; Liu et al., 2017).

Is our understanding of action cost restricted to the physical exertions of body, or does it also encompass the costs of mental exertion? Everyday activities like thinking, writing, and learning are not physically costly (in fact, our bodies are usually still when engaging in them), but they incur a similar subjective disutility–in other words, a sense of exhaustion. More specifically, cognitive operations like loading information into working memory, transforming and maintaining it over long delays, and task switching–in other words, all the elements of rational planning–carry an intrinsic cost (Kool & Botvinick, 2018; Shenhav et al., 2017; Westbrook & Braver, 2015). Because of this cost, we do not always engage in rational planning; sometimes we use computationally cheaper heuristics, such as selecting actions proportional to their historical rewards. Experiments show that while people often often avoid costly rational planning, they become more likely to bear this cost when it is associated with a sufficiently large prospect of reward (Kool, Gershman, & Cushman, 2017).

What is the role of mental effort in our analysis of other people's actions? Do we assume that mental effort is costly? Do we assume that others would seek to avoid mental effort, all else being equal? Some recent research offers circumstantial evidence in adults (Gershman, Gerstenberg, Baker, & Cushman, 2016): When participants are asked what someone with a strong habit (e.g., to take a certain route to work, or turn a doorknob clockwise) will do in a new situation, they respond that the person is likely to rely on habit, especially under time pressure. This is consistent with the possibility that adults associate cognitive effort with model-based control, and use this association to predict and explain other people's actions.

There is, however, strong reason to believe that the ability to represent and reason about mental effort develops slowly over childhood. Although preschool-aged children understand that other people have emotional states, perceptions, beliefs, and knowledge (Wellman, 2002), they do not reliably know when people are thinking, struggle to make reasonable inferences about what they might be thinking about, and do not reliably report the content of their own thoughts (Flavell, Green, & Flavell, 1995). Furthermore, children are relatively poor at monitoring their own comprehension, memory, and learning, at least in ways that can be measured through explicit questioning (Flavell, Friedrichs, & Hoyt, 1970). If the ability to monitor one's own cognition develops slowly, then children may come to reason about the role of mental effort in others' plans at a later age than they reason about physical effort in these plans.

This paper presents a case study of the developmental origins of reasoning about mental effort. Specifically, we ask whether children understand that making choices can lead to both physically and mentally costly outcomes, and whether they understand the trade-offs people make between effort and reward in the context of learning.

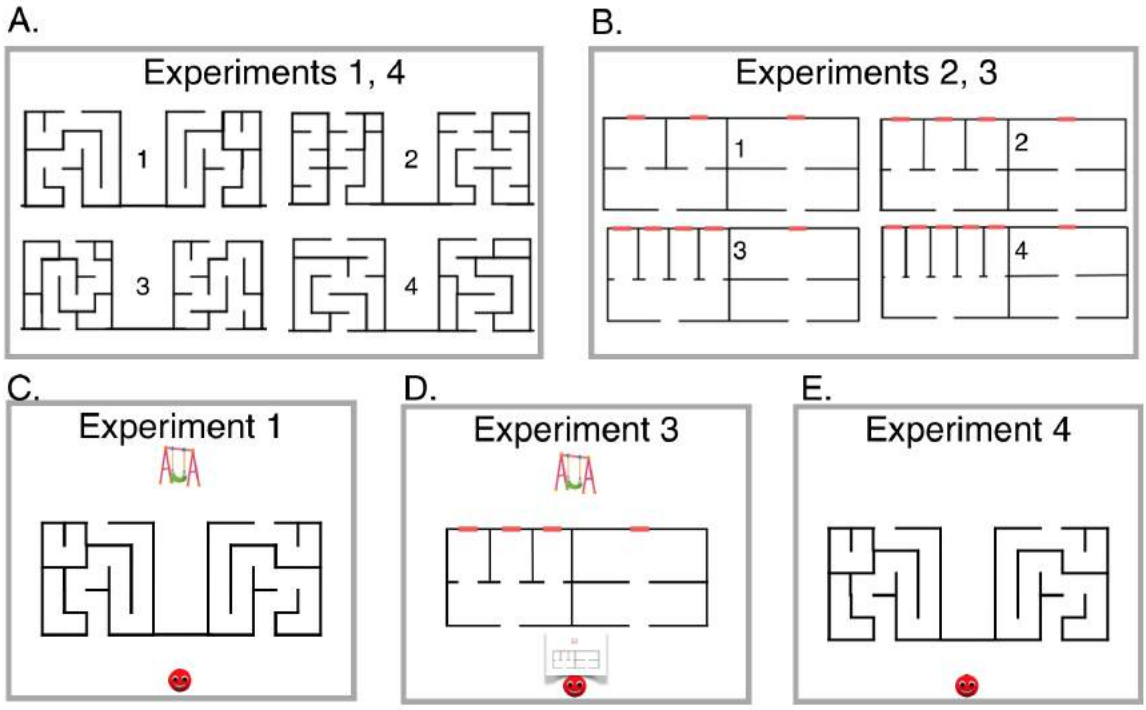

Figure 1: All mazes shown to participants on test trials in (A) Experiments 1 and 4, and (B) Experiments 2 and 3, as well as examples of individual trials from (C) Experiment 1, where a naive agent had the goal of getting to a specific location (D), Experiment 3, where a knowledgeable agent had the goal of getting to a specific location, and (E) Experiment 4, where a naive agent had the goal of getting better at solving mazes.

Experiment 1

In Experiment 1, we investigated whether young children whose attention is drawn to the difficulty of various mazes will choose easier rather than harder mazes for another agent to navigate.

Methods

Participants N=32 children (20 girls, Mean age = 58.94 months, range = 49.63-70.67 months) were included in our final sample of participants. All were recruited through a database of participants in the Boston area, participated at the Harvard Lab for Developmental Studies with the written consent of their parents, and received a small gift and travel compensation for their participation. One participant was excluded and replaced in our sample due to experimenter error. All data collection methods and procedures were approved by the Committee on the Use of Human Subjects at Harvard University. We chose our sample size based on a power analysis from a pilot study. For a pre-registration of the methods and analysis for this experiment, see https://osf.io/fx8yt/.

Materials and Procedure We built our maze stimuli using an online maze generator (http://www.mazegenerator.net/), using a width and height of 5 (4 mazes from test trials) or 6 (1 maze from introduction), an inner width and height of 0, an E-value of 50 (parameter that controls length of solution, relative to size of maze), and an R-value of 50 (parameter that controls length of dead ends subpaths). For the test trials, we selected 4 mazes that had at least 1 wrong turn, with 1 and only 1 solution, hereafter the harder' or more complex' mazes. To generate the simpler versions of these mazes, we added walls blocking all wrong turns, leaving only one available path through the maze. Throughout the experiment, each complex maze was always presented with the simpler version of itself flipped across the vertical axis. See Figure 1A. We presented all experimental materials using Keynote.

During the introduction to the experiment, children saw an animated agent, Bob, travel through an easier and harder maze. The agent's actions were realistic: he traveled through the easier maze without pause, but reached 2 dead ends in the harder maze before finding the solution. Children were asked Which maze took longer to go through?" and Which maze was harder to go through?" with feedback to check and reinforce their understanding of these scenes (e.g., "Yup, that one is harder!" or "Actually, *this* one is harder because it has more paths and ways to get lost").

In Experiment 1, children were told the following cover story: *Bob is at a playground and needs to go through mazes to get to things he wants to play with. He wants to play with as many things as possible before having to go home. He needs your help because he doesn't know anything about these mazes*.

On each test trial, Bob faced a choice between an easier and harder maze that lead to a piece of playground equipment (swings, monkey bars, slide, and a seesaw). Children were first asked to identify the easier (2 trials) or harder (2 trials) maze with feedback. Then, children were asked to help the agent choose which way to go. After participants chose a maze, they were asked to provide explanations for their response. Children viewed a bouncing animation of the agent next to his goal after every test trial, regardless of how they answered, and did not receive feedback for their choice.

We counterbalanced the order of the 4 maze pairs and the left-right position of the easier/harder maze, resulting in 8 different conditions of the procedure. The experiment lasted about 5 minutes.

Data and analysis All comprehension checks and test trials were coded on-line, and then checked offline from videos of the testing session.

We used the lme4 package (Bates, Mächler, Bolker, & Walker, 2015) in R (Team, 2015) to implement all generalized linear mixed effects models (GLMMs). All models with repeated measures included a random intercept for participant identity and maze identity. We used the ggplot2 package (Wickham, 2009) to produce Figure 2. The results sections of this paper were written in R Markdown (Allaire et al., 2014) to enhance reproducibility.

Results

In the introductory phase, prior to any feedback, children correctly identified the more difficult maze at a rate of 0.688, and the maze that would take longer to travel through at a rate of 0.969. During the test phase, which included feedback, children correctly identified the more difficult room at a rate of 0.586.

Our main question was whether children would preferentially choose the easier maze for the agent to travel through. We found that during test trials, children were more likely to select the easier maze than the hard maze, 95% confidence interval (CI) [2.262,10.05], B(SE)=4.932(2.526), z=1.952, p=0.026, one-tailed, OR=138.64, model syntax: `response ~ 1 + (1|subj) + (1|maze)`. Removal of influential cases yielded similar results. See Figure 2.

Discussion

Building on previous findings that infants and children expect agents to minimize the physical effort of their actions (Gergely & Csibra, 2003; Liu et al., 2017), the results of Experiment 1 suggest that children choose lower-effort tasks for others. Nevertheless, the question remains whether children were responding to the physical or the mental effort demands of the complex mazes. The more complex mazes presented a greater planning challenge for the mind, but were also associated with greater travel time and distance (variables that determine physical effort). We conducted Experiment 2 to ask whether children understand that actions can impose cognitive effort in the absence of differences in physical effort.

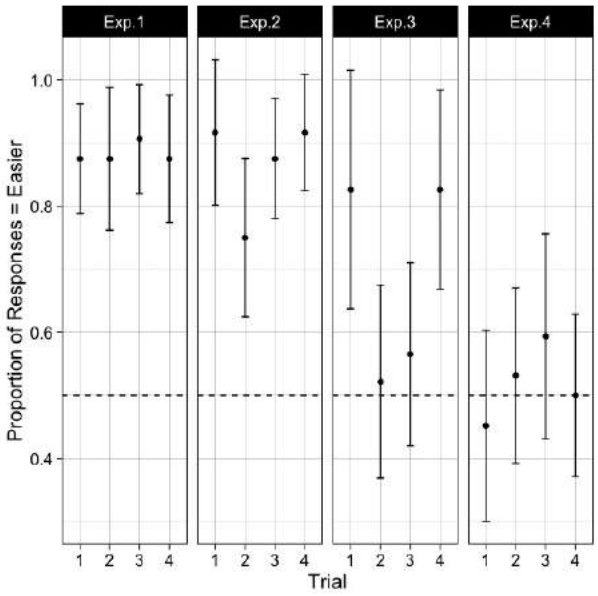

Figure 2: Proportion of choices for the easier maze or room during test trials (4 trials per participant; N=447 responses) across Experiments 1-4. Error bars indicate within-subjects 95% confidence intervals.

Furthermore, Experiment 1 asked children to choose a maze for an agent who was unaware of the effort involved in each choice, but did not ask children to predict which maze a knowledgeable agent would choose for themselves. We conducted Experiment 3 to ask whether children predict the actions of knowledgeable agents the same way they choose to help naive agents.

Lastly, Experiment 1 leaves open the question of whether children always regard mental and physical effort as negative, or whether they understand that harder actions can sometimes generate positive value. Thus, we conducted Experiment 4 to ask whether children appreciate the value of effort in the context of learning.

Experiment 2

In Experiment 2, we asked whether children appreciate that making a decision carries a unique cost, even when equating for physical effort across decision contexts. For a preregistration of the methods and analysis of this experiment, see https://osf.io/9dr7m/.

Methods

Participants N=24 children (14 girls, Mean age = 61.09 months, range = 48.5-71.43 months) were included in our final sample of participants. This sample size was chosen based on a power analysis from Experiment 1. One participant was excluded and replaced in the final sample due to parental interference.

Materials, Procedure, and Analysis Experiment 2 differed from Experiment 1 in three ways. First, the mazes from Experiment 1 were replaced with rooms (see Figure 1B). Pairs of rooms differed in the number of choices available: The more complex room featured multiple hallways for the agent to choose from, and the simpler room consisted of only one path. To equate for the dead ends, we designed these rooms so that all hallways were direct exits; regardless of whether the agent chose the easier or harder room, the agent would exit the first hallway she chose, reaching her goal. To prevent children from reasoning about the agent's line of sight through the rooms, we covered each outlet with a door, which opens only when the agent approaches it. Like in Experiment 1, children were told that the agent was naive about the contents of the rooms, and had the goal of reaching something beyond them. Second, during the introduction of the experiment, the agent moved through the easier and harder room in exactly the same way. This differed from Experiment 1, where the agent took several wrong turns in the harder maze. Third, before each test trial, children were asked to point at the room the agent thinks is harder or easier (2 questions of each kind), and which room the agent thinks has more or less choices (2 questions of each kind) with feedback.

Results

During the introduction to the experiment, prior to any feedback, children correctly identified the more difficult room at a rate of 0.667, and correctly identified the room with more choices at a rate of 0.917. During the test phase, which included feedback, children correctly identified the harder/easier room at a rate of 0.896, and the room with more/less choices at a rate of 0.667.

As in Experiment 1, children were more likely to select the easier room for the agent to travel through, 95% CI [2.278,13.514], B(SE)=7.432(2.871), z=2.588, p=0.005, one-tailed, OR=1689.047[1]. Removal of influential cases yielded similar results. Children's responses did not differ between Experiments 1 and 2, 95% CI [-3.057,2.364], B(SE)=-0.35(1.249), z=-0.28, p=0.779, two-tailed, OR=0.705[2]. See Figure 2.

Discussion

In Experiment 2 we asked whether children appreciated differences in decision complexity between two situations matched for physical path features like travel length and dead ends. As in Experiment 1, children discriminated between these decision structures and chose the simpler option for the naive agent. Together, Experiments 1-2 show that children appreciate the cognitive cost that enters decision-making. Nevertheless, it is less clear whether children expect other agents to willfully minimize their own mental effort, when asked to make a prediction about what a knowledgeable agent would do. Experiment 3 addresses this question.

[1]model syntax: `response ~ 1 + (1|subj) + (1|maze)`

[2]model syntax: `response ~ experiment + (1|subj) + (1|maze)`

Experiment 3

In Experiment 3, children predicted the choice of a knowledgeable agent in the same physical situations as in Experiment 2. For a pre-registration of the methods and analysis of this experiment, see https://osf.io/jyag8/.

Methods

Participants N=24 children (9 girls, Mean age = 60.27 months, range = 48.83-70.7 months) were included in our final sample of participants. This sample size was chosen based on a power analysis from Experiment 2. One participant was excluded due to experimenter error.

Materials, Procedure, and Analysis Experiment 3 was identical to Experiment 2 except that instead of helping the agent, children were asked to predict which room the agent will pick to go through in order to reach the goal, given that he knows everything about both of the rooms. To convey that the agent was knowledgeable, the agent on each test trial always had a map of the two rooms, and children were told explicitly that he knows everything about these rooms". See Figure 1D.

Results

In the introduction to the experiment, prior to any feedback, children correctly identified the more difficult room at a rate of 0.375[3], and the room with more choices at a rate of 0.792. During the test phase, which included feedback ("Yup that's right!" or "Actually, *this* room is easier/harder because he doesn't have to think about where to go") children correctly identified the more difficult room at a rate of 0.781 and the room with more/less choices at a rate of 0.698. As in Experiments 1 and 2, children were more likely to select the easier room for the agent to travel through, 95% CI [-0.296,2.642], B(SE)=1.026(0.598), z=1.716, p=0.043, one-tailed, OR=2.789[4]. Removal of influential cases yielded the same results. However, this effect was significantly weaker than the responses of children from Experiment 2, 95% CI [-4.7,-0.833], B(SE)=-2.397(0.914), z=-2.623, p=0.009, two-tailed, OR=0.091[5]. See Figure 2.

Discussion

In Experiment 3, we asked whether children expect knowledgeable agents to choose to minimize the mental effort of their actions. While we found a positive result, this effect was weaker than when children were asked to help a naive agent in identical environments. There are several possible interpretations of this finding. First, the agent's knowledge about the environments in Exp 3 could have affected children's responses: If a rational agent faces a false choice and knows it, and has a map of the rooms and has already analyzed the

[3]We too are puzzling over why this rate was lower than .5, and lower than in the other experiments.

[4]model syntax: `response ~ 1 + (1|subj) + (1|maze)`

[5]model syntax: `response ~ experiment + (1|subj) + (1|maze)`

choice structure of the two rooms, she may choose randomly. It is also possible that children's expectations about how others spend their mental effort is truly noisier than their intuitions about what is optimal. Regardless of these open questions, Experiments 2-3 provide evidence that children expect other agents to minimize the mental effort of their actions, both when predicting their actions, and when recruited to help them choose an action.

Experiment 4

In Experiment 4, we ask whether children appreciate the tradeoffs between mental effort and information gain. In other words, do children understand that sometimes, it is worthwhile to think and work hard? For a preregistration of the methods and analysis of this experiment, see https://osf.io/w3kh9/.

Methods

Participants N=32 children (17 girls, Mean age = 61.72 months, range = 50.0-71.0 months) were included in our final sample of participants. This sample size was chosen based on a power analysis from Experiment 1. Two participants were excluded and replaced in the final sample, 1 for not responding to any test trial questions, and 1 for experimenter error.

Materials, Procedure, and Analysis Experiment 4 was identical to Experiment 1, except that children were told a different cover story: *Bob wants to learn as much as he can about mazes. Which maze should he go through if he wants to practice solving mazes?* Children were asked what they thought the word practice' meant (19/32 produced passable definitions, like learning something you don't know how to do" and doing something until you know it so much"), and all children were told that to practice meant to try and try again so that you can get better at something". All goals were removed from test trials, and on each trial, and as in Exp 1-2, children were asked which way Bob should go.

Results

During the introduction to the experiment, prior to any feedback, children correctly identified the more difficult maze at a rate of 0.969, and correctly identified the maze that took a longer time to navigate at a rate of 0.875. During the test phase, which included feedback (e.g., "Yup, that one is harder!" or "Actually, *this* one is harder because it has more paths and ways to get lost"), children correctly identified the harder/easier room at a rate of 0.7086.

In contrast to Experiment 1, children in Experiment 4 did not preferentially choose the harder or easier room for the agent, 95% CI [-0.627,0.999], B(SE)=0.15(0.354), z=0.424, p=0.672, two-tailed, OR=1.162[6]. Removal of influential cases yielded similar results. As predicted under the hypothesis that children understand that effort trades off against increases in skill, their tendency to choose the easier maze in Experiment 4 was substantially lower than in Experiment 1, 95% CI [-4.368,-1.503], B(SE)=-2.936(0.731), z=-4.016, p<.001, one-tailed, OR=0.053[7]. See Figure 2.

Results, Experiments 1-4

Effects of experimental manipulations First, we asked which manipulations affected children's responses across all experiments. We found that children chose the easier vs harder action at comparable rates when shown the mazes from Experiments 1 and 4, and the rooms from Experiments, 2 and 3, 95% CI [-0.57,0.87], B(SE)=0.15(0.367), z=0.409, p=0.682, two-tailed, OR=1.162, that children were more likely to choose harder environments for a naive (Exp 3) than a knowledgeable agent (Exp 1, 2, 4), 95% CI [-1.566,-0.117], B(SE)=-0.842(0.369), z=-2.278, p=0.023, two-tailed, OR=0.431. Finally, we found that children were more likely to choose the harder environment when the agent had a learning goal (Exp 4) than an efficiency goal (Exp 1-3), 95% CI [0.793,2.122], B(SE)=1.457(0.339), z=4.298, p<.001, two-tailed, OR=4.293[8].

Role of feedback To address a concern that children's response to the test questions were influenced by the feedback they received during comprehension checks, we asked whether children's comprehension in Experiments 1-4 was different before they received any feedback (during the introduction) and after they began receiving feedback (during test trials 1-4). We found that children responded similarly prior to and after feedback (and if anything, performed less well with feedback), 95% CI [0.845,2.26], B(SE)=-0.243(0.186), z=-1.306, p=0.192, two-tailed, OR=0.785[9].

We also asked whether children's response to the main test question changed across the 4 trials of the experiment. If their responses were influenced by reinforcement during the comprehension checks, these responses should shift towards the direction of the hypothesis over the 4 trials. We tested this by fitting a model using Helmert contrasts, comparing children's responses on each test question (Which way should / will Bob go?") with their average responses on all preceding trials. Relative to all preceding trials, children did not clearly shift their response on trials two 95% CI [-0.669,0.036], B(SE)=-0.316(0.18), z=-1.76, p=0.078, two-tailed, OR=0.729, three 95% CI [-0.145,0.263], B(SE)=0.059(0.104), z=0.567, p=0.57, two-tailed, OR=1.061, or four 95% CI [-0.061,0.235], B(SE)=0.087(0.076), z=1.149, p=0.251, two-tailed, OR=1.091[10]. See Figure 1.

Discussion

Across Experiments 1 and 4, we found that children were more likely to choose a costly action in a context where the

[6]model syntax: `response ~ 1 + (1|subj) + (1|maze)`

[7]model syntax: `response ~ experiment + (1|subj) + (1|maze)`

[8]model syntax: `response ~ maze.or.room + knowledge + goal + (1|subj) + (1|maze) + (1|experiment)`

[9]model syntax: `response ~ phase + (1|experiment)+ (1|subj)`

[10]model syntax: `response ~ trial + (1|subj) + (1|experiment)`

actor's goal was to improve their planning abilities, versus when their plans were means to an end. Our findings show that children appreciate the trade-off between effort and information gain that working and thinking hard can generate.

General Discussion

Across four experiments, we asked whether children are sensitive to the mental and physical consequences of action selection in the context of mazes and rooms. Building on previous evidence that young children expect other people to minimize the physical cost of their actions (Gergely & Csibra, 2003; Liu & Spelke, 2017), we found that children assume complex maze environments are costly (relative to simpler ones), and that having to make choices is costly (relative making no choices). We also found that children do not expect agents to minimize effort in all situations, but instead appear to understand that trying hard is more likely to generate increases in knowledge and skill.

Within the limits of our experimental context, these results begin to reveal how young children reason about other's subjective mental effort costs. Specifically, in these experiments, children appear to place a cost on the process of action selection. This comports with a large literature showing that action selection by planning is, indeed, experienced by most people as costly (Kool & Botvinick, 2018; Westbrook & Braver, 2015; Shenhav et al., 2017). Nevertheless, the mechanisms by which children read out judgments of difficulty and use them to make predictions are not explored in this paper. In the domain of physical effort, past work suggests that even young infants represent action cost as force applied over a path, rather than as any single perceptual feature that correlates with more or less effortful actions (Liu et al., 2017). What information supports similar judgments in the domain of mental effort? Furthermore, it is unclear how much or how little children rely on processes of simulation to solve the tasks in our experiment. Most of the preschoolers in our sample probably came into the lab with prior experience solving mazes, and many of them traced paths through the mazes as part of their explanations for why they answered the way they did. Thus, one important remaining question is what role our experiences of choosing, thinking, and learning play in the development of our understanding of mental effort.

Of course, action selection is not the only costly step of rational planning, or the only difference between habits and plans. Our results thus suggest important new directions for future research. For instance, do children understand that the closer 2 options are in utility, the harder it is to choose between them, or that habits are lower in cost than plans? Our findings also opens the door to studies of children's intuitive theories of other people's and their own knowledge and learning. For instance, do children understand that learners have an optimal zone of task difficulty in which to gain knowledge? Future work in this area can address the many open questions regarding how we conceptualize the mental lives of other people, and its development.

Abstract

Our everyday decisions are driven by costs, risk, and reward. How do people take these factors into account when they predict and explain the decisions of others? In a two-part experiment, we assessed people's perceptions of other people's risk preferences, relative to their own. In Part 1, participants reported their relative preference between a guaranteed payout and lotteries with various probabilities and payouts, and made predictions about other people's preferences. In Part 2, participants estimated the lottery payout that generated a given relative preference between a guaranteed payout and a lottery, both for themselves and others. We found considerable individual variability in how people perceive the risk preferences of others relative to their own, and consistency in people's perceptions across our two measures. Future directions include formal computational models and developmental studies of how we think about our own and each other's decision-making.

Keywords: intuitive psychology; decision making; risk

Introduction

Humans are social beings, who spend much of their time attempting to predict what decisions others will make, and explain why others chose as they did. Adults, and even infants, make predictions about what another person will do based on their beliefs about the person's mental state, and also make inferences about someone's mental state after observing their behavior (Epley, 2015; Kushnir, Xu, & Wellman, 2010; Repacholi & Gopnik, 1997).

Recent computational accounts of such abilities see people as performing Bayesian inference using a model of others as rational planners or intuitive utility maximizers who take actions to maximize their expected reward relative to their incurred cost (Baker, Saxe, & Tenenbaum, 2009; Lucas et al., 2014; Jara-Ettinger, Gweon, Schulz, & Tenenbaum, 2016; Baker, Jara-Ettinger, Saxe, & Tenenbaum, 2017). Previous work has shown that such rewards and costs are early-emerging, separate targets of inference (Jara-Ettinger, Gweon, Tenenbaum, & Schulz, 2015; Liu, Ullman, Tenenbaum, & Spelke, 2017). Here, we study a related variable at the heart of other people's expected utility: the probability of the outcome. Specifically, we study how people perceive and reason about other people's risk preferences, especially compared to their own.

The central role of risk in decision making has been long appreciated (Bernoulli, 1738). For example, many people prefer a 50/50 chance of losing $200 to losing $100 for sure, and prefer gaining $100 for sure over a 50/50 chance of gaining $200, even though the expected value of the options are equal in each case. Under expected utility theory, decision makers weight probabilities linearly, and risk aversion is measured and explained by the curvature of the utility function (Pratt, 1964; Arrow, 1965). Rabin's Calibration Theorem illustrates the difficulties with this approach (Rabin, 2000). A large body of work by psychologists and behavioral economists has shown that decision making under risk involves non-linear weighting of probabilities (Kahneman & Tversky, 1979; Tversky & Kahneman, 1992; Wakker, 2010; Dhami, 2016).

Research has also examined how people perceive the risk sensitivity of others. Some previous work finds that people perceive others as more risk-seeking than themselves (Hsee & Weber, 1997), while a different set of studies finds that, on average, people assume others are more risk-averse (Eckel & Grossman, 2008), although the focus of this study and others (Siegrist, Cvetkovich, & Gutscher, 2002) was the role of gender stereotypes in risk perception. Differences in cross-national risk perceptions have also been explored (Hsee & Weber, 1999). This paper differs from previous work in a number of ways. First, the previous literature used group-based analyses that collapsed across people and a small number of gambles, and so could not determine whether the average results reflected homogeneous perceptions across individuals, whereas we additionally consider individual level perceptions. Second, participants in past studies made predictions about binary choices between lotteries, whereas in our study participants give more fine-grained predictions about their degree of relative preferences for a lottery over a sure thing. Third, participants previously only made predictions about the decisions of others, whereas we additionally have participants estimate the monetary value of gambles that would cause a particular preference in other people.

We use a two-part experiment to study how people perceive the risk preferences of others. In Part 1, we present participants with choices between $100 for sure and a lottery, with eight levels of payout and five levels of probability. For each choice, participants reported their own preferences and predicted the preferences of others, using a five point Likert scale. In Part 2, we ask the same participants to estimate the (unseen) payout that led others to report a specific preference, and that would lead themselves to report the same preference. We then relate the judgments of participants across the two

parts of the experiment.

We had two main research questions. First, we were interested in the distribution of people's perception of their own risk preferences relative to others. Second, we investigated the consistency of people's perceptions about their own and others' risk preferences across two tasks, one that asked people to make predictions about preferences, and the other that asked people to make inferences about lottery payouts given preferences.

Experiment

Participants

We recruited 205 participants on Amazon Mechanical Turk, restricted to the United States. Of these, we excluded 33 participants for (1) failing to pass an attention check, or (2) providing the same answer for all questions in Parts 1 or 2, or (3) taking less than 5 minutes to complete the experiment, or (4) giving payout judgments larger than $2000 in Part 2. These criteria were specified ahead of data analysis but not ahead of data collection. After exclusion our sample consisted of 172 participants (median age=34 years, median annual income=$47,000, 75 female, 96 male, 1 other). All participants gave informed consent prior to participating. All recruitment and study procedures were approved by the MIT Committee on the Use of Humans as Experimental Subjects.

Methods

Participants were presented with a series of hypothetical choices between lotteries and $100 for sure. Each lottery consisted of a random draw from a box of 10 balls. If a player were to enter the lottery, a ball would be drawn at random from the box, and the player would win the amount of money on the ball. For example, a lottery where a player has a 50-50 chance to win $500 would contain 5 balls worth $0 each, and 5 balls worth $500 each.

In Part 1, participants saw 40 trials, each involving a choice between $100 for sure, or a [.1, .3, .5, .7, or .9] chance of winning [$100, $150, $200, $300, $400, $600, $800, or $1000]. For each decision, participants gave their own preference, and predicted the preference of an average other player, on a 5-point Likert scale (1=$100 is a lot better, 2=$100 is somewhat better, 3=$100 and lottery are equally good, 4=lottery is somewhat better, and 5=lottery is a lot better). We note that these Likert ratings do not express participants' valuation of the lottery itself, but rather differences between the utility of the lottery and the utility of the sure reward. See Figure 1.

In Part 2, participants saw 5 trials, each involving a choice between $100 for sure, or a 50-50 lottery to win some other amount of money, this time unknown to the participant (Figure 1, bottom). On each trial, participants were informed that, on average, other players rated the lottery one of the five possible levels of the Likert scale (i.e., on the first trial participants were told that other players on average strongly preferred the $100, on the second trial that other players slightly preferred the $100, etc.). Participants were asked to estimate how much money was at stake in the lottery given this preference, and gave their response using a freeform text field.

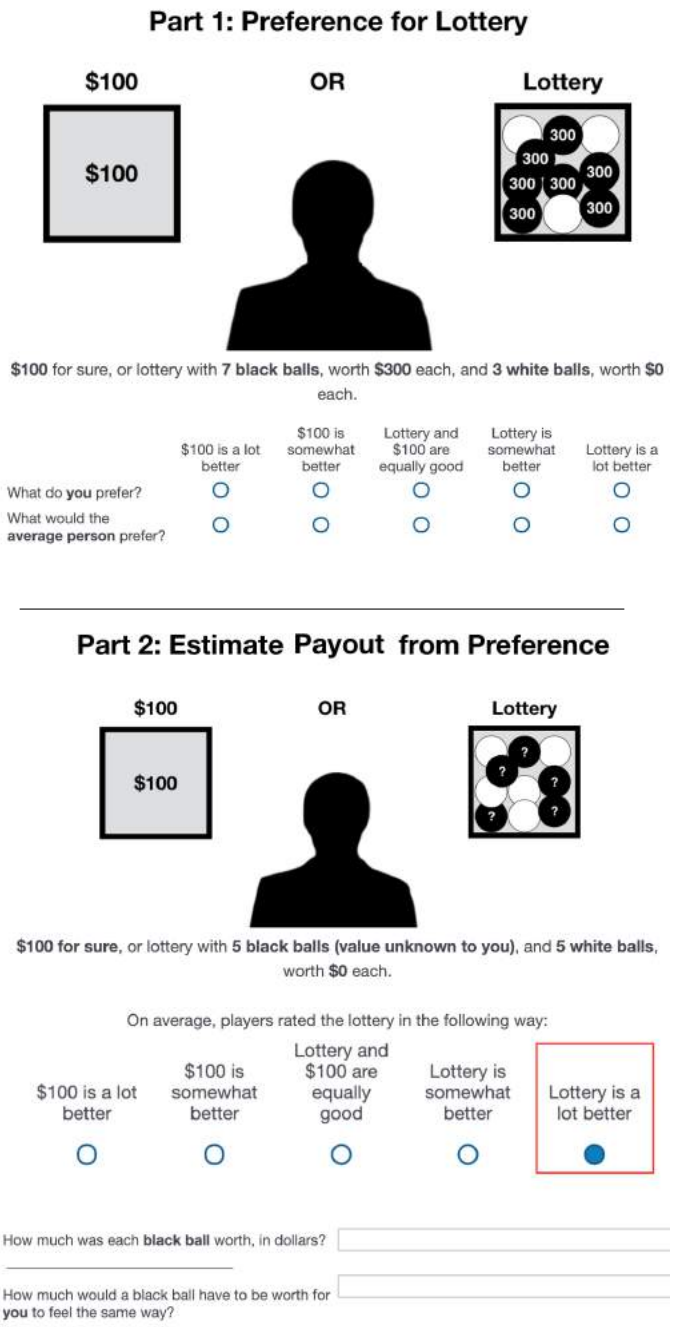

Figure 1: Example trials from the experiment. In Part 1, participants rated their own preferences between $100 for sure and a lottery, and predicted the preference of others. In Part 2, participants were told the preference of another person and both estimated the payout of the lottery, and judged how much money would have to be at stake for them to feel the same way.

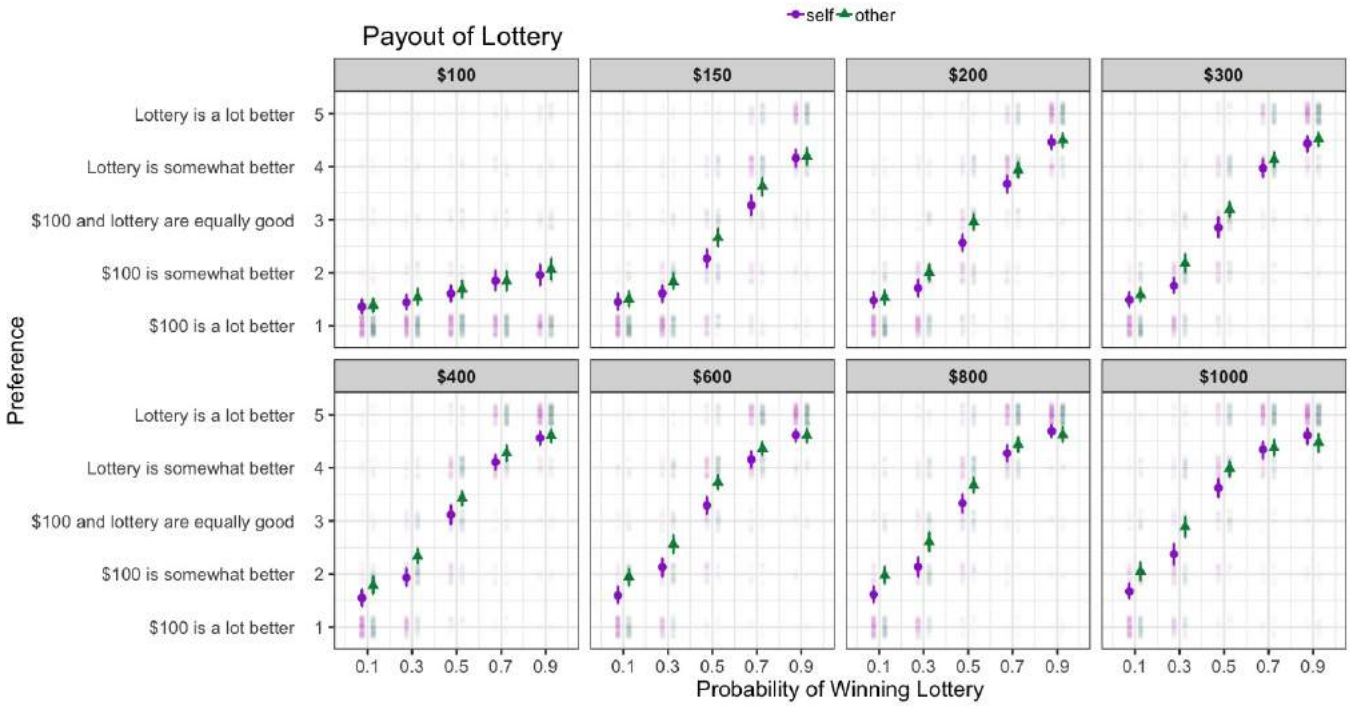

Figure 2: Participant Likert ratings indicating preference for lottery or guaranteed $100, and their predictions for the average other player, across all probabilities and payouts. Opaque points indicate mean Likert ratings with bootstrapped 95% confidence intervals. Translucent points indicate raw data plotted with vertical jitter.

Participants then estimated how much money would have to be at stake in the lottery for they themselves to give the same rating. See Figure 1.

In Parts 1 and 2, trials were presented in a random order, and the left-right orientation of the lottery vs $100 and the anchors for the Likert scale were consistent within participants, but randomized across participants.

Results

The data were analyzed using mixed effects linear models (Bates, Mächler, Bolker, & Walker, 2015; Team, 2015), unless noted otherwise. All models included random intercepts for participant identity (i.e. responses are nested within participants), and for trial number (i.e. responses are nested within linear trial order). We report coefficients from modeling the Likert rating as continuous for ease of interpretation, but fitting a Cumulative Link Model yields similar results. Bracketed values indicate 95% confidence intervals of unstandardized coefficients (e.g. the effect of increasing the stake of the lottery by $1 on preferences for the lottery in Likert ratings), and p-values are all two-tailed. Participant gender and annual household income are included as regressors.

Part 1: Preferences between a lottery and sure thing

People's own risk preferences. Before turning to our first question concerning how people perceive the risk sensitivity of others compared to their own risk sensitivity, we conducted a basic analysis of the data to confirm that 1) people more strongly preferred the lottery as its probability and payout increased, and 2) whether people, on average, were risk averse. As expected, across all 40 trials, participants' preference for the lottery increased as the payout increased ([1.2e-3,1.4e-3], $p<.001$), and as the probability of winning increased ([3.456,3.637], $p<.001$), see Figure 2.[1]. To measure participants' level of risk aversion, we examined the two trials that included lotteries equal in expected value to receiving a guaranteed $100 (i.e. the 50-50 lottery with $200 payout, and the 10-90 lottery with $1000 payout). In both of these trials, people preferred the guaranteed $100 over the lottery (Likert mean=2.56, median=2 for 50-50 lottery, $p<.001$; mean rating=1.67, median=1 for 10-90 lottery, $p<.001$, one-sample t-test against $\mu=3$).

Perceptions of risk preferences of others. We repeated the same basic analyses as reported above, this time on people's judgments of others. Across all 40 trials, participants' estimates of others' Likert ratings increased as the payout increased ([1.3e-3,1.5e-3], $p<.001$), and as the probability of winning increased ([3.171, 3.353], $p<.001$). We again analyzed the two trials that included lotteries with an expected value of $100. In the trial with the 50-50 lottery, participants predicted that others would be indifferent between the

[1]Model formula: `response ~ payout + probability + gender + log(income) + (1|participant) + (1|trial)`

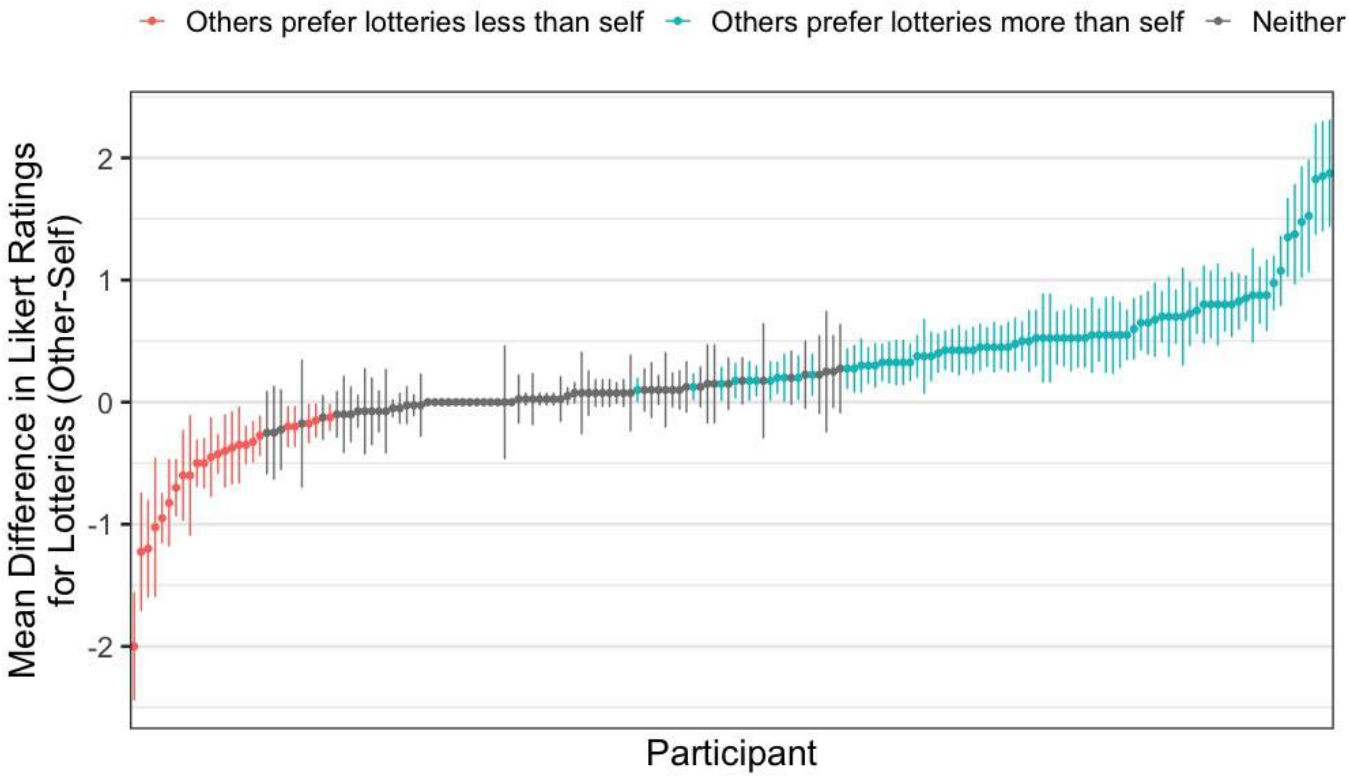

Figure 3: Differences in people's own preference for the lottery and their prediction of the preference of others, shown for each participant and averaged across trials. Each point indicates the mean difference between a single participant's Likert ratings for themselves and predicted ratings for others (40 pairs per participant), estimated by a paired-samples t test. Error bars indicate 95% confidence intervals around the mean. Participants without confidence intervals gave the same rating for themselves and others on every trial (but different ratings across trials). Of 172 participants, 81 (47%, blue) judged that others were significantly more risk-seeking than themselves, 24 (14%, red) judged that others were significantly more risk-averse than themselves, and 67 (39%, gray) gave similar ratings for themselves and others as discussed in the text.

50-50 lottery and the guaranteed \$100 (mean rating=2.96, median=3, p=.602, one-sample t-test against μ=3). In the trial with the 10-90 lottery, participants predicted that others would slightly prefer the \$100 (mean rating=2.05, median=2, $p<0.001$, one-sample t-test against μ=3).

Comparing risk preferences for self and other. Our first main question is how people perceive the risk preferences of other people, relative to their own. A group level analysis indicated that participants predicted other people to be more risk-seeking than themselves. That is, they expected others to prefer the lottery (rather than the guaranteed \$100) more than themselves, across payout amounts and lottery probabilities ([0.086,0.123], $p<.001$)[2]. See Figure 2.

A group level analysis, however, can obscure important individual heterogeneity. Figure 3 shows, for each participant, the average difference between the participant's prediction of how much other people prefer the lottery and how much they themselves prefer the lottery. While these differences clearly fall on a continuum, we were interested in what proportion of participants judged that others were more risk averse or risk seeking, relative to themselves. By this measure, 47% of participants believed that others were more risk-seeking than themselves (by a paired sample t-test on each participant, the estimated average difference for these participants had confidence intervals strictly above 0), 14% believed others were less risk-seeking (confidence intervals strictly below 0), and 39% did not show a significant difference between their preferences and those they predicted for others (confidence intervals crossed 0). These results are consistent with a paired sample sign test on each participant, which identifies 43% of participants who believe that others are more risk-seeking, 9% who believe that others are more risk-averse, and 48% who do not show a significant difference between the ratings of themselves and others (all at the $p<.001$ level).

[2]Model formula: `response ~ probability + payout + agent + gender + log(income) + (1|participant) + (1|trial)`

Part 2: Estimating the payout of lotteries given a preference

As a reminder, in Part 2 we asked participants what payout of a 50-50 lottery would cause themselves and others to have a given preference for the lottery (from much preferring the guaranteed $100, to much preferring the lottery).

Estimates of lottery payouts for self. As in our analysis of the data from Part 1, we first conducted a basic analysis to examine people's inferences about the lottery conditional on choices for themselves. Across all trials, participants reasonably believed that a greater preference for the lottery meant that the payout of the lottery was higher ([112.65,131.60], $p<.001$)[3]. When the Likert rating was 3 (indifferent between the lottery and guaranteed $100), participants judged that the 50-50 lottery payout must exceed $200 for them to have given this rating (mean=$267, median=$200, $p<.001$, one-sample t-test against μ=$200), indicating risk aversion.

Estimates of lottery payouts for others. We repeated the same analyses as reported above, this time on people's judgments of others. Across all five trials, participants judged that other people having a greater preference for the lottery was caused by a higher lottery payout ([110.15,127.90], $p<.001$). When the average Likert rating reported by others was 3 (indifferent between the lottery and guaranteed $100), participants estimated that the 50-50 lottery payout for other people was no different than the risk-neutral value of $200 (mean=$210, median=$200, p=.384, one-sample t-test against μ=$200).

Comparing payout estimates for self and other. Our first main research question concerns differences in participant's estimates for the lottery payment for themselves and others. Across all participants and trials, for a given Likert rating participants judged that the estimated lottery payout was lower for other people than for themselves (agent coefficient was significantly negative, [-24.983,-6.939], p=0.001)[4].

Since there are only five trials per participant in Part 2 (5 paired estimates for self and other), to assess individual level differences, we computed for each participant the mean difference between the payout that they believed would be required to make the lottery equally attractive to themselves and other people: 51% of participants gave higher estimates, on average, for themselves than others (i.e. believed that others were more risk-seeking), 29% gave lower estimates, on average, for themselves compared to others (i.e. believed that others were more risk-averse), and 20% gave, on average, equal estimates for themselves and others (i.e. believed that they and others had the same risk preference).

Predictions of preferences and estimates of lottery payouts given a preference Our second main research question was whether people's judgments were consistent across our two tasks. We found that participants' average difference in Part 1 between their own preferences and their ratings of the preferences of others corresponded to the average difference between their payout estimates for themselves and others in Part 2 ([46.2, 102.1], $p<.001$).[5]. That is, the more a participant judged that others would prefer the lottery more than themselves in Part 1, the more lottery payout that participant needed to give the same rating as others in Part 2.[6]. See Figure 4.

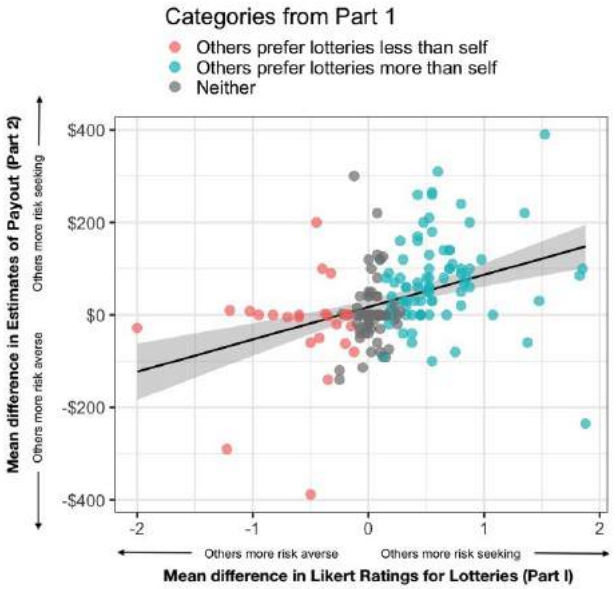

Figure 4: Relating individual differences in relative risk preference as measured in Part 1 and Part 2 of the experiment. Each point indicates one person's mean difference in preferences for 40 lotteries for themselves vs others (x-axis), and the mean difference in their estimated payout for themselves vs. others over 5 preferences for a 50-50 lottery vs a guaranteed $100 (y-axis). Solid line indicates regression between these values with 95% confidence interval. Colors of points indicate classification of participants based on Part 1, as in Figure 3 and the main text.

Discussion

Risk matters, both for our own decisions, and in our reasoning about the decisions of others. We presented participants with choices between lotteries and guaranteed payouts, and used prediction and estimation measures to explore individual variability in people's beliefs about the risk preferences of others. Across both measures, we found two large subsets of participants: participants who believed that others were more risk seeking than themselves, and participants who believed that other people exhibited roughly the same degree of risk sensitivity as themselves. People's beliefs about how their

[3]Model formula: `response ~ likert + gender + log(income) + (1|participant) + (1|trial)`

[4]Model formula: `response ~ probability + payout + agent + gender + log(income) + (1|participant) + (1|trial)`

[5]Model formula: `diffpart2 ~ diffpart1 + gender + log(income)`

[6]Performing the same comparison using Spearman's rank correlation yielded similar results, ρ=0.472, $p<.001$

own risk sensitivity compared to other people were fairly stable across the two parts of the experiment.

Our findings are consistent with, but also complicate, the framework of Bayesian Theory of Mind. This framework models people's reasoning about others by assuming that others are carrying out a rational planning procedure to achieve goals given constraints (Baker et al., 2009, 2017; Jara-Ettinger et al., 2016). While most previous work in this literature assumed, for simplicity, that people reason about others as maximizing expected value, behavioral economics has long highlighted how people deviate from simple expected value (for example, by being risk-averse) (Dhami, 2016). Recent work has investigated deviations from optimal rational planning and the use of bounded agents in Bayesian Theory of Mind and Inverse Reinforcement Learning, for example by replacing the ideal rational planner with an agent that has false beliefs and exhibited temporal inconsistency (Evans, Stuhlmüller, & Goodman, 2016). Along the same lines, one could replace the rational planner with an agent that displayed either risk-seeking or risk-averse behavior, for example either by manipulating the agent's utility function or its probability weighting function. We are currently pursuing this direction so as to explore the cognitive processes underlying the results presented in this paper.

Another future direction suggested by the results in this paper are the downstream consequences of differences in people's own risk sensitivity and their perception of the risk sensitivity of others. For example, do people use their own or their perception of others' risk preference when making decisions on behalf of others? What do people expect others to do, when others are assigned to make decisions on their behalf?

Our experiment focused on risk of a specific kind, but risk may not be a unified concept (Loewenstein, Weber, Hsee, & Welch, 2001; Wallach & Wing, 1968). Moreover, most situations are ambiguous rather than simply risky - people are not confronted with explicit, known probabilities, but must instead act in the face of uncertainty given their beliefs. Similar experiments could examine how people perceive the degree to which other people exhibit ambiguity aversion, relative to their own ambiguity preferences.

While all our participants were adults, it is interesting to consider perceptions of other's risk sensitivity through the lens of development. Infants and children are sensitive to other people's preferences (Woodward, 1998; Jara-Ettinger et al., 2015), and the probabilities of events (Téglás et al., 2011; Xu & Garcia, 2008, 2008). Recent studies suggest that children use probability (Denison & Xu, 2010, 2014) and reward (Feigenson, Carey, & Hauser, 2002) to make decisions and analyze the decisions of others (Wellman, Kushnir, Xu, & Brink, 2016; Lucas et al., 2014). But these experiments leave open when children become sensitive to risk in their own decisions, and when they understand others as risk-sensitive.

In this paper, we examined risk in the context of a series of simple lotteries. This is a common laboratory paradigm, but is less common in real life. Outside the lab, risk is a major force in consequential decisions, from starting wars, to developing new technologies, to making medical decisions for ourselves and our loved ones. Such decisions are not made in isolation, but in consultation, collaboration, and competition with other people. Thus, studies of risk—a fundamental component of our decisions and social lives—bear on all of these situations, by revealing the nature of how we represent other people's decisions, and our own.

Verb Frequency Explains the Unacceptability of Factive and Manner-of-speaking Islands in English

Abstract

The unacceptability of wh-extraction (e.g., question formation) out of certain syntactic structures, known as 'island' effects, has been a central topic in theoretical syntax for many years (Ross, 1967; Chomsky, 1973). A prominent example of islands is that extraction out of a sentential complement introduced by factive and manner-of-speaking verbs ('What did John *know/whisper* that Mary bought?') is less acceptable than extraction from a clause introduced by "bridge" verbs ('What did John *say* that Mary bought?'). We aimed to replicate Ambridge and Goldberg (2008) who argued that extraction from a sentential complement is unacceptable in proportion to its discourse salience. We failed to replicate their results and found that there is no true island effect for such structures: instead there are separate, additive penalties based on two factors: (a) verb-frame frequency (cf. Dabrowska, 2008), and (b) the presence of extraction. These penalties give rise to apparent island effects as a result of the nonlinear relationship between true acceptability and acceptability ratings as measured in Likert scales and forced-choice tasks.

Keywords: Sentence Processing; Frequency Effect; Acceptability of Sentences; Long-distance Dependencies

Introduction

An important feature of human languages is that they contain constructions that license long-distance dependencies--so-called "filler-gap" constructions, such as wh-questions, relative clauses, clefts and topicalization, among others. For example, the declarative form of a simple clause is provided in (1a), along with a wh-question version of this information in (1b), where the patient (object) is extracted. A corresponding relative clause is provided in (1c) and a cleft is in (1d)[1]:

(1) a. Mary bought some apples.
b. wh-question: What$_i$ did Mary buy __$_i$?
c. relative clause: The apple that$_i$ Mary bought __$_i$
d. cleft: It was the apple that$_i$ Mary bought __$_i$

[1] Following standard notation in the linguistics literature, we will notate the position in the declarative that is associated with fronted element with an empty element "__". We provide a subscript such as "i" to the fronted element (the "filler") and the empty position.

Some long-distance extractions are allowed (1), but others are not (2)&(3) (Ross, 1967):
(2) a. * What$_i$ did [$_S$ you hear [$_{NP}$ the statement that Jeff baked __$_i$]] ?
b. * Who$_i$ do [$_S$ you think [$_{NP}$ the gift from __$_i$] prompted the rumor] ?

(3) (relative clause versions of 2):
a. * The bread that$_i$ [$_S$ you heard [$_{NP}$ the statement that Jeff baked __$_i$]]
b. * The politician who$_i$ [$_S$ you think [$_{NP}$ the gift from __$_i$] prompted the rumor].

The unacceptable versions in (2) and (3) have been called 'islands' to extraction: unacceptable long-distance filler-gap constructions. The major theoretical interest in island phenomena began with Chomsky (1973), where he argued for a pure structural account, *Subjacency*: noun phrase (NP) and sentence (S) syntactic nodes are bounding nodes for extraction. Extraction across two bounding nodes was proposed to be ungrammatical. Consequently, extractions across the NP and S nodes in (2ab) and (3ab) result in an unacceptable form. Furthermore, Chomsky argued that these constraints must be innate and unlearnable, because (a) the unacceptable extractions occur independent of the meaning of the constructions involved; and (b) a child would not be exposed to the right input across all the different constructions in which they hold (see Schütze et al., 2015, for a summary).

In this paper we focus on extractions out of sentence-complements (S-complements) of factive and manner-of-speaking verbs, as in (4). Researchers have long noted that extraction out of sentence-complements taken by factive verbs – such as "know" (4b), "regret", and "notice", whose S-complements are presupposed (Kiparsky and Kiparsky, 1971) – and manner-of-speaking verbs – such as "whisper" (4c) "mutter", and "mumble", which describe physical characteristics of the speech act (Zwicky, 1971) – are less acceptable than extraction out of "bridge" S-complement taking verbs (4a) (e.g., Erteschik-Shir. 1973; Snyder, 1992; Ambridge & Goldberg, 2008). Note that the definition of a "bridge" verb is not independently defined. A bridge verb is simply one for which extraction from its S-complement is

possible – such as "say" or "think", which makes the 'bridge' baseline of the previous accounts unclear. That is, the notion of 'bridge' is not defined in terms of the meaning of the verb, and thus immediately calls into question a potential meaning basis for an observed difference.

(4) a. Bridge verb
What did John **say** that Mary bought?
b. Factive verb
??What did John **know** that Mary bought?
c. Manner-of-speaking verb
??What did John **whisper** that Mary bought?

Previous and Current Theories:

Syntactic Accounts: In order to explain the difference between extraction across bridge verbs (4a) on the one hand and extraction across factive and manner verbs (4b/c) on the other, a syntactic account requires different syntactic structures for bridge verbs compared to the other two kinds of verbs. For instance, it has been claimed that bridge verbs take embedded clauses as arguments, while embedded clauses of manner-of-speaking verbs and factive verbs contain extra covert structures at an abstract level ('deep structure' of the Chomskyan framework), such as an invisible complex NP (Kiparsky & Kiparsky, 1971; Snyder, 1992; Stowell, 1981; Stoica, 2016). In this way, the unacceptability of extraction across factive and manner-of-speaking verbs could be captured by syntactic constraints of extraction such as *Subjacency*. However, there are no independent reasons to propose these covert complex structures.

Discourse Accounts: The fundamental idea of discourse accounts is that grammatical constructions specify certain parts of a sentence as 'foreground' or 'background', and the gap in a filler-gap construction can't fall within a backgrounded domain. In this spirit, Ambridge & Goldberg (2008) (henceforth A&G) proposed an account they call Backgrounded Constituents are Islands (BCI), arguing that extraction from an S-complement is unacceptable in proportion to its 'backgroundedness'. The more backgrounded the embedded clauses, the less acceptable the extraction.

Frequency Accounts: Frequency accounts link extraction difficulties to low exposure: less frequent or unpredictable extractions are more difficult to process (cf. Hale, 2001; Levy, 2008). Dabrowska (2008) proposed that speakers store prototypical templates corresponding to frequent combinations they have encountered in their experience such as 'Wh-word *do you think/say* S-complement?'. Filler-gap constructions that are more similar to the prototypical constructions are more acceptable.

We will propose a different generalization of Dabrowska's account, following the results of Exp 1 (presented below):

***The verb-frame frequency hypothesis*:** The acceptability of an utterance is best captured by 2 independent, separate effects: (i) the frequency or the type of the construction (e.g., wh-questions vs. declaratives) and (ii) the frequency of the verb head-structure.

Extractions are rated less acceptable than declaratives, because extractions are less common compared to declaratives in communication, or they require more cognitive resources. As for acceptability variance within declaratives or extractions out of S-complements, the major determining factor is the frequency of the matrix verbs taking S-complements (P (matrix verb, S-complement)). This account does not predict an interaction ('island') effect between the acceptability of declaratives and extractions. (The interaction obtained in previous works may be a result of applying linear models to non-linear acceptability.)

Following this new *verb-frame frequency hypothesis,* manner-of-speaking wh-questions such as (4c) are less natural, because the manner verbs rarely take S-complements. Factive verbs that take S-complements with a similar frequency to bridge verbs should form equally good wh-questions. A major outlier to our account, the verb '*know*', may be explained by pragmatic factors.

Predictions of The Three Theories on Factive and Manner-of-speaking Islands:

Prediction of the Syntactic Accounts: All factive and manner-of-speaking wh-questions should be less acceptable than all the bridge ones due to categorically distinct covert structures (e.g., Kiparsky & Kiparsky, 1971; Snyder, 1992), as in Fig.1a.

Prediction of the BCI Account (A&G 2008): There should be a correlation between the acceptability of wh-questions and the backgroundedness of the S-complements taken by the verbs, as shown in Fig.1b. Factive verbs take presuppositions, the most backgrounded constituents, and therefore should form the most unnatural wh-questions. Manner-of-speaking verbs should form less strong islands, while bridge verbs form fully acceptable wh-questions.

Prediction of Verb-frame Frequency Hypothesis: The acceptability of extraction out of SC verbs should depend primarily on the frequency of those verbs taking S-complements, and the effect of frequency should be similar on both wh-questions and declaratives (no 'island' effect), as plotted in Fig.1c.

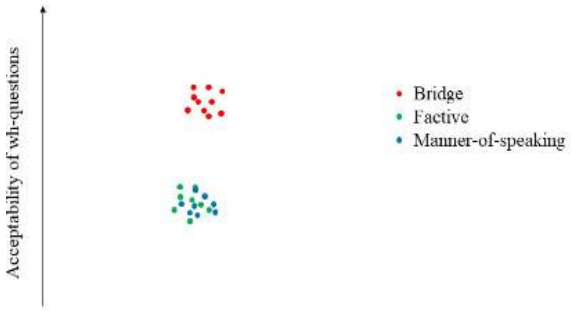

Figure 1a: The prediction of the syntactic accounts

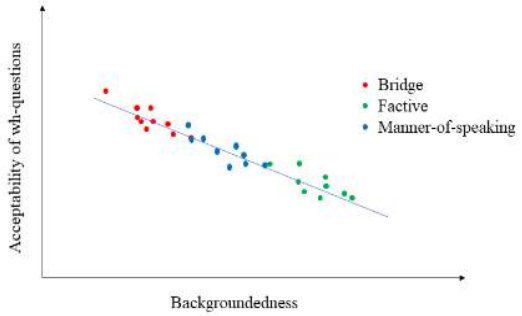

Figure 1b: The prediction of the BCI account.

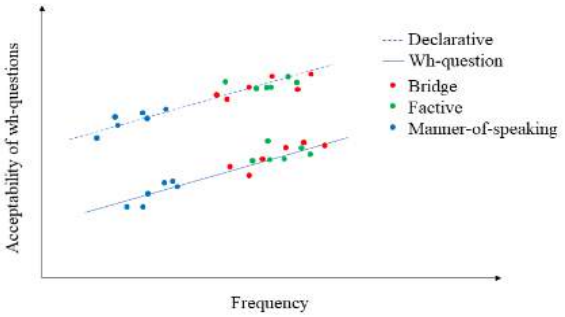

Figure 1c. The prediction of our frequency account.

Experiment 1: Replication of Ambridge and Goldberg (2008)

Experiment 1 is an attempted replication and extension of A&G (2008) using an expanded set of 24 verbs in the 3 categories (A&G tested 12 verbs). There were 2 sub-experiments. Experiment 1a: acceptability judgements of wh-questions formed by the 3 groups of verbs and their corresponding declarative controls. Experiment 1b: negation test to measure the backgroundedness of S-complements of those verbs where extraction appeared. The BCI account predicts a negative correlation between the backgroundedness of the extraction domain and the acceptability of the wh-questions (A&G, 2008).

This experiment also tests the syntactic theories via collecting acceptability ratings of wh-questions formed by the 3 groups of verbs.

Methods

Participants: 180 subjects participated in this experiment via Amazon Mechanical Turk in exchange for $2 each: 120 participants answered acceptability questions for wh-questions and declarative clauses. Another 60 subjects completed the negation task.

In all the experiments reported here, data from participants who did not self-report themselves as native speakers of American English or didn't answer all the comprehension questions with at least 85% accuracy were excluded. Responses from 116 participants in the acceptability task and 49 participants in the negation task were analyzed.

Design and Materials: The acceptability and negation tasks were constructed for 24 sentence complement (SC) verbs of the 3 categories, as listed in (6)[2].

(6) a. Bridge verbs: **say, decide, think, believe**, feel, hope, claim, report, declare

b. Factive verbs: **know, realize, remember, notice,** discover, forget

c. Manner-of-speaking verbs: **whisper, stammer, mumble, mutter,** shout, yell, scream, murmur, whine

In the acceptability task, wh-questions and their corresponding declarative sentences were designed as (7a) and (7b) respectively. 96 pairs of wh-questions and declaratives were constructed, and each of the 24 tested verbs in (6) formed 4 pairs. In each pair of wh-question and declarative control, NP1 and NP2 are common names, V1 comes from (6), and V2 is the past tense form of one of the frequently used 25 verbs (*like, eat, buy, build, cook, destroy, dislike, drink, draw, fix, find, know, learn, lose, make, mention, need, see, sell, steal, take, teach, throw, want, write*). To reduce the possibility of semantic plausibility confounds, we used 'something' instead of a specific NP as the embedded object.

(7) a. What did [NP1] [V1] [[that] [NP2] [V2]]?
e.g., What did Susan know that Anthony liked?
b. [NP1] [V1] [that] [[NP2] [V2+something]]
e.g., Susan knew that Anthony liked something

The 96 pairs were split across 2 lists: each list contained 2 declaratives and 2 different wh-questions per verb. Each participant saw 96 sentences (from 1 list) in a random order. They were asked to rate how natural each sentence was with a rating scale from 1 (extremely unnatural) to 5 (extremely natural). Each sentence was followed by a comprehension question about the content of the preceding sentence to check if participants were paying attention to the task.

In the negation-test task (from A&G, 2008), each trial included a negated complex sentence (8a) and a negated

[2] Verbs in bold are those tested in A&G (2008). The labeling of a verb as 'bridge' was obtained from previous literature, such as Erteschik-Shir (1973), Snyder (1992), A&G (2008).

simple sentence (8b) which is the negated version of the S-complement in (8a).

(8) a. [NP1] didn't [V1] [that] [NP2] [V2+Appropriate NP]
e.g., Susan didn't know that Anthony liked the cake.
b. [NP2] didn't [V2+Appropriate NP]
e.g., Anthony didn't like the cake.

Participants were asked to rate how true they thought the second sentence was, given the first sentence, with a scale from 1 (false) to 5 (true). A&G proposed that these negation scores reflect how "backgrounded" the information in the S-complement is.

Results and Discussion:

A&G (2008) calculated the difference scores between the ratings of wh-questions and declarative clauses as the measurement for acceptability of those wh-questions, and they found a strong correlation between these difference scores and negation scores ($r=-0.83$, $p<0.001$; see Fig.2a). We applied the same analysis to our data. The obtained correlation in our data was in the same direction as in A&G (2008) but the effect was smaller both in the 12 verbs they tested ($r=-0.39$, $p=0.2$) and in the full set of 24 verbs ($r=-0.31$, $p=0.13$; see Fig.2b). Further, we found overlap between acceptabilities for factive and bridge verbs, contradicting the syntactic accounts, which predict non-overlapping acceptability between factive and bridge wh-questions given their distinct covert deep structures.

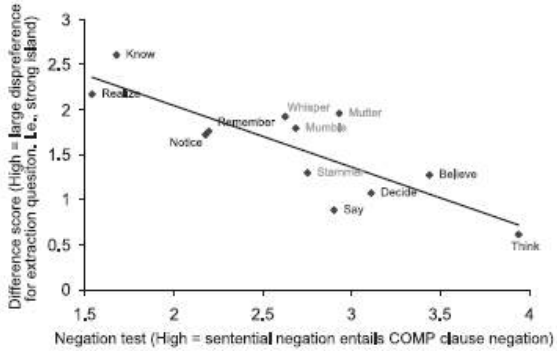

Figure 2a: A&G (2008) - correlation between mean difference scores and mean negation test scores by verb (12 verbs)

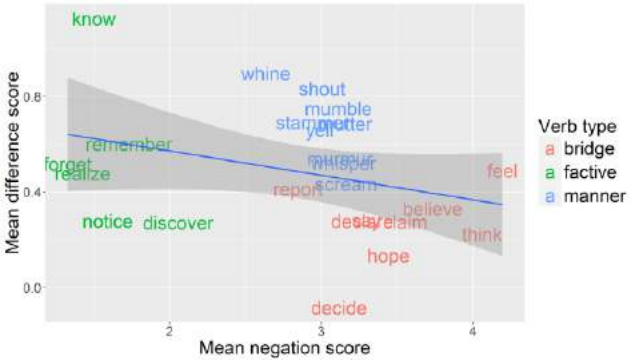

Figure 2b: Our study - correlation between mean difference scores and mean negation test scores by verb (24 verbs).

In a post-hoc analysis, we collected the frequency of the 24 verbs followed by the complementizer 'that' from the Google books corpus as a proxy for relative verb frame frequency. Acceptability ratings for wh-question forms were significantly correlated with verb frame frequency ($rho=0.72$, $p<0.001$), as plotted in Fig.3, as were the corresponding declaratives ($rho=0.76$, $p<0.001$). Furthermore, 74.6% of ratings were between 4/5 and 5/5 for both the wh-questions and declaratives of verbs, suggesting that participants were not using the full range of the scale.

Thus, we propose *the verb-frame frequency hypothesis*: the acceptability of an utterance is best captured by 2 independent, separate effects: (i) the frequency of the type of construction (e.g., wh-questions vs. declaratives) and (ii) the frequency of the verb head-structure- the frequency of the matrix verbs taking S-complements P(matrix verb, S-complement). This hypothesis suggests the impact of verb frame frequency on filler-gap constructions should be similar to that on declaratives.

An outlier to this account is the verb 'know'. We hypothesize that the idiosyncratic behavior of 'know' was due to pragmatic factors in the wh-question: a question is a request for knowledge but a question with 'know' implies that the speaker already has the knowledge. We hypothesize that 'know' might not be an outlier in other extraction constructions whose meaning does include implicit knowledge of the interlocutor, such as clefts, which is tested in Exp3.

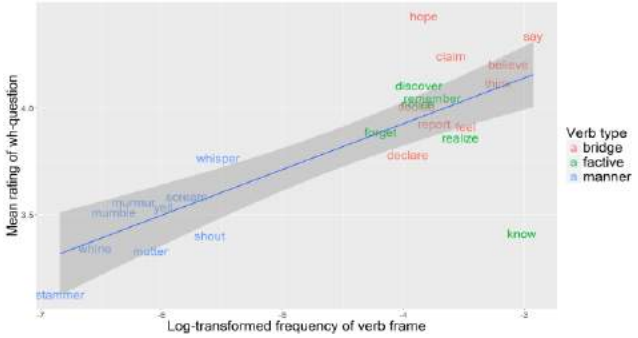

Figure 3: Correlation between mean ratings of wh-questions and log-transformed frequencies by verb ($rho=0.72$, $p<0.001$).

Experiment 2: Wh-questions with 48 Verbs

The goal of this experiment was to test the frequency account with more matrix verbs beyond the 3 categories (bridge, factive, manner-of-speaking). The *verb-frame frequency hypothesis* predicts that the verbs that frequently take S-complements would be more acceptable as wh-questions and declaratives, regardless of the verb category. The syntactic accounts make no predictions for verbs outside the 3 categories.

Given that the 5-point scale does not seem to be appropriate for measuring the acceptability of these sentences, we performed a forced-choice binary acceptability judgment task in this experiment and applied mixed-effects logistic regression to the data.

Methods:

Participants:120 people participated via MTurk, and each was paid $2. Responses from 110 participants were included in the analysis.

Design and Materials: The design was similar to Experiment 1a, with 48 verbs. The verbs included 8 for each of the 3 categories and another 24 outside the 3 categories, as listed in (9). The 24 'other' type verbs were not clearly categorized in the previous literature.

(9) **Matrix verbs**:

Bridge (8): feel, say, believe, hope, think, report, declare, claim,

Factive (8): know, remember, realize, notice, discover, forget, learn, hate

Manner (8): whisper, mumble, murmur, mutter, whine, shout, yell, scream

Other (24): hear, recall, blab, conjecture, conceal, proclaim, hint, remark, infer, confirm, deny, guess, confide, maintain, testify, reveal, suspect, verify, prove, insist, guarantee, presume, hypothesize, complain

Wh-questions and declaratives were constructed for the 48 matrix verbs with 6 items for each verb (288 items in total). The design of the items is the same as Experiment 1a.

As in Expt 1, participants were assigned to 1 of 2 lists made up of 3 declaratives and 3 wh-questions for each of the 48 verbs. Each participant saw 288 sentences in a random order. Participants were asked to rate each sentence using a binary scale (acceptable vs. unacceptable) based on how natural they thought the sentence was. Each sentence was also followed by a comprehension question.

Results and Discussion:

Acceptability judgments were analyzed with a mixed-effects logistic regression using the *lme4* package in *R. Sentence type (declarative vs. wh-question)*, *log-transformed frequency of the verb frame* and their interaction were entered as predictors. The model was fit with the maximum random effect structure which contained random by-*subject* and by-*verb* intercepts as well as slopes for *sentence type*frequency* by-subjects and slopes for *sentence type* by-verb.

The results were in line with the *verb-frame frequency hypothesis*. Wh-questions and declaratives formed by verbs that frequently take S-complements were significantly more acceptable (β=0.58, z=3.98, p<0.001). There was also a significant main effect of sentence type: declaratives were rated more acceptable than wh-questions (β=-3.27, z=-2.924, p<0.004). No interaction was found (p>0.4), suggesting no island effect was present. The log-odds of an 'acceptable' response for a given verb frame frequency are plotted in Fig.4a. Note that an island theory would predict the effect of frequency would have a steeper slope for wh-questions than declaratives, but Fig.4a shows the opposite (non-significantly). A pattern resembling a spurious interaction ('island' effect) shows up when log-odds are converted into probabilities of acceptance, as shown in Fig.4b.

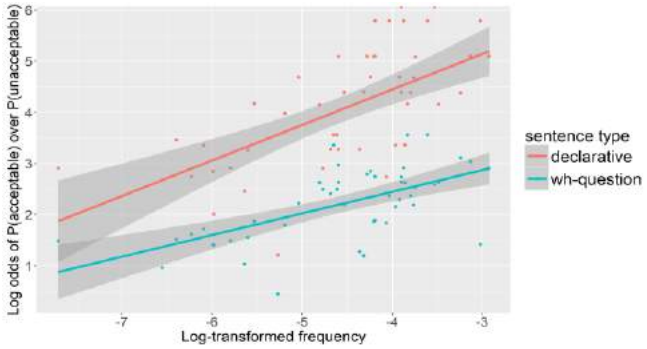

Figure 4a: Log-odds of 'acceptable' response for wh-questions and declarative clauses against log-transformed frequencies by verb (48 verbs).

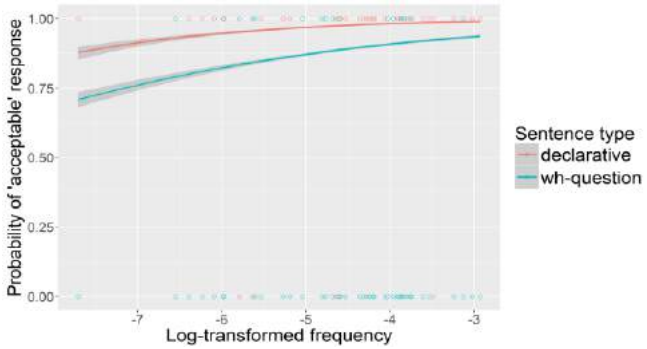

Figure 4b: Probability of 'acceptable' response for wh-questions and declaratives against log-transformed frequencies by verb (48 verbs)

Experiment 3: Cleft Structure

Experiment 3 aims to further test the *verb-frame frequency hypothesis* and check if 'know' is always idiosyncratic in filler-gap constructions with respect to the frequency account. The syntax-based theories claimed that extractions obey the same set of constraints regardless of construction, which indicates extraction difficulties across different verbs should be the same across constructions (e.g., in wh-

questions and cleft structures). However, an alternative is that the unusual behavior of 'know' in Experiment 1 might be related to the 'information-obtaining' function of wh-questions. If so, then 'know' should not be an outlier in cleft structures, because cleft structures are modifications of an NP and not associated with 'knowing'. We thus propose that, beyond verb frame frequency, extraction difficulties may differ depending on the meaning and function of the specific construction (Abeillé et al., 2018).

Methods:

Participants: Data from 120 participants were collected via MTurk, and each was paid $2. Responses from 104 participants were analyzed.

Design and Materials: Cleft structures and their corresponding declarative sentences were designed as in (10a) and (10b) respectively. 96 pairs of clefts and declaratives were constructed, and each of the 24 tested verbs in (6) formed 4 pairs as in Exp 1a. Participants were asked to rate each sentence with a binary rating scale. Each sentence was followed by a comprehension question.

(10) a. It was the pie that Angela mumbled that Kevin liked
b. Angela mumbled that Kevin liked the pie.

Results and Discussion:

Acceptability responses were analyzed in the same way as in Exp 2. Sentences with higher frequency verb frames were significantly more acceptable (β=1.2, z=2.7, p<0.01) and cleft structures were less likely to be acceptable (β=-14.6, z= 2.5, p<0.011). The interaction of sentence type and frequency was not significant (β=-0.87, z=-0.9, p=0.34), thus providing no evidence of an island effect (Fig. 5). These data are best explained by positing that verb frame frequency and extraction have independent, additive effects in log-odds space, as predicted by the *verb-frame frequency hypothesis*.

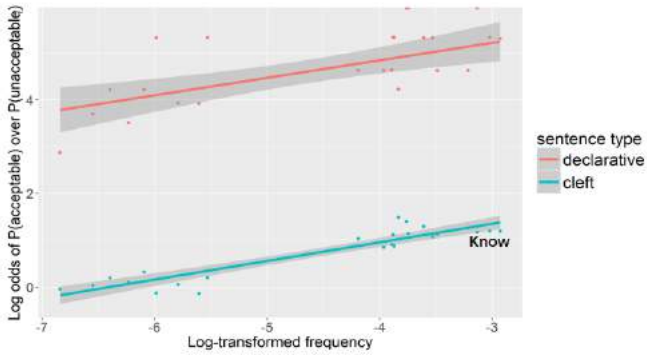

Figure 5: Log-odds of 'acceptable' response for clefts and declaratives against log-transformed frequencies (24 verbs)

As predicted by the meaning-based approach to long-distance dependency acceptability, 'know' is not an outlier for the frequency account in the cleft structure. The idiosyncratic behavior of 'know' seems to have been due to pragmatic factors in the wh-question: a question is a request for knowledge but a question with 'know' implies that the speaker already has the knowledge. If the long-distance dependency structure does not involve the meaning of '*know*' (as in clefts), then extraction out of S-complements of '*know*' is acceptable. Such distinct behaviors of 'know' in wh-questions and cleft structures suggest extractions vary across constructions, due to their meaning differences.

General Discussion

The results of all three experiments show that the amount of exposure is a key determining factor for the acceptability of filler-gap constructions formed by various SC verbs, including factive and manner-of-speaking verbs. The apparent interaction ('island' effect) may be a false positive caused by the use of linear models with ordinal acceptability ratings.

Interestingly, we also found that island constraints are not the same across constructions. Though different extractions may share similar cognitive processes, variation across constructions does exist and can be attributed to different meanings or functions associated with those different types of extractions. Though we didn't find strong evidence for the discourse-based accounts in the phenomena investigated here, frequency and discourse accounts are not necessarily mutually exclusive in capturing filler-gap constructions (and other phenomena) in general (Abeillé et al., 2018).

Our results suggest that (un)acceptable filler-gap constructions could potentially be learnable via exposure. Although direct negative evidence is missing especially for such complex structures, it is likely that children could use indirect negative evidence to acquire long-distance dependencies. Children may draw statistical inference from the input and regard the absence of a type of extraction in the input as evidence of its unacceptability or ungrammaticality.

Unflinching Predictions: Anticipatory Crossmodal Interactions are Unaffected by the Current Hand Posture

Abstract

According to theories of anticipatory behavior control, action planning and control is realized by activating desired goal states. From an event-predictive perspective, this activation should focus sensorimotor processing on expected, upcoming event boundaries. Previous studies have shown that peripersonal hand space (PPHS) is remapped to the future hand location in a grasping task before the movement commences. Here, we investigated if the current hand posture interferes with the anticipatory remapping of PPHS. Participants had to grasp virtual bottles from two differently oriented starting postures. During the prehension, they received a vibrotactile stimulus on their right index finger or on their thumb, while a visual stimulus appeared at the bottle, either matching the future finger position, or not. Participants had to name the stimulated finger. While the hand posture affected verbal response times, the anticipatory remapping remained unchanged. Apparently, the predictive processes that realize the anticipatory remapping, generalize over initial hand postures.
Keywords: Event Predictive Cognition; Anticipatory Behavioral Control; Peripersonal Space; Virtual Reality

Introduction

According to theories of anticipatory behavior control, the initiation of goal-directed actions requires the activation of event-predictive structures or *schemata* (EPSs; e.g. Butz, 2016; Butz & Kutter, 2017; Hommel, Müsseler, Aschersleben, & Prinz, 2001; Hoffmann, 2003; Zacks, Speer, Swallow, Braver, & Reynolds, 2007; Richmond & Zacks, 2017). These EPSs are considered to encode the final outcome of an action, but also the sensorimotor changes that usually unfold during an action, as well as the situational pre-conditions of successful action execution. In relation to free-energy based theories of cognition (Friston, 2009), EPSs are assumed to be involved in the more general active inference process that realizes action planning, decision making, and control (Butz, 2016). This perspective is closely related to the *ideomotor principle* (Greenwald, 1970) from cognitive psychology and essentially states that anticipated final outcomes and sensorimotor dynamics are activated before actual goal-directed motion takes place.

Empirical evidence for the assumed active inference process comes from eye-tracking studies, showing that the fixation pattern on a grasping target depends on the interaction goal (Belardinelli, Stepper, & Butz, 2016). Apparently, visual processing was tuned to those spatial locations which were critical for a successful object interaction. Considering the multisensory information, which is expected to be represented in EPSs, predictive processing should not be limited to eye-movements, but should also involve other action relevant representations. One example fur such representations are spatial body representations, like the peripersonal hand space (PPHS). PPHS seems crucial for successful object interactions and tool-use (Graziano & Cooke, 2006) . PPHS has also been found to be highly flexible in adapting to interaction possibilities (Holmes, 2012). Furthermore, PPHS enforces multisensory processing (Holmes & Spence, 2004; Bernasconi et al., 2018). According to the outlined theory, one would expect that PPHS is involved in predictive processing and might be remapped towards the grasping target during action planning. If this is the case, typical PPHS-related effects should be observed at the grasping target before the actual hand arrives. One typical indicator of PPHS is the selective interaction between vision and touch, which can be assessed by means of the crossmodal congruency paradigm (Spence, Pavani, Maravita, & Holmes, 2004).

In crossmodal congruency tasks, participants have to indicate the position of a tactile stimulation. Task-irrelevant visual stimuli occurring close to the stimulated body part can interfere with tactile perception. For instance, participants are slower to identify whether thumb or index finger received a tactile stimulation, if a LED is flashed at the non-stimulated finger (incongruent), whereas a flash at the location of the stimulated finger prompts a faster response (congruent). Previous studies indeed showed that interference between vision and touch can occur in object interaction tasks at the target object location even before movement initiation (Brozzoli, Pavani, Urquizar, Cardinali, & Farnè, 2009; Brozzoli, Cardinali, Pavani, & Farnè, 2010). This implies an anticipatory crossmodal congruency effect (aCCE), which can be used to investigate the anticipatory remapping of PPHS. In more recent studies (Belardinelli, Lohmann, Farnè, & Butz, 2018; Lohmann, Belardinelli, & Butz, 2019; Patané et al., 2018), it was shown that the aCCE can be observed on a trialwise basis without explicit instruction of a certain grasping type. These results imply that the aCCE indeed reflects an adaptive remapping due to action planning instead of a general shift in spatial attention. Apparently, PPHS is involved in the guidance of goal-directed actions, by providing a mapping between the space that can be interacted with and the according actions (Bufacchi & Iannetti, 2018).

While these results imply that PPHS is engaged in predic-

tive processing, some aspects of this mechanism remain illusive. For instance in the studies of Belardinelli et al. (2018) and Lohmann et al. (2019), the orientation of the final grasp modulated the strength of the aCCE. In case of underhand grasps, the aCCE was smaller compared to overhand grasps. This might be due to the fact that underhand grasps are less frequent in object interactions, rendering the planning more difficult. However, since the initial hand posture in these experiments was closer to the overhand grasp, this effect could also imply that the assumed prediction process does not completely generalize over the initial hand posture. This would dovetail with previous results from research on motor imagery, especially on mental rotation, which showed a strong interaction between ongoing motor planning and the actual posture (Parsons, 1987; Qu, Wang, Zhong, & Ye, 2018). Hence, our main aim in the present study was to investigate whether the aCCE depends on a postural match between initial and future hand position. If the aCCE would be affected by variations in the initial posture, this would imply that the sensorimotor changes assumed to be encoded in EPSs are less general than expected. If not, this would corroborate further evidence for the assumption that the aCCE is indeed an indicator for a general movement planning mechanism.

We conducted a behavioral study to discern these alternatives. Participants performed a grasp-and-carry task in VR, interacting with a virtual bottle. At different times before and during the interaction, participants received a tactile stimulation at the thumb or index finger. Concurrently, a visual stimulus appeared at the left or right side of the bottle, either matching the future location of the stimulated finger, or not. Participants had to respond as fast as possible, by verbally naming the finger that was stimulated. A typical aCCE would be reflected by faster responses if the visual stimulus matched the future finger position. The starting position of the hand varied from trial to trial, participants had either to start from a more clockwise, or more counterclockwise rotated starting posture. The main question was whether aCCEs would be modulated by this trialwise variation of the hand orientation.

Method

Participants

Twenty-four students from the University of Tübingen participated in the experiment (ten females). Their age ranged from 19 to 26 years (M = 21.2, SD = 1.9). All but one participant were right-handed and all participants had normal or corrected-to-normal vision. Participants provided informed consent and received either course credit or a monetary compensation for their participation. Two participants had difficulties with the virtual grasping procedure and could not complete the experiment. The respective data were not considered in the analysis.

Apparatus

Participants were equipped with an Oculus Rift© DK2 stereoscopic head-mounted display (Oculus VR LLC, Menlo Park, California). Motion tracking of hand movements was realized with a Leap Motion© near-infrared sensor (Leap Motion Inc, San Francisco, California, SDK version 3.2.1). The Leap Motion© sensor provides positional information regarding the palm, wrist, and phalanges. This data can be used to render a hand model in VR. Participants responded verbally to the tactile stimulation. In order to so, participants were equipped with a headset. Speech recognition was implemented by means of the Microsoft Speech API 5.4. The whole experiment was implemented with the Unity® engine 2017.4.5f1 using the C# interface provided by the API. During the experiment, the scene was rendered in parallel on the Oculus Rift and a computer screen, such that the experimenter could observe and assist the participants.

Tactile stimulation was realized by means of two small (10 mm $\times$ 3.4 mm) shaftless vibration motors attached to the tip of the thumb and the index finger of the participants. The motors were controlled via an Arduino Uno microcontroller (Arduino S.R.L., Scarmagno, Italy) running custom C software. The microcontroller was connected to the computer via an USB port, which could be accessed by the Unity® program. The wiring diagram as well as additional information regarding the components can be found at the first author's webpage. [1]

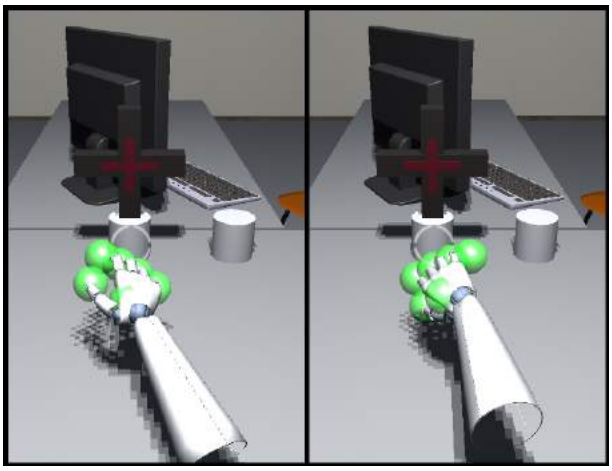

Figure 1: The VR scene with the clockwise oriented (left panel) and the counterclockwise oriented (right panel) starting postures. Participants had to grasp a bottle which appeared on the central pedestal and place it upright onto the right pedestal. The bottle could be either upright, or rotated.

Virtual Reality Setup

The VR setup put participants in an office-like room. Centered about 50 cm in front of them, a pedestal was placed, where, during the trials, the target object appeared. The target was always a 3D model of a plastic bottle either oriented upright or upside down. The bottle was 15 cm in height, sub-

[1] https://uni-tuebingen.de/de/26084

tending a visual angle of 17.1° at the initial location. A second pedestal, 15 cm to the right of the first one, served as the target location (see Fig. 1). The positions of the pedestals were marked with actual cardboard boxes providing haptic feedback regarding the bounds of the task space (participants were seated in a way that they had to stretch their arm to reach the pedestals). Instructions and feedback were presented in different text-fields, aligned at eye-height. At the beginning of a trial, a fixation cross appeared at the initial location of the target bottle (see Fig. 1). The fixation cross was 10 cm wide and 10 cm high, subtending a visual angle of 11.4°. The visual distractor was realized by means of a red, spherical flash with a diameter of 8 cm (equal to a visual angle of 8°) appearing at the left or right side of the bottle.

Procedure

At the beginning of the experiment, participants received a verbal instruction regarding the VR equipment. Then they were equipped with vibration motors and familiarized with the tactile stimulation. Participants were then seated comfortably on an arm chair and put on the HMD. Before the actual experiment, participants performed a grasping training and trained the verbal response until they felt comfortable with both tasks. In the grasp training, participants performed the grasp-and-carry task without receiving a tactile stimulation. Furthermore, participants could familiarize themselves with the two different starting positions. In the verbal response training, participants did not perform a grasping movement, but remained with their hand in the starting position.

The actual experiment combined both tasks in a dual-task paradigm. At the beginning of each trial, participants had to move their right hand into a designated starting position, consisting of red, transparent spheres indicating the required positions of the fingers and the palm. There were two possible variations of the starting position. One was tilted by 15° clockwise in the frontal plane, and one was tilted by 15° counterclockwise in the frontal plane. Accordingly, this required participants' to rotate their hands either clockwise or counterclockwise. The spheres turned green when the respective fingers were in position (see Fig. 1). Furthermore, participants had to maintain a stable looking direction on a fixation cross. Once both requirements were met for 1000 ms, the fixation cross as well as the visible markers of the initial position disappeared and a bottle appeared on the central pedestal. The bottle was either oriented upright, or upside down. Participants were instructed to grasp the bottle with a power grasp, and put it in an upright orientation within the target location. We did not explicitly instruct a underhand grasp in case of upside down bottles, however, all participants performed this kind of grasp. The initial hand postures were close to the respective grasping hand posture for the upright oriented bottle (clockwise hand posture), or the upside down bottle (counterclockwise hand posture).

Besides the grasp-and-carry task, participants had to discriminate which finger received a vibrotactile stimulation and to report the stimulated finger as fast as possible (by saying "index or "thumb, i.e., in German "Zeigefinger or "Daumen) upon vibration detection. The onset of the tactile stimulation varied from trial to trial. A visual distractor appeared at the same time at either the right or the left side of the bottle. Depending on the bottle orientation, this was expected to yield different congruent and incongruent conditions with respect to the aCCE (see Fig. 2).

The experiment consisted of 480 trials, presented in a single block. The experiment was self-paced and participants could pause between trials. The whole procedure took between 90 and 120 minutes, including preparation and training.

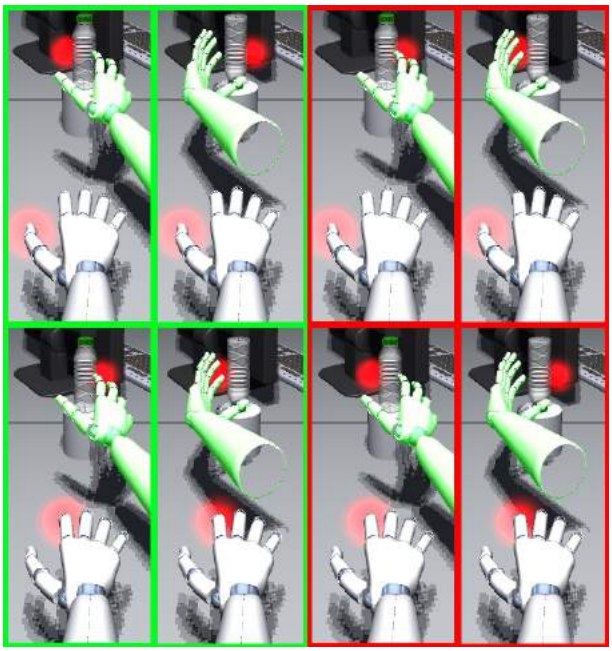

Figure 2: The different congruency conditions with respect to the future hand position (transparent green hand), depending on bottle orientation. The stimulated finger is indicated by a red flash, this was done for the sake of visibility, the participants received no visual cue regarding the tactile stimulation. Red frames indicate incongruent conditions, congruent conditions are marked with a green frame. Please note that the initial hand posture was different from the one shown in this image (cf. Fig 1), the flat hand posture here was used for the sake of visibility.

Factors, Measures, Data Treatment

We varied five factors across trials. First, the target bottle could be oriented upright or upside down (*orientation*). Second, the visual distractor could appear either on the left or the right side of the bottle (*distractor*). Third, the tactile stimulation could be applied either to the thumb or to the index finger (*stimulation*). Fourth, we varied the initial hand posture - clockwise or counterclockwise - which participants had to maintain to start the trial (*posture*). Fifth, we varied the on-

set of the tactile stimulation and the visual distractor (*SOA*): 250 ms after presentation of the bottle (SOA1), at movement onset (SOA2), or after the hand traveled half-way to the bottle (SOA3). We repeated the 2 (distractor) × 2 (stimulation) × 2 (orientation) × 2 (posture) × 3 (SOA) factor combinations ten times, yielding 480 trials. The primary dependent measure were the verbal response times for naming the stimulated finger. Data from error trials (wrong or no verbal response, 1.8% of the trials) were excluded from the response time analyses. Furthermore, we analyzed the error data using a mixed effects logistic regression.

Congruency

For our hypothesis, possible aCCE's were most relevant. aCCE's are reflected by three-way interactions between the factors orientation, distractor, and stimulation (cf. Fig. 2) . For instance, in the case of an upright bottle a tactile stimulation of the index finger along with a visual distractor on the right side of the bottle is congruent. To focus the analysis, we recoded the data accordingly and obtained a congruency factor, combining the visual distractor and tactile stimulus factor. For the response times, we report an analysis of the respective differences (incongruent - congruent) with a 2 (orientation) × 2 (posture) × 3 (SOA) ANOVA. In this analysis a significant, positive intercept would indicate a significant aCCE (faster responses in congruent as opposed to incongruent conditions).

Results

Verbal response times from the 22 considered participants were analyzed with a 2 (congruency) × 2 (orientation) × 2 (posture) × 3 (SOA) repeated measures ANOVA. Verbal response times differences between incongruent and congruent conditions were further analyzed with a 2 (orientation) × 2 (posture) × 3 (SOA) repeated measures ANOVA. Only correct trials were included in the RT analysis. All reported post-hoc comparisons were submitted to a Holm-Bonferroni correction. The analyses were carried out with R (R Core Team, 2016) and the `ez` package (Lawrence, 2015). In case of violations of the assumption of sphericity, p-values were submitted to a Greenhouse-Geisser adjustment. Error rates were analyzed with mixed effects logistic regression, using the `lme4` package (Bates, Mächler, Bolker, & Walker, 2015).

Verbal Response Times

The 2 (congruency) × 2 (orientation) × 2 (posture) × 3 (SOA) repeated measures ANOVA yielded significant main effects for orientation ($F(1,21) = 7.63$, $p = .012$, $\eta_p^2 = .27$), congruency ($F(1,21) = 32.57$, $p < .001$, $\eta_p^2 = .61$), and SOA ($F(1,21) = 28.04$, $p < .001$, $\eta_p^2 = .57$), as well as significant interactions between orientation and SOA ($F(2,42) = 8.74$, $p = .001$, $\eta_p^2 = .29$), orientation and posture ($F(1,21) = 5.54$, $p = .028$, $\eta_p^2 = .21$), orientation and congruency ($F(1,21) = 9.55$, $p = .006$, $\eta_p^2 = .31$), SOA and congruency ($F(2,42) = 10.39$, $p = .001$, $\eta_p^2 = .33$), as well as a three-way interaction for orientation, congruency, and SOA ($F(2,42) = 7.32$, $p = .002$, $\eta_p^2 = .26$; all remaining p's $\geq .168$).

Participants responded faster to upright bottles ($M_{upright}$ = 700 ms vs. $M_{rotated}$ = 713 ms), and in case of congruent stimulation ($M_{congruent}$ = 691 ms vs. $M_{incongruent}$ = 722 ms). Verbal RTs decreased with SOA (M_{SOA1} = 742 ms, M_{SOA2} = 710 ms, M_{SOA3} = 669 ms; all respective p's $<.001$). Regarding the interaction between orientation and SOA, participants responded faster to bottles oriented upright at SOA1 ($t(21) = 3.21$, $p = .016$) and SOA2 ($t(21) = 4.02$, $p = .004$), for SOA3, this difference was no longer significant ($t(21) = -0.54$, $p = .595$). Post-hoc analyses of the orientation × posture interaction showed that participants responded faster to upright than to upside down bottles when starting in a clockwise posture ($t(21) = 3.59$, $p = .010$). The respective difference was not significant for the counterclockwise posture. Furthermore, response times in case of upright bottles and a clockwise posture were significantly faster than response times in the other three conditions (all respective p's $<.04$).

To further analyze the interactions involving the congruency factor, we analyzed the RT differences between incongruent and congruent conditions with a 2 (orientation) × 2 (posture) × 3 (SOA) ANOVA. The analysis yielded a significant intercept ($F(1,21) = 47.00$, $p < .001$, $\eta_p^2 = .69$), significant main effects of SOA ($F(2,42) = 20.43$, $p < .001$, $\eta_p^2 = .49$) and orientation ($F(1,21) = 16.43$, $p = .001$, $\eta_p^2 = .44$), as well as a significant interaction between orientation and SOA ($F(2,42) = 9.20$, $p = .002$, $\eta_p^2 = .30$). No further main effects or interactions reached significance (remaining p's $\geq .230$).

The congruency effect was significantly larger at SOA3 compared to SOA1 and SOA2 (ΔM_{SOA1} = 17 ms, ΔM_{SOA2} = 20 ms, ΔM_{SOA3} = 60 ms; all respective p's $<.001$). For bottles presented upright, the congruency effect was larger than for upside down bottles ($\Delta M_{upright}$ = 54 ms vs. $\Delta M_{rotated}$ = 11 ms). Regarding the interaction between orientation and SOA, after adjusting for multiple comparisons, the only significant difference between upright and upside down bottles was found at SOA3 ($\Delta M_{upright}$ = 98 ms vs. $\Delta M_{rotated}$ = 23 ms; $t(21) = 4.60$, $p < .001$).

To further probe the significance of the aCCE, all of the 2 (orientation) ×2 (posture) × 3 (SOA) mean differences were tested against a true mean of 0. The results are shown in Fig. 3.

Error Rates

Both error and correct trials of all participants, except the trials without response (65 out of 10560 trials) were coded as 0 (error) or 1 (correct) and entered into a mixed effects logistic regression analysis with a binomial distribution. We compared models of increasing complexity with likelihood ratio tests to determine whether the factors orientation, posture, congruency, and SOA were required to account for the error pattern. We kept the error structure simple, applying only a random intercept per participant. After the identification of the null model, we added fixed effects for the ex-

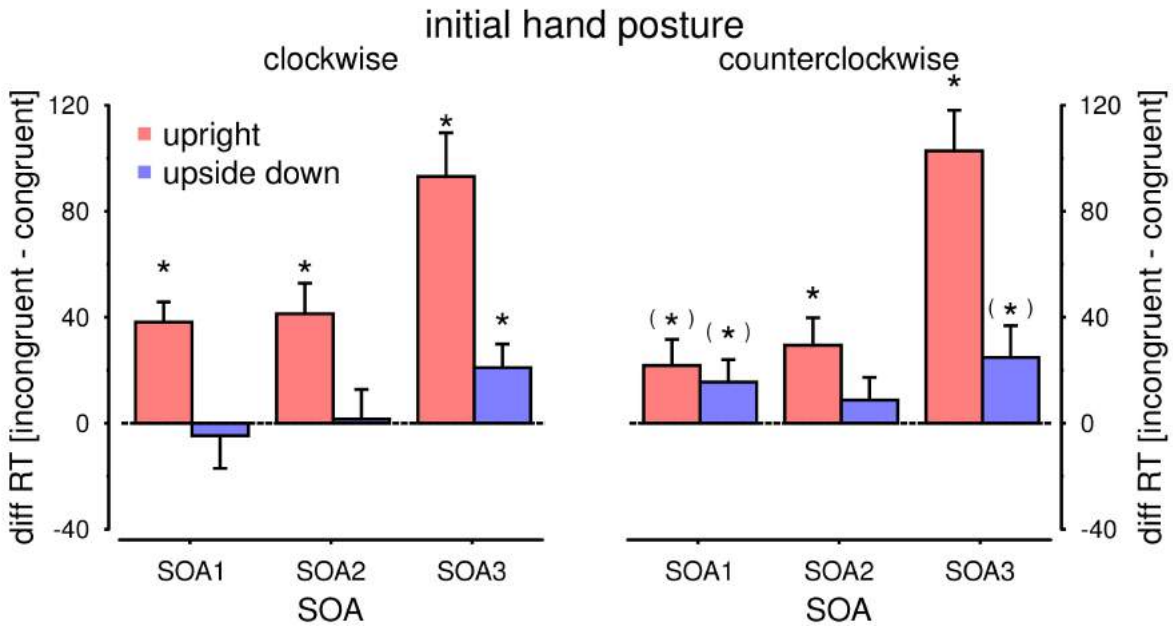

Figure 3: The aCCE – measured as the response time difference between congruent and incongruent trials – including its temporal dynamics and dependency on bottle orientation and initial hand posture. Significant differences from 0 are indicated with an asterisk. Asterisks in brackets indicate comparisons which failed significance after adjusting for multiple comparisons. Error bars indicate the standard error of the mean.

perimental factors to the model as long as the likelihood ratio test between the simpler and the more complex model yielded significant results (with α = .05). We only compared nested models differing with respect to one factor. Models with a single fixed effect were compared with the null model, models with two fixed effects were compared with models with one fixed effect and so on. The best fitting model involved fixed effects for the factors SOA, orientation and congruency, as well as the interaction between congruency and orientation (see Tab. 1, only significant effects are included)[2]. The error risk is increased by a factor of 3.4 in case of later SOAs compared to earlier ones. The error risk decreases by a factor of 0.28 in case of rotated compared to upright bottles. This pattern is further modified by the interaction between congruency and orientation. For upright bottles, the error risk increases in case of incongruent stimulation by a factor of 8.5, for upside down bottles, there is no difference in the error risk for congruent and incongruent stimulation.

Table 1: Effect estimates for the best fitting binomial mixed effects logistic regression model regarding the error rates ($df = 7, logLik = -803.3, BIC = 1671.4$). The logit estimates have been transformed to odds, only significant effects (α = .05) are shown. Z statistics for the Wald test and according p-values are presented in the last two columns.

fixed effect	**odds**	**95% CI**	**Z**	**p**
intercept	0.005	[0.002 , 0.009]	-15.91	$< .001$
SOA3	3.364	[2.295, 4.930]	6.22	$< .001$
orientation	0.288	[0.155, 0.534]	-3.95	$< .001$
orientation $\times$ congruency	8.540	[4.150, 17.574]	5.83	$< .001$

Discussion

We aimed at investigating the mechanism of anticipatory remapping of PPHS in advance of a prehension movement. In order to do so, we investigated anticipatory cross-modal congruency effects (aCCEs) during virtual grasping movements. Participants had to grasp virtual bottles with their right hand, while receiving a tactile stimulation on thumb or index finger of that hand along with a visual stimulation close to one of the future finger positions. The visual distractor could either match the future finger location or not. In line with earlier findings (Belardinelli et al., 2018; Brozzoli et al., 2009, 2010; Lohmann et al., 2019; Patané et al., 2018), we observed dynamic aCCEs, which were more pronounced at later SOAs. To probe whether the strength of the aCCE depends on the match between current and future hand posture, we varied the starting posture of the participants' hands from trial to trial. Participants started either with a clockwise (matching the grasp for an upright bottle), or counterclockwise (matching the grasp for a upside down bottle) posture. While we observed response time differences for the clockwise posture (faster responses for upright bottles, delayed responses for upside down bottles), the congruency effect itself remained unaffected by the initial hand posture. Also with respect to the

[2]Please note that the model assuming the three-way interaction between all factors provided a slightly better fit, however, the respective BIC was much larger than the one of the selected model.

error rates, the initial hand posture yielded no significant influence. A closer inspection of the response time differences for incongruent compared to congruent stimulation implied a small increase in the congruency effect for upside down bottles in case of the counterclockwise posture, while at the same time slightly decreasing the congruency effect for upright bottles. However, these effects seem too small to become significant with the applied sample size. In general, congruency effects were more pronounced for upright compared to upside down bottles (with respect to both RTs and errors). Since this was still the case for the counterclockwise posture, this difference seems not to be due to an initial mismatch between current and future hand position. It rather implies a planning advantage for canonical object orientations.

While the observed interaction between bottle orientation and hand posture dovetails with findings that the current body posture can indeed interfere with mental imagery processes (Parsons, 1987; Qu et al., 2018) and has a significant weighted impact on the actual chose hand grasp posture (Herbort & Butz, 2012), this modulation did not apply to the congruency effect itself. Apparently, the anticipatory control process that gives rise to the aCCE generalizes over the actual hand posture, remapping PPHS towards the future goal, irrespective of the current hand posture. In general, the reported results on the aCCE provide support for theories of probabilistic, event-oriented, active inference (Butz, 2016; Butz & Kutter, 2017): the results confirm that PPHS is adaptively remapped onto future event boundaries during the preparation and for the control of goal-directed behavior.

However, the understanding of the remapping mechanism requires further investigation. In our data, as well as in the results reported by Belardinelli et al. (2018), and Lohmann et al. (2019), the aCCE was much more pronounced for bottles presented upright. It seems that the remapping works more efficient in case of canonical object orientations. As it was pointed out by Bufacchi and Iannetti (2018), measures of PPHS like the aCCE are not only modulated by proximity, but by many other factors like learning, stimulus valence, and environmental characteristics. Hence, a modulation of the aCCE by familiarity seems plausible, but a systematic comparison between bottles and objects with a less pronounced canonical orientation is pending. Moreover, there is still much further light to be shed on the dynamics of this process and its dependency on event-predictive precision estimates. From the event-predictive, anticipatory behavioral control perspective, it can be expected that the future horizon will reach the deeper into the future, the more precise the predictive model estimates are expected to be. That is, the higher our confidence about the upcoming environmental events and sequences thereof, the more we will look ahead and act in a more versatile and flexible goal-directed manner.

Abstract

How do children's visual concepts change across childhood, and how might these changes be reflected in their drawings? Here we investigate developmental changes in children's ability to emphasize the relevant visual distinctions between object categories in their drawings. We collected over 13K drawings from children aged 2-10 years via a free-standing drawing station in a children's museum. We hypothesized that older children would produce more recognizable drawings, and that this gain in recognizability would not be entirely explained by concurrent development in visuomotor control. To measure recognizability, we applied a pretrained deep convolutional neural network model to extract a high-level feature representation of all drawings, and then trained a multi-way linear classifier on these features. To measure visuomotor control, we developed an automated procedure to measure their ability to accurately trace complex shapes. We found consistent gains in the recognizability of drawings across ages that were not fully explained by children's ability to accurately trace complex shapes. Furthermore, these gains were accompanied by an increase in how distinct different object categories were in feature space. Overall, these results demonstrate that children's drawings include more distinctive visual features as they grow older.

Keywords: object representations; child development; visual production; deep neural networks

Introduction

Children draw prolifically, providing a rich source of potential insight into their emerging understanding of the world (Kellogg, 1969). Accordingly, drawings have been used to probe developmental change in a wide variety of domains (Fury, Carlson, & Sroufe, 1997; Karmiloff-Smith, 1990; e.g., Piaget, 1929). In particular, drawings have long provided inspiration for scientists investigating how children represent visual concepts (Minsky & Papert, 1972). For example, even when drawing from observation, children tend to include features that are not visible from their vantage point, yet are diagnostic of category membership (e.g., a handle on a mug) (Barrett & Light, 1976; Bremner & Moore, 1984).

As children learn the diagnostic properties of objects and how to recognize them, they may express this knowledge in their drawings of these categories. Indeed, children's visual recognition abilities have a protracted developmental trajectory: configural visual processing—the ability to process relationships between object parts (Juttner, Muller, & Rentschler, 2006; Juttner, Wakui, Petters, & Davidoff, 2016)—may mature slowly throughout childhood, as does the ability to recognize objects under unusual poses or lighting (Bova et al., 2007).

Inspired by this prior work, our goal is to understand the relationship between developmental changes in how children draw visual concepts and their representations of these visual concepts. In particular, we hypothesize that children's drawings become more recognizable in part because children learn the distinctive features of categories that set them apart from other similar categories (Figure 1). If so, we would expect an increase in the distinctiveness of children's drawings across childhood that is not explained by improvements in children's visuomotor ability. However, this goal poses several methodological challenges to overcome.

First, it requires a principled and generalizable approach to encoding the high-level visual properties of drawings that expose the extent to which they contain category-diagnostic information (Fan, Yamins, & Turk-Browne, 2018). This approach stands in contrast to previous approaches, which have relied upon provisional criteria specific to each study (e.g., handles for mugs) (e.g., Barrett & Light, 1976; Goodenough, 1963), which limited their ability to make detailed predictions on new tasks or datasets. Recently, deep convolutional neural network (DCNN) models that have been trained on challenging object recognition tasks have been shown to extract high-level visual information from images (Yamins et al., 2014). As these models have been directly optimized to recognize objects in photographs, features in higher layers of these networks represent high-level visual information that is important for distinguishing between object categories. We thus meet this challenge by capitalizing on prior work validating the use of these higher-layer features to analyze the high-level visual information in drawings (Fan et al., 2018; Long, Fan, & Frank, 2018). In particular, we investigate the extent to which children include distinctive features in their drawings by assessing how well these visual features can be used to identify the category (e.g., dog, bird) that children were intending to draw.

Second, it requires a large sample of drawings collected under consistent conditions from a wide range of participants to identify robust developmental patterns (e.g., M. Frank et al., 2017). This is in contrast to the relatively small samples that have characterized classic studies in this domain (Bremner & Moore, 1984; Karmiloff-Smith, 1990). To meet this challenge, we installed a free-standing drawing station in a local science museum, allowing us to collect a large sample of drawings (N = 13205 drawings) of 23 object categories

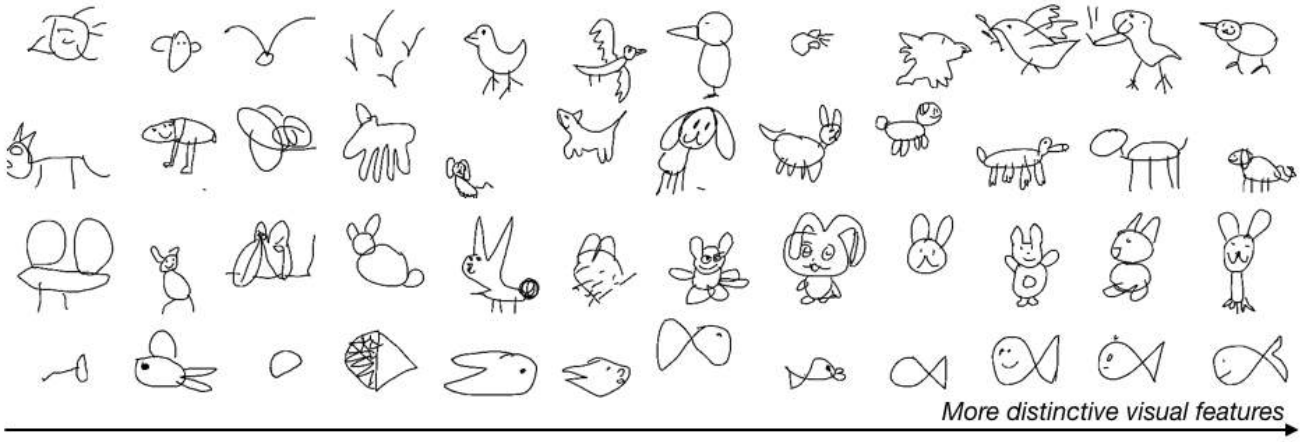

Figure 1: Examples of drawings that have increasingly more distinctive visual features of their categories, making them more easily recognizable. These examples are generated from the results of the classification process outlined below.

over a wide developmental age range (i.e., 2-10 years) under consistent task conditions.

Third, it requires simultaneous and detailed measurement of developmental changes in other cognitive and motor abilities that may influence children's ability to include relevant information in their drawing (Freeman, 1987; Rehrig & Stromswold, 2018). For example, children's developing visuomotor abilities may limit their ability to include the diagnostic visual features in their drawings. In this paper, we focus on visuomotor control, operationalized as performance on shape tracing tasks, because they share many of the same demands on controlled, visually-guided movement with our primary object drawing task. Critically, because we collected both tracings and drawings from every participant in our dataset, we are able to model the contribution of both individual and age-related variation in tracing task performance for explaining how well children produce recognizable drawings.

In sum, our paper provides an advance over our prior work investigating developmental change in drawing behavior (Long et al., 2018) in three ways: first, we build a free-standing drawing station to continually crowdsource children's drawings under consistent conditions, enabling the collection of a substantially larger dataset; second, we exploit this larger dataset to characterize the category-level distinctiveness inherent to children's drawings across a wide range of ages; and third, we develop an automated procedure for analyzing concurrent changes in visuomotor control using a tracing task.

Methods

Dataset

Drawing Station We installed a drawing station that featured a tablet-based drawing game in a local science museum. Each participant sat in front of a table-mounted touchscreen tablet and drew by moving the tip of their finger across the display. Participants gave consent and indicated their age (in years 2-10 or adult) via checkboxes and no other identifying information was collected; our assumption was that parents would navigate this initial screen for children. To measure fine visuomotor control, each session began with two tracing trials, followed by a copying trial. On each tracing trial, participants were presented with a shape in the center of the display. The first shape was a simple square, and the second was a more complex star-like shape (Figure 2). On the subsequent copying trial, participants were presented with a simple shape (square or circle) in the center of the display for 2s, which then disappeared. They then were asked to copy the shape in the same location it had initially appeared. Next, participants completed up to eight object drawing trials. On each of these trials, participants were verbally cued to draw a particular object category by a video recording of an experimenter (e.g., "What about a dog? Can you draw a dog?"). On all trials, participants had up to 30 seconds to complete their tracing, copy, or drawing. There are 23 common object categories represented in our dataset, which were collected across three bouts of data collection focused on 8 of these objects at a time. These categories were chosen to be familiar to children, to cover a wide range of superordinate categories (e.g., animals, vehicles, manipulable objects), and to vary in the degree to which they are commonly drawn by young children (e.g., trees vs. keys).

Dataset Filtering & Descriptives Given that we could not easily monitor all environmental variables at the drawing station that could impact task engagement (e.g., ambient noise, distraction from other museum visitors), we anticipated the need to develop robust and consistent procedures for data quality assurance. We thus adopted strict screening procedures to ensure that any age-related trends we observed were not due to differences in task compliance across age. Early on, we noticed an unusual degree of sophistication in 2-year-

old participants' drawings and suspected that adult caregivers accompanying these children may not have complied with task instructions to let children draw on their own. Thus, in later versions of the drawing game, we surveyed participants to find out whether another child or an adult had also drawn during the session; all drawings where interference was reported were excluded from analyses. Out of these 2685 participants, 700 filled out the survey, and 156 reported interference from another child or adult (5.81%). Raw drawing data (N = 15594 drawings) were then screened for task compliance using a combination of manual and automated procedures (i.e., excluding blank drawings, pure scribbles, and drawings containing words), resulting in the exclusion of 15.3% of all drawings (N = 13205 drawings after exclusions). After filtering, we analyzed data from 2443 children who were on average 5.28 years of age (range 2-10 years).

Measuring Tracing Accuracy

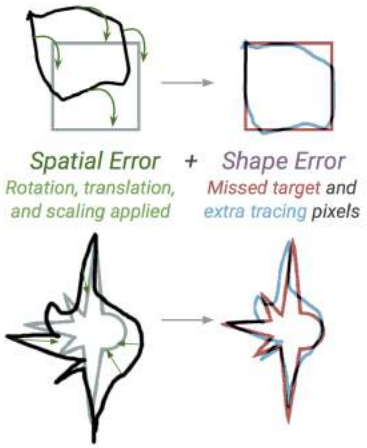

Figure 2: Measurement of tracing task performance reflects both spatial and shape error components. Left: The grey shape is the target; the black shape is the raw tracing. After applying affine image registration, the spatial error reflects the extent of translation, rotation, and scaling transformation required to minimize shape error. Right: Shape error reflects how closely the contour of the transformed tracing aligns with the target.

We developed an automated procedure for evaluating how accurately participants performed the tracing task, validated against empirical judgments of tracing quality. We decompose tracing accuracy into two components: a shape error component and a spatial error component. Shape error reflects how closely the participant's tracing matched the contours of the target shape; the spatial error reflects how closely the location, size, and orientation of the participant's tracing matched the target shape (Figure 2).

To compute these error components, we applied an image registration algorithm, AirLab (Sandkhler, Jud, Andermatt, & Cattin, 2018), to align each tracing to the target shape, yielding an affine transformation matrix that minimized the pixel-wise correlation distance between the aligned tracing, T, and the target shape, S: $Loss_{NCC} = -\frac{\sum S \cdot T - \sum E(S)E(T)}{N \sum Var(S)Var(T)}$, where N is the number of pixels in both images.

The shape error was defined by the final correlation distance between the aligned tracing and the target shape. The spatial error was defined by the magnitude of three distinct error terms: location, orientation, and size error, derived by decomposing the affine transformation matrix above into translation, rotation, and scaling components, respectively. In sum, this procedure yielded four error values for each tracing: one value representing the shape error (i.e., the pixel-wise correlation distance) and three values representing the spatial error (i.e., magnitude of translation, rotation, scaling components).

Although we assumed that both shape and spatial error terms should contribute to our measure of tracing task performance, we did not know how much weight to assign to each component to best predict empirical judgments of tracing quality. In order to estimate these weights, we collected quality ratings from adult observers (N=70) for 1325 tracings (i.e., 50-80 tracings per shape per age), each of which was rated 1-5 times. Raters were instructed to evaluate "how well the tracing matches the target shape and is aligned to the position of the target shape" on a 5-point scale.

We fit an ordinal regression mixed-effects model to predict these 5-point ratings, which contained correlation distance, translation, rotation, scaling, and shape identity (square vs. star) as predictors, with random intercepts for rater. This model yielded parameter estimates that could then be used to score each tracing in the remainder of the dataset (N=3242 tracings from 1886 children). We averaged scores within session to yield a single tracing score for each participant (2245 children completed at least one tracing trial).

Measuring Object Drawing Recognizability

We also developed an automated procedure for evaluating how well participants included category-diagnostic information in their drawings by examining classification performance on the features extracted by a deep convolutional neural network model.

Visual Encoder To encode the high-level visual features of each sketch, we used the VGG-19 architecture (Simonyan & Zisserman, 2014), a deep convolutional neural network pretrained on Imagenet classification. We used model activations in the second-to-last layer of this network, which contain more explicit representations of object identity than earlier layers (Fan et al., 2018; Long et al., 2018; Yamins et al., 2014). Raw feature representations in this layer consist of flat 4096-dimensional vectors, to which we applied channel-wise normalization.

Logistic Regression Classifier Next, we used these features to train an object category decoder. To avoid any bias due to imbalance in the distribution of drawings over cate-

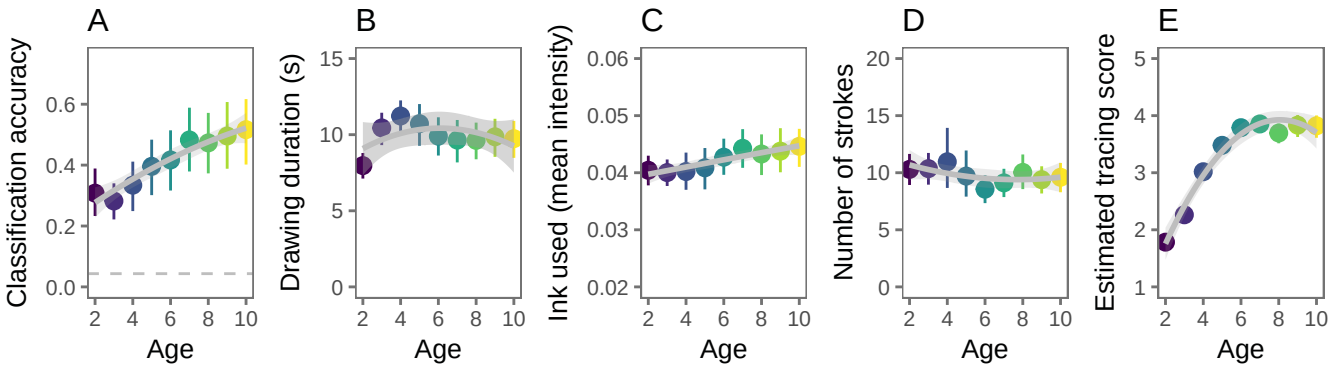

Figure 3: (A) Leave-one-out classification accuracy (grey dotted line indicates chance) (B) the amount of time spent drawing in seconds, (C) the amount of ink used (i.e., mean intensity of the drawings), (D) the number of strokes used, and (E) the average estimated tracing scores are plotted as a function of childrens age.

gories (since groups of categories ran at the station for different times), we sampled such that there were an equal number of drawings of each of the 23 categories (N=8694 drawings total). We then trained a 23-way logistic classifier with L2 regularization under leave-one-out cross-validation to estimate the recognizability of every drawing in our dataset.

Predicting Object Drawing Recognizability If children's drawings contain more features that are diagnostic of the drawn categories, then these visual features (estimated via VGG-19) should lead to greater classification accuracy. However, we anticipated that classification accuracy may also vary with children's tracing abilities as well how much time and effort children invested in their drawings; we thus recorded how much time was taken to produce each drawing, how many strokes were drawn, and the proportion of the drawing canvas that was filled. Our main statistical model was then a generalized linear mixed-effects model predicting classification accuracy from the category decoder, with scaled age (in years), tracing score (averaged over both trials), and effort cost variables (i.e., time, strokes, ink) modeled as fixed effects, and with random intercepts for each child and object category.

Measuring Category Distinctiveness To investigate changes in the underlying feature representation of children's drawings that may help explain variation in classification accuracy, we computed a measure of pairwise category distinctiveness D_{ij} for each pair of categories i, j within each age. This metric is a higher-dimensional analog of d-prime that incorporates both the distance between each pair of categories as well as the dispersion within each category. We first computed the category centers as the mean feature vector for each category, $\vec{r}_i$ and $\vec{r}_j$. The distance between each pair of categories i, j was then taken as the Euclidean distance between their category centers, $\|\vec{r}_i - \vec{r}_j\|_2$. The dispersion for each category was computed as the root-mean-squared Euclidean distance of each individual drawing vector from the category center vector $\vec{r}$ and is expressed as s. By direct analogy with d-prime, we compute the distinctiveness D_{ij} of each pair of categories i, j by dividing the Euclidean distance between category centers by the quadratic mean of the two category dispersions, $D_{ij} = \frac{\|\vec{r}_i - \vec{r}_j\|_2}{\sqrt{\frac{1}{2}(s_i^2 + s_j^2)}}$.

Results

Overall, drawing classification accuracy increased with age (Figure 3A), validating our basic expectation that older children's drawings would be more recognizable. Our mixed-effects model on drawing classification revealed that this age-related gain held when accounting for task covariates—the amount of time spent drawing, the number of strokes, and total ink used (Figure 3B,C,D)—and for variation across object categories and individual children. All model coefficients can be found in Table 1.

	Estimate	Std. Error	z value	Pr(>|z|)
(Intercept)	-0.714	0.274	-2.606	0.009
Tracing	0.311	0.034	9.141	0.000
Age	0.282	0.033	8.499	0.000
Draw Duration	0.136	0.034	3.976	0.000
Avg Intensity	-0.064	0.033	-1.910	0.056
Num. Strokes	-0.034	0.034	-1.009	0.313
Tracing*Age	0.011	0.029	0.357	0.721

Table 1: Model coefficients of a GLMM predicting the recognziability of each drawing

We next examined the relationship between children's ability to trace complex shapes and the subsequent recognizability of their drawings. Tracing abilities increased with age (Figure 3E) and individual's tracing abilities were good predictors of the recognizability of the drawings they produced. This main effect of tracing ability also held when accounting for effort covariates (number of strokes, time spent drawing, ink used). However, children's tracing abilities did not interact with the age-related gains in classification we observed (Figure 4) and we observed age-related classification gains at each level of tracing ability.

To examine the contributions of age and tracing ability to

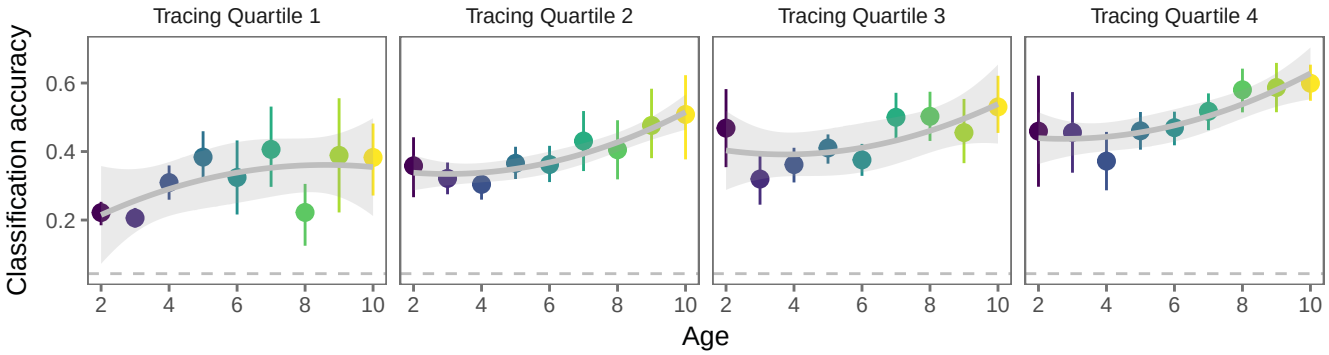

Figure 4: Data are divided into four quantiles based on the distribution of tracing scores in the entire dataset; these divisions represent the data in each panel. In each panel, the average classification accuracy is plotted as a function of childrens age. Error bars represent 95% CIs bootstrapped within each age group and subset of tracing scores; grey dotted lines indicate chance.

recognizability, we also fit reduced versions of the full model and examined the marginal R^2 (Nakagawa & Schielzeth, 2013). The fixed effects in a null model without tracing or age (which mainly captures drawing effort) accounted for very little variance (marginal R^2 = 0.004). Adding only children's age to the model increased R^2 (marginal R^2 = 0.037) as did only adding tracing (marginal R^2 = 0.039). Adding both factors without their interaction (marginal R^2 = 0.05) had a similar effect to adding both factors and their interaction (marginal R^2 = 0.05). Attesting to the immense variability between individuals and categories, adding random effects (and many more parameters) accounted for a much larger amount of variance (conditional R^2 for full model = 0.403). Finally, as we had many more younger participants in our dataset, we also repeated these analyses with a subset of the dataset that was balanced across both children's age and category (N=2691 drawings), and found the same pattern of results.

These age-related changes in classification accuracy show that the underlying feature representations of older children's drawings were more linearly discriminable. This finding led us to investigate a potential source of this enhanced discriminability: that drawings from different categories were spread further apart in feature space, while drawings within a category were clustered closer together. To evaluate this possibility, we used a measure of pairwise category distinctiveness D_{ij} that accounts for both the distance between each pair of categories, as well as the dispersion within each category. We found that category distinctiveness increased consistently with age (Figure 5).

Taken together, these results reveal developmental changes in how well children are able to emphasize the relevant distinctions between object categories in their drawings that thereby support recognition. Moreover, they show that these age-related gains in classification are not entirely explained by concurrent development in visuomotor control.

General Discussion

How do children represent different object categories throughout childhood? Drawings are a rich potential source of information about how visual representations change over development. One possibility is that older children's drawings are more recognizable because children are better able to include the diagnostic features of particular categories that distinguish them from other similar objects. Supporting this hypothesis, the high-level visual features present in children's drawings could be used to estimate the category children were intending to draw, and these classifications became more accurate as children became older. These age-related gains in classification were not entirely explainable by either low-level effort covariates (e.g., amount of time spent drawing, average intensity, or number of strokes) or children's tracing abilities. In addition, these gains in classification were paralleled by an increase in the distinctiveness between the categories that children drew (Figure 5).

Taken together, these results suggest that children's drawings contain more distinctive features as they grow older, perhaps reflecting a change in their internal representations of these categories. While children could simply be learning routines to draw certain categories—perhaps from direct instruction or observation, our results held even when restricted to a subset of very rarely drawn categories (e.g., couch, scissors, key) arguing against a simple version of this idea.

Nonetheless, there are limitations on the generalizability of these findings due to the nature of our dataset. First, while this dataset is large and samples a heterogenous population, all drawings were collected at a single geographical location, limiting the generalizability of these results to children from other diverse cultural or socioeconomic backgrounds. Second, while we imposed strong filtering requirements on the dataset, we were not present while the children were drawing and thus cannot be sure that we've eliminated all sources of noise or interference. At the same time, additional interference would only generate extra noise in our data rather than the observed age-related trends. In any case, these correlational results call for validation in more carefully controlled

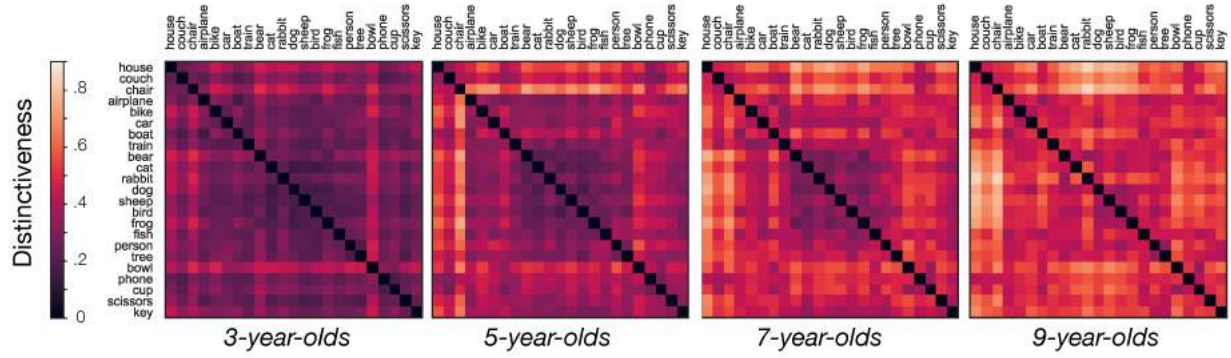

Figure 5: Pairwise category distinctiveness for drawings made by 3-, 5-, 7-,and 9-year-olds; darker (vs. lighter) values represent pairs of categories that have more overlapping (vs. distinctive) representations.

contexts and across more diverse populations.

Furthermore, they open the door for future empirical work to establish causal links between children's drawing behavior and their changing internal representation of visual concepts. For example, it would be valuable to explore the extent to which a child's ability to include the most distinctive visual features in their drawings of object categories predicts their ability to perceptually discriminate those object categories. Another promising direction would be to investigate the relationship between children's general ability to retrieve relevant information from semantic memory (e.g., that a rabbit has long ears and whiskers), and their ability to produce recognizable drawings of those categories. Insofar as such retrieval mechanisms are engaged during drawing production, developmental changes in semantic memory systems may also explain an important portion of the age-related variation in drawing behavior.

Overall, we suggest that children's drawings change systematically across development, and that they contain rich information about children's underlying representations of the categories in the world around them. A full understanding of how children's drawings reflect their emerging perceptual and conceptual knowledge will allow a unique and novel perspective on the both the development and the nature of visual concepts—the representations that allow us to easily derive meaning from what we see.

Acknowledgements

We thank the San Jose Children's Discovery Museum for their collaboration and for hosting the drawing station where these data were collected. We are also grateful to members of the Stanford Language and Cognition lab for their feedback. This work was funded by an NSF SPRF-FR Grant #1714726 to BLL and a Jacobs Foundation Fellowship to MCF.

Abstract

How do humans compute approximate number? According to one influential theory, approximate number representations arise in the intraparietal sulcus and are amodal (independent of any sensory modality). Alternatively, approximate number may be computed initially within sensory systems. We tested for approximate number representations in the visual system using steady state visual evoked potentials (SSVEPs). We recorded EEG from human subjects while they viewed dotclouds presented at 30 Hz. Alternating the dotcloud numerosity at 15 Hz evoked a 15 Hz SSVEP detectable over the occipital lobe (Oz). The SSVEP amplitude increased as the numerical difference between dotclouds increased, indicating that subjects visual systems were differentiating dotclouds on the basis of their numerical ratios. Critically, subjects were unable to consciously discriminate dotcloud numerosity, indicating the rapid presentation disrupted reentrant feedback to visual cortex. Approximate number appears to be computed within the visual system, independently of higher-order areas such as the intraparietal sulcus.

Limits on the Use of Simulation in Physical Reasoning

Abstract

In this paper, we describe three experiments involving simple physical judgments and predictions, and argue their results are generally inconsistent with three core commitments of probabilistic mental simulation theory (PMST). The first experiment shows that people routinely fail to track the spatio-temporal identity of objects. The second experiment shows that people often incorrectly reverse the order of consequential physical events when making physical predictions. Finally, we demonstrate a physical version of the conjunction fallacy where participants rate the probability of two joint events as more likely to occur than a constituent event of that set. These results highlight the limitations or boundary conditions of simulation theory.

Keywords: intuitive physics; mental simulation; inference; conjunction fallacy

Introduction

Successful interaction with our environment often requires reasoning about the physical world (e.g., predicting if a stack of books on a desk is unstable), but the mental processes that support this ability remain poorly understood. Simulation is a technique used for physical reasoning in many applications ranging from modeling molecular interactions to designing realistic video game physics engines. In a simulation, a program starts with an initial state, and then applies the relevant dynamic laws of physics to compute what will happen over a series of (typically short) time steps; in effect, computing a "movie" of how the scenario progresses.

Some researchers have recently argued that humans use cognitive strategies analogous to computer simulation when intuitively reasoning and making predictions about the physical world (Battaglia, Hamrick, & Tenenbaum, 2013; Hamrick, Battaglia, Griffiths, & Tenenbaum, 2016; Hamrick, Smith, Griffiths, & Vul, 2015; Smith, Dechter, Tenenbaum, & Vul, 2013; Smith & Vul, 2017; Ullman, Spelke, Battaglia, & Tenenbaum, 2017). In order to account for the more imprecise and qualitative nature of human physical reasoning, they propose that multiple simulations are run from a range of different initial configurations. For instance, consider a person asked to predict whether a tower of wooden blocks will fall over. A *probabilistic* mental simulation begins by assuming that each observer has an imperfect perception of the positions of the blocks (i.e., their precise locations in physical space) owing to perceptual limitations and occlusion. Based on this uncertain percept, the simulator samples a number of slightly different towers, each altered according to random (perceptual) noise. According to the theory, a reasoner might start with, for instance, ten initial towers and run a (possibly noisy) physics simulation forward until some termination point with the resulting outcomes driving their stability judgment. For example, if 8 of the 10 simulated towers fall over then a reasoner might estimate a 0.8 probability that the structure is unstable (Battaglia et al., 2013). We refer to this approach as "probabilistic mental simulation theory" (PMST).

PMST has been found to approximate human judgments in a diverse set of tasks, including judging how a 3-D tower of blocks will collapse (Battaglia et al., 2013), predicting the destination of a virtual ball on a 2-D bumper table (Smith et al., 2013), and predicting the proportion of a poured liquid that will end up on either side of a divider (Bates, Yildirim, Tenenbaum, & Battaglia, 2015), among others. However, this theory has been contested (cf., Davis & Marcus, 2015, 2016). Criticisms of this theory include the incompatibility of an accurate physical simulation engine with decades of psychological work documenting human errors in simplified physical reasoning tasks (Hegarty, 2004; Kubricht, Holyoak, & Lu, 2017; McCloskey, Caramazza, & Green, 1980; Proffitt, Kaiser, & Whelan, 1990; Siegler, 1976). In addition, in many situations, simulation would be computationally inefficient or impossible. For instance, if a closed can half full of sand is shaken, simulation would require calculating all the collisions of all the grains of sand (e.g., Kubricht et al., 2016) but if the goal is just to predict whether the sand remains in the can, that can be done through the application of a simple rule (Smith et al., 2013)

The goal of the present paper is to provide a strong empirical test of PMST. We begin by describing three core tenets of PMST that transcend specific applications of the theory and make important testable claims about human physical reasoning. We then describe three novel experiments that test these principles by setting up pre-registered (here) edge-cases where we might expect the predictions made by PMST to fail.

Three key principles of probabilistic mental simulation theory (PMST)

An agent using a probabilistic simulation of the physical world to solve physical reasoning problems should adhere to the following three principles. While we accept that PMST may include limitations and shortcuts (Ullman et al., 2017), the principles outlined here are necessary for simulation to be a viable strategy.

Object Persistence A reasoner using PMST is required to maintain interacting objects within all simulations/samples. Objects occupy particular locations within space and time and a mental simulation must encode these relative spatiotemporal positions and update them according to the rules of physics. This is a core aspect of the theory, because drop-

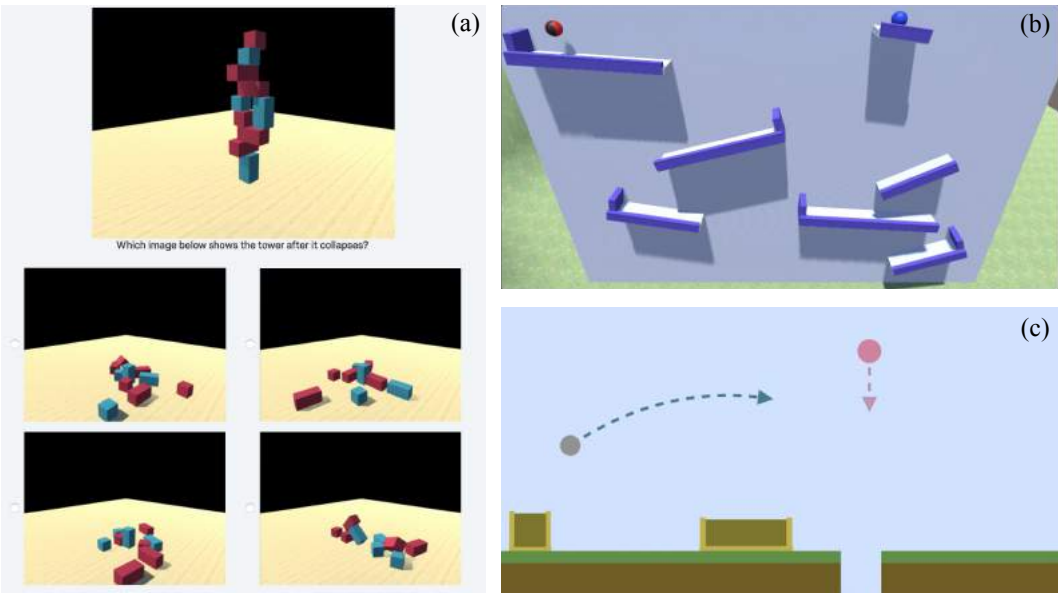

Figure 1: (a) A "Minus One" block tower question, as it appeared to participants. The answer in the upper left is correct; the other three answers are each missing one block. (b) A "marble run"-type temporal consistency question. (c) An example probabilistic coherence scene. Dotted arrows indicate approximate motion over the 2/3 second clip.

ping an object from a simulation or deleting it (as is possible in a video game engine) would radically alter possible outcomes and subsequent predictions. For example, imagine a person thinking about a table. If their mental simulation accidentally deleted its representation one of the table legs (even temporarily), the result would be a major disruption to the simulation; e.g., the otherwise static table might begin to fall. Keeping track of the location of objects in space and time and accounting properly for their movements is fundamental to what it means to "simulate" a physical scene. Any plausible physics engine must keep track of all the interacting objects involved in order to maintain coherent predictions about the future. Physics engines do make mistakes and approximations, but deleting or radically altering objects is not the kind of mistake they make.

There are, of course, some cases where objects may be ignored. In video game physics engines, for example, objects at rest are often put to "sleep" to save on computation, and it has been suggested that mental simulation might make use of this trick as well (Ullman et al., 2017). When a physics engine puts an object to sleep, however, this simply means that the engine assumes that the object is stationary, and it does not mean that the physics engine forgets that the object exists.

This leads to the key prediction tested in our first experiment: in interacting multi-object scenes, every object from the initial percept will be represented in each simulation's final state, because every object is necessarily represented and tracked throughout each simulation.

Temporal Consistency Building upon the first principle, an iterative simulation must advance all interacting objects simultaneously. This step-by-step, synchronous nature of the simulation ensures that the order of events is preserved. Preserving the order of events is important for generating accurate simulations and using them to make decisions. When two processes might interact, it is necessary for their simulations to be properly synchronized in order to predict whether and how they interact. Consider a case where a bottle is rolling towards the front door of a house, which is slowly closing. To predict if the bottle ends up inside or outside the house, the simulator has to represent whether the door will swing shut before the bottle gets there. Time cannot for instance run faster for the bottle than for the door if reasoning is to be coherent. A synchronous approach does this, and ensures that there is no way for one event to get ahead of, or fall behind another, because they share a common timeline.

We refer to this property of mental simulation as *temporal consistency*. A person using PMST to reason about a physical scene should preserve the temporal order of events.

Probabilistic Coherence According to PMST, after running multiple (noisy) simulations, the final scene configurations from each simulation are used to make predictions and inferences about the physical world. A variety of ways of aggregating across these simulations have been proposed. For example, in Battaglia et al. (2013), the output of the model was the average proportion of towers that fell across the set of the simulations. In this example, PMST uses the Monte Carlo principle to estimate probabilities. An event that is almost certain to occur will occur in all the simulations while a more uncertain event (or one more sensitive to perceptual noise) will occur less frequently. Although approximate, computing probabilities from samples or simulations still conforms to the axioms of probability theory. Indeed, this is a key virtue of the approach, and helps to relate the theory to existing Bayesian theories of human inference.

One classic signature of coherent probabilistic reasoning is that the probability of a conjunction of multiple events must always be less than the probability of any component (i.e., $P(A \wedge B) \leq P(A)$). However, people in many cases will estimate conjunctions to be more likely than one of their components (known as the "conjunction fallacy", Tversky & Kahneman, 1983). While they have been found in a number of domains including social reasoning, conjunction fallacy errors have not (to our knowledge) been observed in reasoning about physical outcomes, and all of the methods PMST proposes for estimating probability from the results of simulation predict that conjunction fallacies should not regularly occur. If likelihood is calculated by tallying the relative outcomes of different random simulations, the conjunction rule will not be systematically violated, because it is impossible for a sample to have more outcomes that include a conjunction than outcomes that include one of the constituent elements.

Study 1: Object Persistence

The first experiment tested the principle of Object Persistence. In particular, we tested if people are able to keep track of the number, size, and color/identity of a relatively small number of objects when predicting the future state of a simple scene. If people fail consistently at this task, it calls into question a key assumption of PMST; that simulations preserve objects over time. The assumption that we make in designing this test is that if an object is represented and tracked in each simulation, then it should be available for other judgements such as being identified/recognized. If people are limited in this regard, it calls into question if people use PMST or, alternatively, refines this theory by pointing out the cognitive inaccessibility of object-level details from the mental representation of the scene.

The experiment builds upon the block tower designs first used by Battaglia et al. (2013). Rather than asking participants to make predictions about the collapse of a standing tower, we showed participants one standing tower (the target) and then a set of four collapsed towers and asked them to judge which collapsed option was the result of the target tower falling according to gravity (with one of the four options being the ground truth of running the standard tower through a physics engine). Given the target tower, a simulation based reasoner could simply simulate the standing tower forward to generate one or a set of collapsed tower states. The actual result of the tower collapsing should be similar to several results generated by the simulation.

Method

Participants We ran groups of 9 at a time until the number of participants who meet the criteria reached or exceeded the planned number of participants, which was 100[1]. We recruited 201 participants (71 female, mean age = 33.9, SD = 9.8) on Amazon Mechanical Turk (AMT). Participants could earn a bonus of $3 depending on the accuracy of their predictions. Of these, 101 participants were eligible for our analysis. We analyzed the first 100 (39 female, mean age = 34.0, SD = 10.0). This collection plan and all criteria were outlined in our preregistration (here).

Stimuli The stimuli were still images of standing but unstable block towers (targets). Each target tower consisted of 10 blocks, similar to what has been used in previous research (e.g. Battaglia et al., 2013; Hamrick et al., 2016). The blocks came in three colors (red, blue, and green) and in three dimensions (the "cube" in 1x1x1, the "brick" in 1x1x2, and the "plank" in 1x0.5x2; units are relative).

For each target tower, there were four still images of possible resting states, i.e., what the tower might look like once it had collapsed under gravity. One of the resting states was always the real result of the target tower collapsing in the physics engine we used to create the stimuli.[2] The other three were incorrect and impossible in one of the following ways. In "Change Type" questions, one of the blocks was replaced with a block of different dimensions. In "Change Color" questions, one block was switched to a different color. In "Swap Color" questions, two-color towers swapped the colors of all blocks; e.g. all red blocks would become blue and all blue would become red. In "Plus One" questions, an additional block was included. In "Minus One" questions, one block was missing (e.g. Figure 1a). In "Minus Two" questions, two blocks were missing. In "Minus Three" questions, three blocks were missing.

The impossible endstates were created by changing the original tower (e.g. deleting, adding, or changing the properites of one or more blocks), adding some noise (so that all the incorrect answers were not identical), and then allowing the simulation to run to rest. Materials were created until there were three impossible endings that had no blocks that fell outside the viewing area nor were entirely obscured by other blocks.

Procedure Participants read a detailed description of the task. This included several example videos generated from the PhysX materials, and example images like those that appeared in the main body of the task. Participants were asked to watch each video a few times so that they would know how the blocks act when they fall.

The main body of the study consisted of 14 4AFC trials randomly intermixed with 10 easy trials. The easy trials were designed so that the correct answer would be obvious to a participant who was paying attention. Trial order was randomized. When choosing between the four fallen towers the original tower of blocks was still visible on the screen (see

[1] In an earlier preregistration (here), we allowed for a small number of exclusions. However, when we began collecting data for this study we realized that the exclusion rate was much higher than expected. As a result, we stopped data collection and developed a new protocol with a fixed n per experiment *after* exclusions. See Kennedy, Clifford, Burleigh, Waggoner, and Jewell (2018) for discussion of why the exclusion rate may have been unusually high during the summer of 2018, when the majority of these data were collected. In addition, due to space limitations we can report only the key planned analyses in this conference paper.

[2] The PhysX physics engine, through the Unity interface (*Unity*, n.d.).

Figure 1a).

Results

In accordance with our preregistered analysis plan, we pooled the number of correct answers participants gave on the 14 critical items, and used both a two-tailed one-sample *t*-test and the one-sample *"Bayesian Estimation Supersedes the* t-*Test"* or BEST (Kruschke, 2013) to estimate credible intervals for overall performance. The average number of correct answers was 6.33 (SD = 2.37). We calculated a 99% confidence interval of [5.75, 7.00], and the one-sample BEST gave a 99% credible interval of [5.72, 6.98]. Performance at this simple physical reasoning task is thus exceedingly poor; this contrasts sharply with the high performance at predicting whether towers are unstable found by Battaglia et al. (2013)

These errors varied by trial type. The mean number correct (out of 2) were 0.38 for Change Type items, 0.79 for Change Color items, 0.59 for Swap Color items, 0.65 for Plus One items, 1.18 for Minus One items, 1.36 for Minus Two items, and 1.38 for Minus Three items. We calculated confidence intervals corrected for multiple comparisons (Bonferroni with .05/7 = 0.00714) for all items. Intervals for Swap Color and for Plus One were consistent with a null of 0.50. For these item types, participants perform as poorly as if they were given no information at all. The 99.29% interval for the items with the highest accuracy, Minus Three, was [1.19, 1.59], the upper limit being just less than 80% accuracy. Notably, 39 of the 100 participants gave the correct answer to fewer than half of the items. Only 3 participants made no errors at all.

We included a free-response question after all trials, asking participants: "Roughly speaking, how did you try to solve the problems? Please tell us a little about your approach below." Three coders who had not been involved in the design of the study or the collection of data coded the free responses into the following categories: 0) No response, Nonsensical response, or "Other" strategy, 1) Simulation, Visualization, or Imagination, 2) Heuristics or Rules, 3) Both Simulation & Heuristics. To conduct subgroup analyses, we used a best 2 out of 3 approach to resolve disagreements among the coders, and had the three coders manually resolve disagreement for the small number of self-reports where all three coders coded the response differently. The ratings had a Cronbach's alpha of 0.85, indicating acceptable agreement (Kline, 2013).

When participants were asked to describe the way they completed the relevant tasks, 19 gave answers that suggested a simulation or visualization approach, 50 said they used specific rules or heuristics, 20 said that they used both simulation and heuristics, and the remaining 11 gave an uninterpretable answer. Results did not differ between participants who reported using different strategies.

Discussion

Reasoning about sets of 10 simple objects should be well within the abilities of a person using PMST (Battaglia et al., 2013; Hamrick et al., 2016). Despite this, performance was remarkably poor.

This behavioral result seems very unlikely if participants were tracking every block, which in causally-bound systems is a requirement of PMST. While it is possible that simulators might not always keep track of things like color, tracking shape is necessary to predict object interactions, and tracking every object is fundamentally necessary for the task. Because of this requirement, every object will end up in the end states of every simulation. It would seem trivial then to detect a mismatch between the end state of a mental simulation and a provided image of such a final scene. Alternatively, if one retained the spirit of the PMST approach, this result significantly constrains the availability of particular information within a mental simulation. Introducing this new constraint seems hard to reconcile with the ability of people to judge if the tower will fall via simulation because it would imply someone could answer the falling question ("will this block tower fall over?") but not a question about an individual block within a tower (e.g., "will the long red block remain standing when the tower falls over?").

Study 2: Temporal Consistency

PMST conducts simulations in an iterative fashion. At every time-step, the system applies elementary physical rules to each object in the simulation. This is done recursively; once every object has been updated at time t, the system moves on to time t+1, updates all objects again, and so on (Battaglia et al., 2013). This ensures that events will generally occur in the correct order, as long as the approximate trajectory is clear. In this study, we assessed if people have difficulty predicting the order in which events occur, for physical events with reliable trajectories.

The materials for this study consisted of video clips of events in a simple 3-D world. Participants viewed the first two seconds of several short clips of physical scenes in which two independent physical processes unfolded. For example, the physical processes might be two balls, each rolling down its own series of ramps (see Figure 1b), or they might be two lines of dominoes falling over. Each physical process followed a predictable trajectory, and we informed participants of this fact.

In each scene we identified one object in each process (usually "the red ball" and "the blue ball"), and participants were asked to predict which of the two objects would hit the ground first. Participants did not see the outcomes of the video clips, so they had to engage in prospective reasoning in order to make this judgment. The key dependent variable was the proportion of scenes for which participants thought the wrong event would occur first.

Method

Participants As above, our stopping rule was designed to collect a fixed number of participants *after* exclusions. We collected 78 participants (29 female, mean age = 35.1, SD = 9.8) in groups of 9 at a time on Amazon Mechanical Turk. Participants could earn a bonus of $3 depending on the accuracy of their predictions. Of these participants, 63 met our exclusion criteria, and we analyzed only the first 60 partici-

pants (22 female, mean age = 36.4, SD = 10.2), as stated in our preregistration.

Stimuli The main stimuli were video clips (example clip) showing the first two seconds of a scene (full version of same scene). Each scene included two key objects, one red and one blue, each involved in its own causal chain, which would eventually lead to each object colliding with the ground.

Each scene was designed to make the outcome that would occur second seem, at the end of the 2-second clip, more likely to occur first. The object that would actually strike the ground second was moving faster, had gone further, had fewer "obstacles" in its way, etc., or some combination of these factors. We iterated the design of the scenes based on these heuristics until we believed that pausing at the two-second mark would lead to incorrect judgment of the conclusion. PMST predicts that no such items should exist, as long as the trajectories are clear.

In the full scenes, the first object always struck the ground at least 2/3 of a second before the second one did, sometimes much earlier. The full scenes took about 10s to complete.

Procedure Participants read a detailed description of the task which included several example videos of the physics engine we used, and example clips similar to those that appeared in the main body of the survey. Participants were assured that the simulations were designed to be as much like real physics as was possible, that both critical objects would always eventually reach the ground, that there were no hidden objects or forces that would interfere, and that everything relevant to the scene was readily visible in the video clips.

In the main body of the study, participants viewed several video clips of the first two seconds of a physical scene where two independent chains of events unfold. In each case there were two items of interest, one red and the other blue, and participants judged which of the two would reach the ground (indicated by a grass texture) first.

The study presented four questions each of three types ("Marble Run", "Parthenon", and "Domino"), for a total of twelve critical questions. There were also four filler scenes, which were designed to be trivially easy.

Results

We used both a two-tailed one-sample t-test and one-sample BEST to determine if, on average, accuracy was different from chance. Participants answered a mean of 4.77 questions correctly (SD = 2.55), which was less than chance (6), according to both a t-test, $t(59) = -3.75$, $p < .001$, 95% confidence interval [4.11, 5.42] and a one-sample BEST, 95% Credible Interval: [4.11, 5.45].

In answering the 12 critical questions, 56.7% of the participants gave the incorrect answer to more than half of the questions. Every participant made at least two errors. The highest level of performance was ten of twelve correct, achieved by only two participants. Further, 3.3% of the participants gave the wrong answer on all twelve trials.

The same three coders coded free response reports of strategy according to the system described above. The ratings had a Cronbach's alpha of 0.74, indicating acceptable agreement (Kline, 2013). When participants were asked to describe the way they completed the relevant tasks, 8 gave answers that suggested a simulation or visualization approach, 35 said they used specific rules or heuristics, 8 said that they used both simulation and heuristics, and the remaining 9 gave no answer or an uninterpretable answer. Results did not differ between participants who reported using different strategies.

Discussion

In this study, participants saw two processes with predictable trajectories, and were asked to estimate which process would complete first. Overall, participants reversed the order of the events in their predictions, predicting that the event that truly occurred second would occur first, and did so more often than chance. Admittedly, the scenarios used in this study were deliberately designed to be adversarial. If we were to imagine the (hypothetical) space of all possible scenes, it is likely that few cases would prompt the reversals in judgment we observed. However, PMST suggests that *no items* showing such reversals should exist, barring major uncertainties in trajectory, etc. That there exist any items where this kind of reversal is consistently found is evidence that PMST is not the approach being used to make these judgments.

Study 3: Probabilistic Coherence

When making predictions about a physical scene, a key claim of PMST is that judgments reflect probabilistic inference, estimated via repeated stochastic runs of the simulation (Battaglia et al., 2013). As such, people's physical judgments should approximately obey the laws of probability theory.

Conjunction fallacy errors are cases where people rate a joint probability (A & B both occur) as more likely than the marginal probability of one component (e.g. A occurring at all). This is logically contradictory because there is no way for the joint probability to be larger than either of its components. At most, it will be equal to the smaller component.

In the cognitive domain, this is often known as the "Linda Problem", because of a well-known example in which participants judged a hypothetical individual named Linda as more likely to be both a bank teller and a feminist than to be a bank teller in general (Tversky & Kahneman, 1983). To test this commitment of PMST, in this study we assessed if people fall prey to conjunction fallacy-style judgment errors for physical reasoning problems.

Methods

Participants We collected data from 90 participants (28 female, mean age = 33.6, SD = 9.8) on Amazon Mechanical Turk (AMT). Following the criteria outlined in our preregistration, we analyzed only the first 60 participants (18 female, mean age = 34.2, SD = 9.7) of 62 eligible.

Stimuli The main stimuli were video clips, 2/3 of a second long, in which two round objects (a pink "sphere" and a gray "cannonball") interacted in a 2-dimensional world (example video here). This world included gravity and some stationary

objects. There was always "ground" on the bottom edge of the scene, with a green section representing grass on top, and usually one or more boxes resting on the grass. There was always a hole in the ground, wide enough for either object to potentially fall into.

Over the course of each clip, the gray cannonball would travel in a parabola across the screen, while the pink sphere would fall under the influence of gravity (see Figure 1c). The cannonball always traveled toward the sphere, in a way that suggested that the two might collide. Each video ended after approximately 700 ms, well before the cannonball could intersect the pink sphere's path, leaving ambiguity about the outcome of the scene.

Procedure Participants read a detailed description of the task. This included several example simulation videos from the physics engine we used (PhysX) and example clips like those that appeared in the main body of the task. The example videos included many forms of inter-object interactions, including collisions, and participants were allowed to watch these videos as many times as they wanted.

In the main body of the study, participants saw several simple physical scenes. For each scene, participants estimated the likelihood of a particular prompted outcome (e.g., "How likely is it that the pink sphere will end up on the grass?"), as a percentage ranging from 0% to 100% in 1% increments.

Eight of the scenes were considered "critical", and the answers to these provided our primary dependent measure. Unknown to participants, each critical scene appeared twice, for a total of 16 critical trials.

For each scene that appeared twice, in one appearance participants were asked the question, "How likely is it that the pink sphere will end up on the grass?" and in the other, "How likely is it that the cannonball will hit the pink sphere, and then the pink ball will end up on the grass?" Scenes did not repeat until after several filler scenes were presented.

Results

We averaged the difference scores (conjunction probability - sole probability) for each participant for each of the eight critical scenes. Positive values on these difference scores indicate that participants rated a conjunction as more likely than the constituent sole probability, which is a form of the conjunction fallacy. The average rating difference score was 7.29 (SD = 13.07), which was reliably greater than zero, according to both a t-test, $t(59) = 4.32$, $p < .001$, 95% confidence interval [3.92, 10.67], and a one-sample BEST (Kruschke, 2013), 95% Credible Interval: [4.06, 10.79]. This suggests that, on average, participants were inclined to commit the conjunction fallacy in a physics domain.

In rating conjunction and sole probabilities on critical trials, 72% percent of the participants show a bias toward the conjunction event. In addition, 62% percent of subjects committed the conjunction fallacy for more than half of the pairs.

The same three coders coded free response reports of strategy according to the system described above. The ratings had a Cronbach's alpha of 0.75, indicating acceptable agreement (Kline, 2013). When participants were asked to describe the way they completed the relevant tasks, 23 gave answers that suggested a simulation or visualization approach, 17 said they used specific rules or heuristics, 12 said that they used both simulation and heuristics, and the remaining 8 gave no answer or an uninterpretable answer. Somewhat surprisingly, we found that participants actually made *more* extreme conjunction fallacy errors when they reported using a simulation approach, $F(3, 56) = 3.90$, $p = 0.013$.

Discussion

Participants making judgments about outcomes in physical processes routinely predicted that conjunctions were more likely than one of their constituent events. PMST states that judgments about the outcomes of physical processes are made by aggregating over the result of multiple noisy runs of a simulation, and so conjunction fallacy errors contradicts this aspect of the theory.

General Discussion

Simulation has been argued to be an important and effective way in which people reason about the physical world. In this paper we ask about the limits on the use of simulation as a strategy. Across three studies, we found empirical contradictions to the natural predictions made by PMST.

First, when trying to identify the resting state for an unstable tower of 10 blocks, participants have great difficulty distinguishing between the true set of blocks and sets that differ because of changes of color, changes of dimensions, additions, or deletions. PMST suggests that this should not happen without significant additional assumptions about the content and accessibility of particular features of simulated representations.

Second, when judging the order of events in a scene with highly predictable trajectories, participants consistently make incorrect predictions about the order of events. Although the examples were designed to be adversarial, PMST does not admit the existence of such examples because judgments are made using an iterative simulation where every object is advanced synchronously in each unit of time.

Third, participants consistently commit the conjunction fallacy (Tversky & Kahneman, 1983) when reasoning about simple physical scenes, a result that contradicts the claims of PMST about how estimated judgments of physical scenes are made by aggregating across probabilistic samples.

The design of our experiments tried to mimic many of the empirical studies which have supported PMST in complexity and content. Thus we believe they represent an interesting test bed for the generalization of the theory.

As the field tries to grapple with these complex questions, we argue that any complete account of human physical reasoning must contend with both the cases where people appear to do well and the situations where they apparently are limited or deceived. As a result, experiments exposing the limits of simulation can be as informative as those that show the successes.

Acknowledgments The authors thank Ellie Robbins, Michael Lepori, Xuechen Sheryl Zhang, and Adi Kwiatek for help with this research and Gregory L. Murphy for helpful comments.

Abstract

This study examined age effects on real-life language use and within-person variations in language use across social contexts. We used the Electronically Activated Recorder (i.e., a portable audio recorder that periodically records sound snippets) to collect over 31,300 snippets (30 seconds long) from 61 young and 48 healthy older adults in Switzerland across four days. We examined vocabulary richness and grammatical complexity across the social contexts of (a) activities (i.e., socializing, working); and (b) conversation types (i.e., small talk, substantive conversation). Multilevel models showed that vocabulary richness and grammatical complexity increased during socializing and substantive conversations, but decreased in small talk. Moreover, young adults produced shorter clauses at work than not at work. Furthermore, compared with young adults, older adults used richer vocabulary and more complex grammatical structures at work; and used richer vocabulary in small talk. In contrast, young adults used richer vocabulary than older adults during non-socializing and non-working occasions, such as watching TV and exercising. Results are discussed in the context of cognitive aging research with a novel emphasis on context.

Keywords: vocabulary richness; grammatical complexity; social context; cognitive behavior; electronically activated recorder (EAR); naturalistic observation method

Introduction

Real-life language use is mostly embedded in social interactions and conversations (e.g., Clark, 1996). While effects of social context on language use have been widely acknowledged in sociolinguistics, linguistic ethnography, and social psychology (e.g., Finkbeiner, Meibauer, & Schumacher, 2012), they have been underrepresented in cognitive aging research (e.g., Horton, Spieler, & Shriberg, 2010). Rooted in laboratory experiments, cognitive aging research assumed that cognitive change with aging was the primary determinant of variations in language use (Burke & Shafto, 2008). However, unlike in the laboratory, where the upper limits of one's abilities are tested (Baltes, Dittmann-Kohli, & Dixon, 1984), in real life, contexts should also play a role in influencing behaviors (Lewin, 1951). Although some cognitive aging studies have controlled for the effects of social context in their examination of age and real-life language use, they have not treated social context as an essential determinant in their theoretical frameworks (Meylan & Gahl, 2014; Moscoso del Prado Martín, 2016). Furthermore, past studies, focusing on comparisons of different speakers in different contexts (i.e., between-person differences), were limited in inferring how the same individuals varied their language across contexts (i.e., within-person variations; Hamaker, 2012). Moreover, many real-life speech samples in the literature have been collected via telephone conversations between strangers, which may not be representative of naturally occurring language use. In sum, only one recent study has combined cognitive aging effects with within-person variations across social contexts in the investigation of language use in real life (Luo, Robbins, Martin, & Demiray, under review).

The current study used a naturalistic observation method to collect speech samples in real life and examined age effects in language use across different social contexts. Using the Electronically Activated Recorder (EAR; Mehl, Pennebaker, Crow, Dabbs, & Price, 2001), a digital recorder which periodically and unobtrusively captures ambient sounds in natural environments, we assessed language use and social contexts by examining speakers' moment-to-moment conversations. Vocabulary richness and grammatical complexity are related to cognitive changes with age (e.g., Horton, et al., 2010). We examined vocabulary richness and grammatical complexity across two types of social contexts that have been shown relevant to language use: (a) activities (i.e., socializing, working); and (b) conversation types (i.e., small talk, substantive conversations; Levinson, 1992). Our goals were to examine (1) whether individuals changed their language across real-life social contexts; and (2) whether age effects on language use differed across social contexts. Thus, this study is the first to examine cognitive aging effects on real-life language use in relation to within-person variations across different activities and conversation types.

Cognitive Aging Effects in Language Use

The differences in language use between young and older adults have been associated with cognitive changes with age. For example, the observations of older adults using richer

vocabulary than young adults have been explained as due to lifelong vocabulary accumulation in old age (e.g., Horton, et al., 2010). Moreover, the findings of older adults producing simpler grammatical structures than young adults have been interpreted as due to decreasing working memory in old age (e.g., Cheung & Kemper, 1992). Majority of these findings came from laboratory tasks, which asked participants to describe a novel picture, an important person, or a historical event (e.g., Cheung & Kemper, 1992). These studies assumes that cognition was the primary determinant of vocabulary richness and grammatical complexity and that participants' speech reflected their cognitive abilities in a controlled and consistent environment.

In theory, behavior is conceptualized as the interactions between personal characteristics and different supporting or impeding contexts (e.g., WHO, 2015; Verhaeghen, Martin, & Sędek, 2012). That is, in real life, where the environment is more diverse than in the laboratory, contextual effects should be taken into account. In order to improve the generalizability of their findings, some researchers examined speech outside of the laboratory, such as in telephone conversations (e.g., Horton, et al., 2010). These studies examined age effects on language use and controlled for contextual factors (e.g., talking with different conversional partners; Meylan & Gahl, 2014; Moscoso del Prado Martín, 2016). However, these studies examined between-person differences, instead of within-person variations across contexts (Hamaker, 2012). Additionally, the telephone conversations between strangers may not represent naturally occurring conversations.

In sum, some studies have identified effects of social context on language use, but they have not considered social context as an essential determinant of language use in their theoretical frameworks. Additionally, past studies have not examined contextual effects on vocabulary richness and grammatical complexity in naturally occurring language use with a within-person research design. Amid the growing interest in examining age effects on language use in real life, it is necessary to understand contextual effects on language use with data that properly capture within-person variations in language use in naturally occurring conversations.

Contextual Effects in Language Use

Social context is an important construct in the theoretical frameworks of language use in social psychology, sociolinguistics and linguistic ethnography (e.g., Clark, 1996; Finkbeiner, et al., 2012). There are substantial variations in language use across different social contexts, such as types of activities (i.e., socializing, working; Levinson, 1992). For example, speakers use more swearing words in leisure activities than at work (Cameron, 1969). Speakers refer to themselves more often in socializing and entertaining activities than while working (Mehl & Pennebaker, 2003). Furthermore, types of conversations (e.g., small talk, substantive conversation) also have effects on language use. Conversation topics and discourse markers (e.g., "anyway" and "you know") are different in small talk versus formal conversations, and the differences influence the degree of trust among speakers (Bickmore & Cassell, 2001). In addition, how speakers engage in small talk and substantive conversations is associated with their well-being (Mehl, Vazire, Holleran, & Clark, 2010).

Past studies have shown that the contexts of activity types and conversation types have effects on language use. However, majority of these studies have explained effects of social context from the perspective of social role and social identity and have not linked their findings to cognitive effects (e.g., Mehl & Pennebaker, 2003). In fact, cognitive-biological and socio-cultural determinants of language use are intertwined and inseparable (e.g., Gerstenberg, & Voeste, 2015). Furthermore, variations in language use across social contexts are likely to differ between young and older adults (e.g., Adams, Smith, Pasupathi, & Vitolo, 2002).

In sum, research that identifies effects of contexts on language use has highlighted the importance of understanding variations in language use across contexts. Thus, it is important to consider cognitive and contextual effects in the examination of real-life language use.

The Current Study

This study used the EAR to periodically and unobtrusively capture ambient sounds and speech in real life. The intensive and repeated sampling approach of the EAR captures multiple observations from each participant and, thus, allows us to analyze within-person variations in language use across social contexts. We treated social contexts and age as two important concepts in our theoretical model and inspected their joint effects on real-life language use.

The first goal of our study was to examine contextual effects on real-life language use. We focused on vocabulary richness and grammatical complexity that are associated with cognitive aging. We examined the contexts that have been found to have effects on language use: (a) activities (i.e., socializing, working); and (b) conversation types (i.e., small talk, substantive conversation). If activities and conversation types had effects on language use, we considered it in line with our assertion that contextual factors should be examined in the understanding of real-life language use. However, as there was a lack of evidence on how these social contexts would influence vocabulary richness and grammatical complexity, we refrained from forming hypotheses about the directionality of contextual effects. The second goal of our study was to explore whether age effects on real-life language use varied across different social contexts. If age effects on language use differed across different contexts, we considered it offered support for our anticipation that age effects on language use would be influenced by contexts.

Method

Participants

Our sample included over 31,300 sound files collected from 48 healthy older adults (62-83 years, M = 70.5, SD = 4.7; 22 men, 26 women) and 61 young adults (19-31 years, M = 23.0, SD = 3.10; 24 men, 37 women). Participants were recruited

via the participant pool of our department, via flyers in university buildings and advertisements in a local newspaper, and through snowball sampling used by a research assistant. All participants were local residents and spoke Swiss German.

Older participants were healthy with no record of neurological or psychiatric illness and lived independently. Their years of education ranged from seven to 25 (M = 10.55, SD = 3.02). Five of them were working part-time or full-time. They were compensated with 50 Swiss Francs. Young participants were mostly university students, whose years of education ranged between three and 17 years (M = 12.35, SD = 2.41). Eight of them had a part-time or full-time job. They could choose between 50 Swiss Francs and research credits for compensation.

Procedure

The study included an introduction session, a four-day EAR observation period, and a feedback session. In the introduction session, participants were given instructions on the study. They were asked to sign an informed consent form and to complete questionnaires including demographic and psychological measures. Next, participants received an iPhone with the EAR application installed. Participants were informed that the EAR would randomly record 30 seconds of ambient sounds. They were told that they would not notice when the EAR was recording, so that they could continue their normal lives. They were informed that they would have the opportunity to review and delete any sound files at the end of the study, before anyone listened to them.

After the introduction session, participants carried the EAR with them for four consecutive days. Additionally, they kept a diary every evening about their hour-by-hour activities of that day. Finally, participants met with the researchers again for a feedback session, in which they returned the phone and completed further questionnaires. They evaluated their experience with carrying the phone. They were given a password-protected CD containing all of their sound files to review. All procedures were approved by the local ethics committee.

EAR We provided each participant with an iPhone 4S, where the EAR application was installed (version 2.3.0). We programmed the EAR to record 30-second sound files at random times throughout the day. It was set to record 72 sound files per day (a total of 288 sound files per participant). We set a blackout period between midnight and 6 AM, when the EAR was inactive. We turned on the "Airplane mode" of the iPhone and locked it with a screen-lock password. Thus, participants could not access the EAR settings or use the phone for other purposes. We set a reminder in the phone calendar to automatically beep every evening at 9 PM to remind the participants to charge the iPhone overnight.

Linguistic Measures

All utterances of the participants captured by the EAR were transcribed. A research assistant created the transcripts, which were then checked and corrected by a second research assistant. Swiss-German dialect was translated word-by-word into standard written German and then transcribed. The utterances of interlocutors or bystanders were not transcribed due to ethical reasons.

We used the the TreeTagger (Schmid, 1999) via the R package of "koRpus" version 0.10-2 (Michalke, 2018) to process the transcripts. First, we identified each word according to its grammatical class (e.g., a noun, a verb), a process called *part-of-speech tagging*. We also turned each word to its lemma form, a process called *lemmatization*. For example, we turned *isst* ("eats"), *aß* ("ate"), and *gegessen* ("eaten") to the lemma form of *essen* ("eat"). Subsequently, we calculated the following two linguistic measures.

Vocabulary Richness: Entropy. Vocabulary richness was calculated with Shannon entropy measure, representing the diversity of words (e.g., Moscoso del Prado Martín, 2016). We calculated the frequency of occurrence of each word based on its lemma form and part-of-speech tag. Afterwards, we calculated the Shannon entropy of each sound file using the frequency. We used the R package of "entropy" (version 1.2.1; Hausser & Strimmer, 2018) to calculate Shannon entropy and corrected the results with Chao-Shen estimator, according to Moscoso del Prado Martín (2016). Higher scores of entropy indicate higher usage of unique words.

Grammatical Complexity: Clause Length. Clause length is the word count in a clause, representing the complexity of grammatical structures (e.g., Horton, et al., 2010). We used the German Pro3Gres parser (Sennrich, Schneider, Volk, Warin, 2009) to identify the following patterns as clauses: (a) a root element, i.e. the top element of a sentence, typically the inflected verb; (b) a relative clause (which is attached with the label rel to the NP it modifies); (c) a subordinated adjunct clause (label neb); (d) a subordinated complement clause (label objc or subjc); and (e) coordination at clause level (kon); (f) a fragmented or complete sentence (label s; Foth, 2005). Finally, we calculated word count per clause in each sound file.

EAR Coding

Every sound file has been manually coded for the participant's momentary (a) activity (i.e., socializing, working); and (2) conversation types (i.e., small talk, substantive conversations). More specifically, *socializing* refers to when the participant is doing something to socialize or entertain with others. *Working* refers to doing paid work. *Small talk* refers to any conversation that is completely non-instrumental, with no (or very trivial) information being exchanged. Finally, *substantive conversation* is any conversation that serves the purpose of exchanging information and ideas about a topic, e.g., news, politics.

All coding categories were dichotomous, indicating the presence (1) or absence (0) of the targeted item within a sound file. Trained coders coded these categories by listening to the pitch of the participants' voice, ambient sounds, and conversation topics in each sound file, and by referring to the

adjacent sound files. The coders also verified their coding with the participants' diaries. Note that the coders were not aware that vocabulary richness and grammatical complexity would be analyzed. Thus, the coders coded for activity and conversation types without referring to these linguistic measures. Social contexts were coded by only one research assistant, because the reliability of the coding of these contextual variables is found to be high in past EAR studies (e.g., Mehl, & Pennebaker, 2003; Mehl, et al., 2001).

Results

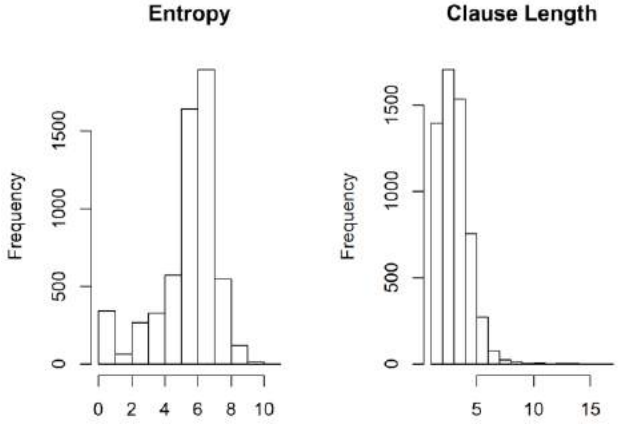
Preliminary Analyses

We collected over 31,300 sound files. For privacy reasons, 15 participants deleted 133 sound files, ranging from 1 to 40 sound files per person. From the remaining sound files, 6,542 included participant speech, ranging from 2 to 158 per participant (*M* = 60.02, *SD* = 32.09). That is, participants were talking, on average, in 21% of the sound files.

Young and older participants reported that the EAR did not affect their daily activities or way of speaking, in line with past EAR studies (e.g., Mehl, et al., 2001). Additionally, the proportion of the sound files in which the participants mentioned the EAR was low (only 0.8% of all sound files that included speech).

Out of the 6,542 sound files, 778 were deleted, as the participants' speech was unclear or included another language than German. This resulted in a final sample of 5,764 sound files. There were over 140,000 spoken words. The average score of entropy was 5.36 (*SD* = 1.9, Range: 0.00-10.24), and the average length of clauses was 3.09 words (*SD* = 1.39, Range: 1-17). The word count in sound files ranged from 1 to 123 words (*M* = 24.34, *SD* = 21.36). Figure 1 shows the histograms of entropy and clause length.

Figure 1. Histograms of Linguistic Measures.



Averaging across participants, in young adults, 7% of sound files (*SD* = 6%, Range: 0-23%) have been coded as including socializing, 2% (*SD* = 5%, Range: 0-19%) included working, 1% (*SD* = 1%, Range: 0-5%) included small talk, and 12% (*SD* = 7%, Range: 0-33%) included substantive conversation. In older adults, 6% of sound files (*SD* = 6%, Range: 0-18%) included socializing, 1% (*SD* = 4%, Range: 0-27%) included working, 2% (*SD* = 1%, Range: 0-7%) included small talk, and 12% (*SD* = 9%, Range: 0-38%) included substantive conversation.

Analytical Approach

The sound files (level 1) are nested within individuals (level 2). We analyzed these hierarchical data with multilevel models, which simultaneously examine between-persons and within-person variances (Bolger & Laurenceau, 2013). We estimated separate models for the two linguistic measures and for the different social contexts. In each model, we first estimated effects of age group and social context, and then added Age Group × Social Context interactions. More specifically, the full model is specified as follows:

Level 1: $\text{Language}_{ti} = \beta_{0i} + \beta_{1i}(\text{Context}_{ti} - \text{Context}_i) + e_{ti}$

Level 2: $\beta_{0i} = \gamma_{00} + \gamma_{01}(\text{AgeGroup}_i) + U_{0i}$

$\beta_{1i} = \gamma_{10} + \gamma_{11}(\text{AgeGroup}_i) + U_{1i}$

where *i* indexes individuals and *t* indexes sound files. At level 1, Language_{ti} represents the linguistic variable. β_{0i} is the random intercept, and β_{1i} represents within-person effects of contexts. The contextual variables were coded such that a non-event served as the reference group (i.e., socializing versus non-socializing, working versus non-working, small talk versus non-small talk, substantive conversation versus non-substantive conversation). This contrast scheme was used in line with the dichotomous nature of the contextual variables (coded as 0 vs. 1). e_{ti} represents the unexplained within-person context-to-context differences in language use. At level 2, β_{0i} represents the intercept of each age group and is modelled in detail through the level-1 model. β_{1i} is the slope of each age group. γ_{00} represents the grand mean of outcomes over all of the participants. γ_{10} represents the grand mean of slopes over all of the participants. γ_{01} and γ_{11} represented effects of age group, where young adults were the reference group. U_{0i} represents the random intercepts of individuals. U_{1i} represents the random slopes of individuals.

We decomposed each dummy-coded contextual variable into between-persons variance and within-person variance (Bolger & Laurenceau, 2013). More specifically, we firstly calculated the average score of context of each participant (Context_i). Afterwards, we deducted the score of context in each sound file from the mean score of context of each participant (Context_{ti} - Context_i; i.e., within-person contextual effect). The within-person contextual variables were our contextual predictors. Finally, we controlled for sex and education in each model.

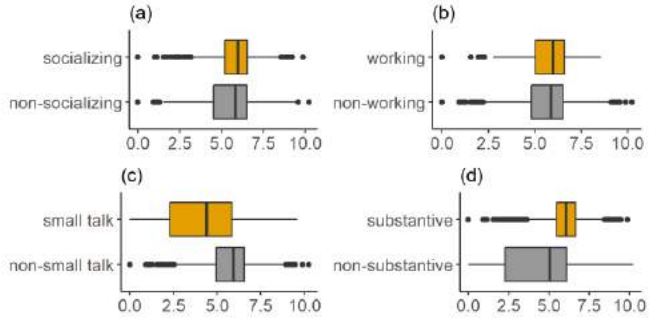
We used the R package "lme4" (version 1.1-17) in R (version 3.5.2) to estimate the models and the 95% confidence intervals (CI). We estimated the models with full information maximum likelihood estimation method, which treated incomplete data as missing at random and adjusted for unbalanced data (Singer & Willett, 2003). We additionally calculated p-values with R package "lmerTest" (version 3.0-1) and considered $p < .05$ as significant.

Major Analyses

Our first research goal was to examine contextual effects on language use. Thus, we estimated models with effects of age group and social context. We, then, added Age Group × Social Context interaction to the model for the second research goal: exploring whether age effects on language use were influenced by different social contexts. Due to their non-significant effects, we dropped sex and education from our final models. Additionally, we dropped the random slope effects from the models of socialization, working, and small talk in vocabulary richness, because the random intercept and slope models did not fit better than the random intercept models.

Vocabulary Richness: Entropy In the model of socialization, as shown in Figure 2 (a), participants used richer vocabulary while socializing than non-socializing (M = 0.32, p = <.001, 95% CI [0.20, 0.44]).[1] As shown in Figure 3 (a), young adults used richer vocabulary than older adults during non-socializing (M = -0.23, p =.014, 95% CI [-0.41, -0.05]). However, there was no age group difference during socializing (M = 0.17, p = .155, 95% CI [-0.07, 0.41]).

Figure 2. Entropy by Contexts

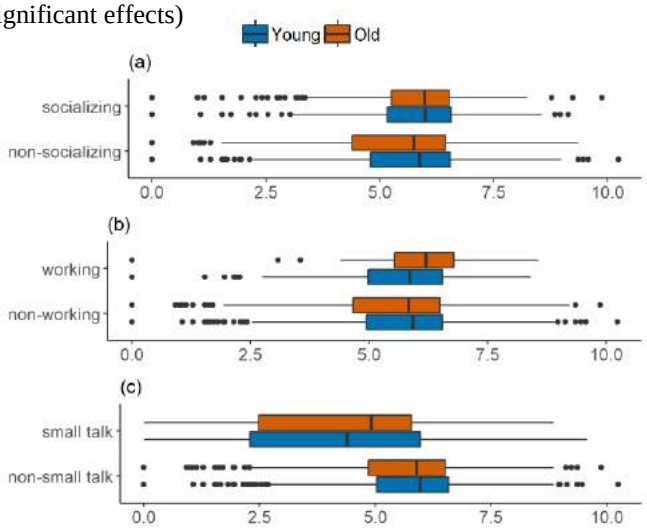


In the model of working, as displayed in Figure 2 (b), there was no significant difference in vocabulary richness between working and non-working occasions (M = 0.17, p = .291, 95% CI [-0.14, 0.47]). As presented in Figure 3 (b), young adults used richer vocabulary than older adults in non-working occasions (M = -0.21, p = .026, 95% CI [-0.38, -0.03]). In contrast, older adults used richer vocabulary than young adults at work (M = 0.96, p = .030, 95% CI [0.09, 1.82]).

Figure 2 (c) shows that participants used richer vocabulary in non-small talk than in small talk (M = -1.31, p < .001, 95% CI [-1.51, -1.11]). Figure 3 (c) shows that there was no significant age group difference in non-small talk (M = -0.18, p = .050, 95% CI [-0.36, 0.00]). However, in small talk, older adults used richer vocabulary than young adults (M = 0.42, p = .041, 95% CI [0.02, 0.82]).

Figure 2 (d) shows that participants used richer vocabulary in substantive conversations than in non-substantive conversations (M = 1.57, p < .001, 95% CI [1.47, 1.67]). There was no significant age group difference in non-substantive conversations (M = -0.14, p = .376, 95% CI [-0.44, 0.17]) or in substantive conversations (M = 0.15, p = .348, 95% CI [-0.17, 0.47]).

Figure 3. Entropy Across Age Groups and Contexts (significant effects)



Grammatical Complexity: Clause Length In the model of socializing (Figure 4 [a]), participants uttered longer clauses while socializing than non-socializing (M = 0.18, p = <.001, 95% CI [0.09, 0.27]). There was no age group difference in non-socializing (M = -0.13, p = .086, 95% CI [-0.27, 0.02]) or socializing occasions (M = 0.11, p = .234, 95% CI [-0.07, 0.28]).

In the model of working (Figure 4 [b]), there was no significant difference in grammatical complexity between working and non-working occasions when examining both older and young adults (M = -0.18, p = .112, 95% CI [-0.41, 0.04]). However, young adults produced shorter clauses at work than not at work (M = -0.31, p = .013, 95% CI [-0.55, -0.07]). As shown in Figure 5, age group difference was non-significant in non-working occasions (M = -0.12, p = .101, 95% CI [-0.27, 0.02]), but was significant at work (M = 0.86, p = .008, 95% CI [0.23, 1.49]). That is, older adults used longer clauses than young adults at work.

Figure 4 (c) shows that participants produced shorter clauses during small talk than in non-small talk (M = -0.60, p < .001, 95% CI [-0.74, -0.45]). There was no age group difference in non-small talk (M = -0.10, p = .170, 95% CI [-0.24, 0.04]) or in small talk (M = 0.01, p = .954, 95% CI [-0.47, 0.50]).

As depicted in Figure 4 (d), participants produced longer clauses than in non-substantive conversations (M = 0.77, p < .001, 95% CI [0.70, 0.85]). There was no age group difference in non-substantive conversations (M = -0.05, p

[1] While our analyses focused on within-person variations in each participant, for simplicity, the figures show within-person variations across all participants.

= .607, 95% CI [-0.24, 0.14]) or in substantive conversations (*M* = 0.00, *p* = .966, 95% CI [-0.21, 0.20]).

Discussion

Using a naturalistic observation method, we examined age group differences in language use across social contexts in real life. We found that for both young and older adults, vocabulary richness and grammatical complexity increased while socializing and during substantive conversations. These findings indicate that participants activated richer vocabulary and produced more complex grammar to communicate information in these social contexts. Moreover, for both young and older adults, vocabulary richness and grammatical complexity decreased during small talk. These findings suggest that small talk includes routine and probably repetitive information. Furthermore, young adults produced shorter clauses at work than not at work. Young adults may have been inexperienced at the workplace and thus grammatical complexity differed at work versus not.

Additionally, older adults used richer vocabulary and more complex grammatical structures than young adults at work; they also uttered richer vocabulary in small talk. Older adults may be more inclined to use formal language than young adults in professional settings or in small talks, e.g., greeting the others. In contrast, we found that young adults used richer vocabulary than older adults during non-socializing and non-working occasions, such as doing housework, watching TV, exercising, or commuting in a bus.

Although vocabulary richness and grammatical complexity have been shown to be associated with cognitive abilities in past cognitive aging studies (e.g., Cheung & Kemper, 1992), our findings indicate that age effects can vary depending on the contexts in real life. In other words, unlike in laboratory studies that are designed to test the upper limits of cognitive abilities (Baltes, et al., 1984), in real life, variations in language use are likely to be associated with not only age, but also social contexts.

In cognitive aging and gerontology research, behavior is conceptualized as determined by the interactions between personal characteristics and contexts (e.g., WHO, 2015; Verhaeghen, et al., 2012). Our findings offer evidence for the effects of context on vocabulary richness and grammatical complexity, in addition to age. This perspective is particularly useful when there is a growing interest in collecting "big data" and understanding cognitive behaviors in real life (e.g., Demiray, Mischler, & Martin, 2017; Demiray, Mehl & Martin, 2018; Luo, et al. under review).

Limitations and Future Work

Despite the novel approach that we contributed to the literature, this study has limitations. First, the small number of observations for working and small talk could have influenced statistical estimations. Although multilevel models adjusted for unbalanced data, it is still worthy to prolong the data collection period in future research to obtain more observations. Second, even though the models' fit seemed passable (i.e., the residuals of the models' estimation looked normal), the distributions of the linguistic measures were not bell-shape normal. Limited by the capacity of the lme4 package, we treated these variables as normal distributions. Future studies could use other estimation approaches, e.g., Bayesian method to estimate the linguistic measures. Third, we observed that language use varied across different social contexts and offered speculative explanation for different contextual effects. Future studies should try to incorporate momentary self-reports from participants to understand the subjective perceptions of participants during language use across different contexts. Fourth, this study included only young and old age groups. Future studies should include middle-aged adults to understand language use across the whole adult lifespan.

Conclusion

We contributed to the literature by using a novel approach to unobtrusively collect thousands of sound files in natural environments and by examining age effects on language use with a focus on context. We found that (1) social contexts had effects on language use; and (2) age effects on language use varied across social contexts. Our findings showed that both personal (i.e., age) and contextual factors (i.e., social contexts) are important determinants in the understanding of real-life language use. We offer a new perspective for understanding age effects on real-life language use, or more generally real-life behavior, in the context of cognitive changes with age.

Role of Working Memory on Strategy Use in the Probability Learning Task

Abstract

Extensive research on probability learning has reported on the ubiquity of the probability matching strategy—choosing options in proportion to their probability of being correct. The current paper explores why the optimal strategy in this task (always choosing the higher probability option) is not intuitive for participants, by examining their decisions in relation to their working memory capacities. We hypothesize that probability matching is a by-product of an automatic recency-based strategy produced by limits in working memory storage and that deliberate strategizing mediated by working memory processing can override recency in favor of optimal responding. A variant of the Expectancy-Valence Learning Model is fit to participant data from a two-choice probability learning task using hierarchical Bayesian modelling. Point estimates of the best-fitting parameter values are then correlated with working memory measures. Results indicate close relations between them, providing support for our hypothesis.

Keywords: working memory; probability learning; recency

Introduction

Decisions in life often condense into simple binary choices—to react or not to react, to speak or not to speak, to do or not to do. An important factor influencing such decision making is the outcomes of previous similar decisions. However, our abilities to integrate the histories of outcomes is strongly constrained by the attentional and processing limits of our working memory (WM), thus compromising the quality of our decision making. Indeed, several researchers have focused on differences in decision making between situations when information is gathered over sequential experience (where the narrow window of WM is likely to have an impact) and when it is obtained from simultaneous description (which is relatively uninfluenced by WM capacity; Hertwig, Barron, Weber, & Erev, 2004). The former is more typical of real-life, emphasizing the importance of examining the role of WM limits. In the current paper, we investigate how limits in storage and processing mechanisms of WM influence behavior on binary choices through the probability learning task.

Probability Learning Task

The probability learning task is a simple experimental paradigm involving multiple trials of choosing between two mutually exclusive and exhaustive outcomes (Vulkan, 2000). For instance, in each trial, participants may be asked to predict which of two presented light bulbs will turn on (Humphreys, 1939). Typically, the two options have pre-determined and unequal probabilities of occurring—e.g., Bulb A will turn on with 0.7 probability, and Bulb B with 0.3 probability. Each trial is independent; hence the optimal strategy is to choose the higher probability side (once it has been identified) 100% of the time. This is known as probability maximizing—in our example such a strategy would lead to 70% accuracy.

However, participants rarely perform this relatively simple strategy of exploring for the high payoff option and then exploiting via probability maximizing. Rather, a typically observed behavior is probability matching—choosing options in proportion to their probability of occurrence. Participants therefore tend to choose Bulb A 70% of the time and Bulb B 30%, leading to a lower accuracy level of 58% (.7×.7 + .3×.3). This behavior typically persists even after enough samples have been drawn to identify the higher probability option with at least some level of certainty (Arrow, 1958). Probability matching has been given wide attention as a supposed lapse of judgement for which several explanations have been proposed, without much consensus regarding the underlying mechanism (Feher da Silva, Victorino, Caticha, & Baldo, 2017).

Working Memory and Probability Matching

One of the primary explanations of probability matching is the recency effect. Human short-term retention abilities are limited, creating a narrow window of recent experience which makes information highly susceptible to time-based decay (Kareev, 1995). In the current task, this constraint encourages decisions to be based on smaller samples of information (most likely the very recent samples), which, given the law of large numbers, is likely to produce probability matching behavior (Plonsky, Teodorescu, & Erev, 2015; Rakow & Newell, 2010). For example, if participants retain only one previous trial in their short-term window and make utility calculations and decisions based on this previous trial, they would exhibit perfect matching. Several studies have fit such one-outcome-based win-stay-lose-shift strategies to decision making with surprising success despite their relative simplicity (Nowak & Sigmund, 1993). More sophisticated reinforcement learning models (such as the EVL and PVL models; Busemeyer & Stout, 2002; Erev & Roth, 1998) also incorporate a recency weighting which discounts the influence of older outcomes. Such findings suggest that probability matching behavior could be a result of overweighting recent outcomes, produced by their higher activation in the attentional window.

It must be noted that most studies find that probability matching does not persist—when enough trials are

presented, participants are often able to switch to the optimal strategy of maximizing. For instance, Restle (1961) found that probability matching disappeared after 1000 trials. Other studies have emphasized that switching to the optimal strategy is more likely if participants are provided with higher monetary payoffs, regular feedback, and more intense practice (Shanks, Tunney, & Mccarthy, 2002). An interpretation of this is that probability matching (produced e.g. by short-term recency) is a default response, which can be overridden in favor of maximizing through conscious deliberation. This dual process hypothesis is supported by correlations between SAT scores and maximizing on a descriptive version of this task (West & Stanovich, 2003).

These features of probability learning behavior—recency-based responding and deliberate strategy shift to maximizing—are likely to be mediated by WM capacity. Several models of WM consist of two core functions, storage and processing (frequently known as the span and control of attention respectively; Cowan, 2008). Here, we refer to storage as the ability to temporarily hold information in an active attentional state, protected from time-based decay and other interference. Decay in storage capacity is likely to produce recency-based performance in the probability learning task, as it constrains the number of previously observed outcomes that are in a readily accessible state when making a new decision (Ricker, Vergauwe, & Cowan, 2016). The processing component of WM directs attentional use, focusing it on goal-relevant information. An important function of WM processing is the inhibition of automatic but incorrect responding, as suggested by correlations with performance on the antisaccade and Stroop tasks (Kane & Engle, 2003; Unsworth, Schrock, & Engle, 2004). In our task, this component is perhaps responsible for resisting convenient recency-based responding and deducing the optimal strategy by steering and focusing attention toward task-relevant information (which could include independence of trials and the existence of a higher probability option).

Based on this previous research, in our study, we hypothesize the following to be correlated: (1) recency-based responding and WM storage capacity, and (2) strategy shift to maximizing and WM processing abilities.

Previous Studies and the Current Experiment

Several experiments have previously linked WM with performance on probability learning or other similar tasks (Gaissmaier, Schooler, & Rieskamp, 2006; Kareev, 1995; Rakow & Newell, 2010). These studies have reported mixed results—some have found positive correlations between WM capacity and maximizing, while others have reported the opposite. Through this paper, we attempt to resolve this debate. Further, unlike previous studies, our primary motivation is to model the interaction of the two WM components in producing recency-based responding and suppressing it in favor of the optimal strategy.

For our task, we used the light bulb setting described earlier. Participants chose between two bulbs and received feedback (i.e., which bulb lit up) after each trial. To model probability learning behavior, we used the Strategy-Shift Expectancy-Valence Learning (SS-EVL) model–a variant of the original EVL model (Busemeyer & Stout, 2002). Recency and strategy shift parameters extracted from this model were correlated with WM scores. Since such statistical analysis is likely to be noisy, our study has a larger sample size than that of previous experiments.

Methods

Participants

One hundred and thirty-one undergraduate students of Indiana University served as participants and were compensated with course credit. Of these, data of eight participants was excluded due to failure to perform at least one of the tasks.

Tasks and Procedure

The experiment consisted of five computer-based tasks (four WM and one probability learning). Each session lasted around 60 minutes and began with administration of the WM tasks.

Memory tasks. Participants performed four WM tasks in the following order: symmetry span, digit span, visual array, and operation span.

WM storage was measured with the digit span and visual array tasks. The digit span is a simple number recall task classically used as a measure of short-term memory (method similar to Quinn, Tuci, Harvey, Di Paolo, & Wood, 2005). The visual array task requires detecting rapid color changes in an array of 4, 6, 8, or 10 colored squares (method similar to Cowan, Fristoe, Elliott, Brunner, & Saults, 2006). Here, task performance depends on temporary storage of colors, and has been frequently used as a measure of storage (Cowan et al., 2006; Shipstead, Redick, Hicks, & Engle, 2012).

The symmetry span and operation span tasks require simultaneous usage of memory and processing and were used as measures of WM processing (methods similar to Oswald, Mcabee, Redick, & Hambrick, 2014). The memory component of these tasks involves the retention of presented items (spatial positions of colored squares for symmetry span and letters for operation span). Memory items are interpolated with processing components (symmetry or arithmetic accuracy judgements respectively) that interfere with rehearsal of memory items.

These specific working-memory tasks were selected because they not only represent the functional components of working memory (i.e., storage and processing), but also use different content modalities—symmetry span and visual array are visuo-spatial tasks, while digit span and operation span are verbal-numeric tasks.

Probability learning task. Participants performed three probability learning games, each involving 100 trials. During each game, participants were presented with an

image of a 'bulb-box', a device containing two lightbulbs (Bulb A and Bulb B). Participants were informed that on each trial one of the two bulbs would turn on and it was their task to guess the correct bulb. For every correct guess, participants gained one point and for every incorrect guess, they lost one point. Number of points won by participants was revealed at the end of each game. To motivate participants to aim for higher points and achieve optimal decisions, participants were rewarded with between 0 to 3 nutrition bars based on performance. The probability with which the two bulbs lit up remained constant within each game but varied from game to game. Three probability contingencies were used—0.60, 0.70, and 0.80—the order of which was determined randomly. Bulb A or Bulb B was set as the more frequent bulb in each game with equal probability. Participants were informed that each 'bulb-box' game had a different underlying 'program' controlling it to minimize tendencies of using previous games as priors for future ones. To further combat this, the color of the lightbulbs was changed from game to game.

Results

Probability matching (selecting the bulbs in proportion to how often they light up) was observed in the aggregated data of participants, decreasing with successive games (Figure 1).

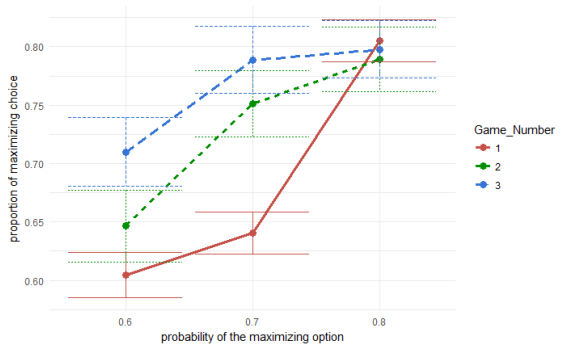

Figure 1: Proportion of maximizing choices averaged across trials (data for all game and probability contingencies)

Further, we found that participants were more likely to choose the maximizing option as the number of trials played increased within each game (Figure 2).

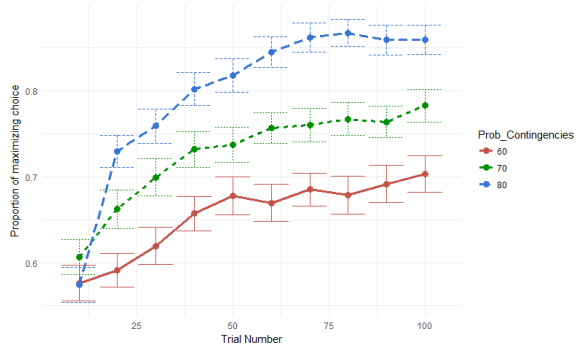

Figure 2: Averaged proportion of maximizing responses across trials

We then calculated correlations between WM scores and frequency of maximizing responding. Maximizing responding was calculated as the proportion of times the maximizing option was selected in a game. Significant correlations were obtained for scores on visual array ($r(123) = 0.2$, $p=.03$) and spatial span tasks ($r(123) = 0.19$, $p=.04$), while correlations with digit span ($r(123) = 0.09$, $p=.36$) and operation span ($r(123) = 0.19$, $p=.07$) were weaker. Stronger correlation with the visuo-spatial WM tasks (as opposed to the verbal ones) could arise if participants were retaining previous outcomes as visuo-spatial information (e.g. *left* bulb, *right* bulb, *right* bulb…).

These positive correlations between WM and optimal responding are in line with our hypotheses. They are consistent with results from some previous studies on WM and probability learning (Rakow & Newell, 2010; West & Stanovich, 2003); but contradict others which have found negative correlations (Gaissmaier et al., 2006; Kareev, 1995).

Modelling

Correlation measures provide us a small peak into the relationship between WM capacity and probability matching. However, they do not reveal the relation between WM capacity and the use of recency or strategy shift to maximizing. We therefore modelled the data using a modified EVL model and correlated parameters with WM scores. We also employed a Baseline Bernoulli model for comparison.

Model Descriptions

Strategy-Shift Expected-Valence Learning Model (SS-EVL). Variants of the EVL model have been previously used to model probability learning (Feher da Silva et al., 2017; Schulze, van Ravenzwaaij, & Newell, 2015) and other reinforcement learning tasks (such as the Iowa and Soochow Gambling Tasks; Ahn, Busemeyer, Wagenmakers, & Stout, 2008). Its parameters typically include consistency c and recency A. In our version of the model, we accommodate a strategy shift toward maximizing through a third parameter—timepoint of shift T.

The model assumes that on every trial, participants assign a utility value to the two lightbulbs—1 if it is correct on that trial, and 0 otherwise. Therefore, in a trial, utility $u(t)$ gained from bulb j based on outcome x is defined by:

$$u_j(t) = \begin{cases} 1 & if\ x(t) = j, \\ 0 & if\ x(t) \neq j \end{cases}$$

This utility is then incorporated into the running expected utility E_j of the two options using a weighted utility updating rule (Rescorla & Wagner, 1972) which discounts older outcomes with a recency parameter A. Larger the value of A, greater is the influence of older outcomes:

$$E_j(t) = A \cdot E_j(t-1) + (1-A) \cdot u(t)$$

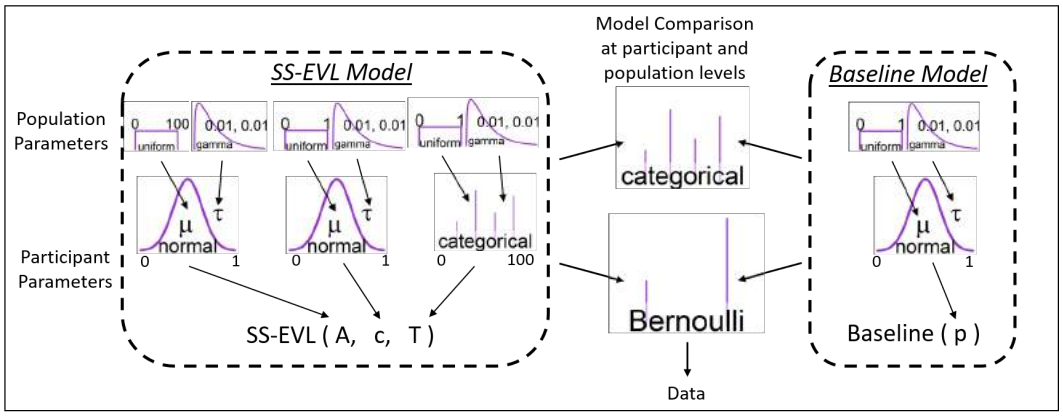

Figure 3: Structure and priors of the hierarchical Bayesian model

The expected utility calculations are then used to make a choice decision D based on Luce's choice rule (Luce, 1959) incorporating exploration θ:

$$\Pr[D(t+1)=j]=\frac{e^{\theta(t)\cdot E_j(t)}}{\sum_{k=1}^{2} e^{\theta(t)\cdot E_k t)}} \;;\quad \theta(t)=(\frac{t}{10})^{c}$$

$\theta(t)$ represents the extent to which participants make choice decisions based on calculated utilities. If $\theta(t)=0$, decisions are random and as $\theta(t)$ increases, decisions are highly sensitive to utilities. The value of θ is dependent on the free consistency parameter *c,* which is constrained between 0 and 1. Though we do not use this parameter for future WM analysis, it is essential to incorporate it in the model—it provides for a cleaner estimate of recency by accounting for the influence of exploration in participant data.

Finally, we assume that at some trial *T*, participants identify and shift to the maximizing strategy. Therefore, from this trial onward, the expected utilities of the maximizing and non-maximizing options are set to 1 and 0 respectively. Hence, the running utility E_j is revised such that:

$$\textbf{\textit{for } t > T}: \quad E_j(t)=\begin{cases} 1 \;\; if\; j = maximizing\; option, \\ 0\; if\; j \neq maximzing\; option \end{cases}$$

Baseline Model. A simple Bernoulli baseline model was also fit to data. The Baseline model has only one parameter—probability that participants choose the maximizing option, $p(j=1)$. Therefore, the model predicts unequal probabilities of choosing between the two bulbs, which are independent of outcomes observed by participants and constant across trials.

In our task, participants could be using varied strategies (e.g., looking for patterns in outcomes or random guessing). This model serves to filter out such participants who are better modelled by a random Bernoulli process than by a recency model which assumes positive dependency on observed outcomes. Thus, this model is not intended to be a process model of the underlying mechanism, but rather a useful cache for unaccounted strategies. If a larger number of participants are better fit by this model than the SS-EVL, it suggests that our proposed mechanism of probability matching is not dominant in the population.

Model Fitting

We used Bayesian hierarchical modelling for parameter fitting and model comparison (see Figure 3 for details about prior and multilevel structure). We combined the two models into a single hyper-model and employed a categorical distribution to determine the strategy used by each participant— on each MCMC timestep, for each trial, it sampled from one or the other model based on its probability of being the true process underlying that participant's data. In a similar way, we also estimated the population level posterior probability for each model. The analysis was implemented on JAGS via R. We drew 200,000 samples via three MCMC chains. Inspection of diagnostic plots indicated convergence for most parameters.

Here we only fit data from the first probability learning game of each participant because of considerable order and practice effects in future games.

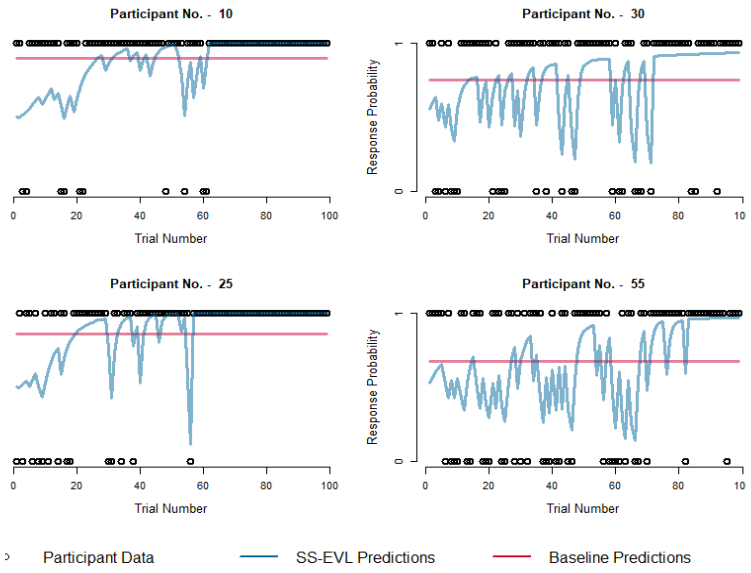

Figure 4: Model fitting of individual participants

Model Comparisons

Overall, the SS-EVL model outperformed the Baseline, with a posterior probability *P(model=SS-EVL|D)* of 0.71. Further, 85 out of 123 participants were categorized as employing an SS-EVL strategy (for examples of individual fit, see Figure 4). SS-EVL also better captured the participants' average pattern of performance across trials (Figure 5).

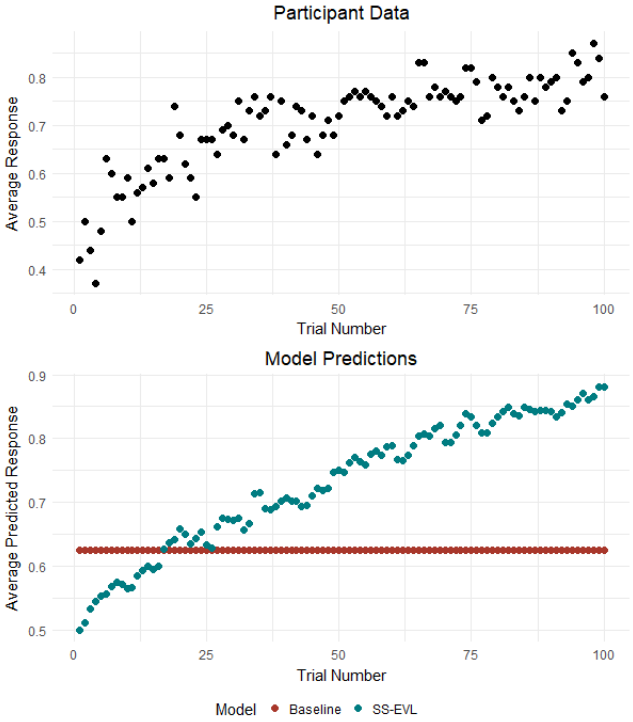

Figure 5: Average participant data and model predictions across trials

Correlations with WM scores

To test our hypothesis that WM components correlated with strategy use, we analyzed those participants who were better fit by the SS-EVL model. Point estimates (modes) of two SS-EVL parameters were correlated with WM scores—recency *A* and timepoint of strategy shift *T* (Table 1). As in the behavioral correlations reported above, visual array and symmetry span were more strongly correlated than other measures. Of the two measures of WM storage, only visual array showed indication of correlation with recency, providing partial support for hypothesis 1 that overweighting of recent outcomes is a by-product of WM storage limits. As predicted in hypothesis 2, measures of WM processing shared a significant negative correlation with timepoint shift—participants with higher WM processing abilities were likely to shift toward the maximizing strategies within fewer trials.

Discussion

Our study demonstrates the process by which WM components work together to produce typical probability learning behaviour. The picture that emerges suggests that the limits of the WM store intensify weighting of recent events, producing default responses that require greater WM processing to inhibit them in favor of the optimal strategy. In the real world, such a tendency toward recency makes sense as it allows us to adapt to our dynamic and temporally autocorrelated environment, where making decisions based on older information is often unsuccessful and recent events are a good indicator of the current state of the world (Plonsky et al., 2015). It appears that the two components of WM thus work together to produce appropriate everyday behavior—limits in the WM store allow for quick recency-based responses to environmental stimuli while WM processing acts as a correctional mechanism, stepping in to replace the recency-based strategy if an optimal strategy is found.

It would therefore be hasty to call probability matching a lapse in judgement (Vulkan, 2000)—participants do not fail to arrive at successful decisions in the probability learning task because of some cognitive failure. Rather, they do not always use the optimal strategy because the task itself is not representative of natural environments: unlike typical real-world situations, here the event probabilities are stationary across trials, and the trials are independent of one another. Participants therefore must deploy deliberate processing to resist responding automatically based on assumed environmental structures where recency would be best. While binary decisions may be common to our everyday life, the probability structure underlying this task is not, making the optimal strategy unintuitive. Future work can examine participant performance using real-world probability structures—for instance having the probabilities of the bulbs shift or be autocorrelated across trials (Gaissmaier & Schooler, 2008).

As mentioned earlier, previous studies have found mixed

Table 1: Correlations between WM obtained parameter values

	WM storage measures		WM processing measures	
	Visual Array	Digit Span	Symmetry Span	Operation Span
Recency *(A)*	0.19^{+}	0.08	0.18^{+}	0.11
Timepoint of shift *(T)*	−0.16	−0.11	-0.24^{*}	-0.20^{+}
$^{+}p<.1$. $^{*}p<.05$. $^{**}p<.01$. $^{***}p<.001$ N=85				

results when relating WM to performance in similar tasks—some have obtained positive correlations, providing support to our results (e.g., Rakow & Newell, 2010; West & Stanovich, 2003), while others have obtained the opposite (e.g., Gaissmaier et al., 2006; Kareev, 1995). While, the differing results could be due to difference in task structure—the studies reporting negative correlations use a correlation-detection task, which involves estimating two probabilities and not just one (for details of the task, refer to Kareev, 1995)—this is an unlikely explanation since our model would still predict positive correlations for such a task structure. Therefore, a more likely possibility is that participants employ different strategies (such as pattern matching, random responding etc.), producing different results. In the current paper, we only focused on recency-based responding—the SS-EVL model fit participants for this specific strategy and our results suggested that it was the dominant strategy in our sample when compared to a Bernoulli baseline. We then correlated the obtained parameter estimates for participants best fit by this model with WM scores, therefore excluding any effect of other strategies. However, future work must model other possible strategies, determine their frequency in the sample and their relation to WM capacity.

Further work must also be done to narrow in on the mechanisms underlying these decisions. While our model estimates the timepoint at which the strategy-shift toward maximizing occurs, it does not uncover the mechanism that produces this shift. Our correlational evidence argues that this mechanism is associated with the processing component of WM, but we do not know what operation within this component leads to optimal strategizing and why it reaches a threshold at a particular timepoint. Identifying the likely mechanisms at work in making decisions based on recent and older information will help us understand the role of limited WM storage and processing in these common choice settings.

Abstract

Sensorimotor information plays a fundamental role in cognition. However, datasets of ratings of sensorimotor experience have generally been restricted to several hundred words, leading to limited linguistic coverage and reduced statistical power for more complex analyses. Here, we present modality-specific and effector-specific norms for 39,954 concepts across six sensory modalities (touch, hearing, smell, taste, vision, and interoception) and five action effectors (mouth/throat, hand/arm, foot/leg, head excluding mouth, and torso), which were gathered from 4,557 participants who completed a total of 32,456 surveys using Amazon's Mechanical Turk platform. The dataset therefore represents one of the largest set of semantic norms currently available. We describe the data collection procedures, provide summary descriptives of the data set, demonstrate the utility of the norms in predicting lexical decision times and accuracy, as well as offering new insights and outlining avenues for future research. Our findings will be of interest to researchers in embodied cognition, cognitive semantics, sensorimotor processing, and the psychology of language generally. The scale of this dataset will also facilitate computational modelling and big data approaches to the analysis of language and conceptual representations.

Keywords: embodied cognition; semantics; norms

Background

Sensorimotor information is central to how we experience and navigate the world. We acquire information through our senses, while our bodies provide feedback, as we physically interact with objects, people, and the wider environment. Many theoretical views of cognition describe a fundamental role for such sensorimotor knowledge (e.g., Barsalou, 1999; Connell & Lynott, 2014; Smith & Gasser, 2005), with numerous empirical demonstrations supporting such claims (e.g., Connell, Lynott & Dreyer, 2012; Kaschak et al., 2006; Matlock, 2004; Zwaan & Taylor, 2006).

In order to test such embodied (or grounded) theories of cognition, researchers need appropriate stimuli for empirical tests and for developing mathematical or computational models. Lynott and Connell (2009, 2013) developed a set of modality-specific sensory norms for concepts where each sensory modality (e.g., auditory, gustatory, haptic, olfactory, visual) maps onto distinct cortical regions (e.g., gustatory cortex, auditory cortex etc.). By having individuals provide ratings for each modality separately, the norms capture the extent to which something is experienced across different sensory modalities, without risk of ignoring or distorting the role of particular modalities (Connell & Lynott, 2016). Subsequent empirical studies have found that such modality-specific measures are good predictors of people's performance across a range of cognitive tasks (e.g., lexical decision, word-naming) and often out-performed long-established measures such as concreteness and imageability (e.g., Connell & Lynott, 2012; 2014). For example, in examining performance on lexical decision and word naming (reading aloud) tasks, Connell and Lynott (2012) found that modality-specific experience (and specifically the highest level of perceptual experience on any modality for a given concept, or "max strength") was a more reliable predictor of performance than either concreteness and imageability.

An added advantage of using measures of sensory experience for specific modalities is that it allows researchers to tap into effects that relate to particular modalities and not others. Connell & Lynott (2010) showed how a processing disadvantage for tactile stimuli observed during perceptual processing (Spence, Nichols & Driver, 2001) was also observed when processing modality-specific words. Connell and Lynott (2014) derived contrasting modality-specific predictions relating to lexical decision and reading aloud for individual words. Thus, for lexical decisions, a visually-focussed task, strength of perceptual experience in the visual modality (but not the auditory modality) was a reliable predictor of performance. By contrast, reading aloud, requires additional attention on the auditory modality (as participants must monitor their speech output to ensure correctly articulated responses). Consistent with this idea, both strength of auditory experience and strength of visual experience were reliable predictors for performance for the reading aloud task. Other semantic measures (such as concreteness or imageability) could not have been used as they do not offer sufficient granularity in terms of sensory experience. Thus, modality-specific measures of sensory experience provide the capacity to generate and test novel predictions related to modality-specific processing and representations.

More recently, Connell, Lynott and Banks (2018) showed that interoception (i.e., sensations inside the body) also plays an important role in semantic representations, and could be a primary grounding mechanism for abstract concepts. It was found that strength of interoceptive experience was higher for abstract concepts, such as *hungry* and *serenity*, compared to more concrete concepts like *capacity* or *rainy*. What's more, interoceptive experience was found to be most important for emotion concepts, especially for negative emotions such as *fear* and *sadness,* with interoceptive experience found to be just as important as other sensory modalities in capturing semantic knowledge.

Finally, speaking to the utility of sensory norms and broader interest in this area, several research groups have extended this earlier work, either by developing modality-specific norms in other languages, including Russian, Serbian, Dutch and Mandarin (Miklashevsky, 2018; Đurđević et al., 2016; Speed & Majid, 2017; Chen et al., 2017), or by applying these norms in novel ways. For example, the original modality-specific norms have been used to examine stylistic differences of authors (Kernot, Bossomaier & Bradley, 2019), test models of lexical representations (Johns & Jones, 2012), and evaluate the iconicity of words (Winter et al., 2017).

Nonetheless, a notable gap in the work discussed above is that it focuses solely on sensory experience, and has not included parallel measures of action or effector-specific experience. However, there is good evidence for the relevance of action experience to people's semantic representations of concepts (e.g., Glenberg & Gallese, 2012; Hauk, Johnsrude & Pulvermuller, 2004). For instance, manual action verbs like *throw* activate some of the same motor circuits as moving the hand (Hauk et al., 2004), and their processing is selectively impaired in patients with Parkinson's disease, which entails neurodegeneration of the motor system (Boulenger et al., 2008; Fernandino et al., 2013). Critically, the motor basis to semantic knowledge is specific to the bodily effector used to carry out a particular action. Applying transcranial magnetic stimulation (TMS) to hand and leg areas of the motor cortex differentially influences processing of hand- and leg-action words: hand area TMS facilitates lexical decision of hand-action words like *pick* compared to leg-action words like *kick*, whereas this effect is reversed with leg-area TMS (Pulvermueller, Hauk, Nikulin & Ilmoniemi, 2005). Such double dissociations in motor-language facilitation underscore the importance of individually examining separate action effectors when norming the motor basis of words and concepts.

Some existing measures have attempted to capture action knowledge, but have alternatively used feature production methods as opposed to rating dimensions of action (e.g., where people verbally list features associated with concepts: McRae et al., 2005; Vinson & Vigliocco, 2008), focused on generalised action (e.g., body-object interaction: Tillotson, Siakaluk, & Pexman, 2008; relative embodiment: Sidhu, Kwan, Pexman, & Siakaluk, 2014; see Connell & Lynott, 2015, for review), or on a restricted subset of action types (e.g., graspability: Amsel, Urbach, & Kutas, 2012: actions associated with lower limb, upper limb, or head: Binder et al., 2016) that omits other parts of the body involved in action. For example, the action of *pushing* can also involve the torso (Moody & Gennari, 2010), and mouth actions are cortically distinct from other actions of the face (Meier, Aflalo, Kastner, & Graziano, 2008). To our knowledge, therefore, there is no large-scale set of norms that taps into a comprehensive range of effector-specific action experience. In the present work, we address this gap by collecting effector-specific action strength norms for a large number of concepts.

Here, we present sensorimotor norms collected across 11 dimensions for approximately 40,000 concepts, comprising 6 modality-specific dimensions of perceptual strength (auditory, gustatory, haptic, olfactory, visual, interoceptive) and 5 effector-specific dimensions of action strength (head, arm/hand, mouth/throat, leg/foot, torso).

Study 1: Sensorimotor Norms

Method

Participants A total of 4,557 unique participants completed 32,456 surveys via Amazon's Mechanical Turk platform (M = 7.12 samples per participant). Data for perceptual strength ratings and action strength ratings were gathered separately. Participants were self-selecting and had English as their first language. We recruited only experienced MTurk users who had already completed over 100 HITS, and high-quality participants who had >97% HIT approval. Participants were remunerated at a rate above minimum wage in the US.

Materials Perceptual and action ratings were collected for a total of 39,954 words. These words were taken from Brysbaert, Warriner, & Kuperman's (2014) work on concreteness ratings, which included 37,058 English lemmas and 2,896 two-word expressions. These words were split into 832 lists of 48 items, along with 5 calibrator words and 5 control words occurring in each. Responses to controls and calibrators (selected for being highly familiar, and low in variance based on previous norms) were used for quality checks, which we describe below in the subsection on Data Quality and Exclusions. Lists were populated to provide words that varied in terms of familiarity ("percentage known" in Brysbaert et al's study) and concreteness.

Procedure Using Qualtrics survey software, a template survey was created that followed procedures developed in Lynott & Connell (2009, 2013). At the start of the survey participants read an information sheet, and indicated their informed consent to continue with the study. Specifically, each concept in a 58-word sample was presented individually on a screen (order randomised by participant) followed by question text. For perceptual strength ratings, the text was "To what extent do you experience WORD," where WORD was replaced with the concept in question. Underneath were six rating scales, one for each of the perceptual modalities under investigation, labelled "By feeling through touch", "By hearing", "By sensations inside your body", "By smelling" and "By tasting,". The order of the ratings scales was randomised by sample.

For the action strength ratings, the text read "To what extent do you experience WORD by performing an action with," followed by choices of "Foot / leg", "Hand / arm", "Head excluding mouth", "Mouth / throat", "Torso". For these ratings, each scale also contained an image of a body avatar that highlighted the body part relevant to each intended effector. Participants were asked to rate the extent to which they experience each concept through each of the named senses or effectors; both the sensory and motor components had 6-point scales ranging from 0 (not at all) to 5 (greatly).

There was no default value selected on the scale and participants clicked on a button under the relevant value to select or change their response. Participants were explicitly told there were no right or wrong answers and they should use their own judgment; they were also instructed to select the "I don't know the meaning of this word" option if the word was unfamiliar to them. Progress to the next item could only occur if values were selected for all perceptual senses or action effectors or the "I don't know the meaning of this word" option was checked. The study was self-paced and timed to last 18-20 minutes.

Data quality and exclusions In order to ensure the data collected is of sufficiently high quality, we instituted a number of checks, in terms of individual performance, item performance, and agreement for each list of words. Overall, only 0.8% of all responses were removed following data checks. Participants whose scores exhibited a Pearson's r < 0.2 with the controls or who responded 'don't know the meaning of this word' for more than five control and calibrator words, were dropped from the sample. Additionally, there were a small number of participants who completed the same sample of words more than once, when this happened only the earliest submitted responses were retained. Cronbach's alphas (Cronbach, 1951) were calculated for each modality for all other participants; results were only retained when the mean alpha for all samples was >= 0.8.

Norms Data The final set of norms, results, analyses, and scripts are available on the project's Open Science Framework page: https://osf.io/7emr6/

Results

Summary statistics were calculated for all valid samples, with 39,707 words included in the overall norms, following exclusion criteria. Each word in a sample is represented by a row that contains ratings for each of the 11 dimensions. Each dimension has separate values for mean score, standard deviation, median score, trimmed mean, trimmed standard deviation by modality/effector, and the percentage of participants who knew the word. Inter-rater reliability by modality/effector was high for both perceptual and action ratings: mean Cronbach's alphas for perceptual modalities were: auditory 0.93, gustatory 0.96, haptic 0.92, interoceptive 0.92, olfactory 0.94 and visual 0.90; for action effectors mean alphas were: foot 0.93, hand 0.91, head 0.85, mouth 0.92 and torso 0.89.

Following Lynott and Connell (2009; 2013), additional variables of interest were calculated for each of the words in the sensorimotor norms. This included: Exclusivity scores (i.e., a measure of the extent to which a particular concept is experienced through a single dimension, calculated per word as the rating range divided by the sum of the ratings, and extending from 0%, for completely multidimensional, to 100%, for completely unidimensional); separate exclusivity scores were calculated for the perceptual (6 modalities) and action components (5 effectors), in addition to scores calculated across all 11 dimensions. Similarly, each concept was assigned a dominant dimension (i.e., the dimension that had the highest mean rating), for the perceptual, action and the full sensorimotor norms. When the highest mean rating was found in more than 1 dimension (Perceptual: N = 593; Action: N = 706; Sensorimotor: N = 478), a random dimension was assigned.

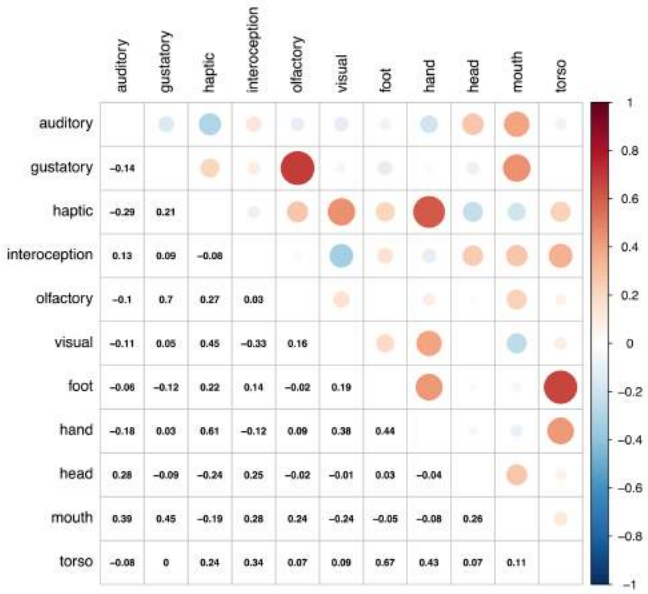

Figure 1 Correlation matrix plot between 11 dimensions for mean ratings of the sensorimotor strength norms (N = 39,707). Larger circles indicate stronger correlations, with red shades being positive, and blue shades being negative.

The norms confirm previous reports that we predominantly experience the world perceptually through our visual modality (Lynott & Connell, 2009; 2013; Winter, Perlman & Majid, 2018 – See Table 1), with the head emerging as the primary action effector. The least prominent dimensions were gustation and olfaction, highlighting the fact that only a small subset of the conceptual system is experienced strongly through these modalities. For the action norms, the head was observed to be the dominant effector and the torso had the least dominance.

Bayesian correlation analysis (Figure 1) between the dimensions showed that almost all the dimensions were significantly correlated with one another, with the exception of gustation~torso, as well as head~vision, with correlations approaching zero. It should be noted however, that a large number of the correlations were very weak, which is to be expected as each dimension is tapping into different aspects of sensorimotor experience. In some cases of course, certain dimensions often co-occur in our sensorimotor experience,

with notable relationships found between gustation~olfaction (r = .70), foot/leg~torso (r = 0.67) and hand/arm~haptic (r = 0.62).

	M	*SD*
Perceptual Modality		
Auditory	1.514	0.991
Gustatory	0.324	0.697
Haptic	1.074	0.934
Interoceptive	1.032	0.880
Olfactory	0.390	0.619
Visual	2.897	0.902
Action Effector		
Foot/leg	0.807	0.750
Hand/arm	1.447	0.907
Head	2.276	0.719
Mouth/throat	1.257	0.903
Torso	0.816	0.670

Table 1 Mean Strength Ratings (0–5) and Standard deviations (SD) per Sensorimotor Dimension

Study 2: Modelling Lexical Decision

In Study 2, we address three issues. First, we determine what is the best composite variable (i.e., single value) for representing a concept's sensorimotor profile. Second, we wish to replicate the utility of perceptual strength ratings in modelling people's performance in cognitive tasks (e.g., Connell & Lynott, 2012), and establish the independent utility of action strength as a performance predictor. Third, we will check the generalisability of the findings, by examining performance across two different data sets (i.e., English Lexicon Project, British Lexicon Project).

While an 11-dimension sensorimotor profile is a rich source of semantic information about a particular concept, it can nonetheless be somewhat unwieldy for some uses. It is often useful to aggregate multiple dimensions into a single composite variable, such as for use as a predictor in regression analyses without unnecessarily inflating the number of parameters. A single variable would also facilitate comparisons with other single-variable measures of people's experience (e.g., concreteness, valence etc.) There are many different methods of creating a composite variable. Previous work on perceptual strength has used strength of the dominant modality (i.e., maximum perceptual strength rating across all modalities) as the preferred composite variable (e.g., Connell & Lynott, 2016; Connell, Lynott, & Banks, 2018), finding it offered a better fit than alternatives to visual word recognition performance (Connell & Lynott, 2012). However, work in Serbian (Đurđević, Stijačić & Karapandžić, 2016) found the best fit emerged from summed perceptual strength (i.e., sum of perceptual strength ratings across all modalities) or vector length (i.e., Euclidean distance of the multidimensional vector of perceptual strength ratings from the origin). It is difficult to be certain whether this variability is due to language differences (i.e., English vs Serbian) or sampling differences (i.e., hundreds of words with limited overlap).

We therefore sought to empirically determine the best single composite variable for the 11-dimension sensorimotor profile using a much larger and more representative sample of concepts in English. As with previous studies (e.g., Connell & Lynott, 2012), we judge the "best" variable to be the one that offers the best fit to lexical decision latency, a task where semantic facilitation emerges from automatic and implicit access to the sensorimotor basis of the concept.

Method

Materials A total of 22,297 words were collated, representing the intersection of data available between the sensorimotor strength norms and lexical decision data from the English Lexicon Project (Balota, et al., 2007). A separate set of 11,768 words was also collated from the British Lexicon Project (Keuleers, Lacey, Rastle & Brysbaert, 2012).

Candidate Composite Variables Composite variables were calculated separately for sensorimotor (all 11 dimensions), perception (6 dimensions) and action (5 dimensions) dimensions. Most of the candidate variables we tested are distance metrics in vector space of a particular concept (i.e., an 11-dimension vector) from the origin. Minkowski distance (with exponent parameter *m*) is a generalisation of these distance metrics: roughly speaking, the highest-value dimension always contributes to the calculated distance, and *m* determines the extent to which the other dimensions contribute according to how close their values are to the highest-value dimension. That is, low-value *m* means that all dimensions make noticeable contributions to the calculated distance, whereas high-value *m* means only the highest-value dimension(s) make noticeable contributions to the calculated distance.

For example, for Minkowski 10 distance (Minkowski distance at m = 10 of the vector from the origin), theoretically, it represents sensorimotor strength of the dominant dimension plus an attenuated influence of any other dimensions that are nearly as strong as the dominant dimension. By contrast Minkowski 3 distance represents sensorimotor strength in all dimensions but the influence of weaker dimensions is attenuated.

Our set of candidate variables comprises: maximum strength, Minkowski 3, Minkowski 10, Euclidean vector length, Summed strength, and single PCA component.

Design and Analysis We performed Bayesian linear regressions predicting the dependent variable of zRT (i.e., standardised Lexical Decision RT per participant) and accuracy from 2 datasets: Elexicon (ELP) and the British Lexicon Project (BLP). First, for each dependent variable we built a null model of lexical predictors (log SUBTLEX word frequency, number of letters, number of syllables, orthographic Levenstein Distance), all of which are known to reliably predict lexical decision performance. In subsequent models, we then added one of the candidate composite variables to the model and use Bayes Factors to quantify the evidence in favour of each. In Table 2, we report R-squared change for each model comparison, to allow comparisons with other megastudies in the literature (e.g., Pexman, Muraki, Sidhu, Siakuluk & Yap, 2019).

Results

Overall, we found that the sensorimotor norms reliably predicted lexical decision performance for both response times and accuracy, and in both the English Lexicon and British Lexicon datasets. Each of the six composite measures accounted for a significant amount of additional variance, over and above the basic model of lexical variables (see Table 2). Log Bayes Factors for each variable (ranging from 50 to 228 for zRT, and from 29 to 138 for accuracy) revealed very strong support for their inclusion in the models. Minkowski 3 was the best performing measure in both the ELP and BLP datasets, while PCA, although still considerably improving model fit over the basic model, was the weakest performing composite measure.

Subsequently, using Minkowski 3 as the best predictor, we also found that the inclusion of action effector ratings improved model fit over and above perceptual ratings alone (see Table 3). Furthermore, adding action effector ratings provided better model fit for both ELP and BLP datasets, across both reaction time and accuracy measures.

In summary, these findings replicate the finding that perceptual information is a good predictor of people's performance in lexical decision tasks, provides new support for the utility of action effector experience in modelling cognitive performance, and shows that the findings generalise over more than one largescale data set.

General Discussion

We present a set of almost 40,000 words, normed for perceptual and action strength across 11 dimensions. The first study shows that these sensorimotor norms provide a rich dataset, with the data revealing complex patterns between various dimensions. The second study provides support for the utility of modality-specific and effector-specific sensorimotor information in modelling human performance in classic psycholinguistic tasks.

While these norms extend earlier modality-specific norms, they also quantify important new relations, such as between specific effectors and particular perceptual modalities, as well as including often ignored perceptual dimensions, such as interoception Connell, Lynott & Banks, 2018). What's more, we show that effector-specific information is also predictive of data from lexical decision tasks, over and above using perceptual-specific information alone. These findings provide evidence for a broad role for perceptual and action information in terms of their possible involvement in conceptual representations and their recruitment during cognitive processes.

A notable difference in the new set of norms is the identification of a different single composite variable that could be used in place of the full multi-dimensional vector. In the previous sets of norms (Connell & Lynott, 2012), Maximum Perceptual Strength (i.e., the highest value of any single dimension) was identified as the best single value predicting lexical decision data. In the current analyses, although max strength continued to perform very well, it was outperformed by the Minkowski 3 measure. This is an interesting pattern to emerge, as Minkowski 3 has previously been identified as an optimal parameter when modelling the integration of multiple perceptual cues (To, Baddeley, Troscianko, & Tolhurst, 2011), suggesting greater weighting to higher value dimensions. To and colleagues provided evidence that Minkowski values around 3 actually represent a general principle for perceptual integration, and may reflect the summation of neural responses to perceptual stimuli.

The current norms provide a rich source of information, and provide lexical coverage that reflects a grown adult's conceptual system. As such, we hope that they will provide many avenues for further research. There is much scope for combining the current norms with other data sets to provide even broader coverage of the human conceptual system. These and other data could then be useful for predicting human performance in a diverse array of cognitive tasks. With the increased size of the norms, they may be amenable to some machine learning techniques, for example to acquire semantic representations that could be used in robotics, or perhaps as diagnostic tools (as has been used by Kernot, Bossomaier & Bradley, 2019). Those interested in linguistics, could further investigate the role of grammatical differences in people's sensorimotor experience, and there are also opportunities to extend these norms to other languages and populations, which will enable researchers to consider cross-cultural similarities and individual differences.

Acknowledgments

This research was supported by the Leverhulme Trust, UK (RPG-2015-412, to DL, LC & MB) and the European Research Council (ERC) under the European Union's Horizon 2020 research and innovation programme under grant agreement No. 682848 to LC. We thank Rosie Meers and Peidong Mei who provided help with data collection and quality control during the project, and David Balota for permitting us to include data from the English Lexicon Project in our deposited analysis files.

Abstract

Pervasive behavioral and neural evidence for *predictive processing* has led to claims that language processing depends upon *predictive coding*. In some cases, this may reflect a conflation of terms, but predictive coding formally is a computational mechanism where only deviations from top-down expectations are passed between levels of representation. We evaluate three models' ability to simulate predictive processing and ask whether they exhibit the putative hallmark of formal predictive coding (reduced signal when input matches expectations). Of crucial interest, TRACE, an interactive activation model that does not explicitly implement prediction, exhibits both predictive processing and model-internal signal reduction. This may indicate that interactive activation is functionally equivalent or approximant to predictive coding, or that caution is warranted in interpreting neural signal reduction as diagnostic of predictive coding.

Keywords: prediction; predictive coding; language; computational modeling; neural networks

Prediction in spoken language processing

Listeners often predict upcoming information in spoken language. They anticipate upcoming phonemes based on lexical expectations (Grosjean, 1980; Allopenna, Magnuson, & Tanenhaus, 1998), and upcoming words based on lexical, syntactic, and/or discourse expectations (Altmann & Kamide, 2007; Magnuson et al., 2008; Strand et al., 2018). There is also neural evidence consistent with prediction. Indeed, many ERP studies test the magnitude and timing of responses to expectation violations, including responses that precede complete bottom-up specification. Despite difficulties replicating one classic example (Delong, Urbach, & Kutas, 2005 vs. Nieuewland et al., 2018), a large number of studies support varying degrees of prediction (for reviews, see Kuperberg & Jaeger, 2015; Hickock, 2012).

Evidence for predictive *processing* (PP) is often considered evidence for *predictive coding* (PC), and there may be instances where these terms are conflated and treated synonymously. PC, however, is a computational formalism enaling efficient coding by comparing bottom-up inputs to predictions from a top-down model and passing forward (and backward) only *deviance from prediction* (Rao & Ballard, 1999). This deviance is the novel *information*; sending bottom-up details would be redundant when predicted by higher-level expectations. Thus, formal PC predicts reduced feedforward and feedback signal when inputs conform to top-down expectations. In light of several reports of neural signal reduction when word-level expectations are met (e.g., Blank & Davis, 2016; Gagnepain, Henson, & Davis, 2012), we next consider what evidence for PP and PC implies for models of spoken word recognition (SWR).

Implications for models of spoken word recognition

First, even without considering sentence-level contexts (beyond the scope of current models), models of SWR must be able to simulate attested word level PP. Intuitively, some models might do this readily (e.g., a simple recurrent network [SRN; Elman, 1990] trained to predict the next phoneme given the current phoneme), while others may not. For example, Gagnepain et al. (2012) suggest that the interactive activation model, TRACE (McClelland & Elman, 1986), may be inconsistent with PC because they describe its primary mode as *competitive* rather than *predictive*.

Second, given growing neural evidence consistent with formal PC (reduced neural signal when expectations are confirmed vs. violated; e.g., Sohoglu & Davis, 2016) we can also ask whether a model of SWR exhibits this hallmark of PC: internal signal reduction when expectations are confirmed. This leads us to two questions for models of SWR. (1) Do models with explicit prediction (e.g., SRNs) and without explicit prediction (e.g., TRACE) simulate PP? (2) If so, do they show hallmarks of formal PC (model-internal signal reduction when expectations are confirmed)? To address these questions, we will compare three models.

Model comparisons

Our simulations are based on human experiments by Gagenpain et al. (2012). In those experiments, there were three critical stimulus types: an **Original** word (e.g., *formula*), a **Trained** nonword (e.g., *formubo*), and an **Untrained** nonword (e.g., *formuty*). In the examples, we have underlined letters corresponding to the critical phonemes. Prior to training, both Trained and Untrained nonwords differ from expectations at 1-3 phonemes from offset; this position follows the *deviation point*. The critical question is how the system responds at the phoneme(s) following the deviation point before a training phase and after. In the training,

participants get extensive exposure to the *trained* nonwords. Prior to training, Gagnepain et al. (2012) found reduced neural activity in left superior temporal gyrus following the deviation point for Original items vs. both types of nonwords. Following training (and sleep), Trained items showed the same reduction relative to Untrained items as real (Original) words. In the following sections, we examine whether each of 3 models is able to simulate PP (sensitivity to expectations at the deviation point) in simulations of this paradigm, and whether they exhibit the hallmark of PC: signal reduction when top-down lexical expectations are met.

Model 1: Predictive Cohort

Gagnepain et al. (2012) used a simple mathematical model to generate predictions for their experiment. We call their model "predictive cohort" because it simply looks up the set (cohort) of words that remain consistent with the phoneme-by-phoneme input for each item. For example, given *formula*, at position 1, all /f/-initial words are possible and the prediction for position 2 is the frequency-weighted probability distribution of each phoneme following /f/. As input progresses, probability distributions narrow. For *formula* (/formjul^/), by /u/ at position 6, very few possibilities remain (*formula, formulaic, formulation*) and all predict /l/. Gagnepain et al. (2012) derived positional prediction error for the three item types. Given a prediction of 1.0 for /l/ at position 7, *formula* would garner zero prediction error, while prediction error would be high for *formubo* and *formuty*.

The logic is that a formal PC implementation would pass back a prediction of /l/ at position 7 given the input for positions 1-6, and therefore pass forward a very weak signal given *formula,* where the prediction error is low, compared to the nonword cases. Note that prediction error is not an internal signal in this model; it is a derived term meant to stand in for computations that would occur in formal PC.

Methods

Materials We implemented predictive cohort as described by Gagnepain et al. We selected 37.6k words ≤ 12 phonemes long from the English Lexicon Project (ELP; Balota et al., 2007). Critical items were 54 Original-Trained-Untrained triples from Gagnepain et al. (mean length: 6.3 phonemes). Deviation points were 1-3 positions before offset.

Procedure We conducted two suites of simulations with all 54 x 3 = 162 items. In *pretraining*, the lexicon was restricted to 37.6k real words; thus, the Original items were words, and the Trained and Untrained items were nonwords. *Post-training*, Trained items were simply added to the lexicon, changing the positional probability distributions embedded in the lexicon (as done by Gagnepain et al.). For each simulation, we computed predicted probability distributions at each position, and calculated implied prediction error.

Results are presented in Fig. 1. Consistent with PP, the probability for Original items continues to increase beyond the deviation point at Pretraining, and probabilities also increase for Trained items Post-training. Because error is summed over all phonemes, the maximum is 2.0 (e.g., if predicted values for /l/ and /b/ were 0.8 and 0.0, but the input were 0.0 for /l/ and 1.0 for /b/, summed error would be 1.8). Error plots do *not* reflect model-internal information. Rather, error is meant to approximate what the forward signal would be *if a formal PC model were implemented.* Thus, while the predictive cohort model is able to exhibit PP, it does not inherently exhibit PC. Of course, a fully-implemented PC model would show such signal reduction.

Model 2: Simple Recurrent Network

The second model we tested was a Simple Recurrent Network (SRN; Elman, 1990). An SRN would seem likely to naturally produce PP, given that an SRN is typically trained to predict

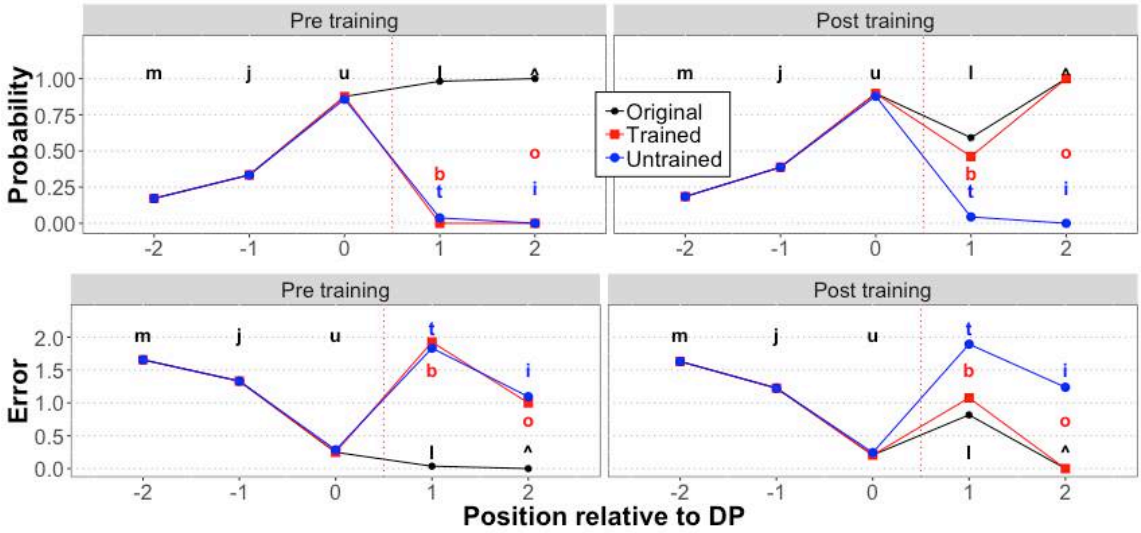

Figure 1: Predicted phoneme-by-phoneme probabilities (top) and derived errors (bottom), pre- (left) and post- (right) training for the Predictive Cohort model. The X-axis is position relative to the deviation point (allowing us to align results for all items). The dashed lines between positions 0 and 1 indicate the deviation point.

the next item in a series. We created an SRN with localist phonemic inputs (41 nodes, one for each phoneme) with forward connections to 200 hidden units with forward connections to 41 localist phonemic output nodes. The hidden nodes feed an exact copy of their states with a 1-cycle time delay to *context* nodes, which feedback to hidden nodes (providing a memory sensitive to multi-step contingencies).

Methods

Materials We used the same materials as for Model 1.

Procedure The model was presented with a continuous series of phonemes constructed by randomizing the order of the 37.6k words and presenting each phoneme-by-phoneme, without any break or indication of a word boundary. The network was trained using backpropagation of error to predict the next phoneme. At each time step, output activations were compared to the desired output pattern (1.0 for the following phoneme, 0.0 for all others). Backpropagation allows "blame" to be assigned to all connections in the network (i.e., to calculate how small changes to all weights could alter the network such that if the same input sequence were applied again, the network would come closer to the target pattern).

After approximately 2000 epochs (each epoch is 1 pass through all 37.6k words in random order), error plateaued (aggregated over small batches of words). This does not mean error rate was uniform. Rather, output activations come to resemble the probability distributions calculated by the predictive cohort model (Model 1). Thus, error is relatively high near word onset and diminishes as the input progresses.

For the *pretraining* test of the model, only the 37.6k words selected from the ELP for Model 1 were included. Because the SRN is a learning model, we were able to actually train the model on Trained items. The 54 Trained items were presented in novel random orders for 50 epochs. This number of instances was sufficient for the model to achieve Original-level accuracy with Trained items without impairing the model's ability to process items already in its lexicon.

Results are in Fig. 2, and are similar to those from Model 1, but with output activations for relevant phonemes. Error indicates the summed error over all 41 output phoneme units. Like Model 1, the SRN exhibits PP pre- and post-training in that phonemes from trained items become more probable after training. Also like Model 1, though, note that error is not a model-internal value; it is calculated externally. Model-internal signals (here, activations) *do not exhibit the reduced-signal hallmark of PC*. Instead, activations are *higher* when expectations are met (when the input sequence corresponds to a word in the lexicon). Thus, even the most intuitively predictive model of SWR one might propose (short of a formal PC model) – an SRN – does not inherently exhibit PC.

Some might disagree with this analysis, since SRNs are trained using backpropagation of error, and these error terms could be considered to be passed back through the model, even if error is typically not passed during tests and is not necessary for a trained SRN to function. We might counter that backpropogation is model-external (the procedure is not part of the network dynamics of an SRN; adjustments to weights are imposed on the network, rather than an emergent property. One might contrast this with Hebbian learning, where weight changes occur through biologically-inspired interactions among nodes. On the other hand, while backpropogation may not have a direct analog in biology, functionally-equivalent, neurally-plausible mechanisms are not far-fetched (Lillicrap & Santoro, 2019). It may be sensible, then, to consider the error signal in an SRN as a feedback signal, in which case SRNs show the PC hallmark of relative signal reduction when inputs match expectations.

Model 3: TRACE

TRACE (McClelland & Elman, 1986) is an interactive activation model: a neurally-inspired, parallel-distributed processing model with feedforward connections from inferior to superior levels (features→phonemes→words) and lateral inhibition within levels. It also has feedback from words to constituent phonemes. As mentioned earlier, TRACE may

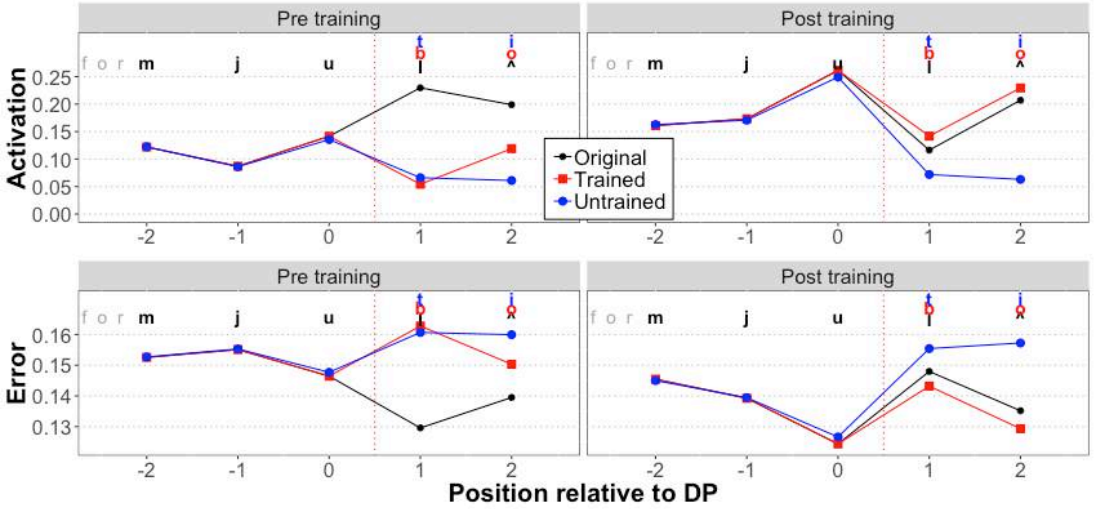

Figure 2: Phoneme-by-phoneme SRN output activations indicating how strongly the model predicted each upcoming phoneme (top) and those activations converted to error scores over time (bottom).

not seem to be a predictive model (e.g., Gagnepain et al. [2012] describe TRACE as having a primarily competitive mode of processing, dominated by lateral inhibition). However, word→phoneme feedback in TRACE provides a generative model (McClelland, 2013; Magnuson et al., 2018): as features and phonemes consistent with a specific word are presented, the lexical node for that word form sends increasingly strong feedback to *all* its constituent phonemes, including those that have not yet occurred. This allows graded pre-activation of phonemes (as a function of how strongly *expected* they are due to feedback from one or more words). But is there any possibility that TRACE exhibits the hallmark of PC – reduced signal when expectations are confirmed vs. violated?

Methods

Materials We used the original 212-word TRACE lexicon, wherein we identified 15 six-phoneme words on which to base item sets. From each set, we created 2 nonwords by changing the final two phonemes. For example, from the Original /art^st/ (*artist*) we created /art^da/ and /art^pi/.

Procedure Simulations were conducted with all 15 (set) x 3 (item type) items. We tracked activations of phonemes and words over time as well as the total amount of activation (and inhibition) flow between and within levels during each simulation. For pre-training, the lexicon consisted only of the TRACE lexicon, including the 15 Original items. For post-training, the 15 Trained items were added to the lexicon.

Results We begin by comparing lexical activations for each item type (Original, Trained, Untrained) pre- and post-training (Fig. 3). Pre-training, we see significantly weaker Original activation when input ends with final phonemes of Trained or Untrained items. Post-training, we see a decrease in Original activation given Untrained input, and a massive decrease given Trained input. This is because Trained items are now words in the lexicon; with clear input, Trained items strongly activate and inhibit their Original counterparts. The post-training panel in Fig. 3 includes a red line marked with an open red square; this indicates activation of Trained items given corresponding input. This line is directly on top of the Original line; since both items are words in the lexicon, clear corresponding input drives both similarly.

Next, consider the phoneme level (Fig. 4). Activations of phonemes one position beyond the deviation point are plotted for the Original word, as well as replaced phonemes in the case of the Trained and Untrained nonwords. In Fig. 4, we can see differences in the lines with open symbols that achieve high activation. These correspond to activations of replaced phonemes (/d/ in /art^da/ or the /p/ in /art^pi/). Pre-training, the highest activation is achieved for the phoneme in penultimate position in the Original word, thanks to support from both bottom-up input and top-down lexical feedback. There is only a slight disadvantage for the replaced phonemes; given clear bottom-up input, phonemes will be strongly activated, even in the absence of lexical support. Post-training, with Trained items added to the lexicon, the 'replaced' phoneme in a Trained item achieves nearly identical activation as a phoneme in an Original item, since both receive lexical support.

To address PP, Fig. 5 zooms in on the regions delineated with dashed squares in Fig. 4. Pre-training, the activation of the Original phoneme is higher than that for replaced phonemes beginning ~12 cycles prior to the deviation point. Phoneme activations from cycles ~18 to ~33 (just past the deviation point, indicated by the dashed vertical line) are driven nearly exclusively by top-down feedback. Bottom-up input begins to override feedback just after the deviation point. At this point, when the input has a replaced phoneme (one of the nonworeds), the activation of the Original phoneme drops, while activation of the replaced phonemes when they are actually the input (dashed lines, open symbols) jumps dramatically. Post-training, we see a lexical advantage for phonemes after the deviation point for both Original and Trained items (for Trained items, activations after the deviation point is slightly less due to a small trend for those items to have lower transitional probability in the lexicon, even when they have been added to the lexicon). In summary, training elicits clear PP: increased activation of critical phonemes prior to the deviation point.

Next, let's consider PC, which could manifest as reduced feedforward or feedback signal when expectations are confirmed; to be fully consistent with PC, both the feedforward and feedback signal would have to be reduced when expectations are met. However, the standard in many cognitive neuroscience studies is that any evidence of signal reduction is taken as evidence for PC. We therefore tracked the total amount of activation flowing between levels

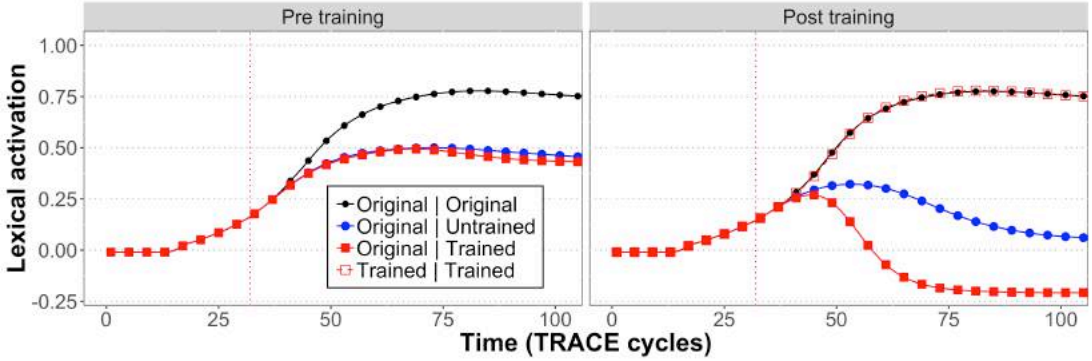

Figure 3: Lexical activations in TRACE before and after 'training'. Note that 'Trained | Trained' is only valid post-training.

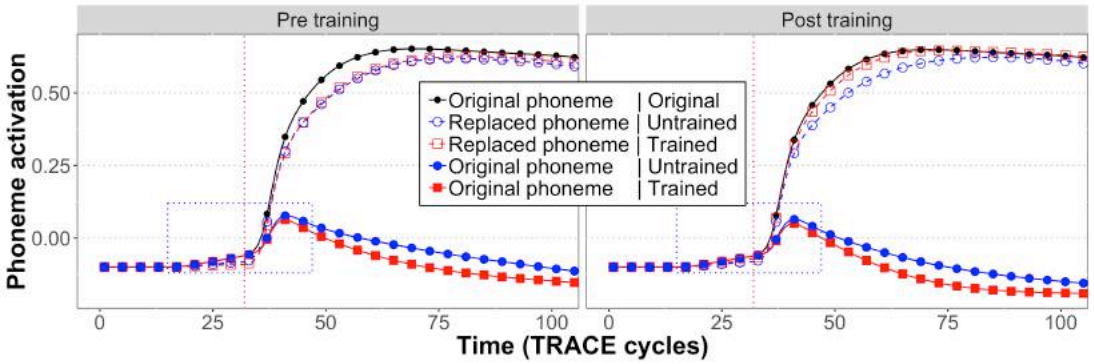

Figure 4: Activations of critical phoneme (following deviation point) in TRACE.

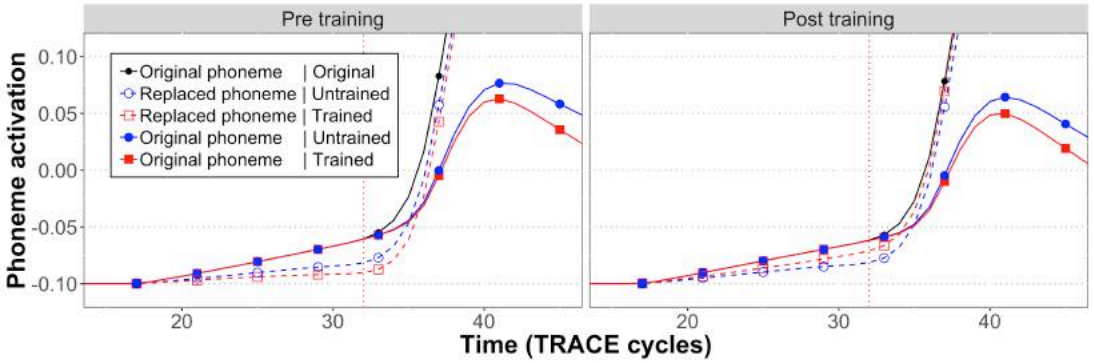

Figure 5: Zoomed view of critical time period from Figure 4.

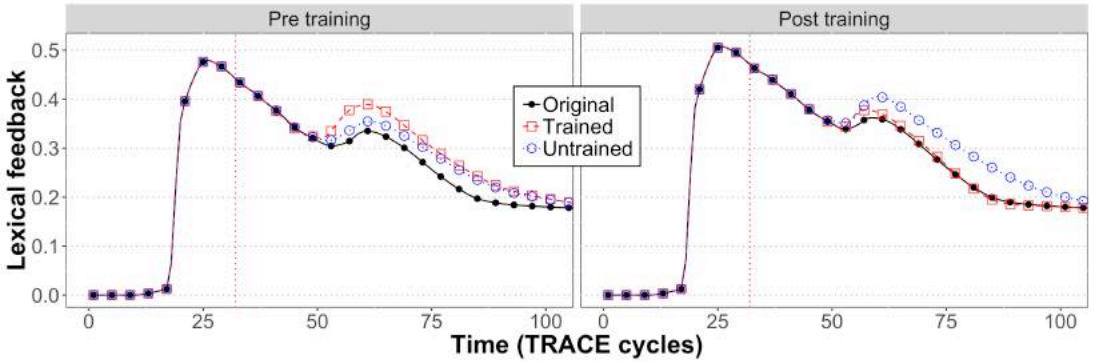

Figure 6: Total lexical feedback over time in TRACE, showing robust signal reduction when expectations are met.

(forward and backward) and within levels (lateral inhibition), looking for any signal reduction.

Two activation indices were reduced when expectations were met: word→phoneme feedback (Fig. 6) and lateral inhibition (absolute value). The latter shows virtually the same pattern as Fig. 6, but we omit it due to length constraints and challenges in interpreting a reduction in a signal with negative valence. In Fig. 6, total lexical feedback is *lowest* when expectations are met (for Original words pre- or post-training, as well as for Trained items post-training). This is because when an unexpected phoneme occurs, Original items already have strong support and continue to send substantial feedback. Additional feedback comes from words partially activated by replaced phonemes (any word unit containing the unexpected phoneme *aligned* with the unexpected phoneme[s] would get activated; e.g., a word unit for *piano* aligned at position 5 overlaps with the /pi/ of /art^pi/]). This follows from the *total* amount of feedback actually being less when one word can strongly dominate and inhibit other words; there can actually be *more* total feedback when many words are weakly activated. Thus, only TRACE, the model one might have predicted to be least likely to exhibit PC, shows a *model-internal signal reduction* often considered *diagnostic* of PC in cognitive neuroscience.

Discussion

All three models tested – predictive cohort, an SRN, and TRACE – exhibit PP. The first two showed model-internal signal *increases* when expectations were met. While these increases can be converted to predicted error, this takes place outside the current instantiation of these models (though see our earlier discussion of backpropagated error in SRNs). TRACE shows model-internal signal *reduction* when expectations are confirmed, in the form of lesser top-down

lexical→phoneme feedback.

This raises the possibility that interactive activation (as implemented in TRACE) may provide a generative model that is functionally equivalent (or functionally approximant) to a Bayesian generative model (McClelland, 2013) or even PC. Addressing this question will require the development of explicit, formal PC models of SWR based on formalisms like those introduced by Rao and Ballard (1999). This is a tall order; such a model must work on over-time inputs (if not real speech), must be validated with a moderately large lexicon (at least hundreds of words), and must be comprehensively compared to other models, such as TRACE.

There are promising starts in this direction. For example, Yildiz et al. (2013) have reported a PC model of SWR that operates on real speech. However, this model was limited to a 10-word vocabulary (names for the digits 0 to 9). Another promising example comes from Blank and Davis (2016), who implemented simple network models of SWR with lexical→phoneme feedback that was either multiplicative (as in TRACE) or subtractive (one possible interpretation of PC). Both models correctly simulated one experiment, but their subtractive feedback model correctly predicted neural signal reduction in a second experiment where the multiplicative model predicted signal increase (but with radical parameter changes required to fit the two experiments; in one, they ran models for more than 300 cycles, while for the second, they ran models for only 1 cycle). This sort of work, along with comprehensive tests of models on at least moderately large vocabularies (to verify that the models are consistent with known facts about SWR), are needed to advance understanding of the potential role for PC in SWR.

In the absence formal PC models, we must exercise caution when interpreting neural signal reduction. Though our results indicate that TRACE exhibits model-internal signal reduction, it remains an open question whether interactive activation is indeed functionally equivalent or approximant to PC. Similarly, it may be premature to consider evidence of a reduction in neural signal when expectations are met as *diagnostic* of PC.

Individual differences in reading experiences: The roles of mental imagery and fantasy

Marloes Mak
Radboud University, Nijmegen, Netherlands

Roel M. Willems
Radboud University, Nijmegen, Netherlands

Abstract

It is well established that readers form mental images when reading a narrative. The influence of mental imagery on the way people experience stories is however still unclear. In two experiments reported here, participants received instructions aimed at encouraging or discouraging mental imagery before reading literary short stories. After reading, participants answered questions about their reading experiences. The results from the first experiment suggested an important role of mental imagery in determining reading experiences. However, the results from the second experiment showed that individual trait differences in how imaginative participants are predicted reading experiences much better than guided mental imagery. Moreover, the role of mental imagery did not extend to aspects of the reading experience other than mental imagery. The implications of these results for the relationship between mental imagery and reading experiences are discussed.

Hands in mind: learning to write with both hands improves inhibitory control, but not attention

Abstract

Embodied cognition theories predict that changing motor control would change cognitive control, as cognition is considered to emerge from action in this theoretical approach. We tested this prediction, by examining the attention and cognitive control capabilities of a group of school students (12-13-year-olds) trained to write using both hands (experimental group, N=28), compared to a group of age-matched children (control group, N=33) who did not receive such training. The key tasks used were the attentional network test (ANT) task and the hearts and flowers (HF) task. Results from the ANT task showed that there was no significant difference in the three attentional networks between the groups. However, results from the HF task showed that the experimental group had better inhibitory control. This second result provides support to the embodied cognition prediction that cognitive control and motor control are related, and the former can be changed to some extent by changing the latter.

Keywords: Embodied Cognition; Handedness; Executive Functions; Motor Control.

Introduction

Embodied theories of cognition argue that cognitive processes are shaped by the way the body interacts with the environment (Glenberg et al., 2013). This is because the brain evolved to control coordinated actions in multicellular creatures, and cognitive and affective processes evolved later, to guide action. This evolutionary view is partly based on the work of Rudolfo Llinas (2001), who argues that "A nervous system is only necessary for multicellular creatures (not cell colonies) that can orchestrate and express active movement -- a biological property known as "motricity"".

The embodied cognition position would thus predict that changes in motor control would lead to changes in cognition and affect, as the latter are derivative systems. Supporting this view, a series of studies have linked the manipulation of motor system with changes in executive functions of children as young as 5-year-olds (Stein et al., 2017; Rueda et al., 2012). Motor functions have also been shown to influence inhibition and cognitive flexibility (Livesey et al., 2006). Further, executive functions have been shown to be related to physical activity (Campbell et al., 2002; Becker et al., 2014), and motor functions (Livesey et al., 2006; Davis et al., 2011) in both kindergartners and older children (Stein et al., 2017). These effects of motor functions on cognitive functions are supported by the fact that the biological development of both motor and cognitive functions are closely related (e.g., Sibley and Etnier, 2003), and cognitive functions are stimulated and required when learning and executing new motor skills (Best, 2010; Diamond, 2000).

A related empirical thread has examined the role of handedness, and lack of consistent handedness, on cognitive and affective abilities (Casasanto, 2009; Coren, 1992). It has been shown that handedness (ranging from strongly right-handed to strongly left-handed) predicts whether electrical excitation via transcranial direct current stimulation causes an increase or decrease in the experience of approach-related emotions. (Brookshire and Casasanto, 2012). In such studies, handedness is typically considered a marker of motor training, and thus not explored further. The development of handedness and its results, particularly how training to use both hands at a young age affects cognitive abilities such as attention and executive functions, has not been much explored.

To understand the relation between handedness development and cognitive abilities, we conducted a study based on the Attentional Network Test (ANT) Task and Hearts and Flowers Task (HF). Both ANT and HF tasks are standard psychological tasks that reliably provide independent measures for different attentional networks (i.e. alerting, orienting, and executive control; Fan et al., 2002; Rueda et al., 2004) and executive function components (i.e. working memory, inhibition, and flexibility; Davidson et al., 2006). These tasks were selected as they tap into different types of inhibitory control. The ANT task involves resolving conflict of the stimulus-stimulus type (e.g. both the target and the distractors are visual stimuli in a flanker task). The HF task involves resolving conflict of the stimulus-response type (e.g. overcome the default propensity to make a response matching the stimulus location). These tasks were administered to two student groups (experimental, control) from two schools. The experimental group students studied in a school that provided a school-wide basic training to write using both hands. The control group studied in a school that had no such training.

Methods

Demographics Owing to the uniqueness (only 2 identified schools in India) of the experimental group

school[1] in imparting training to write with both hands, this school was assigned to the experimental group by default. Another school which was similar in all other aspects (other than the training) was assigned as the control group school. The criteria for selecting a relevant and comparable control group were multifold: similar parents' profession and annual incomes (migrant laborers), similar school infrastructure (both low-income private schools), similar curricular and extracurricular aspects (including training on physical activities), same age groups (12-13-year-olds), and an equivalent number of languages exposed to the students (each group was familiar with at least three different languages). Apart from the training to write with both hands, the other major difference between the groups was the location: the experimental group school was a village school while the control school was in a slum in the heart of a metropolitan city. The experimental group students were familiar with Kannada, English, and Hindi while the control group students had familiarity with Hindi, English, and Marathi.

Training Process An ethnographic study of the experimental group school showed that students start their training by using their dominant hand to write during the first six months after being admitted into the school. Thus, students may start the training as early as 3 years (kindergarten) or as late as 12 years (7th grade) depending on when they join the school. They are then instructed to use the non-dominant hand for the next six months. The training starts with making lines and curves, then progresses to writing alphabets and numbers, and concludes with words and sentences. Instruction is given in small, often mixed-age groups (4-5 students per group). A teacher first demonstrates the techniques by writing on a blackboard. She then allows students to practice on the board and on their notebooks. After 3rd grade, however, these practice sessions are considered an extracurricular activity (optional) that students are free to pursue before/after school hours. Students who participated in our experiment had an average of 2.1 years (S.D. = 0.69 years) experience writing with both hands.

Attention Network Task (Child Version)

Participants 27 students (Mean age = 12.5 years, S.D. = 0.57, 12 male, 15 female) from the experimental group and 32 students (Mean age = 12.8 years, S.D. = 0.80, 19 male, 13 female) from the control group participated in the experiment. The school principal and teachers were communicated in advance about the purpose and nature of the study. Participants were explained in detail about the consent process (including the option to discontinue whenever they wanted) and the tasks, following which signed consent was obtained from each participant and school principal prior to the study. All communication between participants and experimenters was in the language that participants understood most clearly (Kannada for the experimental group and Hindi for the control group).

Stimuli and apparatus The stimuli were presented using Inquisit 5's ANT (Child version), a commercial application by Millisecond[2], run on laptops (all 15.6-inch screens: 34.54 cm x 19.41 cm) with Windows 10 OS. Participants viewed the screen from a distance of 53 cm (approx.), and responded to the stimuli by pressing two keys on the laptop keypad.

The stimuli consisted of a central fixation (+ sign) that appeared at the beginning of each trial, presented against a constant blue-green (0, 255, 255) screen background. This was followed by one of four warning cue conditions: no-cue, center-cue, double-cue, or spatial-cue. A black dot (cue) appeared in the center instead of the + sign for the center-cue condition. The double-cue condition involved the cue being presented on target locations both above and below the + sign. In the spatial-cue condition, the cue appeared either above or below the + sign. The no-cue condition did not provide any warning about the forthcoming stimulus, while the center-cue and double-cue conditions warned the participants when the target will appear. The spatial-cue condition alerted as well as indicated the locations of the target stimulus (see Fan et al., 2002; Rueda et al., 2004 for more details). (See link for a schematic diagram)

The target stimuli were a yellow color-filled line drawing of either a single fish or an array of five fish that appeared above or below the central fixation. Each fish projected a visual angle of 1.6° and the contours of adjacent fish were at a distance of 0.06° from each other. The total visual angle projected by the array of 5 fish was 8.4°. The target stimuli were presented at 1.08° above or below the central fixation.

Procedure Participants were instructed to focus on the hungry central fish and feed them by pressing the "E" (when the fish facing left) or "I" (when the fish facing right) key. While receiving the instructions, participants were asked clarifying questions to ensure that they understood the context and task requirements.

Each session lasted ~30 minutes and consisted of one practice block (24 trials) and three experimental blocks (48 trials). The trials in the experimental blocks had one of the following combinations: 4 cue conditions (no-cue, center-cue, double-cue, spatial-cue) x 3 flanker conditions (congruent, incongruent, neutral) x 2 target stimuli positions (up, down) x 2 target stimuli directions (left, right). (See link for a schematic diagram). The order of the trials was random.

Each trial sequence had the following trial structure: fixation period with randomly chosen presentation time (between 400-1600 ms), followed by a warning cue for 100 ms, followed by a fixation period of 400 ms after the disappearance of the cue, and concluding with the appearance of the target stimulus, either alone or along with

[1] https://www.youtube.com/watch?v=PDVDw60sG5c

[2] https://www.millisecond.com/

flankers for 1700 ms. Participants had to respond within this 1700 ms duration, after which the stimulus disappeared. The inter-trial interval was set at 1000 ms. Participants received audio-visual feedback for both correct and incorrect responses during the practice block. The experimental blocks did not have any feedback.

Hearts and Flowers Task

Participants The participants for this experiment were the same as those in the ANT experiment.

Stimuli and apparatus The stimuli were presented through Inquisit 5's Hearts and Flowers Task (Child-friendly version). Other apparatus remained the same as the previous task.

The stimuli consisted of a central fixation (+ sign) followed by a heart or a flower (target stimuli) that appeared on the left or the right of the fixation cross. The fixation sign was constantly present on the white background screen while the stimuli appeared in red. The hearts/flowers appeared at a visual angle of 5.6° to the left or right of the central fixation. A heart subtended a visual angle of 2.04° whereas a flower subtended a visual angle of 2.16° (Davidson et al., 2006). (See link for a schematic diagram)

Procedure Each session lasted for ~20 minutes and consisted of three sequential blocks: Congruent-only block (Hearts as stimulus) followed by Incongruent-only (Flowers as stimulus) followed by Mixed (both Hearts and Flowers as stimulus). Each block had 8 practice trials and 20 experimental trials. The experimental trials were initiated only if participants reached an accuracy of minimum 75% in the practice trials. Participants received audio-visual feedback during the practice trials for both correct and incorrect responses. The experimental trials did not have any audio-visual feedback.

Each trial sequence in the experiment block started with the presentation of the target stimulus. The maximum response time was 5000 ms (for congruent-only and incongruent-only) and 6000 ms (for mixed block). The inter-trial interval was set at 1000 ms. Participants were required to press "A" for a heart appearing on the left of the + sign and "L" for a heart appearing to the right of the + sign (congruent trials). For the flower stimulus, participants had to press the "A" key for a flower appearing on the right of the + sign and "L" for the flower appearing to the left of the + sign (incongruent trials). Both congruent-only and incongruent-only blocks had the stimulus on the left of + sign for ten trials and on the right for the remaining ten, appearing in random order. In the mixed block, there were 10 hearts (5 right, 5 left) and 10 flowers (5 right, 5 left) that appeared in a random order, with the following constraint: a maximum of 3 trials of the same type (congruent or incongruent) could be run consecutively, and the number of switch trials (i.e. from congruent to incongruent and vice-versa) would vary from trial to trial (with a minimum of 6 per trial).

Edinburgh Handedness Inventory (EHI)

26 participants (Mean age = 12.5 years, S.D. = 0.58, 11 male, 15 female) from the experimental group and 28 (Mean age = 12.9, S.D. = 0.85, 18 male, 10 female) from the control group were provided with the EHI questionnaire (Oldfield, 1971). Participants were asked to respond orally to a 12-item questionnaire, using one of five responses: always right, usually right, both equally, usually left, always left. Since the participants were not familiar with surveys, concrete everyday examples were provided for clarification of each questionnaire item, along with the response categories. Participants were asked to act out how they would perform each of the items in the questionnaire while reporting their response. The Laterality Quotient (LQ) score for each participant was calculated as below:

$$LQ = 100\frac{(\sum\text{number of positives} - \sum\text{number of negatives})}{(\sum\text{number of positives} + \sum\text{number of negatives})}$$

Where "always right" was assigned ++ (2 positives), "usually right" was + (1 positive), "both equally" was +- (one positive, one negative), "usually left" was - (1 negative), and "always left" was -- (2 negatives). An LQ score closer to +100 denoted strongly right-handed, -100 denoted strongly left-handed, and a 0 represented an equal preference for both hands in the tasks. Scores other than the above represent the use of both hands but not in an equal measure.

Results

One-way ANCOVA using group (experimental, control) as the fixed factor and age and gender as covariates on LQ scores showed a significant main effect of group [$F(1,50) = 6.481$, $p = 0.014$, $\eta_p^2 = 0.115$]. Results revealed that the experimental group ($M = 65.62$, $S.D. = 23.63$) had significantly lower LQ score compared to control group ($M = 83.14$, $S.D. = 13.75$) (see Fig 1a). This suggests that training to use both hands might have influenced the participants to use both their hands for motor activities other than writing, as the LQ score in EHI is calculated by taking into consideration the handedness preference in various everyday general motor activities.

Attention Network Task

Overall Accuracy Analysis An 80% overall accuracy criterion led to the elimination of five participants (1 in experimental and 4 in the control group), giving 54 participants' data for further analysis. JASP software was used to perform statistical analysis. One-way ANCOVA using group (experimental, control) as the fixed factor and age and gender as the covariate on accuracy showed a main effect of group [$F(1,50) = 6.52$, $p = 0.014$, $\eta_p^2 = 0.115$] while the effect of gender and age were not significant, suggesting that the experimental group ($M = 95.78$, $S.D. = 2.90$) had significantly higher overall accuracy in the ANT task, compared to control group ($M = 92.71$, $S.D. = 5.44$)

(see Fig. 1b). However, when participants' LQ score was used as a covariate, it could explain the difference in overall accuracy between the two groups [$F(1,51) = 4.446$, $p = 0.04$, $\eta_p^2 = 0.08$]. To further understand the relationship between LQ scores and overall accuracy scores, Pearson's correlation analysis was performed. Results indicated a significant negative association between LQ score and overall accuracy ($r(52) = -0.383$, $p = 0.004$), suggesting that participants with low LQ scores performed better compared to those with high LQ scores. Low LQ scores indicate more usage of both hands for everyday motor activities, whereas high LQ scores indicate more usage of a single or dominant hand.

Flanker type x Cue type x Group Analysis We performed 3 (*Flanker type:* congruent, incongruent, neutral) x 4 (*Cue type:* no-cue, center-cue, double-cue, spatial-cue) x 2 (*Group:* experimental, control) mixed ANOVA with flanker type and cue type as within subject factors and group as between subject factor on the median RTs. The main effect of flanker type [$F(1.46, 76.27) = 77.67$, $p < .001$, $\eta_p^2 = 0.599$] and cue type [$F(2.56, 133.55) = 66.30$, $p < .001$, $\eta_p^2 = 0.56$] were found to be significant. However, the main effect of group was not significant [$F(1, 52) = 0.701$, $p = 0.406$, $\eta_p^2 = 0.013$]. Planned comparisons showed that participants were significantly faster [$t(53) = 3.52$, $p < 0.001$] in the congruent flanker condition ($M = 625.33$ ms, $S.E. = 15.23$) compared to the incongruent one ($M = 697.46$ ms, $S.E. = 16.71$), showing the standard flanker effect (Ericksen & Ericksen, 1974).

Planned comparisons for different cue conditions showed that participants were significantly [$t(53) = 4.026$, $p < 0.001$] faster in the double-cue condition ($M = 633.08$ ms, $S.E. = 15.39$) compared to the no-cue condition ($M = 675.97$ ms, $S.E. = 15.08$) demonstrating the typical alerting effect of the cue on RT. Also, the difference between center-cue ($M = 645$ ms, $S.E. = 14.38$) and spatial-cue ($M = 596.63$ ms, $S.E. = 13.86$) was significant [$t(53) = 4.541$, $p < 0.001$], demonstrating the orienting effect of the spatial-cue. The difference between center-cue and no-cue was also significant [$t(53) = 2.907$, $p < 0.05$] suggesting that even the single cue had an alerting effect, though the magnitude was less compared to the double cue. There was a significant interaction between cue type and group [$F(2.56, 133.55) = 3.04$, $p = 0.031$, $\eta_p^2 = 0.055$]. Post-hoc analyses showed no significant difference between experimental and control group for each cue type.

Alerting, Orienting, and Conflict Analysis The measures of effects for the three networks were calculated by subtracting different cue type and flanker type conditions. The altering effect was calculated by subtracting the double-cue condition RT from the no-cue condition RTs. The orienting effect was calculated by subtracting the spatial-cue condition RT from center-cue condition RTs. The conflict or executive function effect was calculated by subtracting congruent flanker condition RT from incongruent flanker condition RT (Rueda et al., 2004).

Pearson's correlation analysis revealed that there was no significant correlation between any of these three networks [alerting and orienting, $r(52) = 0.081$, $p = .562$; alerting and conflict, $r(52) = 0.173$, $p = .211$; orienting and conflict, $r(52) = 0.212$, $p = .124$], thus supporting the finding in previous studies that the three networks are independent.

A series of one-way ANOVA were performed to examine the effect of group, age, and gender on the mean of median RTs and errors for the alerting, orienting and conflict quotients. None of the comparisons reached significance, except for a group difference in percentage error for alerting quotients [$F(1,49) = 4.891$, $p = 0.032$, $\eta_p^2 = 0.091$].

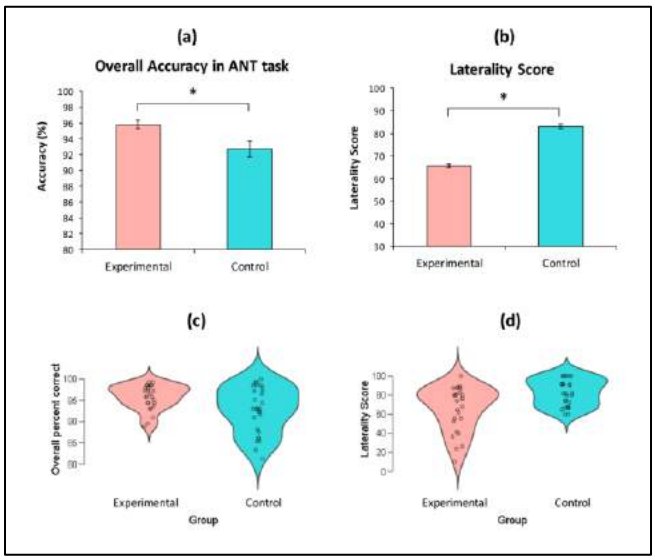

Figure 1. The top panel shows the bar plot for (a) overall accuracy in the ANT task, and (b) LQ score for both groups. The bottom panel shows the corresponding violin plot. Error bar represents S.E. of mean. * indicates <0.05

Hearts and Flowers Task

Overall Accuracy and Reaction Time An 80% overall accuracy criterion led to the elimination of five participants (3 in experimental, 2 in control). Additionally, two participants from the control group didn't complete the task. This resulted in a total of 52 participants' data for further analysis. One-way ANCOVA using group (experimental, control) as the fixed factor and age, gender, and LQ score as covariates showed no significant difference in overall accuracy between the two groups [experimental group 92%, control group 91.4%; $F(1, 48) = 0.225$, $p = 0.637$, $\eta_p^2 = 0.005$]. Similarly, there was no significant difference in overall mean RT as a function of group [$F(1, 48) = 0.388$, $p = 0.536$, $\eta_p^2 = 0.008$; experimental group, $M = 636.3$ ms, $S.E. = 28.11$; control group, $M = 660.9$ ms, $S.E. = 26.48$].

Block x Group Analysis Two-way 3 (*block type:* congruent, incongruent, mixed) x 2 (g*roup:* experimental, control) mixed ANOVA with block type as within subject factor and group as between subject factor on the mean RTs showed a significant main effect of block type [$F(1.64, 83.83) = 164.33$, $p < .001$, $\eta_p^2 = 0.763$]. However, the main effect of group and interactions were not significant. Planned comparisons showed the expected significant differences between congruent, incongruent and mixed block types. That is, participants were significantly faster in the congruent block ($M = 497.1$ ms, *S.E.* = 18.20) compared to both incongruent block [$M = 590.22$ ms, *S.E.* = 20.26; $t(52) = 3.642$, $p < .001$] and mixed blocks [$M = 899.194$ ms, *S.E.* = 31.51; $t(52) = 15.72$, $p < .001$]. Also, the difference between incongruent block and mixed block was significant [$t(52) = 12.08$, $p < .001$].

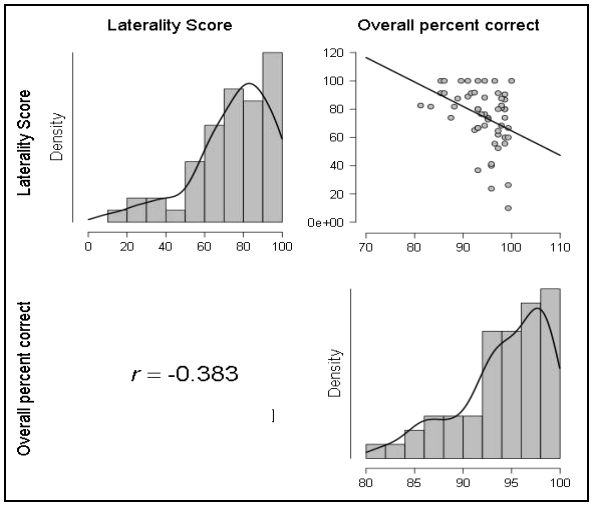

Figure 2. The correlation matrix between overall accuracy in ANT and LQ score.

Another similar 3 (block) x 2 (group) mixed ANOVA on the mean accuracy revealed a significant main effect of block type [$F(1.41, 71.99) = 54.02$, $p < .001$, $\eta_p^2 = 0.514$]. However, the main effect of *group* [$F(1, 51) = 0.119$, $p = 0.731$, $\eta_p^2 = 0.002$] and interaction [$F(1.41, 71.99) = 2.704$, $p = 0.091$, $\eta_p^2 = 0.05$] were not significant. Planned comparisons for the different block types revealed significant differences between all the groups [congruent vs. incongruent, $t(52) = 2.933$, $p < 0.05$; congruent vs. mixed, $t(52) = 8.624$, $p < 0.01$; incongruent vs. mixed, $t(52) = 5.69$, $p < 0.01$]. Results replicated the expected effects of block type on reaction time and accuracy, wherein participants became slower and less accurate as the task demand increased from congruent to incongruent to mixed block.

Inhibitory Control and Cognitive Flexibility To measure inhibitory control, the congruent block RTs (working memory) were subtracted from the incongruent block (working memory + inhibition control), and to measure cognitive flexibility the incongruent block RTs were subtracted from the mixed block (working memory + inhibition + cognitive flexibility). The switching score was obtained by subtracting the non-switch trials from the switch trials in the mixed block.

Pearson's correlation analysis was used to evaluate the association between inhibitory control, cognitive flexibility, and switching scores. Results showed a negative association ($r(52) = -0.464$, $p < .001$) between inhibitory control and cognitive flexibility, whereas other correlations were not significant [inhibitory control and switching, $r(52) = 0.162$, $p = 0.247$; cognitive flexibility and switching, $r(52) = -0.138$, $p = 0.325$]. Further analysis is needed to understand this relationship. (See link for correlation matrix)

We performed a series of one-way ANCOVAs for all the three subtraction scores, with group as the between subject variable and laterality as covariate. The only significant main effect of group was in the inhibition control for both reaction time [$F(1, 51) = 8.749$, $p = 0.005$, $\eta_p^2 = 0.146$] and accuracy [$F(1, 51) = 6.431$, $p = 0.014$, $\eta_p^2 = 0.112$]. These results suggest that participants with training to write with both hands were better in inhibitory control, compared to participants in the control group (see figure 3). (See http://handedness.surge.sh/ for more tables, figures, and a detailed analysis)

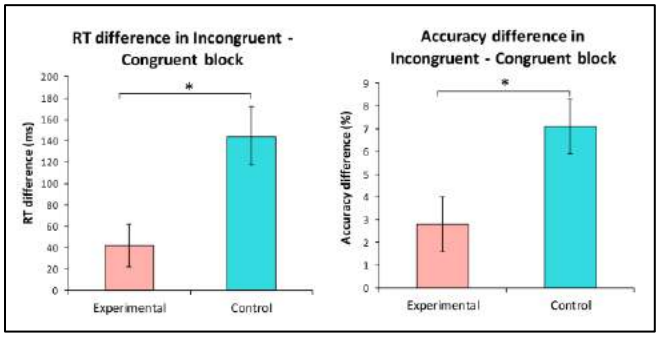

Figure 3. The bar plot displaying the difference in RT between incongruent and congruent block (left), and difference in accuracy between incongruent and congruent block (right).

Discussion

In both ANT and HF tasks, standard effects were observed, suggesting that the tasks were executed successfully. The central result was the significant group difference observed in inhibitory control, as measured by the HF task. The ANT results revealed that training to write with both hands improved overall accuracy, without significantly hampering response time. However, participants from the experimental group were slower in response (though not significantly) compared to the control group, suggesting a kind of speed-accuracy trade-off. This group difference in accuracy covaried with the differences in the LQ score. Laterality and overall accuracy were negatively correlated, suggesting that participants with low LQ scores had higher accuracy, while participants with high LQ scores had lower accuracy.

Overall, the writing training did not significantly improve performance in any of the attentional networks. Similar results were obtained by Rueda et al., (2012), where computer-based attentional training provided to school children did not significantly improve the alerting and orienting networks. However, there was an enhancement in the executive network, which overlapped with the domain of training provided to participants. Similarly, even though we did not find any significant group difference for alerting, orienting and conflict networks in ANT, we observed a significant group difference in inhibitory control as measured by the HF task.

The Hearts and Flowers task can be viewed as a child version of the Simon task, which tracks a standard tendency to inhibit the prepotent impulse when the stimulus location overlaps with the response side. People with better inhibitory control would be able to resolve this conflict faster, and would thus be less prone to the Simon effect. It has been shown that playing video games, but not visual training, improves inhibitory control, and reduces the cost of Simon effect (Hutchinson, Barrett, Nitka, &Raynes, 2016).

These results suggest that learning to write with both hands could be understood as leading to the improvement of inhibitory control. However, it is not clear how this improvement in inhibitory control is related to writing with both hands. One possibility is a heightened activation model, where writing with both hands leads to both hands getting activated by motor plans for writing, and active inhibition of one is required to write with the other. This process requires, and improves inhibitory control.

This model fits well with our ethnographic data, which showed that when students were asked to write a novel paragraph using both their hands, they did so with only with one hand at a time i.e., they did not write *simultaneously* with both hands. Some students wrote one character with one hand and the next with the other. Others wrote a word or multiple characters of a word with one hand before moving to write the next word or the remaining characters with the other hand. Based on this data and the heightened activation model, learning to write with both hands could be understood as having effects similar to learning to speak in more than one language, where all the known languages get activated when planning to speak. The speaker thus needs to inhibit the other activated languages when choosing to speak in one, and also when trying to understand speech, as many candidate words will be activated. This choosing process requires, and supports, heightened inhibitory control, whose effects would be seen in other control situations. Supporting this model, bilingualism studies show that executive function improves through learning more than one language (see Bialystok, 2001, 2011). Although these studies show that bilingualism improves cognitive control (the "bilingual advantage"), there exists a debate regarding the main effect (Anton et al., 2014). Some studies show that bilingual training only provides a domain-specific advantage (i.e. improves inhibition and control of perceptual or stimulus-stimulus type representations), and no drastic improvement in inhibition and control of motor or habitual or stimulus-response type representations (Blumenfeld & Marian, 2014; Martin-Rhee & Bialystock, 2008; Poarch, 2018). This fits well with our findings, as which show benefits of motor training on inhibitory control in the HF task but not in the ANT task. The growing literature on the cognitive control effects of *changes* in motor control (Stein et al., 2017; Stuhr et al., 2018; for a review see Diamond & Ling, 2016) -- to which our study contributes -- shows that training motor control abilities might have global effects, which are reflected in tasks wider than the immediate context of training. Apart from our results on inhibitory control, our Edinburgh Handedness Inventory (to determine handedness or the level of hand preferences for various everyday motor tasks) also found that participants who had received training to write with both hands used both hands for other everyday motor tasks, suggesting that hand preferences change in a global fashion with such training. These, and related results showing the role of action in language and imagination (Pulvermuller, 2001; Glenberg, 1997), open up the possibility of using the motor system as an intervention channel, particularly to change higher-order cognitive and affective systems.

However, this intervention possibility needs to be approached with caution, as the relationship between higher-order systems (such as imagination and language) and motor control is not straightforward, as higher-order systems typically draw on, *and recombine*, many networks, including from frontal regions of the brain. Further, tasks in higher-order cognition, such as physics problem-solving, requires bringing together many cognitive components, such as reading, imagining, calculating, reasoning, etc. Whether these processes and their integration, are improved by motor control is currently unclear.

Thus, even though schools that train students to write with both hands do so with possible educational effects in mind, the results related to wider control capabilities we report here cannot be taken as an indication of training to write with both hands improving problem-solving abilities. Further studies need to be done to investigate whether such improvements could follow from motor training. While this study leveraged the opportunity provided by a particular school that trains students to write with both hands, future studies would benefit if the above experiments are conducted as part of a controlled intervention study. This study provides a good starting point in demonstrating the effect of bimanual writing on cognitive flexibility. However, a more extensive and controlled study is required to replicate as well as extend the results.

Abstract

Languages partition semantic space into linguistic categories in systematic ways. In this study, we investigate a semantic space which has received sustained attention in theoretical linguistics: person. Person systems convey the roles entities play in the conversational context (i.e., speaker(s), addressee(s), other(s)). Like other linguistic category systems (e.g. color and kinship terms), not all ways of partitioning the person space are equally likely. We use an artificial language learning paradigm to test whether typological frequency correlates with learnability of person paradigms. We focus on first person systems (e.g., 'I' and 'we' in English), and test the predictions of a set of theories which posit a universal set of features (±exclusive, and ±minimal) to capture this space. Our results provide the first experimental evidence for feature-based theories of person systems.

Keywords: artificial language learning; categorization; person systems; extrapolation; typology; linguistic universals

Introduction

One of the fundamental goals of cognitive science is to understand how human languages carve up semantic space into linguistic categories. Research on the typology of categorization systems, from colour names, to noun classification and kinship terms suggests that not all systems are equally likely.

For example, despite some cross-linguistic variation, certain ways of carving up the continuous color space into linguistic categories are much more common than others. This has been argued to provide evidence for a universal basis for color categorization, reflecting properties of the human perceptual system (Kay & Regier, 2007; Zaslavsky, Kemp, Tishby, & Regier, 2018; Gibson et al., 2017). Similar arguments have been made to explain the distribution of kinship systems across languages (Kemp & Regier, 2012; Kemp, Xu, & Regier, 2018).

Here, we focus on a semantic space which has garnered substantial attention in theoretical linguistics: person systems (e.g., Zwicky, 1977; Harley & Ritter, 2002; Harbour, 2016; Ackema & Neeleman, 2018). Such systems–exemplified in pronoun paradigms (e.g. 'me', 'you', 'her')–describe how languages categorize entities as a function of their role in the context of a speech event (i.e., speaker(s), addressee(s), other(s)). Like color and kinship systems, person systems have long been observed to exhibit constrained variation.

The person space

Research on the typological distribution of person systems has hypothesized an inventory of four discrete categories: first exclusive (speaker only), first inclusive (speaker and addressee), second (addressee) and third (other) (Harley & Ritter, 2002; Cysouw, 2003; Bobaljik, 2008). The interaction with number multiplies the possible distinctions.

Here, we focus specifically on *first* person systems, as they allow us to investigate a contrast that is not instantiated by English (1^{st} inclusive vs. 1^{st} exclusive). Theories of first person systems have posited two binary features, one for person (±addressee) and one for number (±minimal) (Bobaljik, 2008; Cysouw, 2011; Harley & Ritter, 2002).[1] This two-feature system is designed to instantiate all first person categories, as illustrated in Figure 1.[2]

A language which takes advantage of the maximal 4-way contrast will have a person *paradigm* with 4 distinct forms (e.g., Ilocano pronouns). Alternatively, the contrast between some cells can be neutralized within a paradigm, in which case different cells will use the same form. Such paradigms exhibit *homophony*.

Homophony which neutralizes one of the two hypothesized features–person or number–has been called *systematic homophony* (Harbour, 2008; Baerman, Brown, Corbett, et al., 2005). For example, a paradigm that neutralizes only the person contrast (keeping the number one) would have just two pronominal forms, one for both minimal inclusive and exclusive, and another for

[1] The ±minimal feature encodes an asymmetry in status between the minimal group consisting of the speaker and addressee, and a larger group including others. This is used rather than the more intuitive singular/plural contrast to distinguish between the two inclusive categories.

[2] The two-feature system in Figure 1 is a simplification of current proposals for the complete person space (i.e. including 2^{nd} and 3^{rd} persons). Most approaches rely on the existence of at least two different person features and three number features (Bobaljik, 2008; Harbour, 2016; Bobaljik & Sauerland, 2018).

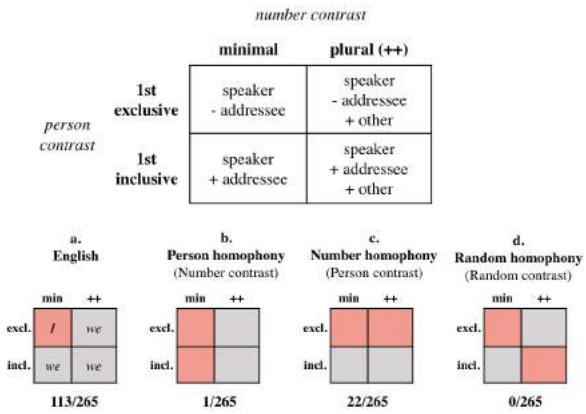

Figure 1: First person system (top) and four possible paradigms obtained by homophony (bottom, a-d) along with typological counts (Cysouw, 2003).

the two non-minimal (plural) categories ('Person homophony', Figure 1b). A paradigm that neutralizes only number (keeping the person contrast) would have one inclusive and one exclusive form ('Number homophony', Figure 1c). Homophony of both features is also possible, as in English ('we' for inclusive and exclusive plural, and minimal inclusive). Finally, a paradigm can partially neutralize one feature, for example, number homophony in the inclusive, but two distinct exclusive forms.

Random homophony patterns, not based on feature neutralization, are in principle also possible. For example, minimal exclusive and plural inclusive could share the same form, minimal inclusive and plural exclusive another ('Random homophony', Figure 1d).

Feature-based theories of person systems (cf. Figure 1) predict that systematic homophony is a natural consequence of feature-neutralization (or loss), and should arise regularly and be (easily) learnable. By contrast, they argue that there is no linguistic basis for random homophony, which is expected to arise only by historical accident, and be less readily learnable. Intuitively, there is nothing which ties together homophonous cells in a random homophony paradigm, therefore they should be less natural for learners. Notably, these theories are formulated on the basis of typological samples of person paradigms (the largest of which include <300 languages). Interestingly, while their predictions hold when considering complete paradigms, it is less clear for first person systems. According to Cysouw (2003), most of the possible paradigms for the 4-cell 1^{st} person space have not been documented. Among those that are attested, the skew is zipfian: the English-like pattern (Figure 1a) is by far the most frequent, the next most common systems have partial or complete number homophony (e.g., Figure 1c). Unexpectedly, both random *and* person (only) homophony appear to be very rare (see also Sauerland & Bobaljik, 2013; Baerman et al., 2005).

Experimental goals and predictions

The principal goal of this paper is to set out a method for investigating person systems experimentally. The first step we take here is to test whether some first person paradigms are more natural than others. Our measure of naturalness will be learners' likelihood of inferring the relevant paradigm. We will test three main hypotheses: the first is a sanity-check, and the second two are derived from the theories outlined above in combination with the typology.

The first hypothesis is that, all things equal, learners generally assume a new language to have the same structure as their own. Learners in our experiment are native English speakers, therefore this predicts that they will be most likely to infer a first person paradigm that is English-like in its homophony pattern. The second hypothesis is that typologically frequency is correlated with learnability (Culbertson, 2018). This predicts that learners will be more likely to infer a paradigm characterized by number homophony than person or random homophony.[3] The third hypothesis is that there is a universal set of person/number features, as in (3), which learners are sensitive to regardless of their native language. This predicts that natural homophony patterns–which neutralize one specific feature–should be more likely to be inferred by learners than random homophony.

To test these predicted patterns of inference, we use an artificial learning paradigm in which learners are required to generalize (or extrapolate) from ambiguous evidence (a.k.a 'Poverty-of-the-Stimulus design, Wilson, 2006; Culbertson & Adger, 2014). Participants are trained on two cells of a first person paradigm, and must then use the forms they have learned to express all the cells in the paradigm. In other words, they must extrapolate the forms they have learned to the remaining two categories. For example, if a learner is trained on two distinct forms for exclusive minimal (speaker only) and exclusive plural (speaker plus others), they will be tested on the two remaining categories that include the addressee. If they use the plural form for both new categories, then they have inferred an English-like paradigm. Different patterns of extrapolation would indicate person or random homophony (as described in detail in Table 1).

[3] In principle this also predicts that learners should be most likely to infer an English-like paradigm, since this pattern of person *and* partial-number homophony is much more common. However, we cannot test this prediction with English-speaking learners.

Table 1: Summary of conditions.

Condition		Critical training set	Critical held-out set	Compatible paradigms
(1)		excl.min, excl.++	incl.min, incl.++	**English-like**, Person Hom., Random Hom.
(2)		excl.min, incl.min	excl.++, incl.++	**English-like**, Number Hom., Random Hom.
(3)		incl.min, incl.++	excl.min, excl.++	**Person Hom.**, Random Hom.
(4)		excl.++, incl.++	excl.min, excl.min	**Number Hom.**, Random Hom.

Methods

This experiment, including all hypotheses, predictions, and analyses, was preregistered.[4]

Participants

A total of 332 English-speaking adults were recruited via Amazon Mechanical Turk (female = 152). Participants were paid 2 USD for their participation which lasted approximately 15 mins. Per our pre-registered plan, participants were excluded if (a) their accuracy rates during exposure training were below 80%, or (b) their accuracy rates for trained cells during the test phase were below 66%. This resulted in analysis of 181 participants (Conditions 1: 46; Condition 2: 50; Condition 3: 49; Condition 4: 36).[5]

Design

Participants were randomly assigned to one of four possible conditions, summarized in Table 1. Conditions differed in which subset of two first person categories was trained (*critical training set*) and held-out (*critical held-out set*). This determines which alternative full paradigms are consistent with the two categories participants have learned. Conditions 1 and 2 are consistent with an English-like pattern (or systematic homophony). Conditions 3 and 4 are each consistent with one type of systematic homophony, and random homophony.

All participants were additionally exposed to another four pronominal forms which mapped into the second and third person singular and plural categories. These forms were used as controls.

Table 2: Highlighted family members for each category.

Category	Highlighted set
1st excl.min	speaker
1st incl.min	speaker, addressee
1st excl.pl	speaker, other(s)
1st incl.pl	speaker, addressee, other(s)
2nd sg.	addressee
2nd pl.	addressee, other(s)
3rd sg.	one other
3rd sg.	multiple others

Materials

The language consisted of 6 different pronoun forms, used for the control categories (2nd sg/pl, 3rd sg/pl), plus the critical first person forms. For each participant, these 6 lexical items were randomly drawn from a list of 8 CVC non-words created following English phonotactics: 'kip', 'dool', 'heg', 'rib', 'bub', 'veek', 'tosh', 'lom'. Items were presented orthographically.

To express the pronoun meanings, we commissioned a cartoonist to draw scenarios involving a family of three sisters and their parents. Each family member has a clearly-defined role in the conversational context. The two older sisters are speech act participants (in all scenarios they are either speaker or addressee). The third (little) sister was spatially close, but never a speech act participant. The parents were seated in the background (serving as additional others).

Pronouns were used as one-word answers to questions like 'Who will be rich?'. Meanings were expressed by highlighting subsets of family-members, as in Table 2.[6] An example illustrating 1st incl.min is provided in Figure 2. All questions were English interrogative sentences of the form 'Who will...?', which were randomly drawn from a list of 60 different tokens.

Procedure

Participants were first introduced to the family, including the names of the sisters, and were told they were going to see the sisters playing with a hat that had two magical properties: whoever wore it could see the future but would also talk in a mysterious ancestral language. Participants were instructed to figure out the meanings of words in this new language. They were given a hint that the words were not names, and an example trial with an English pronoun ('her').[7]

[4]Maldonado, M., & Culbertson, J. (2019, January 29). Extrapolation to bipartitions. https://doi.org/10.17605/OSF.IO/J2RCN.

[5]High accuracy rates on trained critical items were required because extrapolation of these forms is not interpretable if participants have not learned them.

[6]To ensure that forms were not associated with specific quantities, in all non-minimal categories, pronouns randomly referred to two or three individuals. Third person singular meanings were always expressed with a female other.

[7]In addition, the speaker and addressee roles switched during the experiment to highlight that the words were de-

Figure 2: Trial example in the test phase for the inclusive minimal category.

The experiment had two phases. In the training phase, participants were taught the pronouns in the control and training sets (6 person categories). Each training trial had two parts: a scene where a question is asked, and a scene where the question is answered with a pronoun form in the language (cf. Figure 2). There were 12 training trials (2 repetitions per form). Participants were given feedback on their answers.

After this initial training phase, participants were given an initial test of the trained forms. Each trial consisted of a question and answer scene, as in training, followed by a 'what if?' scene in which a new set of individuals was highlighted. They were asked to pick the correct word for that meaning among two options. There were 16 such trials (2 repetitions per control form, 4 per critical training form). Participants were given feedback on their answers. The test phase involved a similar procedure but included trials for the two remaining critical categories, i.e. the held-out set. This phase consisted of 48 trials (6 repetitions per form). Participants received no feedback during this phase.

The experimental session lasted approximately 15 minutes. The order of presentation of meanings was fully randomized within training and test phases for each participant.

Results

Recall that participants were taught two pronominal forms (coded as forms 1 and 0), which they had to use to describe both a critical trained set of first person meanings, and a held-out set. Figure 3 shows the proportion of trials on which participants chose the 'form 1' (pronoun) for each first person category during the test phase. Choice of the same form across categories indicates homophony. A visual inspection of Figure 3 suggests that participants in Conditions 1 and 2 are consistently using one form for 1st excl.min., and the other for the remaining three categories: this indicates inference of an English-like paradigm. Participants in Conditions 3 and 4 appear somewhat noisier in their responses, however, distinct patterns are evident. In Condition 3, one form is used for the two minimal categories, and the other for the plurals (consistent with person homophony). In Condition 4, one form is used for the two exclusive categories, and, at least for some participants, the other form is used for the two inclusive categories (consistent with number homophony).

Following our pre-registered plan, we conducted three analyses to evaluate these patterns statistically[8]:

Prediction 1: Preference for L1 pattern Figure 3 suggests that participants in Conditions 1 and 2 are more likely to infer a stable pattern, as predicted if an L1-like pattern is easier to learn. To test this, we used *joint entropy* of the two held-out categories to measure how variable participants' are in their mapping of the taught forms for the two held-out categories. The entropy value for a given category indicates the degree of uncertainty or variability in the responses. The joint entropy will therefore reveal the level of variability or uncertainty for each of the two held-out categories, with higher joint entropy values for participants who are less consistent in their answers. We fit a simple linear regression model predicting joint entropy by Condition (4 levels, treatment coded, Condition 1 as baseline). No random effects were included in the model, as each participant had a single joint entropy value associated. As predicted, joint entropy rates were significantly higher for Conditions 3 and 4 (intercept= .28; vs. 3: $\beta = .639$

pendent on contextually-determined speech-act roles.

[8] All analyses used the lme4 package in R (Bates, 2010). The data and analyses script can be found here.

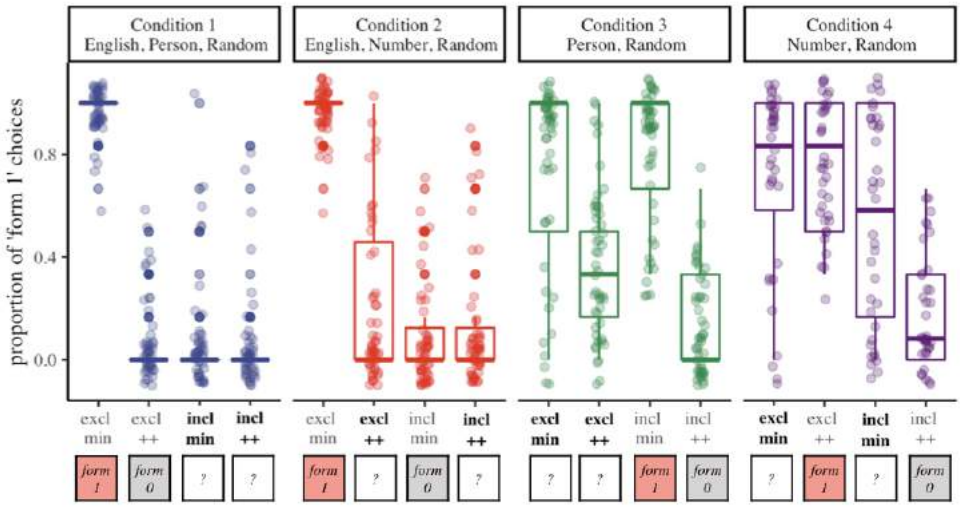

Figure 3: Proportion of 'form 1' choices for each first person category during the test phase. The held-out set for each condition is highlighted in bold-face. Choice of the same form (1 or 0) across categories indicates homophony. Dots are means of individual participants. Boxplots show by-participant means, quartiles, and range.

$\pm.12$, $p < .001$; vs. 4: $\beta = .447 \pm .13$, $p < .001$). Joint entropy rates for Condition 2 were marginally higher than Condition 1 ($\beta = .232 \pm .12$, $p = .055$).

Prediction 2. Preference for number over person homophony Figure 3 provides some evidence that participants in Conditions 3 and 4 are inferring paradigms with person and number homophony. Based on typological frequency, we predicted that number homophony should be more readily inferred than person homophony. If this is the case, then we should see a higher overlap in forms that share number in Condition 3 (columns in table 1) than forms that share clusivity in Condition 4 (rows). We measured this degree of homophony using the joint entropy between the relevant cells. For person homophony, we merged cells within a column and calculated joint column entropy. For number homophony, we merged cells within a row and calculated joint row entropy. The lower the joint entropy levels for a given homophony type, the more likely it is that participants are inferring a paradigm which neutralized that distinction. A simple linear regression model predicting joint entropy by Condition (2 levels, treatment coding, Condition 3 as baseline) revealed a marginally significant difference ($\beta = .207 \pm .11, p = .068$), with higher rates of person homophony (Condition 3) than number homophony (Condition 4). This fails to confirm our prediction.

Prediction 3. Preference for systematic over random homophony Finally, are participants in Conditions 3 and 4 in fact more likely to infer systematic rather than random homophony (as suggested by Figure 3)? To test this, the joint column/row entropy scores for systematic homophony computed above were compared to a random homophony score: the joint entropy of *all* alternative two-category combinations.[9] We ran separate mixed-effects models for Conditions 3 and 4, predicting entropy by homophony type (systematic vs. random) and including random intercepts per subject. We used likelihood ratio tests to compare these models to models with no fixed-effects. In both cases, entropy score for the systematic homophony pattern was significantly different from the random homophony score (person vs. random in Condition 3: $\chi^2 = 171.6$, $p < .001$; number vs. random in Condition 4: $\chi^2 = 84.4$, $p < .001$). This confirms that participants are more likely to use forms in a way that is consistent with systematic, not random homophony.

Discussion

In this experiment, we exposed English-speaking learners to sub-paradigms expressing person categories in a new language. We focused on first-person systems, which have been argued to have a universal basis in two features, encoding person and number. Participants were taught labels for two first person meanings, and asked to extrapolate to the two remaining meanings. We tested three hypotheses, designed to evaluate (1) whether learners were most likely to infer an English-like paradigm; (2) whether number homophony was more likely than person homophony (expected based on typological frequency); and (3) whether systematic homophony was more likely than random homophony

[9]For example, the joint column entropy in Condition 3 was compared to the joint entropy of each pair of diagonal and horizontal cells.

(predicted by feature-based theories).

Our results confirm that learners' are indeed highly likely to infer an English-like pattern when their training is consistent with this, producing systematic patterns of extrapolation from trained forms to new meanings. This result functions as a sanity check: it shows that participants are indeed understanding the stimuli in terms of a pronominal system.[10]

Our results also indicate that systematic homophony–which neutralizes either the number or person feature–is more natural than random homophony. This supports the claim that learners perceive the first person space as based on these two distinct features. Importantly, this finding cannot be accounted for solely based on experience with English. Inferring a person homophony pattern requires making a productive use of the ±minimal distinction. This is not the same number contrast made in English pronouns, which distinguish atomic (speaker only) and non-atomic entities (i.e., the more familiar singular/plural distinction). Similarly, inferring a number homophony pattern requires participants to learn and generalize the ±exclusive contrast, which is completely absent in English.

As for the typological difference between number (more common) and person (very rare) homophony, this does not appear to correlate with a learning difference in our task. Learners were, if anything, marginally more likely to infer paradigms characterized by person (Condition 3) rather than number homophony (Condition 4). One possibility is that, unlike random homophony, the rarity of person homophony in first person systems cross-linguistically is purely accidental, or reflects low sampling numbers. Indeed, person homophony is found for other parts of the person space (e.g., homophony of 1st and 2nd person in some languages). However, it may also reflect participants' experience of person homophony in English. Assuming that English encodes an atomic/non-atomic number distinction, it is possible to characterize English as a case of (only) person homophony (Harbour, 2016). In other words, English speakers have more experience with distinctions in number than in clusivisty. Indeed, a *posthoc* analysis shows that accuracy rates on trained categories (before exclusion) are higher in Condition 3 than 4 ($p < .001$), suggesting that the person distinction was harder to learn than the ±minimal distinction.

Finally, it is worth noting that differential sensitivity to person and number may also explain the marginal difference between Conditions 1 and 2. Both of these conditions allowed participants to generalize to an English-like paradigm, but they differed in whether a person or a number contrast was learned during the training phase (cf. Table 1). It could be that learning a new or unexpected distinction–between inclusive and exclusive minimal forms–led learners to be less likely to neutralize this feature in the plural.

[10]This is further confirmed by a debrief questionnaire, in which most participants reported having understood the new words as pronouns. For example, participants in Condition 4 have described the meaning of form 1 as 'Me or us not including you' and the meaning of form 0 as 'Us including you'.

Conclusion

In this study, we present the first experimental evidence for differences in learnability between alternative person paradigms. This was prompted by recent research in cognitive science on semantic spaces, and a lively literature in theoretical linguistics on the universal basis of person systems. We find, perhaps unsurprisingly, that English learners have a strong bias for first person paradigms that resemble their native language. They are more likely to infer paradigms analogous to English, and show a greater tendency to neutralize features that English also neutralizes (i.e. person). However, we also find that participants are sensitive to contrasts not found in their native language. Learners make productive use of both the ±minimal and ±exclusive distinctions, neither of which is present in English. Importantly, as predicted by feature-based theories of first person systems, learners were more likely to infer patterns which neutralized these features as compared to patterns in which featurally-unrelated cells were randomly homophonous. These initial results suggest that the paradigm we have developed can answer theoretically-motivated about how languages carve up the person space. Future work will target the full person paradigm, and incorporate recent insights about the potential role generally cognitive biases, such as simplicity, and communicative pressures like need probability (Kay & Regier, 2007; Kemp & Regier, 2012).

The Acquisition of French *Un*

Abstract

How does cross-linguistic variation in grammatical structure affect children's acquisition of number words? In this study, we addressed this question by investigating the case study of young speakers of French, a language in which the number *one* and the indefinite article *a* are phonologically the same (i.e., *un*). We tested how French-speaking children interpret *un,* and whether it more closely resembles the English word *a* or *one.* We found that French-speaking children almost always accepted sets of 1 for *un,* but that their responses for sets of 2 were more equivocal, with many children saying "Oui" (Yes) when asked whether there was *un.* Overall, French children's interpretation of *un* differed from how English-speaking interpret both *a* and *one*. This suggests that French-speaking children's interpretation of *un* reflects the ambiguity of the input that they are exposed to. We conclude that French morphological structure may pose a challenge to French-speaking children in acquiring an exact numerical meaning for the word *un,* potentially causing a delay in number word learning.

Keywords: Number; language; cognitive development

Introduction

How does the grammatical structure of a language affect children's acquisition of number words? By some accounts, morphology plays a central role in the acquisition of number words as it provides a conceptual framework for understanding small number words prior to conceptualizing them in terms of positive integers (Carey, 2004; Sarnecka, Kamenskaya, Yamana, Ogura, & Yudovina, 2007). The acquisition of these number words is progressive and follows a specific order (Le Corre & Carey, 2007; Sarnecka & Carey, 2008; Wynn, 1990). First, children learn the meaning of *one*, such that when they are asked to provide one object, they are able to correctly give one object and avoid giving one for other number requests. At this stage, these children are called "one-knowers". Then, children learn an exact meaning for *two*, and can give one or two when asked for one and two objects, but provide an incorrect response for other numbers. At this stage, children are called "two-knowers". Following the same pattern, children become "three-knowers" and sometimes "four-knowers". Finally, sometime after learning these number words, children seem to realize that they can use the count list to generate and give sets of any cardinality and for this reason, they are referred to as "Cardinal-Principle-knowers" (CP-knowers).

According to Carey (2009) and Sarnecka et al. (2007), morphology occupies a central role in the numerical acquisition process as children initially interpret *one*, *two* and *three* as markers of grammatical number categories. On this hypothesis, when children hear the word *one* in their input, it frequently occurs with singular agreement (e.g., *one cat*), whereas larger number words typically occur with plural nouns (e.g., *two cats*). Such cues might speed learning, allowing children to "bootstrap" number word meanings from grammatical morphology, such that, initially "one" is assigned a meaning similar to "a", and "two" is interpreted like a plural (Barner & Bachrach, 2010; Bloom & Wynn, 1997; Clark & Nikitina, 2009). Compatible with this, children learning languages like English, which has a grammatical singular/plural distinction, learn the meaning of *one* earlier than children exposed to languages that lack obligatory singular/plural marking, such as Japanese and Mandarin (Barner, Libenson, Cheung, & Takasaki, 2009; Le Corre, Li, Huang, Jia, & Carey, 2016; Sarnecka et al., 2007). Additionally, 2- to 4-year-old children learning Slovenian and Saudi Arabic, languages that have singular/dual/plural systems, acquire the meanings of *one* and *two* earlier than children exposed to any other previously tested language, despite being less familiar with counting overall (Almoammer et al., 2013; Marusic et al., 2016).

While previous tests of the relation between morphology and number word learning have focused mainly on how differences in grammatical morphology across languages might impact number words, few studies have asked whether the grammatical form of the numbers themselves might impact learning. Although children might initially interpret "a" and "one" similarly in English to learn a preliminary meaning of "one", they differentiate these words by at least 2 years of age: when children are shown a plate with two strawberries and are asked, "Is there *a* strawberry on the plate?" and, "Is there *one* strawberry on the plate?", 2-year-olds answer "Yes" for *a* strawberry but "No" for *one* strawberry, and do so as soon as they become one-knowers (Barner, Chow, & Yang, 2009). This suggests that *a* receives a purely existential interpretation (compatible with sets of 2 objects), while *one* receives an exact interpretation (compatible with sets of only 1 object). This suggests that, to acquire an exact meaning of "one", English children's input for "a" and "one" must differ.

Interestingly, however, other languages, like French and German feature the same phonological representation for both "a" and "one", a fact which might make it more difficult for them to determine whether to assign an existential or exact meaning to any particular instance of the word. For

example, in French, the word *un* is used both as an indefinite article and as a numeral. Consequently, French learners are presented with a potentially difficult learning problem, since the same phonological form is associated with both exact and non-exact meanings in their input.

Here, we investigated how French-speaking children interpret *un* – whether it resembles more closely the English *a* or *one* – and whether their interpretation of *un* differs based on the context of the task and whether surrounding test items are numerals or are restricted to non-exact quantifiers like "some" and "all". To further understand the impact of the ambiguity of the French morphological structure on children's interpretation of *un*, we compared the French-speaking children's interpretation of *un* to those of English-speaking children for *a* and *one* (obtained from Barner, Chow, & Yang, 2009).

Method

Participants

In total, 63 French monolingual children, aged 2;4 to 4;5-year-old were included in the study (M = 42.6 months). An additional 13 were excluded from analysis because of failure to complete all 3 tasks (n=2), bilingual status (n=7) or because they were not yet one-knowers or greater (non-knower; n=4). Participants were recruited from preschools in Québec (Canada). Informed consent was obtained from the parents. The study received approval by the ethics committee of UCSD.

Materials and procedure

Participants were tested at their preschool in a quiet corner of their classroom. Each session lasted approximately 15 min and included (1) a Truth-Value Judgement task, (2) the Give-a-Number task and (3) the Highest Count task. All participants were administered the tasks in this order. Children received a small prize for their participation at the end of the session.

Truth-Value Judgement Task (TVJ). This task was adapted from Barner, Chow, and Yang (2009) and its goal was to measure children's comprehension of the quantity terms: *un, des, deux, tous* (i.e., one/a, some, two, all) by asking them questions like, "Est-ce qu'il y a un canard dans la maison?" (Is there a/one duck in the house). Stimuli consisted of a drawing of a farmhouse and a forest, as well as three sets of small plastic animals (i.e., cats, pigs, and ducks). These animals were chosen as they are denoted by masculine nouns in French and therefore accompanied by the masculine form of the quantifier *un* (in contrast to the feminine *une*), which is the same form that typically corresponds to the number one (*un*). Animals were presented in separate piles organized by kind (Figure 1). Children were presented with the following instructions: "*Ça c'est la maison des animaux et ça, c'est la forêt. Moi je vais mettre des animaux dans la maison puis je vais te poser des questions. Toi, tu dois me répondre par oui ou non, ok?*" (i.e., "This is the animals' house and this is the forest. I will put animals in the house and ask you some questions. You need to answer by yes or no, ok?"). For each trial, the experimenter moved a certain number of animals into the farmhouse and asked the child a yes/no question. The animals were returned to their original piles after each trial. Children were randomly assigned to one of two conditions that differed with respect to the filler items that they included: (1) the Number condition, (2) the Quantifier condition. Children in the Number condition were presented with *un* and, as filler items, the number word *deux* (two), as well as the quantifier *tous* (all). Children in the Quantifier condition were also presented with *un*, in addition to the quantifiers *des* (some) and *tous* (all). Each item was presented with two different sets of animals. In both conditions, *un* was presented with sets of 1 and 2 objects. Children in the Number condition were asked questions with *deux* in the presence of 2 and 3 objects, to check whether they would interpret the number as exactly two and not compatible with larger sets (even by one object). Children in the Quantifier condition were questioned about *des* with sets of 1 and 2 objects, to check whether they would have a plural interpretation of *des*. In both conditions, *tous* was presented with sets of 3 and all 4 objects, to ensure that children had an interpretation of *tous* that was compatible with only all objects being present. Each combination of item and set was presented three times, for a total of 18 critical trials. The order of critical trials was counterbalanced across subjects.

Figure 1: Material used in the TVJ task.

Give-a-Number Task (Give-N). This task was adapted from Wynn (1990) and its goal was to evaluate children's understanding of number words. Stimuli consisted of a puppet, a red plastic plate, and 10 foam paper cookies. Children were asked to put a certain number of cookies into the plate (e.g., "*Peux-tu mettre trois biscuits dans l'assiette?*" i.e., "Could you put three cookies into the plate?"). After this first prompt, children were asked to count to verify that they had provided N, and if they had chosen to fix their answers, only their final responses were recorded. Each child was given 15 trials: three trials for each of the numbers 1, 2, 3, 4, 6. Order of trials was counterbalanced across children. Children were credited as N-knowers (e.g., two-knowers) if they correctly gave N cookies two out of three times when asked for N, and failed to give the correct N two out of three

times for N+1. In addition, to be classified as an N-knower, children could not use N more than 50% of the time for requests other than N. Finally, children were credited as CP knowers if they could correctly give six, two out of three times.

Highest Count Task (HC). Participants were asked to count as high as they could. The last number reached before making an error was taken as the highest count.

Results

Our primary question of interest was how French-speaking children interpret *un* and whether their interpretation differs according to the presence of other exact expressions in the context. In our first set of analyses, we tested whether performance in both conditions (Number and Quantifier) differed in terms of knower-levels (Give-N), Age, and Highest Count. Then, we conducted a series of analyses on *tous*, *des,* and *deux* to ensure that children either performed similarly across conditions (i.e., tous) or as expected given their respective conditions (i.e., des/deux). In our third set of analyses, we addressed our principal question of interest: Whether acceptance of sets of 1 or 2 objects for *un* differed across conditions. Finally, in a fourth set of analyses, we assessed how the acceptance rates for *un* compare to those for *a/one* in English by statistically comparing previously published data from English-speaking children (obtained from Barner, Chow, & Yang, 2009).

Preliminary Analyses

Knower-Levels. Table 1 shows the distribution of knower-levels across Conditions (Number vs Quantifier). Aside from a slightly greater number of one-knowers in the Quantifier condition, the conditions were similar in terms of their representation of each knower-level. Knower-level was not included as a factor in subsequent analyses comparing conditions both because our hypothesis is neutral to differences in knower level, and because such analyses require very substantial sample sizes to obtain adequate power.

Table 1: Distribution of Knower-Levels in the Number and Quantifier condition

	1K	2K	3K	4K	CP
Number	8	6	6	3	5
Quantifier	13	6	8	4	4
Total	21	12	13	7	9

Table 1: Here, 1K refers to one-knower, 2K to two-knower, 3K to three-knower, 4K to four-knower and CP to cardinal-principle-knower.

Highest Count. On average, children had difficulty counting to "dix/ten" (M = 6.30; SD = 4.80). The average Highest Count did not differ between the Number condition (M = 6.50; SD = 4.39) and the Quantifier condition (M = 6.14; SD = 5.18; p = 0.77).

Age. There was no difference in age between children in the Number condition (M = 42.71 months; SD = 6.86) and the Quantifier condition (M = 42.43; SD = 6.84; p = 0.87).

Truth-Value Judgment Task

Preliminary analysis of Tous, Des, Deux. In total, there were 35 children in the Quantifier condition and 28 in the Number condition. Figures 2 and 3 show the percentage of ''oui/yes" responses for each quantity term in each condition. As a first control check, we considered whether conditions differed in their acceptance of *tous* when controlling for Age and Highest Count. To do this, we performed a logistic mixed-effects model comparison,[1] using lme4 and car packages in R (Bates, Maechler, Bolker, & Walker, 2015; Fox & Weisberg, 2011).

In our first model, we predicted acceptance (coded as *yes* or *no*) from Age and Highest Count (HC), with participant as a random factor. In our second model, we added the main effects and interaction of Condition (Number vs. Quantifier) and Set Size (3 or all 4 objects) to the first model. In this model, we expected only a main effect of Set size and no difference between Conditions or interaction between Conditions and Set Size. The models were significantly different ($\chi^2(3) = 315.33$, $p = <.0001$). As expected, in our second model, the only significant predictor was Set Size ($\chi^2(1) = 30.75$, $p = <.0001$). This suggests that, in both conditions (Number and Quantifier), children were more likely to accept sets containing all 4 objects (Number: M = 0.99, SD = 0.11; Quantifier: M = 1.00, SD =0.00) compared to sets of 3 objects (Number: M = 0.25, SD = 0.44; Quantifier: M = 0.18, SD = 0.39).

As our second control check, we asked whether children in the Number condition accepted sets of 2 more often than sets of 3 objects when presented with *deux* (two), controlling for Age and Highest Count. In a model predicting acceptance from Age, Highest Count, and Set Size (with participant as a random factor), only Set Size was a significant predictor ($\chi^2(1) = 21.26$, $p = <.0001$). As expected, children accepted sets of 2 (M = 0.92, SD = 0.28) more often than sets of 3 (M = 0.28, SD = 0.45). Finally, as our last control check, we asked whether children in the Quantifier condition accepted sets of 2 more often than sets of 1 object when presented with *des*, after controlling for Age and Highest Count. Similar to the analysis with *deux*, in a model predicting acceptance from Age, Highest Count and Set Size (with participant as a random factor), only Set Size was a significant predictor ($\chi^2(1) = 15.89$, $p = <.0001$). In this context, children answered

[1] For *tous*, the first model specification was: Acceptance ~ HC + Age + (1|subject). The second was: Acceptance ~ HC + Age + Set Size * Conditions + (1|subject). For *des* and *deux*, the first model specification was: Acceptance ~ HC + Age + (1|subject). The second model was: Acceptance ~ HC + Age + Set Size + (1|subject).

"yes" more often when presented with sets of 2 (M = 0.93, SD = 0.26) compared to sets of 1 object (M = 0.69, SD = 0.47), though acceptance was high overall across these cases (compatible with past findings in English; Barner et al., 2009, and formal semantic analyses of the plural; see Bale, Gagnon, & Khanjian, 2011; Krifka, 1989; Sauerland, Anderssen, & Yatsushiro, 2005; Spector, 2007). Overall, the preliminary analyses combined confirmed that both conditions 1) did not differ in terms of Age and HC, 2) elicited interpretations of *tous*, *des* (Quantifier) and *deux* (Number) that the task was designed to induce.

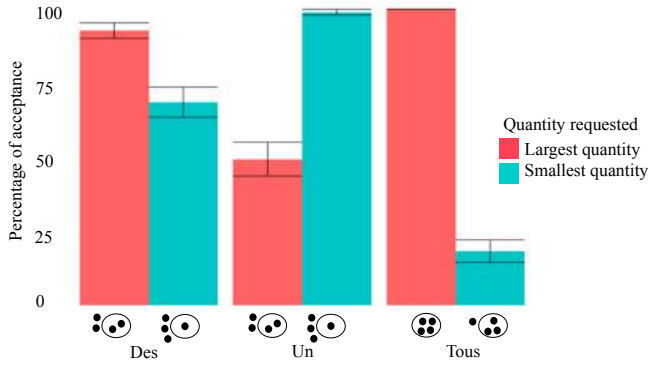

Figure 2: Children's percent saying "Oui/Yes" responses for each quantity term in the Quantifier condition in the Truth-Value Judgment Task. For the quantifier *des*, the largest quantity that was presented is 3 objects while the smallest is 2 objects. For *un*, the largest quantity that was presented is 2 objects while the smallest is 1 object. For *tous*, the largest quantity corresponds to all 4 objects while the smallest quantity consists of 3 objects. Error bars indicate standard error of the mean.

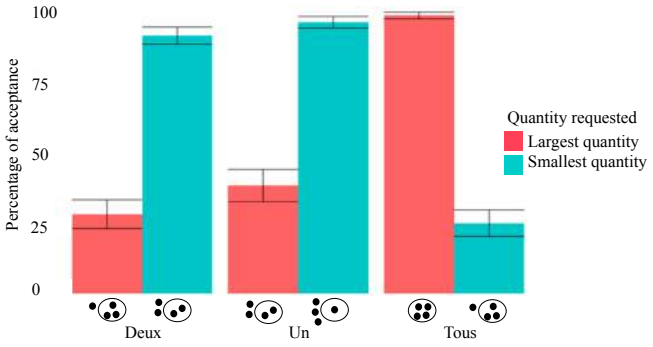

Figure 3: Children's percent saying "Oui/Yes" responses for each quantity term in the Number condition in the Truth-Value Judgment Task. For the numeral *deux*, the largest quantity that was presented was 3 objects while the smallest was 2 objects. For *un*, the largest quantity presented was 2 objects and the smallest 1. For *tous*, the largest quantity corresponded to all 4 objects while the smallest quantity was 3 objects. Error bars indicate standard error of the mean.

Children's interpretation of *Un*. In our main set of analyses, we addressed the question of how French-speaking children interpret *un* and whether their interpretation was exact (compatible with only sets of 1 object), inexact (compatible with sets of both 1 and 2 objects) or ambiguous. To do this, similar to the preliminary analysis, we performed a logistic mixed-effects model comparison.[2] In Model 1, we predicted acceptance from Age and Highest Count, with participant as a random factor, and in Model 2, we added the main effects and interaction of Set Size (1 or 2 objects) and Condition (Number vs. Quantifier) to Model 1. The presence of a main effect of Set Size would indicate of an interpretation of *un* that is either exact or ambiguous. Furthermore, adding Condition to our second model allowed us to test the question of whether acceptance rates differed based on the context of the game. If children have access to two different meanings for *un* that can be triggered by the pragmatic context of the game, then we should expect a significant interaction between Condition and Set Size, and specifically, that the acceptance rate for 2 objects should be higher in the Quantifier condition compared to the Number condition. Models 1 and 2 were significantly different ($\chi^2(3) = 164.79$, $p = <.0001$). However, in Model 2, the only significant predictor was Set Size ($\chi^2(1) = 50.24$, $p = <.0001$). As can be seen in Figures 2 & 3, children in both conditions accepted sets of 1 object (Number: $M = 0.96$, $SD = 0.19$; Quantifier: $M = 0.99$, $SD = 0.10$) more often than sets of 2 (Number: $M = 0.38$, $SD = 0.49$; Quantifier: $M = 0.49$, $SD = 0.50$). These results suggest that French-speaking children almost always accept sets of 1 for *un*, but when presented with sets of 2 objects, their interpretation of *un* is uncertain, hovering around 50% chance of saying "Oui/Yes", regardless of the context in which *un* is embedded.

Thus far, our data are more compatible with the third alternative presented: that French-speaking children have an ambiguous interpretation of *un* that is compatible with sets of 2 objects. In addition, despite the lack of significant difference between conditions, the question of whether French-speaking children have access to one or two meanings for *un* remains open. Indeed, our data are compatible with different interpretations: first, it is possible that French-speaking children only have access to a fuzzy representation of *un* - i.e., one that is neither exact like the English *one*, but not fully inexact like *a*. Second, it is possible that French-speaking children have access to two meanings for *un* but that the context of the task couldn't trigger the different interpretations. In order to further shed light on these possibilities, we compare these French-speaking children's acceptance rates to those of an English-speakers sample.

[2] The first model specification was: Acceptance ~ HC + Age + (1|subject). The second was: Acceptance ~ HC + Age + Set Size * Conditions + (1|subject).

Comparison with English data

To assess how these results compare to English, we obtained previously published data from English-speaking children's performance on the same task (from Barner, Chow, & Yang, 2009) and compared them to our sample of French-speaking children. The English sample included 31 participants of the same age (M = 45.3 months) as the French-speaking children in our study. The original task in Barner et al. (2009) included trials with *a, some, most, all, none, one, two*, with different options of set sizes, but only trials that tested *a* (sets of 1 and 2), *some* (sets of 1 and 2), *two* (sets of 2 and 3), *one* (sets of 1 and 2) and *all* (sets of 3 and all 8 objects) were selected for the current analyses.

First, we compared the acceptance rates for *some/des*, *two/deux,* and *all/tous* across French and English using mixed-effects model comparisons.[3] This was used as a control check to ensure that the linguistic groups didn't differ in the way that they understood and responded to the task. In all model comparisons, we first predicted acceptance from Set Size (with participant as a random factor) and then, added Language (English vs French) and the interaction between the two terms in the second model. There was no difference across languages for *some/des* and *two/deux* (both $ps > 0.01$). There was, however, a significant difference across languages and Set Size for *all/tous* ($\chi^2(1) = 7.13$, $p = <.001$) revealing that French children were more likely to accept sets containing all objects (M = 0.99; SD = 0.07) when asked about all objects compared to English speakers (M = 0.91; SD = 0.30)[4].

Our primary question of interest was whether French- and English-speaking children differed in their acceptance rate of *a, one,* and *un*. This question is also closely related to the question of whether French-speaking children have one or two meanings for *un*. Our prediction was that if French-speaking children had access to two interpretations for *un*, the context could be manipulated to favor one interpretation over the other, and we expected specifically that children in the Number condition would be more likely to have an interpretation of *un* close to *one* but not *a*, while children in the Quantifier condition would have an interpretation of *un* close to *a* but not *one*. To foreshadow, we found that children in the Number condition had an interpretation of *un* that was similar to *one* but not *a* and that children in the Quantifier condition interpreted *un* somewhat closer to *one* but differently than *a*. We obtained these results by performing 4 model comparisons contrasting the acceptance rate of: (1) the Number condition's interpretation of *un* to English speakers' interpretation of *one*, (2) the Number condition's interpretation of *un* to English speakers' interpretation of *a*, (3) the Quantifier condition's interpretation of *un* to English speakers' interpretation of *one*, (4) the Quantifier condition's interpretation of *un* to English speakers' interpretation of *a.* In all our first models, we predicted acceptance from Set Size (with participant as a random factor) and then, added Language (English vs French) and the interaction between the two terms in the second model.[5] When comparing (1) the Number condition's interpretation of *un* to English speakers' interpretation of *one,* we found only a main effect of Set Size ($\chi^2(1) = 2.15$, $p = <.001$) suggesting that all children were more likely to say "Yes" when presented with sets of 1 object (M = 0.96; SD = 0.19) compared to sets of 2 objects (M = 0.31; SD = 0.47), regardless of their linguistic group. Next, we looked at whether (2) children in the Number condition interpreted *un* differently than English speakers' interpretation of *a*. Here, our analysis revealed a main effect of Set Size ($\chi^2(1) = 20.95$, $p = <.001$) and an interaction between Set Size and Language ($\chi^2(1) = 7.42$, $p = <.01$) suggesting that English speakers where more likely to accept sets of 2 when asked for *a* (M = 0.78; SD = 0.42) compared to French speakers asked for *un* (M = 0.38; SD = 0.49). We then turned to children in the Quantifier condition and looked at how their interpretation of *un* compared to English. We first checked whether (1) the Quantifier condition's interpretation of *un* differed from English *one.* Here, we found a main effect of Language ($\chi^2(1) = 8.01$, $p = <.01$) and of Set Size ($\chi^2(1) = 30.22$, $p = <.001$), but the interaction between the two terms was not significant. This suggests that all children were more likely to accept sets of 1 object (M = 0.98; SD = 0.12) compared to sets of 2 objects (M = 0.39; SD = 0.49) and that French-speaking children (M = 0.77; SD = 0.42), on average, were more likely to say "Yes" compared to English-speaking children (M = 0.51; SD = 0.50). Finally, we looked at (4) how interpretation of *un* in the Quantifier condition compared to English speakers' interpretation of *a*. Here, we found a significant effect of Set Size ($\chi^2(1) = 17.47$, $p = <.001$), but most importantly a significant interaction between Set Size and Language ($\chi^2(1) = 6.77$, $p = <.01$), driven by the fact that French-speaking children were less likely to accept sets of 2 objects for *un* (M = 0.49; SD = 0.50) compared to English-speaking children for *a* (M = 0.78; SD = 0.42). Overall, these results suggest that children in the Quantifier condition interpreted *un* differently from English-speaking children's *a* and that children in the Number condition had an interpretation of *un* that was similar to *one* but not *a*.

[3] In all model comparisons, the first model specification was: Acceptance ~ Set Size + (1|subject). The second was: Acceptance ~ Set Size * Language + (1|subject).

[4] The difference between French- and English-speaking children could be explained by the fact that the English speakers, unlike the French speakers, when asked for *tous*, were presented with sets of no object at all in addition to the sets of 3 and all objects. English speakers could have accepted the sets of 3 objects more often simply due to the fact that it was already closer to "all objects" compared to the sets with no object at all. Regardless, the acceptance for sets of 3 in was still lower than 50% and for this reason, was not considered in our next analyses.

[5] In all model comparisons, the first model specification was: Acceptance ~ Set Size + (1|subject). The second was: Acceptance ~ SetSize * Language + (1|subject).

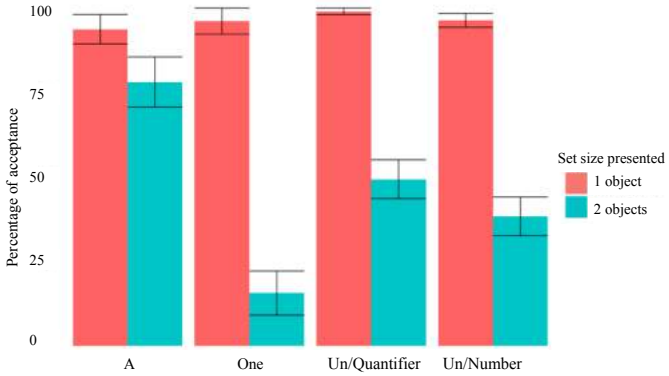

Figure 4: Comparison of English- and French-speaking children's acceptance rates for *a*, *one*, *un* in the Truth-Value Judgment Task (data from Barner, Chow, & Yang, 2009). "Un/Quantifier" represent the performances of children in the Quantifier condition while Un/Number represent the performances of children in the Number condition. Each term was presented with sets of one and two objects. Error bars indicate standard error of the mean.

Discussion

The goal of this study was to investigate the role of the morphological structure on children's acquisition of number words, via the case study of French-speaking children. Specifically, we investigated (1) how French-speaking children interpret *un,* and whether it is interpreted exactly, non-exactly or ambiguously, and (2) whether they have access to different meanings for *un* that can be triggered by the context of a task: an exact meaning that closely resembles English *one* and an inexact meaning similar to English *a*. When comparing acceptance rates across conditions, we found that children almost always accepted sets of 1 for *un,* but that their responses for sets of 2 were more varied, with many children saying "Oui/yes" when asked whether there was *un*, regardless of whether they were in the Number or Quantifier condition. However, an interesting mixed pattern emerged when comparing these acceptance rates to those of English-speaking children of the same age: children in the Number condition interpreted *un* as English-speaking children interpreted *one* (i.e., an exact interpretation compatible with only sets of 1 object), but children in the Quantifier condition interpreted *un* in a way that was not close to English-speaking children's *a*.

Overall, our results suggest that the morphological structure of French has an impact on children's learning. Specifically, our findings support the view that the homophony of *un*, compatible with both an exact and inexact interpretation, matters for the acquisition of the number word *one* as it creates a communicative problem. This homophony of *un* may provide more variable input to French-speaking children, leading to an ambiguous interpretation of the word. The contrast between English- and French-speaking children's interpretations of *un* vs *one/a* also suggests that French-speaking children not only need to learn that *un* can bear different meanings (exact and inexact) but also that meanings are affected by the context.

It has to be noted that the homophony of *un* is not the only aspect of French's morphology that could have an impact on children's acquisition of *un* as a numeral. Indeed, French's plural morphology is less salient in verbal communication compared to other languages like English. For example, in spoken French, very few nouns and verbs mark the singular/plural distinction, with the result that most nouns lack an audible word-final *s* to mark the plural like in English. This lack of salient plural agreement might exacerbate the challenge faced by French-speaking children to acquire an exact interpretation for *un*, but also other number words. Indeed, in English, children could in theory quickly start to notice a distinction between *one* and *two* as *one* always receives the singular agreement while *two* receives the plural. However, in French that distinction is unavailable for children (e.g., chat – i.,e., cat – is pronounced the same way regardless of whether it is presented with *un* or *deux*). As a consequence, French-speaking children might need to rely on more complex syntactic structures to pick up the distinction between *un* and *deux* (e.g., un chat dort/sleeps *vs* deux chats dor*ment*/sleep) and may need a significantly larger amount of input compared to English speakers – as not all verbs change phonetic forms based on plural agreement.

Another interesting aspect of these results is the apparent discrepancy between French children's performance for *un* in the Give-N task and the TVJ task. As a reminder, we excluded children who were not at least classified as One-knower at the Give-N task. This implies that when asked to provide *un biscuit* (i.e., *one* cookie), all children were able to provide exactly 1 object at least 2 out of 3 times. However, from the TVJ task, we can see that these same children still accepted sets of 2 objects as compatible with *un* around 50% of the time. Nonetheless, these results are not necessarily in contradiction. Indeed, these results are compatible with previous accounts which posit that though words like *a* and *one* may be associated with cardinal values of 1, they may not be pragmatically "strengthened" to exclude larger sets, especially in young children (Barner & Bachrach, 2010; Sauerland et al., 2005; Spector, 2007). According to these theories, if a child knows the meaning for *one* and knows that other numerals don't refer to set of 1 object, it would be infelicitous to provide more than 1 object when asked for *one*. For example, if a person asks to provide a fork, it would be pragmatically odd to give 2 or 3 forks. However, it would be more natural to have an existential interpretation of *one/a* in the context of a question – e.g., it seems less odd to say "yes, there is a fork in the bag" when asked whether there is *a/one* fork in bag and there is in fact 2 forks.

Taken together, our results raise the possibility that the ambiguity of French morphological structure poses a challenge to French-speaking children in acquiring an exact numerical meaning for the word un, potentially causing a delay in number word learning. Studies are currently in progress to test the possibility of a delay in the acquisition of early number words in French-speaking children.

Acknowledgments

We would like to thank members of the Language and Development Lab for their support during this project and the reviewers for their helpful comments and feedback.

The complex system of mathematical creativity: Modularity, burstiness, and the network structure of how experts use inscriptions

Abstract

One of the pinnacles of human cognition is the creative insight of expert mathematics. While its concepts are abstract, the actual practice of mathematics is undeniably material and embodied. Mathematicians draw, sketch, write; having created these inscriptions, they interact with them. This iterated process of inscription is the engine of mathematical discovery. But how does this engine work? Here, using a new video corpus of mathematical experts working on proofs, and deploying tools from network and complexity science, we characterize the structure and temporal dynamics of how mathematical experts create and interact with blackboard inscriptions. We find regularities in the structure of this activity (e.g., emergent 'communities' of inscriptions) and its temporal dynamics (e.g., 'bursty' shifts in attention). By characterizing this activity, we gain a better understanding of the distributed ecosystem in which mathematical creativity occurs — including the ways that mathematicians actively construct their own notational niches.

Keywords: mathematical cognition; networks; complex systems; inscription; distributed cognition; embodiment

Introduction

One of the pinnacles of human cognition is the creative insight of expert mathematics. Often working alone, sometimes for years, mathematicians generate new knowledge about completely abstract objects, from infinite sets to imaginary numbers. The actual practice of mathematics, on the other hand, is undeniably concrete, material, and embodied. Mathematicians draw. They sketch. They write out derivations, erase them, start again. Having created these inscriptions, mathematicians interact with them: shifting their attention, talking about and gesturing at them, elaborating them further. This iterated process of inscription is the engine of mathematical discovery.

But how does this engine work? While philosophers, historians, and sociologists have argued that notations, diagrams, and the process of inscription are central to mathematical practice (Barany & MacKenzie, 2014; Mialet, 2012; Muntersbjorn, 2003), we know surprisingly little about the details of this process. Here, we use tools from network and complexity science to characterize the structure and temporal dynamics of expert mathematical activity—in particular, the process by which experts create and interact with inscriptions while working on mathematical proofs.

Notations in mathematical cognition

Past work in a range of disciplines has explored the role of notations and inscription in mathematical reasoning. Within mathematics education, for instance, it has long been recognized that choosing the right notation is often half the battle (Polya, 2004). This is true among experts just as much as it is true for schoolchildren (Muntersbjorn, 2003). Indeed, there is now a growing body of qualitative and theoretical research on the centrality of inscription in mathematical reasoning (Barany & MacKenzie, 2014; Greiffenhagen, 2014; Muntersbjorn, 2003; Roth & McGinn, 1998).

More controlled, quantitative studies have established that notations are a critical part of the distributed system of mathematical reasoning. In particular, there are bidirectional influences between, on the one hand, the specific notations used to solve mathematics problems, and, on the other, the psychological processes used to solve problems (Goldstone, Marghetis, Weitnauer, Ottmar, & Landy, 2017). Both undergraduate students and more expert reasoners, for instance, rely on the correspondence between spatial proximity and algebraic precedence in standard algebraic notation; algebraic performance is improved when this correspondence is maintained, harmed when it is violated (Landy & Goldstone, 2007). Conversely, experience with mathematical notations can reshape the psychological processes used to interact with them. Marghetis and colleagues (2016) found that, among adults who had mastered the syntax of algebra, the visual system had learned to perceive syntactically-related elements as unified visual objects. How we think about a mathematical domain shapes how we interact with inscriptions, and interacting with those inscriptions shapes how we see the problem.

Most of this past work, however, has focused on contexts where the notations are *supplied* rather than created by the participant. In real-world mathematical activity, by contrast, the reasoner must often explore multiple approaches to representing a problem—sketching out specific examples, pursuing different algebraic derivations, drawing a variety of different graphs—before settling on the final approach. Focusing only on the end product of this practice hides the dynamic messiness of mathematical reasoning. As mathematician Reuben Hersh put it, this confuses the clear, organized, pristine 'front stage' of

published or textbook mathematics for the messy, dynamic 'backstage' of real mathematical practice (Hersh, 1991).

Describing expert inscription activity

In this paper, we zoom in on this messy 'backstage' of mathematical reasoning, to try to characterize the dynamic contexts of mathematical creativity. To do so, we draw on tools from network science and complex systems. We describe a video corpus of mathematical experts working on non-trivial mathematical proofs. While this corpus offers endless possibilities for qualitative analysis, here we adopt a quantitative approach that allows us to measure how experts create and interact with mathematical inscriptions by identifying the 'inscription objects' that each expert created (e.g., equations, graphs, etc.) and then creating a timeseries of when, exactly, the expert attended to these objects, from their first creation to their final glance. We use this dense timeseries to describe the structure and dynamics of inscription.

To do so, we adapt tools from network science to offer a new methodology for studying situated cognitive activity: representing each expert's activity as a *directed network*, in which individual inscription objects are represented as nodes, and transitions between objects (e.g., shifting attention from one graph to another) are represented as directed edges (see Methods and Figure 1). This approach is a way to 'coarse-grain' the messy, chalk-covered reality of expert inscription, to better reveal the deeper regularities that characterize expert notational practices.

Methods

Corpus

We created a video corpus of experts solving non-trivial mathematics problems in a naturalistic setting (total corpus length: 4 hours and 40 minutes). Doctoral students in mathematics (N = 7, 4 men and 3 women) were recruited through the website of the mathematics department at a major research university and compensated $10/hour.

These experts solved up to three non-trivial problems in a natural setting: either their own office or a nearby seminar room within the mathematics department. They were encouraged to talk out loud as they solved the problems. All participants made ample use of the blackboard.

Videos were recorded with a Sony HDR-CX405 high-definition digital. The camera was positioned such that the board and the participant were visible.

Mathematics problems

Problems were drawn from the William Lowell Putnam Mathematics competition, an annual mathematics competition for undergraduate students. These problems are typically too difficult for even advanced undergraduate students, but tractable for mathematics experts at the doctoral level or above. Problems were selected to include a range of content areas (i.e., set theory, geometry, analysis):

(1) Find an uncountable subset, S, of the power set of a countable set, such that the intersection of each pair of elements in S is finite.

(2) Let $f : R^2 \rightarrow R$ be a function such that $f(x, y) + f(y, z) + f(z, x) = 0$ for all real numbers x, y, and z. Prove that there exists a function $g: R \rightarrow R$ such that $f(x, y) = g(x) - g(y)$ for all real numbers x and y.

(3) Let d_1, d_2, … d_{12} be real numbers in the interval (1, 12). Show that there exist distinct indices i, j, k such that d_i,d_j, d_k are the side lengths of an acute triangle.

Each participant worked for approximately an hour on the problems, depending on their availability. Most participants were only able to complete two of the problems in that time.

Video Coding

Each participant created dozens of inscriptions on the blackboard and then interacted with those inscriptions—by talking about them, gesturing towards them, or elaborating them with further inscriptions. We conducted a fine grained coding of the video corpus, at a nearly frame-by-frame resolution, to track the creation of and interaction with 'inscription objects' on the blackboard.

Blackboard inscriptions naturally clustered together into objects. For instance, a graph of a function might consist of two axes, labels for those axes ('x,' 'y'), and then a line representing the function. Each of those components, however, naturally cluster together in both meaning (they are all part of the same graph) and in spatial location (they are all located close together, with only minimal blank space in between). We used these two criteria—semantic relatedness and spatial proximity—to identify cohesive 'inscription objects' on the blackboard.

A coder viewed each video and annotated the onset and offset of inscription events: either the creation of a new inscription object, or subsequent interactions with that object (via talk, gaze, gesture, further elaboration, or erasing). This generated a timeseries of events for each inscription object, from its initial creation to the final time that the expert attended to it. For instance, if an expert created a graph at the very start of a session, the timeseries would include the onset and offset times for that process of initially drawing the graph; if the expert later looked at the graph, the timeseries also included that event. All coding was conducted in ELAN, software designed for annotating audio and video (Lausberg & Sloetjes, 2009).

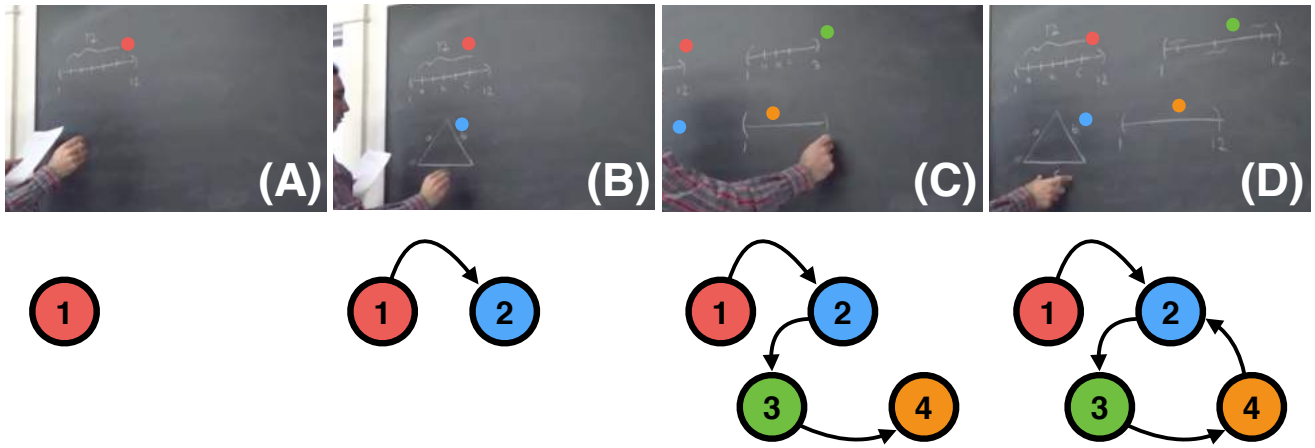

Figure 1. Illustration of a network representation of inscription activity. Blackboard images (top row) capture four consecutive stages in the process of developing a mathematical proof. The network representation of this process (bottom row) includes a node for each inscription object and an edge for transitions in attention from one object to another. We have added colored dots to the blackboard to indicate the location of each inscription object. (Node locations do not correspond to the objects' spatial locations.)

Network representation of inscription activity

To characterize the structure and temporal dynamics of experts' inscription activity, we used tools from network science. For each attempt to solve a problem, we used the timeseries of inscription events to generate a directed network, in which nodes represent inscription objects and directed edges represent transitions between objects.

As a simplified illustration, consider a scenario where an expert begins to solve a problem by creating and interacting with four inscription objects: three number-lines and one triangle (Fig. 1). The final network representation of this inscription activity would consist of four nodes, one for each inscription object, with a directed edge between two nodes whenever the expert attended first to one object and then to the other. For instance, if the expert started by creating a number-line (Fig. 1A), before abandoning that number-line to draw a triangle (Fig. 1B), the network representation of their activity up to that point would consist of two nodes — one for each inscription object — and a single directed edge from the first object to the second. As the expert creates new objects on the blackboard, the network grows (Fig. 1C, D), with their shifts in attention represented by directed edges between nodes 1 and 2, then from 2 to 3, then from 3 to 4, and then back to 2 again as they return their attention to an earlier inscription. This abstract graphical representation thus captures how the expert created and shifted their attention between inscription objects over the course of solving the problem.

Results

We first describe the network *structure* that emerged from the experts' inscription activity, then the *temporal dynamics* of their inscription activity, and finally the relations between the structure and dynamics of their notational activity.

Network structure of inscription activity

Experts created 360 distinct inscription objects, which they interacted with 4718 times. On average, solving an individual problem involved creating 24 inscription objects (SD = 16) and interacting with them 315 times (SD = 191).

Despite working on the same set of problems, experts in the corpus exhibited considerable variability in how they created and then shifted their attention among inscription objects. Figure 2, for instance, illustrates two different approaches to solving the same problem (problem #3, quoted above). For one individual (left), edges between nodes are distributed more or less randomly; nodes do not group together into interconnected clusters. By contrast (right), another individual interacted with inscriptions in interconnected clusters, and were much more likely to transition from one object to another within these clusters. This reflects a strategy where attention is likely to move to another inscription within the same cluster, creating pockets of activity wherein attention jumps between the same subset of inscriptions.

To identify these "communities" of inscriptions, we used the Girvan–Newman algorithm for community detection (Girvan & Newman, 2002), which identifies highly interconnected clusters of nodes using "edge betweenness" — the number of shortest paths between pairs of nodes that go through the edge — to identify highly central edges. In Figure 2, a node's community is identified by its color.

One way of describing the structure of inscription activity, therefore, is by how strongly shifts of attention defined communities of highly interconnected nodes — that is, the *modularity* of the network of inscription activity (Clauset, Newman, & Moore, 2004). Overall, inscription activity was significantly modular (M = 0.18, t_{14} = 4.1, p = .001; positive values indicate modularity, while 0 indicates

no modularity). Modularity exhibited both diversity and regularity. The participant illustrated on the left in Figure 2, for instance, generated a network with below average modularity compared to other experts who solved the same problem (modularity = 0.14), while the participant illustrated on the right had the second highest (modularity = .47). The modularity of individuals' activity varied considerably between problems (correlation in modularity between problems: r = 0.31); the individual who had the most modular activity on one problem, for instance, had the second-lowest modularity on another. By contrast, the two problems completed by most of the experts elicited reliably different modularity in inscription activity (M_{triangle} = 0.26 vs. M_{function} = 0.08, t_{13} = 2.4, p = .03). While modular clustering of inscriptions seems to be a recurring pattern in inscription activity, therefore, the precise amount of modularity likely reflects both the demands of the particular problem and stochastic, situated decisions.

In addition to the reliably modular structure of inscription activity overall, we also found finer grained regularities in the structure of communities themselves. Among communities, we observed two recurring 'motifs' or subgraph structures. One such motif was the 'cluster' motif, in which most nodes within a community were connected to each other (Fig. 3, right). These 'clusters' captured cases where a subset of inscription objects were all 'in conversation' with each other, with the expert shifting their attention among all inscriptions within that community. In contrast to these clusters, other 'loop' communities consisted entirely of a single, recurring route from one node, to another, to another, etc. in a straight, non-branching path (Fig. 3, left). These loops reflect inscriptions with a canonical pathway of attention—such as an algebraic derivation, where the experts attention would typically flow from the first expression to the last, in a set order.

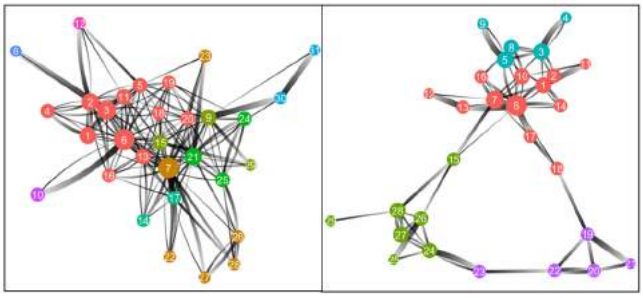

Figure 2. Different approaches to solving the same problem. Two different experts (left and right) solved the same problem, using approximately the same number of inscription objects (nodes). However, they interacted with those inscriptions in different ways, producing networks with different topological properties (see text). (Edge thickness indicates transition probabilities. Node color indicates community membership, as detected using the Girvan–Newman algorithm.)

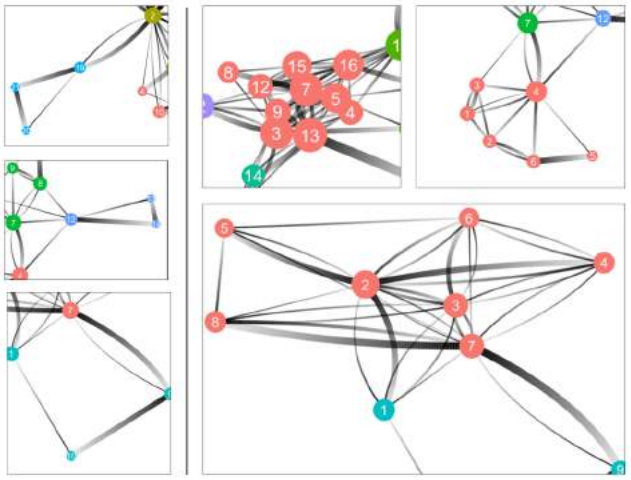

Figure 3. Recurring motifs in network communities. (left) Multiple communities involved only a single, recurring route from one node, to another, to another, etc. in a straight, non-branching path. (right) Other communities were highly interconnected, with most nodes connected to most other nodes.

Temporal dynamics of shifts in attention

We next characterized the temporal dynamics of inscription activity. To do so, we focused on the sequence of inter-event intervals — that is, the amount of time between the onset of attention towards one inscription object and the onset of attention towards the next object. A similar approach has been used to study the temporal dynamics of other human and human-technical systems (Barabasi, 2005; Goh & Barabási, 2008), such as email wait-times and dynamics of phone calls.

Here, we use a measure that have been used previously to characterize complex systems of social and cognitive activity, and to distinguish those systems from natural (e.g., earthquakes) and autonomous physiological activity (e.g., heartbeats): the 'burstiness' of the activity (Goh & Barabási, 2008). Past work has established that human activity systems often exhibit heavy-tailed dynamics — for instance, bursts of high activity followed by long periods of inactivity, with longer periods of inactivity than expected (e.g., assuming a Poisson or Gaussian distribution). This 'burstiness' may reflect interaction-dominant dynamics, with multiple processes combining in non-additive ways, or by an underlying process that involves priority queuing (Barabasi, 2005). The burstiness of a distribution of inter-event intervals {t} is typically measured by:

$$B = \frac{\sigma - M_t}{\sigma + M_t}$$

where σ is the standard deviation and M_t is the mean inter-event interval. More recently, this measure has been found to be sensitive to the size of finite samples, and the following elaboration has been adopted:

$$B = \frac{\sqrt{n+1}r - \sqrt{n-1}}{(\sqrt{n+1}-2)r - \sqrt{n-1}}$$

where r is the coefficient of variation, σ / M_t, and n is the sample size. Both these measures are designed to equal 0 for random, Poisson distributions; -1 for regular, periodic distributions; and +1 for bursty distributions. Past work has found that human activity systems typically exhibit significant burstiness (Goh & Barabási, 2008).

Overall, inscription activity was significantly bursty (B = 0.17, $p < .0001$, bootstrapped with n = 1000 samples). The burstiness was even more pronounced when we considered the distribution of times spent within a community of inscriptions — that is, the time between attending to one inscription object that belonged to a new community, and attending to a new object that belongs to a new community. This timeseries of inter-community dynamics was extremely bursty (B = .47, $p < .0001$, bootstrapped with n = 1000 samples), comparable to the most bursty human systems (Goh & Barabási, 2008). Inscription activity, therefore, was marked by with long periods of time spent within a community of inscriptions, followed by 'bursty' periods with rapid transitions between communities.

Relationship between structure and dynamics

Finally, we sought to characterize the relationship between the topological structure of experts' inscription activity (e.g., community structure and modularity) and the temporal dynamics of that activity.

First, we examined when, exactly, experts transitioned from one community of inscriptions to another. To do so, we took our timeseries of inscription object attention and determined whether the new object of attention belonged to the same or a different community— that is, a community transition. We then tried to predict the transition to a new community, using a generalized linear mixed-effects model of whether the new object belonged to a different community. We included as fixed effects the cumulative time spent on the problem; the amount of time spent attending to the current object; and, critically, the amount of time spent in the current community since most recently beginning to attend to that community ('sticking time'). We included random intercepts and slopes by participants, and random intercepts by problem.

There was no reliable relationship between the cumulative amount of time spent on the problem and the probability of transitioning to a new community of inscriptions (b = 0.22 ± 0.30 SEM, p = .46). By far the strongest predictor, however, was the amount of time spent within the current community, which had a large and negative relationship to the probability of transitioning to a new community (b = -2.29 ± 0.40 SEM, $p < .0001$). In other words, communities of inscriptions were themselves 'sticky,' so that the longer an expert spent within a community of inscriptions, the more likely they were to stay there going forward. This thus helps explain the highly bursty dynamics of transitions between communities, reported above: experts become fascinated with a particular cluster of inscriptions and spend considerable time, before suddenly transitioning to different inscription, and perhaps then undergoing a 'bursty' period of rapid transition between communities.

Finally, we looked at the relationship modular structure and between bursty dynamics. We used a linear mixed-effects model of the burstiness of the inscription activity used to solve each problem, and included predictors for the problem, the total number of events, the total number of inscription objects, the mean duration of an inscription event, a measure of the 'memory' of the activity dynamics (Goh & Barabási, 2008), and, crucially, our measure of modularity. The predictor with the largest relationship to burstiness, and the only one that was statistically significant was modularity (b = 1.29 ± 0.52 SEM, $p < .04$). More modular inscription activity—with communities of densely interconnected inscriptions—was associated with more bursty temporal dynamics (Fig. 4).

Discussion

Drawing on a corpus of mathematical experts working on non-trivial problems, and deploying tools from network and complexity science, we set out to characterize the 'manual labor' of mathematics (Marghetis, Edwards, & Núñez, 2014). We found that expert mathematical practice involved actively creating dozens of inscriptions and navigating between them, shifting attention from one to another. These shifts in attention were not random, however, but exhibited systematic modularity; inscriptions clustered together into 'communities,' subgroups of inscriptions that were likely to follow each other in a cascade of attention. This *structure* of inscription activity was related to the *temporal dynamics* of inscription, with a systematic relationship between inscription modularity and temporal burstiness (a hallmark of complex human activity). Overall, our network analysis of mathematical activity revealed both diversity and regularity in the inscription activity of experts.

The complex 'ecosystem' of cognition

By transforming raw video of situated problem solving into a directed network of inscription activity, we created a tractable representation of an otherwise prohibitively nuanced practice. This allowed us to adopt a quantitative approach without sacrificing a systems-level analysis. This approach shifts the focus away from individuals and skull-confined brain, and toward the ecosystem of mathematical practice, spanning brains, bodies, and blackboards.

From this perspective, the engine of mathematics is not the mathematicians' brain, locked away inside their skull. The brain is undeniably part of that engine. But equally important is the system of notations to which the mathematician has recourse, the particular inscriptions she creates in the moment, and the way her body allows her to

bring all those parts into coordination—by looking, pointing, sketching. The mathematician's creative insights are the product, not of solitary brains, but of a socially and materially distributed cognitive system (Hutchins, 1995). Indeed, this was true even of the physicist Stephen Hawking, who was famously confined to a wheelchair; instead of creating his own inscriptions, he worked closely with his able-bodied students, who created inscriptions on his behalf (Mialet, 2012).

This shift away from traditional intracranial processes to the larger complex system involved in creative mathematics puts a new emphasis on the material context of mathematical discovery. How should we characterize the endless inscriptions that mathematicians produce daily? How do those inscriptions change over the course of their mathematical training? How important are the inscriptions that a mathematician produces for herself, compared to those produced by her colleagues?

These questions suggest an analogy with another context of insight and learning: The early development of infants' visual and linguistic systems. Recent work has begun to characterize the rich visual and linguistic input that is received by the developing child—including how the child actively shapes that input to facilitate learning (e.g., Smith, Jayaraman, Clerkin, & Yu, 2018). Understanding the larger ecosystem in which learning occurs—whether by a pre-verbal child or a highly trained mathematician—will be critical to understanding how, exactly, that learning occurs.

Indeed, this analogy with early child learning highlights another critical component of situated mathematical practice: Mathematicians do not receive carefully formed representations of their problems. They must figure out how to represent their ideas. In this way, the mathematician is like the child who actively shapes their visual input. Children shape their visual context to facilitate learning. Mathematicians transform their material context to facilitate creative insight. By sketching, drawing, graphing, and writing various algebraic expressions, they engage in a form of niche construction: 'notational niche construction.'

Limitations

Our analysis has a number of limitations.

For one, naturally occurring inscriptions need not necessarily cluster into objects defined by semantic relatedness and spatial proximity. In our corpus, however, the inscriptions did typically fall into unambiguous clusters, and the few unclear cases were resolved through discussion among the authors (e.g., deciding whether a vertical stack of equations should count as one object or multiple, distinct objects). Second, one modality by which experts could engage with an object was through gaze; however, since our data consisted only of a single camera, it was not always possible to determine where a participant was looking. Gaze toward an object was only coded when there was unambiguous evidence that the participant had shifted their gaze toward an object, such as when they turned their entire head to look at an inscription that was relatively isolated on the blackboard. As a result of this conservative approach, we may have underestimated the number of transitions between objects. To address both these issues, future work will need to establish the reliability of the coding scheme by using multiple coders and calculating inter-coder reliability.

Third, the methodology introduced here is very time-consuming, both when initially collecting the data (which requires recruiting highly trained experts) but especially when coding the video data afterwards. As a result, the current corpus consists of hundreds of inscriptions and thousands of interactions, but these were drawn from the activity of only seven experts. Were are currently working to expand our corpus in order to investigate the generality of the current findings.

Future Directions and Conclusions

We have not even begun to look at how the structure and dynamics of inscription might change over the course of a problem solving episode. For instance, are there distinct phases of activity—perhaps early exploration of different inscriptions, followed by later exploitation of successful ones?

Relatedly, we have yet to investigate the association between the structure and dynamics of inscription and various other outcome measures. For instance, does the network structure of inscription activity predict the creativity or completeness of the final proof? On a more granular level, what happens immediately before the expert has a sudden insight—can we predict the onset of a critical transition in understanding (e.g., Setzler, Marghetis, & Kim, 2018; Stephen, Boncoddo, Magnuson, & Dixon, 2009)?

Third, future analyses will look in more detail at the *kinds* of inscriptions that experts are creating. Does inscription activity differ between, say, algebraic equations versus Cartesian plots? Might the structure and dynamics of inscription offer insights into how individuals tend to use different kinds of inscriptions—or perhaps reveal that superficially dissimilar inscriptions are actually treated similarly by experts?

Finally, we are curious about which aspects of inscription activity are specific to highly-trained mathematical experts, and which might also occur among novices. Work on other complex systems has found that the temporal dynamics of a complex system can predict the system's health or resilience (Kleiger, Miller, Bigger Jr, & Moss, 1987). One possibility, for instance, is that bursty dynamics during inscription is diagnostic of mathematical expertise.

Answering these questions will bring us closer to understanding how one of the most *abstract* forms of human understanding is so undeniably *concrete:* Covered in chalk, gesturing emphatically at the blackboard, the thinking mathematician is engaged in manual labor — and then, suddenly, she understands infinity.

Navigating the "chain of command": Enhanced integrative encoding through active control of study

Douglas B. Markant (dmarkant@uncc.edu)

Abstract

A growing body of research indicates that "active learning" improves episodic memory for material experienced during study. It is less clear how active learning impacts the integration of those experiences into flexible, generalizable knowledge. This study used a novel active transitive inference task to investigate how people learn a relational hierarchy through active selection of premise pairs. Active control improved memory for studied premises as well as transitive inferences involving items that were never experienced together during study. Active learners also exhibited a systematic search preference, generating sequences of overlapping premises that may facilitate relational integration. Critically, however, advantages from active control were not universal: Only participants with higher working memory capacity benefited from the opportunity to select premise pairs during learning. These findings suggest that active control enhances integrative encoding of studied material, but only among individuals with sufficient cognitive resources.

Keywords: active learning; transitive inference; information search; integrative encoding

Introduction

How does the opportunity to control a learning experience alter subsequent memory of it? Recent research has shown that active control over learning enhances episodic memory for experienced material compared to passive observation of the same information (Markant, DuBrow, Davachi, & Gureckis, 2014; Voss, Gonsalves, Federmeier, Tranel, & Cohen, 2011). This enhancement can arise from a number of mechanisms, including improved attentional coordination, metacognitive monitoring, or enriched encoding associated with volitional control (Markant, Ruggeri, Gureckis, & Xu, 2016).

Less is known about how active control affects the integration of studied material into flexible, generalizable knowledge. Other work has revealed benefits from active information selection when learning categorical rules (Markant & Gureckis, 2014) or causal structures (Steyvers, Tenenbaum, Wagenmakers, & Blum, 2003). However, these studies have not examined a crucial question about improvements in generalization following active control of study: Do they reflect better memory for experienced information itself (which then supports generalization later on) or the formation of relational knowledge during encoding that abstracts away from that experience? Following Zeithamova, Schlichting, and Preston (2012), these alternatives can be mapped onto two types of memory formation: *elemental encoding* of stimuli or associations that are directly experienced during study, and *integrative encoding* through which disparate study episodes are bound together into a unified representation. Whereas existing research has established that active control enhances elemental encoding in a variety of contexts, its relationship to integrative encoding remains unclear.

The present study examined the effects of active control in a well-known example of relational generalization: transitive inference (TI). In TI people learn about an ordered hierarchy (e.g., A $<$ B $<$ C) by studying premises comprised of adjacent items (e.g., A $<$ B, B $<$ C). They are then tested on their memory for studied pairs (*recall trials*; e.g., A ? B) and their ability to infer relationships between items that were never experienced together (*inference trials*; e.g., A ? C).

Transitive inference is a fundamental form of reasoning and has been the subject of a wealth of past research, but has always been studied under passive conditions in which control over the study experience is absent. This study introduces a novel *active transitive inference* task in which participants choose which premises to study during learning. Based on prior evidence that active selection improves episodic memory, active selection was expected to improve recall of studied premises relative to passive study. Active control was also predicted to improve transitive inference, but this advantage might arise from two distinct mechanisms. Enhanced elemental encoding of premises should bolster retrieval at the time of test, allowing participants to make transitive inferences by reasoning across overlapping pairs. Alternatively, active control may enhance integrative encoding during study, aiding the formation of a unified representation of the hierarchy. Importantly, these processes predict distinct relationships between performance and the distance between test items (see below), making TI well-suited to examine how learner control changes the representation of studied material.

Elemental vs. integrative encoding in transitive inference

Transitive inference involves comparing items that have never been experienced together but are linked by one or more studied pairs. TI may be supported by a number of alternative processes which can be distinguished by their dependence on elemental or integrative encoding. Elemental encoding-based inference occurs by reactivating studied premises at the time of test and reasoning across overlapping relations (Kumaran & McClelland, 2012). In this case, successful inference hinges

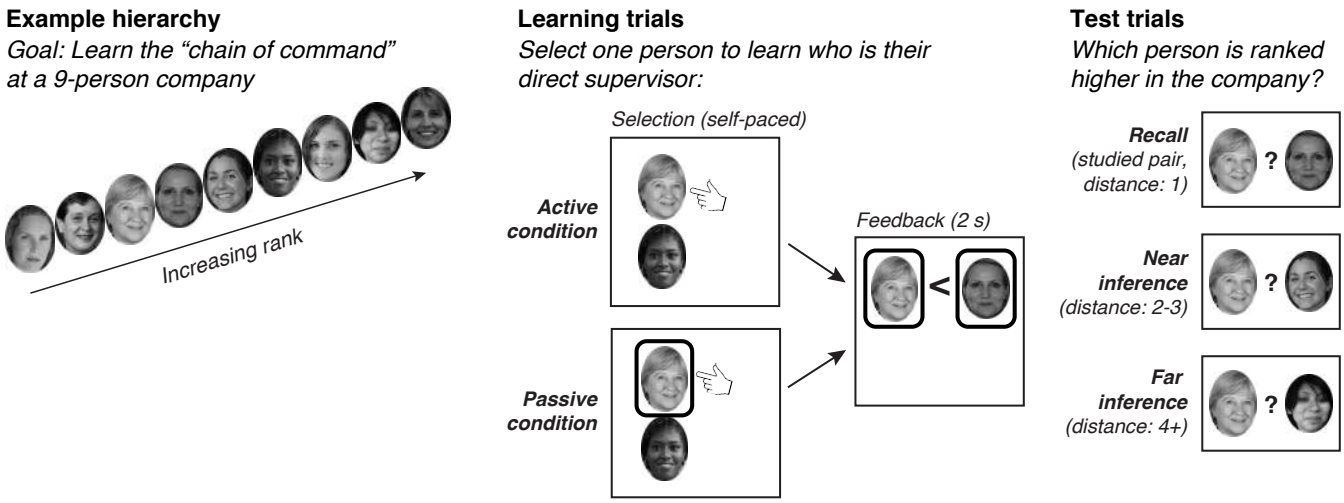

Figure 1: Depiction of the transitive inference task.

on robust encoding of studied pairs to ensure later retrieval. This process implies that large distances between test items (e.g., A ? E) will be associated with lower accuracy since there are more opportunities for retrieval errors along the way.

In contrast, integrative encoding-based accounts of TI postulate the formation of a unified, ordinal representation during study (De Soto, London, & Handel, 1965; Hummel & Holyoak, 2001; Shohamy & Wagner, 2008; Trabasso, Riley, & Wilson, 1975). Inference then entails comparing the positions of any two items along that dimension. Importantly, this process implies accuracy should *increase* with inferential distance, as items that are further apart on that latent dimension are easier to distinguish. Such *symbolic distance effects* are a hallmark of integrative encoding (Moyer & Landauer, 1967).

Although alternative forms of associative or reinforcement learning may also support TI (Frank, Rudy, Levy, & O'Reilly, 2005), the construction of an integrated representation during encoding is especially likely when participants are aware there is an underlying hierarchy to be learned (Greene, Spellman, Levy, Dusek, & Eichenbaum, 2001; Lazareva & Wasserman, 2010). Accuracy is higher among participants who report post-task awareness of the hierarchy (Martin & Alsop, 2004), who are informed about it prior to training (Greene et al., 2001; Smith & Squire, 2005), or when stimuli evoke hierarchical schemas (Kumaran, 2013). Reliance on integrated representations also appears to depend on working memory capacity (WMC) (Titone, Ditman, Holzman, Eichenbaum, & Levy, 2004; Fales et al., 2003). Thus, while constructing an integrated representation is typically associated with superior generalization, it may also depend on explicit awareness of the hierarchical organization of items and incur greater cognitive costs.

Learner control and integrative encoding

Since elemental and integrative encoding predict distinct relationships between inferential distance and performance, TI can be used to examine whether active control has broader benefits for memory formation beyond improved episodic memory for studied pairs. One reason to expect enhanced integrative encoding is that the opportunity to select premises may encourage learners to construct an integrated representation as they learn, which can then guide selection decisions (e.g., allocating study to items from less familiar portions of the hierarchy). At the same time, this process might involve additional demands on aspects of executive functioning such as working memory. To evaluate this possibility an assessment of WMC (operation span) was included in addition to the TI task in the experiment below.

In addition to the main goal of identifying any effect of active control on integrative encoding, the TI task was designed to explore information search during active study. Passive training in TI is often scaffolded such that overlapping pairs are experienced in direct succession (e.g., A $<$ B, B $<$ C, ...), which leads to faster learning than random sequences (Halford, 1984). If studying overlapping premises aids relational integration, active learners may prefer to select such options when possible. Each selection therefore involved a choice between a *near* and *far* option which differed in their distance from the pair studied on the previous trial. This made it possible to identify any search preference during active study and its relationship to inferential accuracy.

Experiment

Participants and Materials

N = 100 participants (60 women; age: M = 21.94 years, SD = 5.60) were recruited from the student population at UNC Charlotte. Participants received either course credit or \$8 (\$4 per session), as well as a \$0–\$5 incentive based on their performance in the first test session. N = 62 participants returned for the second session.

Face stimuli for the TI task were obtained from the 10k US Adult Faces Database (Bainbridge, Isola, & Oliva, 2013). For

Table 1: Estimated fixed effects from mixed effects logistic regression model of test accuracy.

Predictor	OR	95% CI-lower	95% CI-upper	Wald z	p
(Intercept)	4.07	3.30	5.07	12.36	0.00
Condition [passive]	0.76	0.67	0.85	-5.19	0.00
Session [retest]	0.85	0.76	0.98	-2.67	0.01
Distance	1.10	1.02	1.16	3.00	0.00
Operation span	2.06	1.67	2.58	6.47	0.00
Condition [passive] x Session [retest]	0.80	0.68	0.94	-2.68	0.01
Condition [passive] x Distance	0.94	0.87	1.02	-1.33	0.18
Condition [passive] x Operation span	0.55	0.49	0.60	-12.49	0.00

each sex, the stimulus set was filtered to include only faces that were non-famous and which had mean ratings within a 1-point interval centered on the midpoint of the rating scale for perceived age, emotional affect, and memorability. Thirty-six images (18 male, 18 female) were manually chosen from the filtered set to ensure high image quality and the absence of other distinctive features (e.g., jewelry, background objects).

Procedure

There were two sessions. The first session included the TI task followed by the operation span assessment. The second session occurred 6-8 days later and included a second run of the test phases from the TI task.

The TI task (Figure 1) used a within-subjects design with two rounds. Participants were tasked with learning the "chain of command" at two companies. Each participant learned about one 9-item hierarchy in the active condition and a second 9-item hierarchy in the passive condition. Each hierarchy was composed of all female faces or all male faces in order to reduce interference between conditions. The order of conditions and mapping of stimulus set to condition were counterbalanced across participants. Each round was comprised of a learning phase (56 trials) followed by a test phase (72 trials).

The instructions included an example of a 3-item hierarchy in which participants learned about two premise pairs (person A $<$ person B, person B $<$ person C) and were asked to infer the transitive relation (person A $<$ person C). All participants were therefore aware of the hierarchical nature of the stimuli and were explicitly instructed to learn to judge the relative rank of any two individuals in a given company.

Learning phase. The learning phase involved a series of choices between two non-adjacent items in the present hierarchy (excluding the highest-ranking item which was never presented as a choice option). The options on the first learning trial were two non-adjacent items sampled at random. On all subsequent trials, options differed in their distance from the item selected on the previous trial: Each option set included a *near* option that was 1–2 positions away from the item selected on the previous trial, and a *far* option that was 3 or more positions away from the item selected on the previous trial. This manipulation of option distance was designed to test whether participants in the active condition preferred to select items based on their distance. In the passive condition selections were evenly divided between near and far options.

Active study condition. Each trial began with the presentation of the two options in a vertical array in random order (Figure 1, middle). Participants were instructed to select an option at their own pace in order to learn that person's direct supervisor. Following their choice the unselected option disappeared and the premise pair (selected item and superordinate feedback item) was displayed for 2 s.

Passive study condition. In the passive condition participants did not decide which option to select. As in the active condition, the trial began with the presentation of two options, one of which was already highlighted with a red border. Participants were instructed to select the highlighted option at their own pace, at which point the trial proceeded in the same manner as in the active condition.

Test phase. In each test trial, two items were presented side-by-side and the participant clicked on the person they judged to be ranked higher in the hierarchy. The test phase was comprised of three trial types (Figure 1, right): *recall* trials involving a choice between studied premise pairs (e.g., A ? B), *near inference* trials involving items that were 2–3 positions apart (e.g., A ? C), and *far inference* trials involving items that were 4 or more positions apart (e.g., A ? E). In the second session, participants completed a second run of the same test phases experienced during the first session, with test pairs presented in a new random order.

Operation span. In the operation span task, participants attempt to hold a sequence of items in memory while judging the validity of interleaved math operations (Unsworth, Heitz, Schrock, & Engle, 2005). At the end of a trial involving multiple such steps, participants recall the sequence of digits in the same order as they appeared. The set size (number of operations/digits) ranged from 2–7, presented in increasing order, with three trials completed for each set size. Participants were highly accurate at evaluating the validity of the math operations (judgment accuracy M = 0.92, SD = 0.06). Operation span was scored according to the summed number of digits recalled in the correct order for those trials in which no

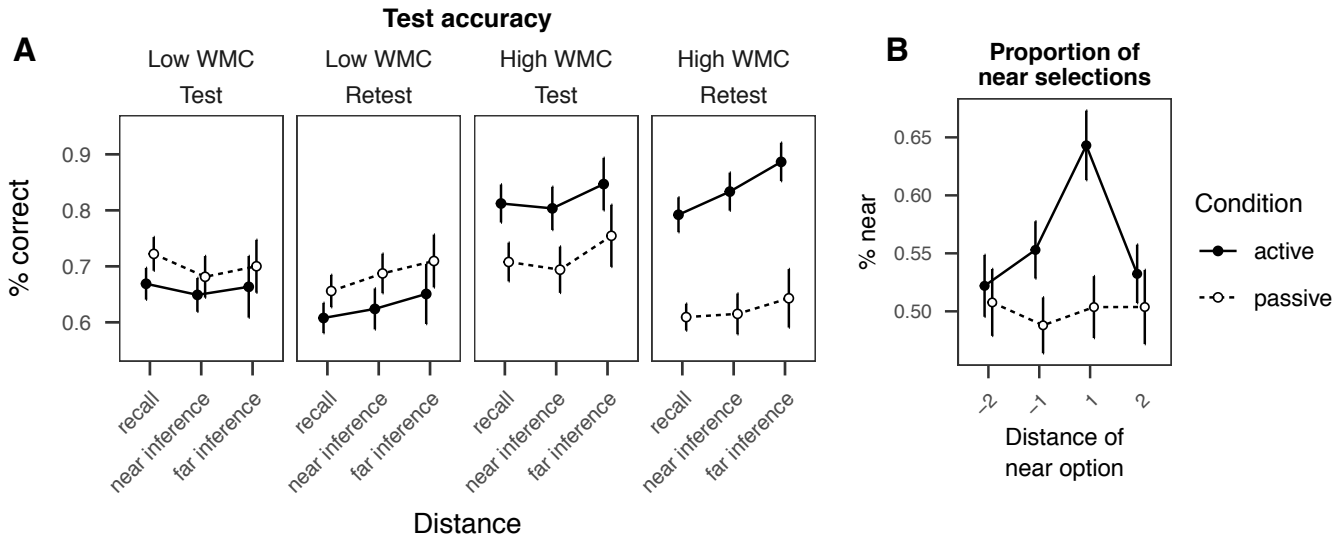

Figure 2: **A:** Test accuracy after median split on operation span, for both the immediate test and delayed retest. Performance is shown as a function of study condition (active/passive) and inferential distance (recall/near inference/far inference). **B:** Proportion of trials in which the *near* option was selected as a function of its distance from the item chosen on the previous trial. All error bars indicate within-subjects 95% confidence intervals.

errors were made (M = 14.86, SD = 11.29, median = 12.50).

Results

Test accuracy. Test responses were scored according to whether participants correctly identified the superordinate item in each test pair (0 = incorrect, 1 = correct). Test trials involving either endpoint of the hierarchy were excluded from analysis since participants could rely on non-transitive strategies to respond. Accuracy was modeled using mixed effects logistic regression (Table 1). The model included fixed effects for condition (active/passive), session (test/retest), distance (recall/near inference/far inference), and operation span (continuous), as well as pairwise interactions between condition and the other predictors. Random intercepts were included for participants and stimuli in each test pair.

Active performance was higher than passive performance in both the immediate test (active: $M = 0.74$, $SD = 0.21$; passive: $M = 0.71$, $SD = 0.21$; $OR = 1.32$, $CI = [1.13, 1.54]$, $z = 5.19$, $p < .001$) and in the retest (active: $M = 0.73$, $SD = 0.21$; passive: $M = 0.65$, $SD = 0.21$; $OR = 1.64$, $CI = [1.37, 1.98]$, $z = 7.64$, $p < .001$). Accuracy declined from the immediate test to the retest in both the active condition ($OR = 0.85$, $CI = [0.71, 1.01]$, $z = -2.67$, $p = 0.007$) and the passive condition ($OR = 0.68$, $CI = [0.57, 0.81]$, $z = -6.48$, $p < .001$).

There was a symbolic distance effect, such that accuracy increased with inferential distance, in the active condition ($OR = 1.10$, $CI = [1.00, 1.20]$, $z = 3.00$, $p = 0.003$) but not the passive condition ($OR = 1.04$, $CI = [0.95, 1.13]$, $z = 1.22$, $p = 0.22$). In addition, operation span was positively related to accuracy in the active condition ($OR = 2.06$, $CI = [1.50, 2.84]$, $z = 6.47$, $p < .001$) but not the passive condition ($OR = 1.13$, $CI = [0.82, 1.54]$, $z = 1.09$, $p = 0.28$). Figure 2A shows test accuracy in each condition following a median split on operation span. Active control of study had markedly different consequences depending on participants' operation span, with active control leading to a large, persistent advantage over passive study only among higher WMC participants.

Selections during learning. The next analysis examined participants' selections during learning and whether they could account for differences in test performance described above. Study condition was not related to item selection frequency (multinomial logistic regression, likelihood ratio test: $\chi^2_{(1,7)} = 7.20$, $p = 0.41$), indicating that the aggregate distribution of experienced premise pairs was comparable across active and passive study.

Each learning trial involved a choice between a near option (1–2 positions away from the option selected on the previous trial) and a far option (3+ positions away). By design, near and far options were chosen with equal frequency during passive study. In the active condition participants had a small but significant preference for selecting the near option ($M = 0.56$, $SD = 0.07$; $OR = 1.30$, $CI = [1.21, 1.40]$, $z = 6.86$, $p < .001$).

Near selections may be especially useful if they cause overlapping premise pairs to be experienced in successive trials, which could facilitate integrative encoding when representations of overlapping premise pairs are simultaneously active. I next examined whether the preference to select near items depended on the distance between the near option and the item selected on the previous trial ($dist_{\text{near}} \in \{-2, -1, +1, +2\}$). When $dist_{\text{near}} = +1$, the near option was immediately superordinate to the previously selected item; that is, the near option had appeared as the feedback in the

previous trial.

Figure 2B shows the proportion of near selections as a function of near option distance. In the active condition, the proportion of near selections did not differ from the passive condition when $dist_{\text{near}} = -2$ (OR = 1.05, CI = [0.86, 1.29], z = 0.63, p = 0.53) or $dist_{\text{near}} = +2$ (OR = 1.15, CI = [0.94, 1.41], z = 1.73, p = 0.08). However, there was a higher proportion of near selections when $dist_{\text{near}} = -1$ (OR = 1.29, CI = [1.07, 1.56], z = 3.48, $p < .001$) or $dist_{\text{near}} = +1$ (OR = 1.75, CI = [1.45, 2.11], z = 7.52, $p < .001$). Within the active condition, the proportion of near selections was markedly higher for $dist_{\text{near}} = +1$ than $dist_{\text{near}} = -1$ options (OR = 1.45, CI = [1.20, 1.75], z = 4.95, $p < .001$). In the active condition participants therefore preferred the near option when it was adjacent to the item selected on the previous trial, and this preference was strongest when the option had appeared as feedback in that trial. Although the aggregate frequency of item selection was similar across conditions, this result suggests that active participants generated study sequences in which overlapping premise pairs were more likely to be experienced in successive trials.

Can this tendency to select overlapping items account for the performance benefit in the active condition? A new model of test accuracy was fit for the active condition which included predictors for the proportion of near selections at each level of $dist_{\text{near}}$. There were no significant relationships between accuracy and the proportion of near selections at any distance ($dist_{\text{near}} = -2$: OR = 1.01, CI = [0.70, 1.44], z = 0.06, p = 0.95; $dist_{\text{near}} = -1$: OR = 1.30, CI = [0.92, 1.85], z = 1.87, p = 0.06); $dist_{\text{near}} = +1$: OR = 0.96, CI = [0.67, 1.38], z = -0.27, p = 0.79; $dist_{\text{near}} = +2$: OR = 1.30, CI = [0.90, 1.89], z = 1.75, p = 0.08). The proportion of near selections at any distance was also unrelated to operation span ($dist_{\text{near}} = -2$: OR = 0.93, CI = [0.80, 1.07], z = -1.34, p = 0.18; $dist_{\text{near}} = -1$: OR = 0.98, CI = [0.85, 1.12], z = -0.38, p = 0.70; $dist_{\text{near}} = +1$: OR = 1.07, CI = [0.93, 1.22], z = 1.19, p = 0.23; $dist_{\text{near}} = +2$: OR = 0.98, CI = [0.85, 1.14], z = -0.30, p = 0.77). Thus, the preference to select overlapping options was a general one and could not on its own account for the gap between active and passive performance.

Discussion

This study used a novel TI task to examine whether active control aids the integration of relational knowledge during study. Control over the selection of premise pairs improved performance relative to passive study in both an immediate test and a retest one week later. Symbolic distance effects observed in the active condition strongly imply that this benefit resulted from enhanced integrative encoding, such that active learners relied on an integrated representation of the hierarchy rather than sequential reactivation of premise pairs at test (Acuna, Sanes, & Donoghue, 2002; Zeithamova, Schlichting, & Preston, 2012). The absence of such effects following passive study suggests that integrative encoding was less prevalent when the same participants lacked the opportunity to select premises for themselves.

Active control did not benefit all learners, however, as working memory capacity strongly predicted accuracy in the active condition. Among higher WMC participants, active control produced a $\sim$10% initial advantage over passive study (increasing to $\sim$20% in the retest) and sustained performance across sessions. WMC was unrelated to accuracy in the passive condition, a finding that conflicts with reports that WMC moderates TI under experimenter-controlled conditions (Fales et al., 2003; Libben & Titone, 2008; Titone et al., 2004). This discrepancy may be due to the relative difficulty of passive study in the present task. Previous studies have typically involved smaller hierarchies and scaffolded training sequences in which participants are likely to experience overlapping premises (e.g., Libben & Titone, 2008). With larger hierarchies and greater distances between successive premises, the passive condition used here may have been especially difficult even for participants with higher WMC. An important next step is to evaluate whether the large disadvantage from passive study among higher WMC persists when observing more useful sequences of premises (e.g., when yoked to participants' selections in the active condition).

This study provides the first evidence of systematic search in active TI: Participants strongly preferred to select options that appeared as feedback on the previous trial ($dist_{\text{near}} = +1$). They thereby naturally generated "chained" sequences of overlapping pairs which tend to improve performance in passive conditions relative to random presentation (Halford, 1984). This preference was widespread: 73 of 100 participants chose the $dist_{\text{near}} = +1$ option in more than half of trials in which one appeared, and the proportion of near selections was unrelated to WMC. Although selection of overlapping pairs should facilitate integrative encoding, not everyone benefited from it. One possibility is that only higher WMC individuals capitalize on chained sequences because they maintain representations of premises from trial to trial. Alternatively, higher WMC individuals may be more likely to use an integrated representation of the hierarchy to decide which option to study next (e.g., choosing to learn about the option whose rank is more uncertain). Further work is necessary to determine whether this goal-directed evaluation of options' usefulness during selection contributes to the active advantage among higher WMC individuals.

Finally, it is important to note that participants in this study were aware that there was an underlying hierarchy to be learned. Awareness influences strategy use in TI (Smith & Squire, 2005) and it is unknown how active control might affect performance in its absence. It is likely that active control would enhance elemental encoding in such conditions, perhaps due to the mere opportunity for volitional control (Murty, DuBrow, & Davachi, 2015) or additional metacognitive processing (Kornell, Klein, & Rawson, 2015). An intriguing further possibility is that active control increases the likelihood of becoming aware of an underlying hierarchy by focusing attention on abstract relationships across

study episodes (Henriksson & Enkvist, 2016). This would lend support to the broader notion that active learning not only enriches memory for experienced materials, but also fosters self-directed discovery of abstract, relational knowledge.

Abstract

Users sometimes face anomalous behaviors of systems, such as machine failures and autonomous agents. Predicting such behaviors of systems is difficult. We investigate the benefits of the memory-based strategy, which focuses on memorization of instances to predict anomalous and regular behaviors of the system, with ACT-R simulations with a cognitive model. In this study, we presumed the parameters defining the encoding processes on anomalous instances and regular instances in the model of the memory-based strategy and performed simulations to verify how these two parameters influence prediction performance. The results of simulations showed that (1) regular instances are not encoded as default values in the memory-based strategy and that (2) such inactivity on regular instances suppresses commission errors of regular instances and does not suppress commission errors of anomalous instances nor omission errors.

Keywords: memory-based strategy; prediction; anomalous behavior; regular behavior; ACT-R

Introduction

There are many various systems around us, and users often predict their behaviors. It is relatively easy for users to predict systems' stationary behaviors by applying schemas (henceforth referred to as "regular behaviors"). However, users sometimes observe that systems' behaviors deviate from regular behaviors (henceforth referred to as "anomalous behaviors"). Predicting anomalous behaviors is effortful (e.g., Besnard & Bastien-Toniazo, 1999; Casner, Geven, & Williams, 2013) and requires users to execute much cognitive processing such as reallocation of cognitive resources (Meyer, Reisenzein, & Schützwohl, 1997). Therefore, it is necessary to process anomalous behaviors and regular behavior differently in order to predict systems' behaviors precisely.

One of the strategies to predict systems' behaviors is the "inference-based strategy," which focuses on inferences and understandings regarding the causal structure from systems' behaviors. The literature from various areas of research show that users apply the inference-based strategy spontaneously when encountering anomalous instances (e.g., Baker et al., 2009; Clary & Tesser, 1983; Howard & Holcombe, 2010; Tremoulet & Feldman, 2000, 2006). Inferences contribute to users' understanding of systems, but these inferences include advanced integration processes of the knowledge and the environment (Darabi, Nelson, & Palanki, 2007); therefore, the inference-based strategy is not always effective for highly complex systems.

We define the "memory-based strategy," which focuses on memorization of instances to predict systems' behaviors without understandings regarding causal structure. A knowledge base, such as a database of prior failure instances, is an example of the memory-based strategy. Experimental studies have demonstrated that the benefits of the memory-based strategy appear in the test situations, which is the same as the learning situations (e.g., Lane, Mathews, Sallas, Prattini, & Sun, 2008).

Our previous study reveals that the memory-based strategy is effective in a high-complexity task and the inference-based strategy is effective in a low-complexity task (Matsubayashi, Miwa, & Terai, in press). This study indicates that the benefits of the memory-based strategy are likely to be provided by the activity in which the instances representing the regular behaviors (henceforth referred to as "regular instances") are not encoded as default values, whereas the instances representing the anomalous behaviors (henceforth referred to as "anomalous instances") are intentionally encoded. In this study, we investigate these features of the memory-based strategy in detail, with a cognitive model.

First, we review our argument that regular instances are not encoded in the memory-based strategy by reproducing the human data in the psychological experiment. We presume the two parameters defining the encoding processes on anomalous instances and regular instances, and then examine whether the simulated data with inactivity of encoding regular instances provide a good fit to the human data. Second, we reveal why the benefits of the inactivity of encoding regular instances appear by confirming the performance with settings of two encoding parameters. Specifically, when the parameters are set for encoding not only anomalous instances but also regular instances, what happens to the simulated performance data?

Experimental Task

Stimulus

The experimental task required participants to predict the final position of the ball based on its observed movement.

The screen used in this task comprises a visible region and an invisible region (see Figure 1). A hidden object is placed in the invisible region. If the ball makes contact with the object, it changes its direction, whose trajectory is defined as an anomalous instance. Conversely, a regular instance is generated when the ball goes straight without direction changes. The ball is ejected from a certain initial position in the outer frame and at a certain angle. The ball is temporarily invisible while it passes through the invisible region. The ball becomes visible again when it enters the visible region. The ball's movement finally stops at the outer frame. Hereafter, an initial position and an initial angle of the trajectory are defined as "input," and a final position and a final angle are defined as "output."

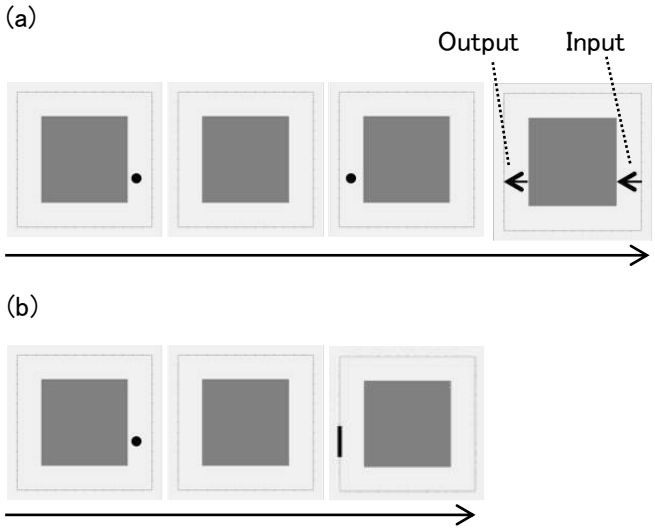

Figure 1: Overview of the task. (a) In the observation phase, the movement of the ball is presented and then the confirmation screen is displayed. (b) In the test phase, participants can move the paddle.

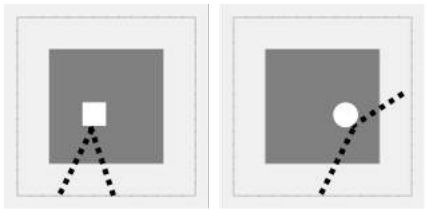

Figure 2: Difficulty settings of the task. Shapes of hidden objects and examples of trajectories in a low-complexity task (left) and in a high-complexity task (right).

Table 1: Composition of the trials in blocks 2−5.

Phase	Instance	Experience
Observation	Anomalous (3)	
	Regular (9)	
Test	Anomalous (6)	Novel (3)
		Experienced (3)
	Regular (6)	Novel (3)
		Experienced (3)

The observation phase and the test phase are alternated repeatedly in this task. In the observation phase, participants observe the movement of the ball from its ejection (i.e., input) until its stoppage in the outer frame (i.e., output). Participants are also shown the confirmation screen with two arrows representing the input and the output (see Figure 1a).

In the subsequent test phase, the ball stops as soon as it enters the invisible region, and a paddle is also displayed (see Figure 1b). To predict the final position of the ball and catch it with the paddle, participants are required to move the paddle with a left click button and determine its position with a right click button. The paddle is displayed at the same location in which the ball would arrive if it went straight without direction changes. In other words, it is not necessary to move the paddle in regular instances but is necessary to move the paddle in anomalous instances to catch the ball. The number of correct trials in which the range of the paddle includes the genuine final position of the ball is regarded as the prediction performance. No feedback on the predictions is provided to participants.

The shapes of the hidden objects in the invisible region determine the complexity of the tasks (see Figure 2). Anomalous instances follow a simple trajectory in a low-complexity task with a square-shaped object and a complex trajectory in a high-complexity task with a circular object.

Procedure

Prior to the observation phase, participants were informed that they were required to predict, as precisely as possible, the final position of the ball in the test phase. Participants were instructed to focus on and memorize the two arrows representing the input and the output in the confirmation screen in the observation phase. Participants are expected to use the memory-based strategy and encode the combination composed of an initial position, an initial angle, and a final position as an instance comprised of the input and the output.

The movement of the ball constituted one sequence, and each sequence constitutes one trial. A block comprised 12 trials in the observation phase and 12 trials in the test phase. All trials in block 1 corresponded to regular instances in the observation phase and in the test phase. Trials comprised three anomalous instances and nine regular instances in the observation phase in blocks 2−5. In the test phase, trials comprised six anomalous instances and six regular instances. In addition, each trial in the test phase comprised three novel instances, which were shown only at this time, and three experienced instances, which had been shown in the previous observation phase (see Table 1).

Participants implemented a 5-block low-complexity task and a 5-block high-complexity task. The positions and the shapes of hidden objects are consistent throughout all the trials in each task.

Summary of Psychological Experiment Results

Overall, the data of 24 participants were analyzed. A summary of the results is described here, and the details are mentioned with the simulation results (see Figure 3).

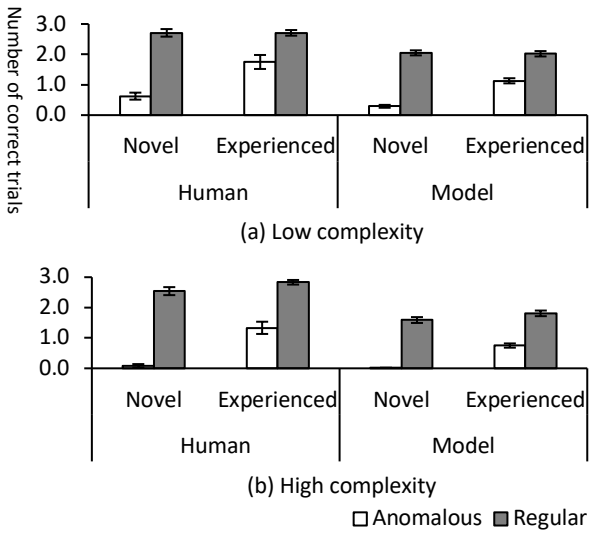

Figure 3: Prediction performance in block 5. Error bars represent standard errors.

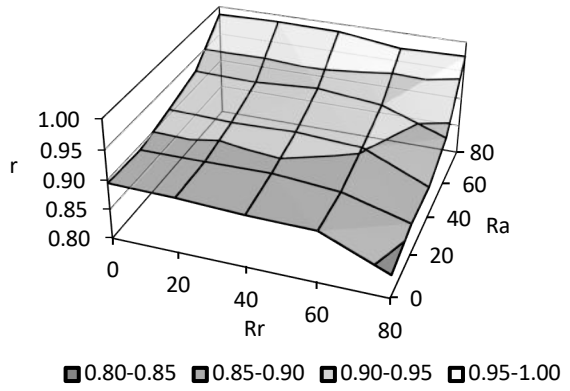

Figure 4: Correlation coefficients on prediction performance in block 5 between the simulated data and human data. Ra represents the rehearsal probability of anomalous instances and Rr represents the rehearsal probability of regular instances.

Statistical results show that the interaction of the instance factor (anomalous/regular) and the experience factor (novel/experienced) was significant for the prediction performance in each task in block 5 (low-complexity: $F(1, 23) = 13.8$, $p < .005$, $\eta^2 = .60$; high-complexity: $F(1, 23) = 10.7$, $p < .005$, $\eta^2 = .47$). Specifically, the performances for anomalous-experienced instances are higher than those for anomalous-novel instances (low-complexity: $F(1, 46) = 27.6$, $p < .001$; high-complexity: $F(1, 46) = 41.6$, $p < .001$). This result indicates that anomalous instances were encoded in the observation phase. Additionally, no differences are observed in the performance for regular-novel instances and for regular-experienced instances (low-complexity: $F(1, 46) = 0.0$, $p = 1.0$, $r = .00$; high-complexity: $F(1, 46) = 2.2$, $p = .13$, $r = .32$). This result indicates that regular instances were not encoded in the observation phase; therefore, they were not retrieved even for regular-experienced instances in the test phase.

Simulations with Cognitive Model

This study adopts ACT-R simulations (Anderson, 2007) with a cognitive model to investigate the details of processing. Two retrieval errors critical to the memory-based strategy are available in ACT-R, that is, commission errors representing that wrong instances are retrieved and omission errors representing that encoded instances are not retrieved.

In this study, we examine the following two points with simulations. First, we reveal the features of the memory-based strategy by performing simulations with two parameters defining the encoding processes of anomalous instances and regular instances. If the simulated data with the parameters meaning inactivity of encoding regular instances provide a good fit to the human data, our argument regarding such an inactivity is supported. Second, we reveal the reason why the benefits of inactivity of encoding regular instances appear in the memory-based strategy. Two research questions are drawn: How does the parameter on encoding regular instances decrease the prediction performance? What type of retrieval error is the cause of such decline in performance?

Simulation Settings

The following is the outline of the memory-based strategy model. In the observation phase, the model detects an input arrow and an output arrow, reads the position and the angle of each arrow, and then encodes them as a chunk in the declarative memory. This chunk comprises three slots—the initial position, the initial angle, and the final position. Next, the model runs rehearsals by repeating retrievals of the chunk. The rehearsal probability parameters determine whether the model continues to run a rehearsal on every rehearsal. There are two types of rehearsal probability parameters. If an input angle is different from an output angle, the model regards this trial as "an anomalous instance" and runs rehearsals on the basis of the rehearsal probability of anomalous instances (henceforth referred to as "Ra"). Additionally, if an input angle is the same as an output angle, the model regards this trial as "a regular instance" and runs rehearsals on the basis of the rehearsal probability of regular instances (henceforth referred to as "Rr").

In the subsequent test phase, the model reads the position and the angle of an input arrow and makes a retrieval request to declarative memory with them as a clue. If the model fails to retrieve an instance or the retrieved final position is included in the range of the paddle, the model does not move the paddle. Otherwise, the model moves it to the retrieved final position with left click button. After that, the model confirms the position of the paddle with a right click button.

Making retrieval errors on two adjacent initial positions is likely because these two positions are highly similar and difficult to distinguish from each other. Therefore, the similarity parameters between two adjacent initial positions are set to −0.5. Other similarity parameters are set to −1.0 as default.

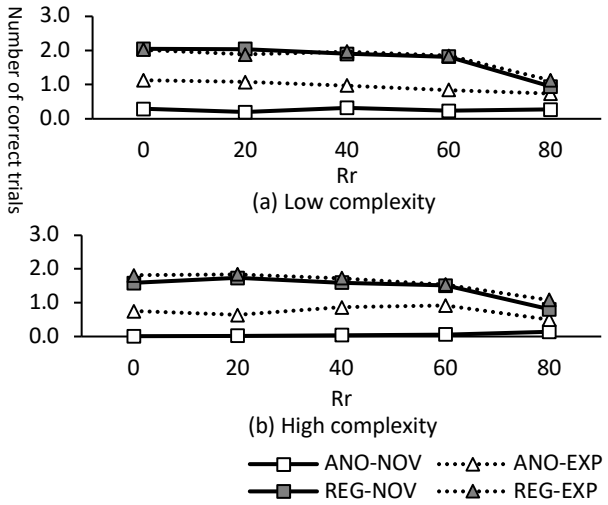

Figure 5: Variations of prediction performance on a function of the rehearsal probability of regular instances (Rr). ANO, REG, NOV, and EXP represent anomalous, regular, novel, and experienced respectively.

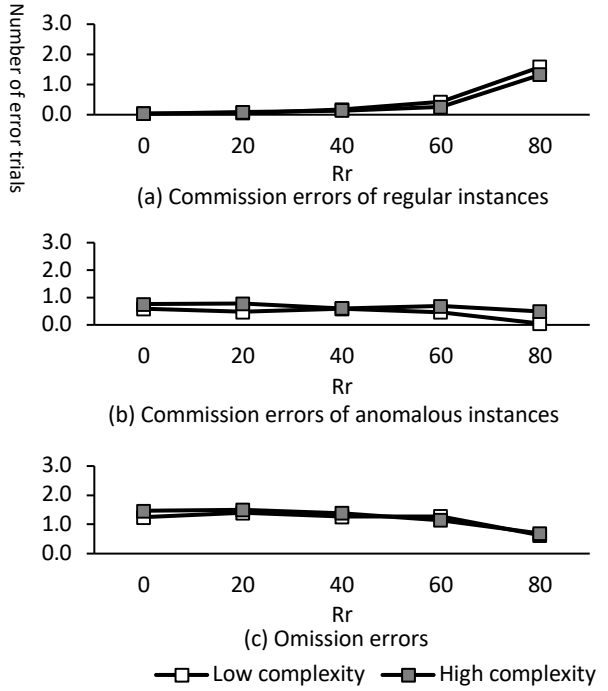

Figure 6: Variations of retrieval errors on anomalous-experienced instances on a function of the rehearsal probability of regular instances (Rr).

Each Ra and Rr has five levels; therefore, 25 parameter combinations are simulated. The five levels of rehearsal probability correspond to 0%, 20%, 40%, 60%, and 80%, that is, the expected values of the number of rehearsals are 0.00, 0.25, 0.67, 1.50, and 4.00 respectively.

Results of Simulations

Best Parameters First, in order to investigate the features of the memory-based strategy, we calculate correlation coefficients between the simulated data and the human data on prediction performance in block 5. Figure 4 shows that the simulated data in which anomalous instances are encoded sufficiently and regular instances are not encoded provide a best fit to the human data. Prediction performance at Ra 80% and Rr 0% is reproduced well. Specifically, there is no difference in the performance for regular-experienced instances and for regular-novel instances, and the performance for anomalous-experienced instances is higher than that for anomalous-novel instances (see Figure 3). These results support our argument that regular instances are not encoded and anomalous instances are encoded. Notably, the simulated data are wholly lower than the human data. We will discuss this topic in Discussion and Conclusion.

Effects of Encoding Regular Instances Second, we investigate the reason why the benefits of the inactivity of encoding regular instances appear in the memory-based strategy. What happens to the prediction performance when the Rr parameter is set to 20% or higher?偏

Figure 5 represents the variations of the prediction performance based on a function of Rr. The results show that the performances for anomalous-experienced instances decrease gradually as Rr increases and that the performances for regular instances decrease rapidly when Rr increases to 80%.

We verify what retrieval error is the cause of decline in performance. There are three types of errors on anomalous instances—commission errors in which regular instances are retrieved incorrectly, commission errors in which another anomalous instances are retrieved, and omission errors, in which no instance is retrieved. On the other hand, there are three types errors on regular instances—commission errors in which another regular instances are retrieved, commission errors in which anomalous instances are retrieved incorrectly, and omission errors. However, the omission errors on regular instances do not correspond to retrieval errors because participants can catch the ball even if they do not move the paddle and such trials are regarded as successful prediction. Therefore, we verify the only two commission errors on regular instances as possible causes of decline in performance for regular instances.

Figure 6 represents the variations of retrieval errors on anomalous-experienced instances. The results show that commission errors of regular instances increase as Rr increases to 80%. Additionally, there is no change on commission errors of anomalous instances and on omission errors from Rr 0% to 60%, but rapid drops appear in these errors at Rr 80% in each task. We found that the cause of declines in performance for anomalous-experienced instances is the commission errors in which regular instances are retrieved inappropriately.

Subsequently, Figure 7 represents the transitions of retrieval errors on regular instances. The results show that commission errors of regular instances increase as Rr increases to 80% and that commission errors of anomalous instances decrease at 80%. As a result, the cause of declines in performance for regular instances is the commission errors in which another regular instance is retrieved.

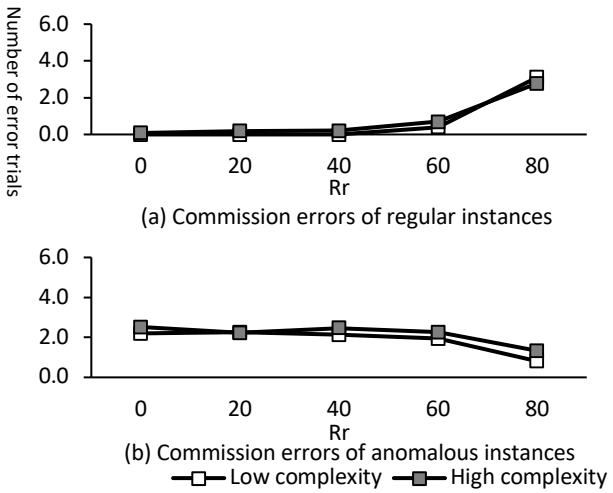

Figure 7: Variations of retrieval errors on regular instances on a function of the rehearsal probability of regular instances (Rr).

In summary, we found that the commission errors of regular instances contribute to the declines in performances on anomalous-experienced instances and on regular instances. That is, encoding regular instances in the memory-based strategy leads to increases in retrieval of inappropriate regular instances. In other words, participants using the memory-based strategy are likely to inhibit the commission errors of regular instances by not encoding regular instances. Additionally, and notably, commission errors of anomalous instances and omission errors do not increase according to Rr and decrease at Rr 80%. We will discuss this topic in Discussion and Conclusion.

Discussion and Conclusion

In this study, we performed the simulations of the processing of the memory-based strategy with a cognitive model and revealed the following two points in the context of the prediction on anomalous behaviors. First, by reproducing the human data, we found that the results support our argument that regular instances are not encoded as default value, and anomalous instances are encoded in the memory-based strategy. Second, the simulations in prediction performance with settings of encoding parameters show that the benefits of the memory-based strategy appear when such inactivity on regular instances inhibits commission errors of inappropriate regular instances and does not inhibit commission errors of anomalous instances nor omission errors.

Processes of Memory-based Strategy

We found that the simulated data in which regular instances are not encoded provide a best fit to the human data. This result confirms our argument that regular instances are not encoded in the memory-based strategy. Additionally, this result corresponds to the results in our previous experiment about participants' subjective evaluations toward anomalous instances and regular instances (Matsubayashi et al., in press).

Although the tendencies on prediction performance in simulations are reproduced well, the simulated data are wholly lower than the human data. This result indicates that participants in the memory-based strategy could perform other additional processing than the encoding processing that we presumed in the current model when they observed various instances. For example, participants might integrate some similar instances into one chunk, make an inference regarding the causal structure through the anomalous trajectories, or revise relevant schema (Meyer et al., 1997).

The studies on category learning have presumed the models that implement multiple processing when observing an instance (Nosofsky, Palmeri, & McKinley, 1994). Furthermore, our previous study indicates that participants adopt the inference-based strategy and the memory-based strategy when not provided explicit instructions about strategies (Matsubayashi et al., in press). The human data cited in this article correspond to the data when participants were urged to use the memory-based strategy, but we cannot dismiss the possibility that the participants use the inference-based strategy alongside. However, the inference-based strategy is possible to consume much cognitive resources (Darabi et al., 2007); therefore, using both strategies could reduce prediction performance. Notably, the trade-off between the costs and the benefits on two strategies must be verified for future work.

Benefits of Memory-based Strategy

The benefits of the memory-based strategy appear because of the inhibition of retrieval errors of inappropriate regular instances. The inactivity on regular instances inhibits commission errors in which regular instances are retrieved incorrectly on anomalous instances and commission errors in which another inappropriate regular instances are retrieved on in-situ regular instances. In summary, such inactivity of the memory-based strategy has a critical role in preventing confusion in encoded instances when they are retrieved and in saving cognitive resources to encode instances. The results of the simulations show that when regulars are encoded as frequently as anomalous instances are, more commission errors of regular instances occur, which indicates that it is critical not to encode regular instances in the memory-based strategy.

On the other hand, the commission errors of anomalous instances or the omission errors do not increase even if regular instances are encoded. Furthermore, we found that these two errors decrease only if regular instances are encoded as frequently as anomalous instances are. These decreases seem to occur, confounded with the effect of the increase in the commission errors of regular instances. If regular instances are encoded as frequently as anomalous instances are, the current model stores three anomalous instances and nine regular instances in the declarative memory in each block, with similar activation levels. Consequently, regular instances are more likely to be retrieved than anomalous instances, which results in a relative decrease in the commission errors of anomalous instances

and omission errors. However, the benefits of encoding regular instances do not appear because the whole prediction performance decreases even if these two errors decrease.

The features of cognitive processing on anomalous instances have been verified with visual search tasks. Studies have revealed that the objects incongruent with the schema of the scene are difficult to identify (Mudrik, Deouell, & Lamy, 2011) and these objects are represented internally prior to the objects congruent with the schema (Hollingworth & Henderson, 2000). Our findings that there are no benefits of encoding regular instances are not contradictory to such studies. Furthermore, our study reveals the cognitive processing on regular instances, which are congruent with the schema, while other studies have referred to that on anomalous instances, which are incongruent with the schema. Model-based approaches can clarify the internal cognitive processes that are difficult to observe and have been used in various areas, such as category learning (Erickson & Kruschke, 1998). Particularly, studies on the cognitive model about instance-based learning have revealed decision making processes from experience (Gonzalez & Dutt, 2011; Paik & Pirolli, 2013). Our findings regarding regular instances could not have been obtained without the simulations with a cognitive model.

In this study, we performed simulations of the processing of the memory-based strategy with a cognitive model from a perspective of predicting anomalous behaviors. First, by reproducing the human data, we found the results that support our argument that regular instances are not encoded as default values and anomalous instances are encoded in the memory-based strategy. Second, simulations in performance with encoding parameters clarified that the benefits of the memory-based strategy appear when such inactivity on regular instances inhibits the commission errors of inappropriate regular instances and does not inhibit the commission errors of anomalous instances nor the omission errors.

Abstract

A central question for cognitive science is whether children's linguistic productivity can be captured by item-based learning, or whether the learner must be guided by abstract, system-wide principles governed by innate constraints. Here, we present a computational model of early language acquisition which learns to discover and use lexically-based frames in a fully incremental, on-line fashion. The model is rooted in simple prediction- and recognition-based processes, subject to the same memory limitations as language learners. When exposed to English corpora of child-directed speech, the model is able learn developmentally plausible frames and use them to capture over 70% of the utterances produced by target children aged 2 to 5. Across a typologically diverse range of 29 languages, the model is able to capture over 68% of child utterances. Together, these findings suggest that much of children's early linguistic productivity can be captured by item-based learning through computationally simple mechanisms.

Keywords: language learning; language acquisition; usage-based approaches; computational modeling; chunking

Introduction

By four years of age, most children have mastered the basic grammatical structures of their native language, an achievement marking the transition to a seemingly unbounded capacity for communicating novel information. But how is such open-endedness possible, given the finite, noisy nature of the input? This is among the foundational questions of cognitive science. For over half a century, researchers have argued that children's learning is guided by system-wide, abstract principles and constrained by innate biases (e.g., Chomsky, 1965). In recent decades, an alternative perspective has emerged in the form of usage-based approaches, which hold that children's linguistic productivity emerges gradually as a process of storing and abstracting over the input (e.g., Tomasello, 2003). In this framework, children's earliest steps towards unbounded productivity come in the form of lexically-based frames: through knowledge of partially overlapping sequences, children form schemas with slots that are filled according to semantic, pragmatic, or phonological constraints (e.g., Braine, 1963).

Among the earliest quantitative studies offering evidence for lexical frames was that of Lieven, Behrens, Speares, and Tomasello (2003), who used a technique known as the "traceback method" to analyze the speech of a single child during its second year. Lieven et al. found that a high proportion of the child's linguistic productivity—utterances which went beyond frozen or recycled sequences to feature novel word combinations—could be explained in terms of lexically-specific frames, such as "*there's the* __ ." Subsequent work improved on the original traceback method and yielded similar findings (e.g., Lieven, Salomo, & Tomasello, 2003).

As highlighted by other researchers (e.g., Kol, Nir, & Wintner, 2014) the traceback method is not automated and is therefore severely limited in terms of the range of corpora and languages to which it can be applied. Moreover, the lack of a computationally explicit formulation means that the general approach does not make specific commitments to the types of learning mechanisms or representations that allow productivity to emerge from lexically-based representations.

This problem highlights a general lack of computational work examining item-based learning as a starting point for linguistic abstraction, which is reflected in the imprecise language with which usage-based theory is often discussed. For instance, researchers have appealed to complex psychological constructs such as analogical reasoning to explain lexically-based frames (e.g., Gentner & Namy, 2006; Tomasello, 2003). Even computational studies examining the transition from item-based learning to abstraction have appealed to analogy while remaining agnostic as to the lower-level mechanisms supporting it (e.g., Bod, 2009).

By contrast, we aim to provide an account of early abstraction which is rooted in basic processes of prediction and recognition. Moreover, we wish to capture such learning in a way that is consistent with the myriad sensory and memory limitations imposed on the learner (as discussed in Christiansen & Chater, 2016). This requires a fully incremental and on-line learning model, in line with memory constraints that force reliance on local rather than global syntactic information. It also means capturing learning in a way that is fully usage-based in the sense that all learning takes place in the context of specific processing events.

Modeling Children's Discovery and Use of Lexically-based Frames

Here, we seek to model children's discovery and use of lexical frames by modifying an existing usage-based computational framework, known as the Chunk-Based Learner (CBL; McCauley & Christiansen, 2014, 2019). Inspired by the aforementioned memory constraints, the CBL model aims to recreate individual children's utterances by learning from the linguistic input to which they have been exposed. The model offers strong performance across a typologically diverse range of languages (McCauley & Christiansen, 2019) while capturing psycholinguistic data from both children (McCauley & Christiansen, 2014) and adults (Grimm, Cassani, Gillis, & Daelemans, 2017). Importantly, previous research has only used CBL to model the discovery and use of concrete multiword units. In the present study, we implement this pre-existing model and modify it to support the incremental, on-line discovery and use of lexically-based frames.

In what follows, we describe the basic workings of the CBL model as well as the modifications we applied to enable the learning of lexical frames. Next, we examine qualitative and quantitative properties of the frames discovered by the model when exposed to corpora of English child-directed speech. We also evaluate the model's ability to use these frames in a sentence production task, exploring the extent to which they can support early linguistic productivity. Finally, we look at the model's ability to use frames in this sentence production task across a typologically diverse array of 29 different languages.

Experiment 1: Modeling the Development of Lexically-based Frames in English

The CBL Model

The model has been described in detail in previous work (e.g., McCauley & Christiansen, 2019). We therefore briefly provide sufficient information to implement the model. The model processes the input corpus on a word-by-word basis, tracking low-level frequency information for words and word pairs (bigrams). This information is used on-line to calculate the backward transition probability (BTP) between words. By maintaining a running average of BTP over previously seen word pairs and using it as a threshold, the model classifies BTPs linking words as either *high* or *low*. High BTPs are used to group words together to form part of a chunk, while low probabilities are used to define chunk boundaries. When a boundary is placed, the preceding word(s)—there is no *a priori* limit on the size of a chunk—are placed as a unit in the model's *chunk inventory*. When the model encounters a previously-discovered chunk in the input, its frequency count is incremented by 1. The resulting chunk inventory thus contains a mix of single-word and multiword units. The model maintains frequency counts for pairs of chunks occurring together, which supports the incremental construction of utterances during production.

The model also uses its chunk inventory on-line while processing the input. Through a combination of prediction- and recognition-based processing, knowledge of previously discovered chunks can assist in further discovery: when a word-pair is encountered, if it has occurred at least twice as part of an existing chunk, it is automatically grouped together (regardless of BTP). Otherwise, the BTP is evaluated against the running average threshold as described above.

A record of the model's on-line chunking of utterances is maintained for later evaluation against the output of a parser. CBL's ability to approximate the output of shallow parsers cross-linguistically has been suggested to capture key aspects of comprehension (cf. McCauley & Christiansen, 2019). The model also aims to capture key aspects of production: as the model makes its way through a corpus of child-directed speech, it encounters utterances produced by the target child of the corpus, at which point the production side of the model comes into play. The model must produce its own utterance by generalizing from the chunks and statistics it has learned up to that point in the simulation. This task is used to evaluate our version of the model and is described below in the subsection entitled Sentence Production Task.

Modifications to the CBL Model

To enable the on-line discovery and use of lexical frames, we made some slight changes to the original CBL implementation. When the model has discovered 5 or more multiword chunks which overlap in all but one position, it creates a lexical frame—a chunk with an empty slot—and stores it in the chunk inventory. When chunks matching this frame are encountered, the frame's frequency count is incremented, as are the counts of matching chunks. The 5+ criterion was selected in light of previous corpus studies of evidence for lexical frames in child-directed speech (e.g., Cameron-Faulkner, Lieven, & Tomasello, 2003, who used a criterion of 4+ in their analyses). As the original version of CBL already uses its chunk inventory during on-line processing, we felt this change was in keeping with the model's intended psychological features.

As an example of frame creation, consider an instance in which the model has already discovered and used the chunks *in the box*, *in the tub, in the bag,* and *in the chair.* When the model discovers the chunk *in the cup*, it also discovers the frame *in the* __ as an automatic generalization over the previous multiword chunks. Both *in the cup* and *in the* __ are initialized in the chunk inventory with counts of 1, the starting frequency value for newly-discovered chunks. The frame's count is then incremented by 1 when the model later encounters *in the box*, a previously discovered chunk, as is the count for that chunk. The frame's count is also incremented by 1 again when the model discovers a new chunk, *in the sink*, and so forth.

As described in the below section entitled Sentence Production Task, the model can rely on its knowledge of lexical frames during production.

Input Corpora

Rather than aggregate across multiple corpora, each of our simulations involved exposing the model to a single corpus of child-directed speech. We selected, from the English language portion of the CHILDES database (MacWhinney, 2000) all corpora meeting the following three criteria: i) contained at least 50,000 words; ii) featured a multiword child-to-adult utterance ratio of at least 1:10; and iii) spanned at least a 6-month period in terms of the target child's age across the corpus. These criteria were met by individual corpora for 43 English-learning children (US: 25; UK: 18). Tags and punctuation were removed from the corpora, leaving, for each utterance, only speaker identifiers and the original sequence of words.

Learning Lexical Frames in English

Across the entire set of 43 simulations, the model discovered a mean of 14 lexical frames per 10,000 words of input. Rather than leading to a combinatorial explosion of units—as might suggest psychological implausibility, or coverage due to trivial factors in subsequent evaluation tasks--frames made up just 5% of the total chunk inventory for the simulation involving the largest corpus (*Thomas*; Maslen, Theakston, Lieven, & Tomasello, 2004), with smaller percentages for smaller corpora (3% on average).

To offer a sense of the qualitative nature of the model's lexical frames, we show, for the largest corpus (Thomas), a range of frequent frames as well as less-frequent but developmentally interesting frames.

Table 1: Frequent and Developmentally Interesting Frames Learned from the Thomas (Dense) Corpus and Corresponding Counts in the Chunk Inventory

Frequent Frames		**Developmentally Interesting Frames**	
the __	56117	*a little __*	2131
a __	42937	*what's __*	2122
your __	8366	*a big __*	1401
in the __	7718	*are you going to __*	1196
on the __	6950	*what do you __*	945
this __	6742	*more __*	837
that __	6343	*I want to __*	427
very __	4911	*on __ own*	228
I don't __	3386	*the red __*	120
going to __	3348	*more __*	103

As can be seen in Table 1, even though slots are allowed anywhere in a chunk, the vast majority of lexical frames featured a slot in the final position. Across all the English corpora, slot-final frames accounted for a large percentage of overall frames utilized, ranging from 85% to 98%.

There is good overlap between the frames appearing in Table 1 and frames postulated by other researchers on the basis of corpus analyses, including some of the earliest to advance the notion of lexical frames: for instance, *more __* is one of the first frames identified in Braine (1963).

Next, we turn to the question of whether the lexical frames discovered by the model can offer insights into the nature children's early productivity. To this end, we evaluate the model according to its ability to capture children's actual utterances in these corpora, and measure the extent to which the model's lexical frames can support production above and beyond concrete multiword chunks.

Sentence Production Task

The sentence production task was based on the bag-of-words incremental generation task first described by Chang, Lieven, and Tomasello (2008). The task rests on the simplifying assumption that the overall message the child wishes to convey can be—very roughly—approximated by treating the utterance as an unordered bag-of-words. When the model encounters a multiword utterance produced by the target child of a corpus, its task is to sequence the items in the bag to produce its own utterance, using only the words and statistics it has discovered prior to that point.

We used a nearly identical version of the task to that described by McCauley and Christiansen (2019): following psycholinguistic evidence for children's use of multiword units (see above), the model was allowed to draw upon previously discovered chunks to populate the bag-of-words. To produce an utterance, the model begins by selecting from the bag the word or chunk with the highest transition probability given the start-of-utterance marker (a marker preceding every line in the corpus). At each subsequent time step the model removes and produces the word or chunk with the highest probability *given the most recently placed chunk*. This process continues until the bag is empty.

Thus, production is implemented as fully incremental, chunk-to-chunk process, relying entirely on local information. In other words, there is no global whole-sentence optimization. In this sense, the model captures the sorts of memory limitations described in the introduction.

Where our version of the task differed from that described by McCauley and Christiansen (2019) was in the additional use of lexical frames: if the model lacked experience of a given sequence in the child's utterance, but had learned a lexical frame capable of fitting that sequence, it was allowed to utilize the frame in the bag-of-words task. Consider the model's attempt to produce the child utterance: "*red one stuck in the jam.*" In a case in which the model has discovered the lexical frame *in the __* but has never encountered the sequence *in the jam* in the input, the model is allowed to use the lexical frame to complete this pattern. Statistics are then calculated over the frame itself, as if it were a fully concrete chunk.

Gold Standard for Sentence Production Task Following each production attempt, the model's utterance is scored against the child's original utterance according to an all-or-nothing scoring metric: if the two utterances do not match completely, a score of 0 is assigned. Otherwise, a score of 1 is given. Thus, the overall accuracy of the model

across a corpus can be calculated as a percentage of correctly produced multiword utterances (single-word utterances are excluded to avoid inflating performance). We call this the *Sentence Production Accuracy* (SPA) score.

Alternate Distributional Models We evaluate the model against two baseline models: the first is the basic version of CBL used as a starting point for the present study (described above; cf. McCauley & Christiansen, 2019). The second is a standard trigram model; this approach was selected as a baseline due to its widespread use and generally robust performance as a probabilistic language model across a range of genres (Manning & Schütze, 1999).

Results and Discussion Across all 43 English simulations, the lexical frames version of the CBL model (CBL+LF) achieved a median Sentence Production Accuracy of 71.3% (mean: 69.5%). This is compared to a median score of 58.5% (mean: 57.8%) for the original CBL model and a median score of just 45.7% (mean: 45.1%) for the trigram (3G) baseline. The distribution of scores for each model are shown in Figure 1.

A linear mixed-effects model fit using logit-transformed SPA scores, with child as a random factor, confirmed that both the CBL+LF model (β=0.53, t=22.8, $p < 0.001$) and the 3G model (β=-0.53, t=-22.6, $p < 0.001$) differed significantly from the original CBL model, in opposite directions.[1]

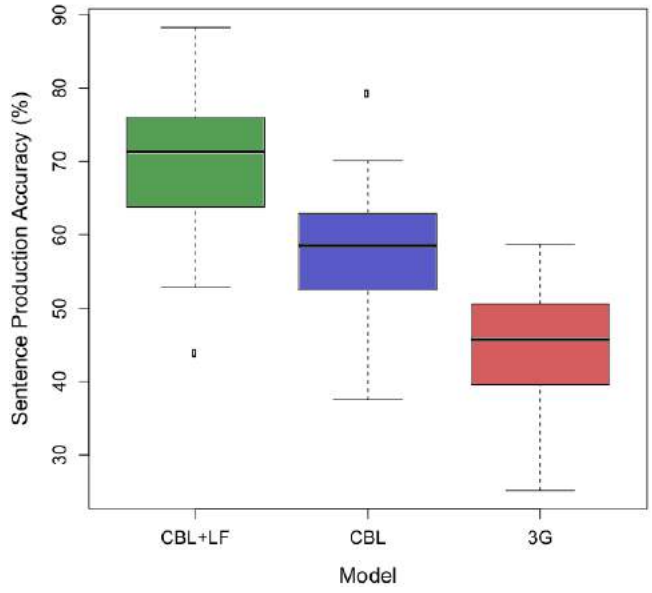

Fig. 1: Box and whisker plots depicting English Sentence Production Accuracy (%) for the model and its baselines.

Thus, in addition to discovering developmentally and psychologically plausible lexical frames, the CBL+LF model was able to use these units to improve upon the CBL model's production performance by nearly 12 percentage-points, surpassing the performance of a standard trigram model by nearly 25 percentage-points.

[1]All p-values computed via Satterthwaite approximation.

Experiment 2: Modeling the Development of Lexically-based Frames Across Typologically Diverse Languages

The vast majority of computational modeling work in the study of language acquisition has focused on English. It is crucial, however, to determine whether the types of linguistic representations and learning mechanisms we ascribe to children can plausibly accommodate languages with typological features that differ greatly from those of English. In the case of the present model, which uses multiword units as much of the basis for learning and processing, morphological features are of particular interest.

A previous study using the CBL model has demonstrated that multiword units do indeed facilitate production for typologically diverse languages, including morphologically rich languages (McCauley & Christiansen, 2019). Here, we ask the question of to what extent limited productivity based on lexical frames can improve the ability of CBL to capture the utterances of children learning a typologically diverse set of languages, above and beyond what can be captured through learning tied to concrete chunks.

Corpora

We selected from the CHILDES database (MacWhinney, 2000) corpora involving single target children, rather than aggregating data across multiple corpora. Due to limitations on the number of corpora for several of the languages in CHILDES, these were selected according to slightly relaxed criteria: each corpus contained at least 10,000 words, at least 1,000 multiword child utterances, and a child-to-adult utterance ratio of no less than 1:20.

These criteria were met by corpora for 160 additional target children from 28 different languages (Afrikaans: 2, Cantonese: 8, Catalan: 4, Croatian: 3, Danish: 2, Dutch: 12, Estonian: 3, Farsi: 2, French: 15, German: 22, Greek: 1, Hebrew: 6, Hungarian: 4, Indonesian: 8, Irish: 1, Italian: 8, Japanese: 10, Korean: 1, Mandarin: 7, Polish: 11, Portuguese: 2, Romanian: 1, Russian: 2, Sesotho: 3, Spanish: 11, Swedish: 5, Tamil: 1, Welsh: 6). Table 2 lists some basic typological properties of these languages.

To get a rough quantitative measure of morphological complexity for child-directed speech in each language, we calculated word type/token ratios (following the reasoning and methods of Chang et al., 2008). We refer to this as the *Morphological Complexity Score*.

Sentence Production Task

We used the same sentence production task as in Exp. 1.

Results and Discussion

Across all 29 languages and 200+ corpora, the lexical frames version of CBL achieved a mean SPA score of 68.4%, compared to 55.3% for the original CBL model and just 45.9% for the trigram model. Means for each language are shown in Figure 2. By discovering and utilizing lexical frames, the model was able to reproduce the majority of the

child utterances in every language, with mean scores ranging from 55% (Swedish) to 81% (Romanian).

A linear mixed-effects model was fit to logit-transformed SPA scores with language and child as random effects, and a by-language random slope of model. This confirmed that the CBL+LF model (β=0.58, t=26.8, $p < 0.001$) and the trigram model (β=-0.32, t=-8.6, $p < 0.001$) differed significantly from the original CBL, in opposite directions.

Because previous work with the original version of CBL demonstrated that the model's performance decreased as a function of morphological richness (McCauley & Christiansen, 2019), we compared CBL performance to CBL+LF in order to determine whether this effect was reduced by the use of lexical frames. Figure 3 depicts the relationship between the CBL+LF model and Morphological Complexity Score.

Table 2: Typological Properties of the 29 Languages

Language	Family	Genus	Word Order	# Cases
Irish	Indo-European	*Celtic*	VSO	2
Welsh	Indo-European	*Celtic*	VSO	0
English	Indo-European	*Germanic*	SVO	2

Note: Information from Haspelmath et al. (2005)

Though Morphological Complexity Score was indeed a predictor of CBL+LF performance (β=-2.01, t=-3.5, $p < 0.001$, r=0.23), we found that the presence of lexical frames reduced this effect in comparison to that observed for the original CBL model (β=-2.4, t=-4.1, $p < 0.001$, r=0.27), as confirmed by a significant interaction between model and Morphological Complexity Score (β=0.15, t=3.03, $p < 0.01$) in a linear mixed model which included model as a categorical factor.

A close inspection of the lexical frames discovered by the model when exposed to English revealed that they were both psychologically and developmentally plausible, but we currently lack the cross-linguistic expertise to offer a detailed analysis of lexical frames for the 28 additional languages. Nevertheless, these simulations offer clear evidence that, in principle, the same types of representations and mechanisms can support the discovery of lexical frames across a typologically diverse range of languages. Indeed, for all the 29 languages, lexical frames capture early linguistic productivity above and beyond what can be achieved through concrete words and chunks: CBL+LF lead to a 13 percentage-point improvement over mean CBL performance and a 23 percentage-point improvement over trigram models.

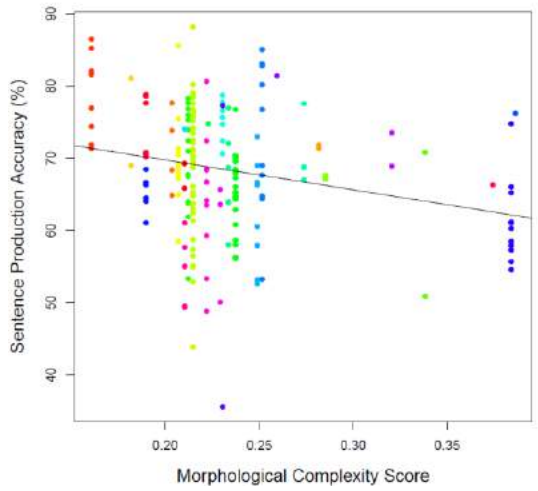

Fig. 3: CBL+LF SPA scores across all children and languages plotted against Morphological Complexity Score. Different colors denote distinct languages. Trendline from simple linear regression.

General Discussion

In this paper, we have demonstrated that a simple, developmentally-motivated model rooted in concrete prediction- and recognition-based processes can discover lexically-based frames that are not only psychologically plausible but also can capture a significant amount of children's early linguistic productivity. In 200+ simulations of individual children across a typologically diverse array of languages, the CBL+LF model was able to capture a significantly higher proportion of child utterances than a version of the model relying solely on concrete words and chunks, offering an even larger improvement over trigram models. Moreover, this was achieved while accommodating the sorts of memory limitations that drive children (and adults) to rely on local information during comprehension and production (e.g., Christiansen & Chater, 2016).

In contrast to previous quantitative studies examining evidence for lexical frames in child speech (e.g., those using the traceback method of Lieven et al., 2003), we 1) capture the actual learning of frames during comprehension, as well as their use in production, and 2) do this for children beyond their second year, with corpora covering child productions during the third and fourth year.

Nonetheless, the CBL+LF approach is not without limitations. Firstly, frames operate on the level of words appearing within chunks; chunks themselves are not yet able to appear in slots. By overcoming this limitation in a principled way, a wider variety of linguistic phenomena could be captured. For instance, non-adjacent dependencies can be learned in the current version of the model: frames like *this __ one* and *those __ ones* capture a number dependency. Extending the model to allow entire chunks in slots will be a necessary subsequent step towards capturing more abstract processing of long-distance dependencies.

A more serious limitation of the present work is that it does not incorporate the learning or use of semantic information. The semantic properties of words and frames are needed to provide constraints on which items that can appear in lexical frames. The learning of such information is crucial for moving towards a framework capable of producing utterances based on meaning representations (and forming meaning representations during comprehension). To this end, ongoing work aims to simulate the learning of lexical semantics, semantic roles, and argument structures through the use of automatically generated, idealized "visual scenes" which are paired with utterances in corpora.

More generally, the promise of item-based computational approaches for tracing a path to more sophisticated forms of linguistic abstraction is great: previous work has shown that the systematic use of pseudographs to align and compare the sentences in a text can give rise to complex context-free grammars (Solan, Horn, Ruppin, & Edelman, 2005). Bayesian induction of item-based grammars from the speech of single target children has also yielded good coverage of those children's increasing productivity (in a manner akin to the traceback method; Bannard, Lieven, & Tomasello, 2009). However, these models are not subject to memory limitations, and involve computations beyond what children are capable of. A motivation for the current approach, therefore, was to take initial steps towards modeling increasingly productive linguistic representations in a way that is psychologically motivated, incremental, and on-line.

Abstract

Subject-auxiliary inversion in interrogatives has been a topic of great interest in language acquisition research, and has often been held up as evidence for the structure-dependence of grammar. Usage-based and nativist approaches posit different representations and processes underlying children's question formation and therefore predict different causes for these errors. Here, we explore the question of whether input statistics predict children's spontaneous non-inversion errors with *wh*- questions. In contrast to previous studies, we look at properties of the non-inverted, errorful forms of questions. Through a series of corpus analyses, we show that the frequency of uninverted subsequences (e.g., "*she is going"* in "*what she is going to do?*"*) is a good predictor of children's errors, consistent with recent evidence for multiword units in children's comprehension and production. This finding has implications for the types of mental representations and cognitive processes researchers ascribe to children acquiring a first language.

Keywords: language acquisition; interrogatives; corpora; corpus analyses; usage-based approach; chunking

Introduction

Whether the input available to children is sufficient to explain their emerging language abilities is a fundamental question in cognitive science (Chomsky, 1957; Skinner, 1957). Central to the ongoing discussion are tensions between the view of grammar as the result of gradual abstraction over the input (e.g., Lieven, Salomo & Tomasello, 2009; Tomasello, 2003), and approaches in which the acquisition process is guided by innate, language-specific biases (e.g., Pinker, 1999; Fisher, 2002).

In the realm of theoretical linguistics, work in support of the latter approach has focused on specific linguistic phenomena, such as interrogatives. A topic of particular interest is that of subject-auxiliary inversion, which has been held up as evidence for the structure-dependence of grammar (e.g., Crain, 1991; Berwick, Pietroski, Yankama, & Chomsky, 2011), and is often still discussed in the same terms as it was half a century ago (Chomsky, 1968).

In developmental psycholinguistics, a great deal of work has also focused on interrogatives, in part because they represent some of the few sentence types for which English-speaking children reliably make errors involving word order (e.g., Klima & Bellugi, 1966; Stromswold, 1990). Moreover, these sentence types provide a means to evaluate subject-auxiliary inversion as evidence for structure-dependence within a developmental framework. This applies to *wh*-questions especially: as both the *wh*-word and the auxiliary are fronted, it has been argued that they are structurally more complex than *yes/no* questions (e.g., Pozzan & Valian, 2017; Jakubowicz, 2011); and unlike *yes/no* questions, children rarely encounter *wh*-questions in uninverted form as part of the input, yet still make errors of uninversion as in (1).

*(1) What they are doing over there ? **

Thus, *wh*- questions represent an ideal case for mediating between nativist and constructionist approaches, as each posit different representations and processes underlying children's errors and therefore predict different error properties. While the former emphasizes abstract structural considerations, the latter perspective stresses the importance of input frequency in supporting lexically-specific representations.

In line with structure-dependence accounts, a number of researchers have argued for earlier acquisition of argument *wh*-questions than adjunct *wh*-questions, based on their structural properties (e.g., Stromswold 1990, de Villiers 1991). Consistent with this, Pozzan and Valian (2017) report higher non-inversion rates for adjunct than for argument *wh*- questions, a finding they argue to be independent of input frequencies (as might be predicted under usage-based approaches). However, frequency is not rigorously controlled for in the design of the stimulus items themselves, nor is the frequency of substrings beyond the

wh-word/auxiliary combination considered (in the following subsection, we discuss why this may be of importance).

Initial support for usage-based approaches to subject-auxiliary inversion came from a corpus analysis of one child's early *wh*- questions (Rowland & Pine, 2000). The authors found that the frequency of specific *wh*-word + auxiliary combinations reliably predicted non-inversion rates. Ambridge, Rowland, Theakston, and Tomasello (2006) extended this finding with an elicited production study in which *wh*-word + auxiliary combinations predicted non-inversion rates in children aged 3;6 to 4;6. Moreover, *wh*-word alone was not found to predict errors, in contrast to structure-dependence accounts (e.g., Pozzan & Valian, 2017). Rather, the pattern of results was consistent with the notion of lexically-specific representations driving performance with particular question types.

In a further elicitation study, Ambridge and Rowland (2009) investigated a wider range of question types, including negative polarity questions, replicating the finding that *wh*-word + auxiliary frames predicted error rates. Though the relevant frequency dimensions were not controlled for in a rigorous way, Ambridge and Rowland also found initial support for the notion that patterns learned from declarative utterances may also shape errors. It is to this possibility that we turn in the present study.

A Role for Multiword Units in Predicting Non-inversion Errors

A serious limitation of previous work on subject-auxiliary inversion is that only the distributional properties of *correct* forms have been taken into account. This partly stems from the lingering influence of theoretical frameworks in which individual words are viewed as the fundamental units over which language processing take place (e.g., Pinker, 1999). After all, the correctly inverted and errorful, non-inverted forms of a question contain the same set of words; only the word order differs. Thus, if words are the fundamental units of language, we would not expect the distributional properties of an errorful form to play a role in question formation.

Recent years, however, have seen an explosion of psycholinguistic data suggesting that language users are not only sensitive to the properties of compositional multiword sequences, but—in some sense—store and actively utilize such sequences in comprehension and production, as linguistic units in their own right. The frequency of such multiword units—or "chunks"—has been shown to facilitate processing in adult comprehension (e.g., Arnon & Snider, 2010; Bannard, 2006; Reali & Christiansen, 2007) as well as production (e.g., Janssen & Barber, 2012). These findings have received further support from event-related brain potentials (Tremblay & Baayen, 2010) and eye-tracking data (Siyanova-Chanturia, Conklin, & van Hueven, 2011).

Importantly, these findings are mirrored in psycholinguistic work with children (see Theakston & Lieven, 2017 for an overview). Bannard and Matthews (2008) found that, when controlling for substring frequency, overall sequence frequency predicted the speed and accuracy with which 2- and 3-year-olds produced compositional phrases. Arnon and Clark (2011) report evidence that multiword chunk frequency intersects with morphological development: errors of noun plural overregularization were significantly reduced when irregular plurals were produced in the context of more frequent sequences. Moreover, multiword units exhibit the same type of age-of-acquisition (AoA) effects as do individual words, when AoA is determined by either subjective ratings or by corpus-based metrics (Arnon, McCauley, & Christiansen, 2017). Taken together, these findings underscore the possibility that multiword chunks serve as building blocks for language learning.

The importance of these findings to more general theoretical debates is further highlighted by computational modeling work which has shown that abstraction over stored sequences can lead to a considerable amount of linguistic productivity (e.g., Solan, Horn, Ruppin, & Edelman, 2005). Even models lacking abstraction have served to demonstrate that associative learning of chunks from naturalistic input can account for a substantial portion of children's language production (McCauley & Christiansen, 2019).

Therefore, if children are sensitive to the properties of multiword sequences, we might expect such information to play a role in *wh*-question formation. Take, for instance, the following correctly inverted and non-inverted (errorful) forms (2-3):

(2) What <u>is she going</u> to do ?

*(3) What <u>she is going</u> to do ? **

If the uninverted strings "*she is going*" or "*is going*" are highly frequent in the child's input, we might expect—given evidence that multiword chunks play a role in learning and processing—that the child is more likely to produce the errorful form. By the same token, we might expect the frequency of "*is she going*" or "*she going*" to alter this likelihood in the opposite direction. From this perspective, chunks from both the correctly inverted and non-inverted forms might be seen as competing. In other words, multiword sequence frequencies from the correctly inverted and non-inverted forms are both important, insofar as they relate to one another.

The Present Study

If such a relationship exists at all, it is likely to be a complex one, mediated by a host of distributional, pragmatic, and semantic factors. In the present study, we take an initial step towards disentangling these factors by considering, simultaneously, the many distributional factors at play. Not only have the frequencies of individual *wh*-words and auxiliaries been argued to shape errors, but also the frequencies of distinct *wh*-word/auxiliary combinations

themselves (e.g., Rowland & Pine, 2000). Given the perspective we have put forth regarding a role for multiword sequences stretching beyond the *wh*-word and auxiliary, it is necessary to consider the distributional properties of individual words and higher-order *n*-grams for both the correctly inverted and uninverted forms of questions, simultaneously.

In the present study, we evaluate the role of multiword units in early *wh*-question production by using distributional statistics from child-directed speech to predict children's *spontaneous* uninversion errors. Using the entire English portion of the CHILDES database (MacWhinney, 2000), we collect distributional statistics for words and higher-order *n*-grams, which are then used to construct a logistic regression model of children's correctly inverted and errorful (uninverted) questions across the 12 most question-rich corpora. Thus, we are able to test whether, and to what extent, frequencies for individual words and multiword combinations predict spontaneous error rates. Moreover, this allows us to evaluate the role played by multiword sequences from the uninverted forms of questions while controlling for the statistics of the correctly inverted forms, and vice-versa.

In this context, usage-based approaches make predictions that are separable and distinct from those made by theories emphasizing abstract, system-wide principles: if children are forming questions based on structural properties, we would not expect to see a role for uninverted *n*-gram statistics in predicting uninversion errors. Moreover, we would expect structural differences in question type (e.g., argument questions vs. adjunct questions) to be better predictors of correct inversion than frequency (e.g., Pozzan & Valian, 2017). By contrast, usage-based approaches would predict experience with particular *wh*-words, auxiliaries, and even specific subjects/verbs to be robust predictors of error rates, and would quite naturally accommodate findings that *n*-gram sequences from the uninverted forms predict error rates. Under such a view, abstract grammatical constructions tied to questions would emerge gradually as a process of abstracting over stored sequences, and this would be reflected in the probabilities with which children fail to correctly invert certain sentences.

Methods

The corpus analysis consisted of three general phases: extraction of all child-produced *wh*- questions from a set of target corpora, followed by semi-automated identification of uninversion errors; collection of *n*-gram statistics for child-directed speech in English; and mixed-effects logistic regression modeling to determine which *n*-gram statistics predicted uninversion errors in the extracted questions.

Corpus Selection and Preparation

We began by extracting the 12 corpora with the highest number of *wh*- questions from the English language portion of the CHILDES database (MacWhinney, 2000). Each corpus followed a single target child and spanned at least one year of development; the age range and nationality for each target child is shown in Table 1 alongside citation information.

Table 1: Details of CHILDES Corpora Used in Analysis of Uninversion Errors

Target Child	Corpus	Age Range
Abe	Kuczaj, 1977	2;04-5;00
Adam	Brown, 1973	2;03-5;02
Eleanor	Lieven et al., 2009	2;00-3;00
Ethan	Demuth & McCullough, 2009	0;11-2;11
Fraser	Lieven et al., 2009	2;00-3;01
Laura	Braunwald, 1976	1;05-7;00
Lara	Rowland & Fletcher, 2006	1;09-3;03
Lily	Demuth & McCullough, 2009	1;01-4;00
Naima	Demuth & McCullough, 2009	0;11-3;10
Ross	MacWhinney, 1991	1;04-7;08
Sarah	Brown, 1973	2;03-5;01
Thomas	Maslen et al., 2004	2;00-4;11

Each corpus was then prepared for analysis using an automated procedure which removed codes, tags, and punctuation, leaving only speaker identifiers and the original sequence of words. Lines consisting solely of morphological tags (included as standard in CHILDES corpora) were unaffected by this procedure and were retained for later use in extracting uninversion errors.

As part of this procedure, contractions were split into their component words: e.g., "what's he doing" was re-coded as "what is he doing." As corpus annotation differs in terms of how contractions are transcribed (leading to arbitrary noise), this step ensured that modeling work reflected accurate *n*-gram frequencies for *wh*- words and auxiliaries across all questions. As a further step we collapsed the pronouns "she" and "he" into a single form to control for individual differences across children's exposure to gender pronouns.

Wh- Question and Uninversion Error Candidate Extraction and Coding

Child-produced *wh*- questions were automatically extracted from the target corpora by utilizing the standard default morphological tagging included in CHILDES. All extracted questions featured a *wh*- word in the first position, followed immediately by an auxiliary. This yielded approximately 13,000 child-produced *wh*- questions across the 12 corpora.

For the purpose of automatically identifying possible uninversion errors, we extracted, from the full corpora, all child questions which featured a *wh*- word in the initial position which was not immediately followed by an auxiliary. These candidate items were then manually coded for error type by the first author, yielding a total of 300 identified uninversion errors produced across the target children. *wh*- questions featuring an error type other than

uninversion (such as doubling or omission errors) were excluded from our dataset. Importantly, our analyses were restricted to questions produced before the age of five years.

N-gram Data Collection

In order to capture *n*-gram statistics which accurately reflected the nature of child-directed speech in the English language, we gathered *n*-gram frequencies for the entire English (UK and US) portion of the CHILDES database. This allowed us to overcome issues of data sparseness arising from corpus size (Manning & Schütze, 1999).

The aggregated corpus was prepared for data collection following the same procedure described in the above subsection. Frequencies were then collected for unigrams (single words), bigrams (word pairs), and trigrams (word triplets), which were then applied to each of the *wh*-questions extracted for the 12 target child corpora. To this end, *n*-gram statistics were calculated for each question (separate unigram counts for each word, separate bigram counts for each word pair, and so forth). Thus, for the question "what is that," three unigram counts (one for each of three word positions), two bigram counts (one for each of two word pair positions), and one trigram count (for the single word triplet position) were available.

Because our statistical analyses aimed to explore the role of multiword chunk frequency in shaping children's uninversion errors, we sought to directly compare the correctly inverted "target question" for children's uninversion errors to the correctly inverted questions which made up the rest of the dataset. To achieve this, we calculated *n*-gram frequencies for the correctly inverted forms of the uninverted questions identified by the earlier procedure. Uninversion errors were "corrected" by hand in order to achieve this.

By the same token, we also sought to explore the role of multiword sequence frequencies for the relevant uninverted question forms in determining error rates. For this, we retained the original child uninversion errors and employed an automated procedure to produce the errorful, uninverted form corresponding to each correctly inverted question in the corpus. The second and third words could not simply be swapped because a large number of questions featured multiword subject noun phrases, such as "where is my red ball?" Thus, to automatically achieve a realistic uninverted form across such a large number of questions, we first chunked utterances using a shallow parser (Punyakanok & Roth, 2001). Shallow parsers are widely used tools in the field of natural language processing which segment out the non-overlapping, non-embedded phrases in a text. For instance, the shallow parser output for the previous example would be: "[where] [is] [my red ball]." After submitting all correctly inverted questions to the shallow parser, we merely switched the second and third chunks, yielding the relevant, uninverted errorful forms, such as "where my red ball is?"

Thus, we collected unigram, bigram, and trigram statistics for each position across all correctly inverted questions (and, in the case of uninversion errors, the correctly inverted target questions), alongside a separate set of *n*-gram statistics for the uninversion errors (and, in the case of correctly inverted questions, the relevant errorful form).

Analysis

In order to evaluate the predictive relationship between multiword chunk frequency and uninversion errors, we used mixed-effects logistic regression modeling (cf. Agresti, 2002). We carried out a set of model comparisons to determine which *n*-gram frequencies were uniquely predictive of the relationship. This involved selecting predictors at each *n*-gram level separately, starting at the unigram level before moving to the bigram level, followed by the trigram level.

Questions originally produced by the target children in their correctly inverted form were coded as 0, while questions produced in an errorful, uninverted form were coded as 1. *N*-gram frequencies were then used as predictors for this binary variable. All models included a random intercept for child, to reflect the fact that the 12 target children may differ in the extent to which their errors could be predicted by *n*-gram frequencies. By-child random slopes were also included where they improved fit.

Our model comparisons sought to evaluate *n*-gram frequencies of both the correctly inverted question and their corresponding uninverted (errorful) forms as predictors of child uninversion error. The model comparison procedure was designed such that the risk of false positives for higher-order *n*-grams was insignificant, as we conservatively prioritized lower-order *n*-grams in the selection process. Importantly, all predictors were log-transformed and scaled. All model comparisons were carried out using log-likelihood ratio tests.

Starting at the unigram level, we used a leave-one-out procedure to determine which predictors explained variance over and above that explained by any other variable. The full baseline model at this level included random effects of the first 5 unigrams (by child) as well as fixed effects for these 5 unigrams. This was then compared to five subsequent models, each leaving out the fixed effect term for a different unigram (random effects by child were included for every unigram in each model). Removal of only the first two unigrams harmed model fit to a significant extent, according to log-likelihood tests. Thus, these two unigrams were held over for the next level of model comparisons.

The same procedure described for unigrams was then carried out for the first four bigrams, but with random (by child) and fixed effects for the first two unigrams also included in each model (as unigrams are identical across the inverted and uninverted forms, only one set was included in the previous step). Importantly, bigrams from both the correctly inverted and the corresponding errorful forms were included at this second step.

For correctly inverted question forms, removal of the third and fourth bigrams harmed model fit to a statistically

significant extent, according to the log-likelihood tests, while for the uninverted forms, removal of the second, third, and fourth bigrams harmed model fit. Thus, in addition to the first two unigrams from the previous step, the third and fourth bigrams from the correctly-inverted question forms and the second, third, and fourth bigrams from the errorful (uninverted) forms were held over for the final set of model comparisons.

For the first three trigrams, the same procedure was followed once more (with random and fixed effects for the first two unigrams and first two bigrams). Only removal of the second and third trigrams from the uninverted/errorful question forms harmed model fit to a significant extent.

Thus, the final set of predictors included the first two unigrams, the third and fourth bigrams from the correctly inverted forms, the second, third, and fourth bigrams from the uninverted forms, and the second and third trigrams from the uninverted forms.

Results

Our model comparison procedure (as described above) yielded a model with 9 *n*-gram predictors: the first two unigrams, third and fourth bigrams from the correctly inverted question forms; and the second, third, and fourth bigrams as well as the second and third trigrams for the errorful (uninverted) question forms. The log-likelihood, chi-squared value, and p-value for each model comparison is shown in Table 2.

Uninverted Trigram (full/baseline)	-614.62	-	-
Uninverted Trigram 1	-614.87	0.505	0.4772
Uninverted Trigram 2	-617.55	5.874	0.02 *
Uninverted Trigram 3	-618.41	7.582	0.01 **

To help understand the relationship of these *n*-gram frequencies with child uninversion errors, we constructed non-partial (single-predictor) models for each of the final variables, as reported in Table 3. Each model included a random intercept for target child and a random effect (by child) for the relevant predictor as well as the fixed effect. This procedure was preferred as, in a multi-predictor model, estimates may change sign based on the relative strength of predictor correlations with the dependent variable (cf. Wurm & Fisicaro, 2014).

The first and second unigram frequencies (corresponding to the *wh*- word and auxiliary) were significant predictors with negative estimates, indicating lower likelihood of an uninversion error with more frequent items. Importantly, for higher-order *n*-gram predictors drawn from the errorful, uninverted question forms, the estimate was positive. This means that the higher the *n*-gram frequency was for the uninverted form of a question, the more likely it was for that question to have been produced in its uninverted form.

Table 3: Results of Non-partial Models

N-gram	β	Std. Error	*Z*	*p*-value
Uni 1	-0.792	0.27	-2.91	0.004 **
Uni 2	-0.634	0.11	-5.34	0.000 ***
Bi 3	0.031	0.11	0.25	0.795
Bi 4	0.239	0.14	1.64	0.100
Bi 2 (*uninv.*)	0.328	0.11	2.89	0.004
Bi 3 (*uninv.*)	0.563	0.13	4.24	0.000 ***
Bi 4 (*uninv.*)	0.207	0.16	1.26	0.207
Tri 2 (*uninv.*)	0.462	0.10	4.44	0.000 ***
Tri 3 (*uninv.*)	0.454	0.11	4.03	0.000 ***

General Discussion

The corpus analyses presented here represent, to our knowledge, the most rigorous attempt to control for input frequency in analyzing non-inversion errors to date. We find that, when *n*-gram frequencies from both the correctly-inverted, "target" form of a question, and the non-inverted, "errorful" form of a question are considered in parallel, frequency is a robust predictor of when non-inversion errors will occur. Moreover, the frequencies of higher-order *n*-

grams from the non-inverted form are shown to be more robust predictors than frequencies from the correctly inverted form.

This finding appears to stem from children's use of multiword units in production (e.g., Bannard & Matthews, 2008). Consider the effect of the (non-inverted) second trigram in the context of the following non-inversion error: "*where we can go today?**" The more heavily *we can go* holds together as a unit in the child's language experience, the less likely the child will be to break up the sequence by fronting the auxiliary *can* (e.g., by relying on a lexical frame for *what can*). Similar reasoning can be applied to the effect of the non-inverted third bigram (*can go,* in this example). Errors caused by the intrusion of overlearned sequences occur in all kinds of human action (Bannard et al., in press).

Thus, our findings weigh in favor of previous proposals that children rely on lexically-based representations in question formation (e.g., Rowland & Pine, 2000) and support the proposal that material learned from declarative utterances can drive systematic errors (Ambridge & Rowland, 2009). Our findings are inconsistent, however, with structure-dependent accounts of children's *wh*-questions (e.g., de Villiers, 1991).

The present study, therefore, offers an interesting additional line of evidence supporting usage-based approaches, especially accounts of language development which stress the importance of multiword units (e.g., Theakston & Lieven, 2017; McCauley & Christiansen, 2019) including exemplar-based approaches (Ambridge, 2018).

Applying Deep Language Understanding to Open Text: Lessons Learned

Marjorie McShane (margemc34@gmail.com)

Irene Nirenburg (irene_bn@yahoo.com)

Cognitive Science Department, Rensselaer Polytechnic Institute
Troy, NY 12180 USA

Abstract

Human-level natural language understanding (NLU) of open text is far beyond the current state of the art. In practice, if deep NLU is attempted at all, it is within narrow domains. We report a program of R&D on cognitively modeled NLU that works toward depth and breadth of processing simultaneously. The current contribution describes lessons learned – scientifically and methodologically – from an exercise in applying deep NLU to open-domain texts. An overarching lesson was that although learning to compute sentence-level semantics seems like a natural step toward computing full, context-sensitive, semantic and pragmatic meaning, corpus evidence underscores just how infrequently semantics can be cleanly separated from pragmatics. We conclude that a more comprehensive methodology for automatic example selection and result validation is needed as prerequisite for success in developing NLU applications operating on open text.

Keywords: natural language understanding; cognitive modeling; language-endowed intelligent agents

Introduction

Operationalizing human-level natural language understanding (NLU) in computer systems has been a goal of AI since its inception. People want intelligent agents to understand not only what they say but what they mean, taking into account the linguistic and real-world context, shared background knowledge, the interlocutors' mutually understood plans and goals, and even their mental, physical, and emotional states. All of these considerations explain why human-level NLU is an AI-complete problem.

It is difficult to carve out a program of R&D for AI-complete problems. With respect to natural language, the field has responded in five broadly-defined ways.[1] **(1)** *Avoid meaning.* For the past 25 years, mainstream NLP has chosen to pursue so-called *knowledge-lean* methods, i.e., the statistical processing of big data with little to no computation of meaning. This has proven useful for certain applications but is not moving toward explainable, human-level NLU in service of intelligent agents. **(2)** *Address select aspects of meaning.* Computing individual aspects of meaning has improved the quality of some primarily knowledge-lean systems. Topics addressed include, e.g., case-role identification, speech act detection, textual coreference resolution, and the semantic clustering of word strings using distributional semantics (Jurafsky and Martin, 2009). **(3)** *Pursue deep NLU in a (very) narrow domain.* This provides systems with the kinds of knowledge and reasoning capabilities that people leverage when interpreting language (e.g., Allen et al. 2007; Lindes and Laird, 2016). **(4)** *Build theories without systems.* Such work anticipates that prerequisites – such as NLU – will be eventually be fulfilled externally, and is typical in the fields like computational formal semantics and machine reasoning. **(5)** *Build extensive theories but implement and evaluate just a subset*. This appears to be the choice of the dialog specialist David Traum (compare Traum 1994 for scientific work with Nouri et al. 2011 for application-oriented work).

The program of R&D described here – developing Language-Endowed Intelligent Agents (LEIAs) within the OntoAgent cognitive architecture – offers a sixth approach to attacking the AI-complete problem of human-level NLU (McShane, Nirenburg and English, 2018). It pursues **depth of analysis and breadth of coverage concurrently**, but with appropriately flexible expectations about the coverage, quality, and confidence of analyses depending on the correlation of text inputs with knowledge bases. It focuses on the *actionability* of language interpretations, as judged by the agent systems that use them.

Of the many theoretical and methodological issues at the core of this program of work (McShane, Nirenburg and Beale, 2016), the following are particularly relevant for this discussion.

1. LEIAs are modeled after humans. Like humans, they do not need to understand everything their interlocutors say and mean; instead, they need to achieve actionable interpretations, defined as interpretations that are sufficient to support reasoning about action.
2. The same knowledge that allows LEIAs to function intelligently in their domain of expertise supports language-oriented reasoning in that domain. Full NLU is not possible without such knowledge.

[1] This is a thumbnail sketch of a long history and extensive literature. See Nirenburg and McShane (2016) for a more in-depth treatment.

3. For both theoretical and methodological reasons, NLU is best implemented as a series of layers of ever-deeper analysis, resulting in ontologically-grounded text meaning representations (TMRs) that are well-suited to agent reasoning.
4. Most narrow-domain approaches seek to avoid disambiguation, one of the hardest problems of NLU; however, such approaches will not attain a human level of understanding until this problem is solved and agents function with a realistic-sized lexicon.
5. A very large number of linguistic phenomena (to name just a few: nominal compounding; all aspects of reference resolution, including fragments and ellipsis; non-literal language; indirect modification; indirect speech acts; implicatures) must be handled by LEIAs no matter their domain of specialization (McShane and Nirenburg, *forthcoming*). The computational microtheories accounting for these phenomena are best investigated using open text.

The original hypothesis underlying the work described here was that we could *quickly* validate many of the implemented microtheories of NLU for LEIAs using an open corpus. Why an open corpus? As discussed in more detail later, this method a) provides useful fodder for improving microtheories, b) makes the work "real" in the eyes of the mainstream NLP community, and c) shows how the analysis capabilities can be usefully applied to open texts.

In formulating the reported exercise, we assumed that a corpus would contain a sufficient number of sentences that could be automatically interpreted using general linguistic and world knowledge, without the need for the finer-grain knowledge resources supporting agent-reasoning capabilities that are available only in narrower domains. Such sentences would be similar in nature, but methodologically preferable, to the invented examples we use to test out individual microtheories.

We further assumed that a simple, automatic method of extracting examples would serve the purpose. However, this experience has shown that, in order to sufficiently evaluate all of the microtheories contributing to the system, we need a more sophisticated example extraction methodology operating over a larger corpus, as well as more human effort devoted to reviewing results. However, rather than change the original hypothesis by allocating more time and effort to data collection, we heeded the lessons learned from the Reproducibility Project (Open Science Collaboration, 2015) and its analytical wake: It is not appropriate to tweak hypotheses or results until they achieve the envisioned threshold. Research habitually involves things not going to plan, and the associated lessons learned are central to progress in the field. This paper focuses on lessons learned. But we must begin with the briefest introduction to the NLU environment at hand.

The OntoAgent Cognitive Architecture

The OntoAgent cognitive architecture underlying LEIAs includes the modules of perception, reasoning and action. Language is one of the perception modes of a LEIA. Language inputs are analyzed into disambiguated, ontologically-grounded meaning representations. For example, the bare-bones basic TMR for *I knocked on the door* (stripped of metadata and calls to the procedural semantic routines for coreference resolution) is as follows:

```
(HIT-1 (AGENT HUMAN-1)
       (THEME DOOR-1)
       (INSTRUMENT HAND (OPENNESS 0))
       (TIME < find-anchor-time)) ; indicates past tense
```

The fact that the instrument is a closed hand is provided by the lexical description of the selected sense of *knock* in the system's lexicon, which also expects the object of the preposition to refer to, among other possibilities, a door.

Although we cannot adequately familiarize readers with the theory of Ontological Semantics, the agent applications that this approach to NLU has supported, the knowledge bases employed, or how the analysis process works (see, e.g., Nirenburg and Raskin, 2004; McShane, Nirenburg, and English, 2018; Nirenburg, McShane and Beale, 2008), the following facts will serve as orientation. The lexicon contains ~30,000 word senses, which are comprised of linked syntactic and semantic representations and, whenever necessary, calls to procedural semantic routines (for example, to resolve coreferences). Argument-taking words, multiword expressions, and polysemy are richly represented. The semantic descriptions are written in an unambiguous ontological metalanguage. The ontology contains ~9,000 concepts (~145,000 RDF triples), mostly from the general domain. Concepts are described using attributes and relations. Scripts detailing complex events are available in select domains.

The lexicon and ontology were mostly compiled through a modest, short-term effort around 25 years ago in service of interligua-based machine translation and have been only minimally modified since. They were not modified at all for the reported exercise. The key benefit of our lexicon is that it is far from toy and, therefore, allows us to develop and test the essential capability of lexical disambiguation. All parts of speech include polysemous entries, and light verbs such as *have, make,* and *do* have dozens of senses, many of which involve multi-word expressions or constructions. The ontology, for its part, provides selectional constraints on case-roles that support disambiguation, as well as a substrate for various types of language-oriented reasoning, such as topic/domain detection based on ontological distance.

Although these resources have served our research goals quite well, their insufficiencies are relevant to the current report. We estimate that the lexicon would need to be around ten times larger to provide baseline coverage of open text, with the necessary acquisition including a large percentage of multi-word expressions and constructions. An

acquisition effort of this size is, we estimate, no more labor-intensive than some of the well-known corpus annotation efforts in service of supervised machine learning.

NLU by LEIAs is reasoning-intensive. The overall process is modeled as two types of incrementality: *horizontal incrementality* involves analyzing elements of input as they become available to the agent (essentially, word by word); *vertical incrementality* involves applying, on an as-needed basis, increasingly sophisticated methods of analysis to the given state of input, be it a fragment, a complete utterance, or a multi-sentence text. Agents dynamically decide how deeply to process chunks of input as they are perceived.

There are six stages of vertical incrementality, described in greater detail in (McShane and Nirenburg, *forthcoming*): **1.** Preprocessing and syntactic parsing, for which we use the CoreNLP toolset (Manning et al. 2014). **2.** Integrating these results into our environment, which includes recovering from unexpected syntax as well as the initial stage of learning new words. **3.** Basic semantic analysis, which uses lexical and ontological knowledge for disambiguation and semantic dependency analysis. This includes such advanced capabilities as the detection and resolution of many types of ellipsis and learning the semantics of unknown words. **4.** Aspects of reference resolution that do not require full contextual grounding. These include resolving textual coreference, identifying which referring expressions do not require a coreferent and why, establishing reference relations that are not *co*reference (e.g., bridging constructions), and reconsidering upstream lexical disambiguation decisions based on coreference relations. **5.** Extended semantic analysis, which treats select instances of residual ambiguities and incongruities using additional general-purpose rule sets. These include, e.g., ontological patterns for interpreting nominal compounds, rules for interpreting metonymies, and dialog-analysis strategies for integrating the meaning of fragmentary utterances into the discourse. **6.** Situated NLU, which applies all of an agent's domain-specific and situational knowledge and reasoning to resolve residual ambiguities and incongruities, and anchors newly learned knowledge to agent memory.

If it sounds like this system is claiming to do *everything,* that is, in a certain sense, correct. The overall challenges of NLU must be addressed in an integrated system, within an architecture and theory that reserves a place for each component microtheory. The microtheories must be crafted as components of such an overall analysis system. This approach avoids the two most serious problems of strictly modular or limited-scope research: the assumption that prerequisites for one's own work will be provided externally; and the avoidance of all cross-modular phenomena.

Stages 1-5 involve what some call *semantic* meaning, as contrasted with *pragmatic* (discourse, situational) meaning. This level of meaning should be understandable at the sentence level, outside of context – even if some expressions (e.g., pronouns) remain underspecified. Following this expectation, individual sentences outside of their context were the focus of the reported exercise. Given that the ~30,000-sense lexicon contains over 1,600 verb senses, and that the system can process proper nouns and learn new words, we projected that there would be plenty of appropriate sentences to seed our exercise. As concerns Stage 6 of processing, it cannot be validated using individual sentences outside context; we are working on that separately, within a robotic application (Nirenburg et al., 2018).

Methodology

Our initial goal was to focus on *validating* our system rather than formally *evaluating* it in the way that has become standard in the field of natural language processing (NLP). That methodology is of no use for systems that seek human-level understanding of language. It is not, therefore, surprising that mainstream NLP has all but officially placed our area of R&D beyond the boundaries of the discipline. For example, in their chapter on "Evaluation of NLP Systems" in *The Handbook of Computational Linguistics and Natural Language Processing* (Clark, Fox and Lappin, 2010), Resnik and Lin do not even address the evaluation of cognitively-oriented systems that integrate scientific and technological goals. They write: "such scientific criteria [involving, e.g., the cognitive modeling of human language processing] have fallen out of mainstream computational linguistics almost entirely in recent years in favor of a focus on practical applications, and we will not consider them further here." (p. 271) So, we need an alternative validation/evaluation methodology.

There is no truly fast, easy, and complete way to validate (no less evaluate) a large and complex knowledge-based system, nor can the full set of options be fleshed out in this short space. As a starting point, consider just a few of the options. **(1)** *Invent test inputs guided by the knowledge bases and system capabilities*. This gives credit for what *does* work but rarely uncovers unexpected phenomena and is viewed skeptically by the field at large. **(2)** *Use inputs limited to a narrowly-defined domain.* This, too, usually involves manual example creation since 'narrowly-defined' must be enforced; moreover, it fails to give the system or component microtheories credit for their applicability across domains. **(3)** *Use randomly selected inputs from the open domain*. Although this is a cornerstone of statistical NLP, it is inapplicable to deep NLU given that the environment is known to have limited lexical coverage. **(4)** *Focus on full sentences from open text that the system analyzes perfectly.* This approach tasks the system with extracting from open text, and processing, only those sentences it hypothesizes it can analyze correctly. During validation, people inspect only the highest-quality results – i.e., those for which exactly one TMR achieves the highest score, and that score reflects high confidence. This is the approach we used for the current exercise. Its insufficiencies underlie many of the lessons learned from this exercise, as discussed in the next section. **(5)** *Focus on subsentential chunks of text from the open domain that the system analyzes perfectly.* Such chunks can represent propositions, individual phenomena (e.g., nominal compounds, instances of verb phrase ellipsis),

or sentences for which all aspects but one – e.g., an unknown adverb – are correctly understood. We have used this method in past formal evaluations (Nirenburg et al., 2018) and have found it useful for vetting individual microtheories. The problem is that it is time-consuming to formulate a vetting regimen for even a single microtheory, let alone the dozens that the system currently comprises, or the interactions among them. Additionally, any of the above methods can also involve inspecting outputs that are partially correct, residually ambiguous, etc.

Results

As should be clear by now, this vetting exercise was primarily intended to guide our continued R&D effort. It did – but more through lessons learned than from compiling examples that work. That being said, we do want to present some examples to show that our NLU system *can,* in fact, work on open text.

To further specify the set-up: The system extracted examples from two randomly selected excerpts of the COCA corpus (Davies 2008), one literary and the other journalistic. It extracted sentences that included a maximum of one unknown word, with "known" implying that the lexicon contained an entry with the necessary part of speech. No other extraction filters were applied. The system processed the sentences into TMRs using Stages 1-5 of our NLU system. We manually reviewed only those results that seemed promising. For example, we did not inspect the TMRs for sentences that were incomprehensible outside of context, or that required knowledge or reasoning beyond that available in Stages 1-5 of NLU.

We spent just a few person-weeks on the exercise, much of which involved code debugging (after all, the exercise was primarily in service of R&D). However, the examples we cite as "correct" were correct *before* any system modifications. No amendments to the knowledge bases were made. It did not take long to determine that we had learned what we could from this exercise, and we, therefore, did not prolong it to collect more working examples.

Unless otherwise noted, all examples presented in this section were analyzed perfectly. Any incorrect portions are indicated by strikethroughs or explanatory text. Every input required disambiguation decisions, in some cases, from a large choice space: e.g., *He looked for the creek* disambiguates between 16 senses of *look*, and *I went into the bathroom* disambiguates between 54 senses of *go*. The examples below are grouped by the specific phenomena they illustrate.

Complex semantic descriptions. For example, the TMR for *I knocked on the door* includes a hand as the instrument, and the TMR for *I pointed at the blood* includes a finger as the instrument.

Disambiguation of highly polysemous particles and prepositions: *She rebelled against him; He stared at the ceiling; She jokes with him; She switched on the light; He passed through the entrance; I called for a blanket; I thought about Amalia; He talked about Leona***.**

Modification and sets: *An old white couple lived in a trailer.*

Multiword expressions: *He took me by surprise*,

Verbal disambiguation using a specificity preference. For example, in *I do not know Dave,* three senses of *know* (glossed as *be acquainted with, be aware of,* and *be able to identify*) formally match the case-role constraints. The sense *be acquainted with* fulfills the tightest case-role constraints, so it wins. This example also shows the correct processing of the modality indicated by negation.

Dynamic sense bunching. This allows the system to underspecify an interpretation rather than end up with competing analyses. E.g., ~~*No, and*~~ *I didn't ask him* does not permit disambiguation between three senses of *ask* – those encoded using the ontological concepts REQUEST-INFO, REQUEST-ACTION and PROPOSE – so the system bunches these into their closest common ontological ancestor, ROGATIVE-ACT, whose case-roles are correctly understood as AGENT and THEME.

Lateral selectional constraints for disambiguation. E.g., in *I heard the hands on the clock* ~~*move*~~*, clock* was correctly used to disambiguate *hands* (but since the CoreNLP misidentified "clock move" as a nominal compound, that aspect of the analysis was wrong). Similarly, in *The arm jerked, eyelids* ~~*rose*~~*,* the meaning of *eyelids* was correctly used to disambiguate *arm* between body part and furniture part (but *rise* as applied to eyelids was misanalyzed).

New word learning. An example of new noun learning is 'uncle' in *The uncle said something to him*, which is understood as referring to a HUMAN since the AGENT slot of ASSERTIVE-ACT must be filled by a HUMAN. The results of learning are understood as provisional, and values of properties of the newly learned concept are expected to be added opportunistically as a side effect of continued processing of input – or, alternatively, by a knowledge acquirer. An example of new property learning is *inconsiderate* in *Burying Leora* ~~*in Pittsburgh*~~ *is inconsiderate*. The system represents the meaning as a generic PROPERTY whose DOMAIN is filled by the event BURY (from *burying*). *In Pittsburgh* was correctly analyzed but incorrectly attached to Leora rather than burying, following a parsing error by CoreNLP. (Reambiguating PP attachments from the CoreNLP parse, so that semantics can weigh in, is on agenda.)

The above presents just a small sampling of linguistic phenomena that the system covers, along with examples of successful analyses. It shows that vision behind the current exercise was not ultimately ill-conceived, and illustrates that the corpus was, in fact, open-domain. But, as we said earlier, we keep this aspect of the report brief in order to focus on the main point: lessons learned.

Lessons Learned

Most of the *types* of outcomes of this exercise were predicable beforehand, but in some cases their *frequency* was rather surprising, thus representing a lesson learned.

1. *It is not possible to automatically detect that a needed multiword expression (idiom, construction, etc.) is missing*

in the lexicon. Multiword expressions are central to a human's knowledge of language and, accordingly, to modeling NLU for LEIAs. When a multiword expression is missing from the lexicon, the system analyzes the components compositionally, which necessarily results in an error. All of the following examples were misanalysed because interpreting the meaning of the underlined portion required a multiword lexical sense that had not yet been acquired. *She is long gone from the club. I got a good look at that shot; The Knicks can live with that. But once Miller gets on a roll, he can make shots from almost 30 feet. I can't say enough about him. This better be good. You miss the point. I should have known better.* The lesson learned involves the frequency with which the system will be overly confident in its analysis, not having recognized that an input component is not semantically compositional.

2. *The methodology of focusing on completely correct TMRs was suboptimal.* Often, the meaning representation of a portion of the input nicely demonstrates a particular functionality, even though some aspect of the overall sentence interpretation is incorrect. Many such mistakes reflect the use of microtheories that are currently underdeveloped, such as those for relative temporal and spatial relations (*in recent weeks, 25 feet right of the hole*, and *for the second time this year*). When, midstream, we decided to revisit partially correct TMRs, we found many interesting correct subanalyses, suggesting that vetting Method #5 described above might be superior to the method we used.

3. *The methodology of focusing exclusively on sentences that resulted in a single TMR was suboptimal*. Outside of context, residual ambiguity is quite common. When we decided to revisit analyses that resulted in two output TMRs – because the analyzer did not have a reason to prefer one over the other – we found examples in which this outcome was actually the correct one. For example, the system correctly detected the ambiguity, and generated multiple correct candidates, for *He stared at the fish,* which could refer to a live fish (FISH) or its meat (FISH-MEAT); and *He glanced at the walls* could refer to parts of a room (WALL) or parts of a person undergoing surgery (WALL-OF-ORGAN).

4. *It can be difficult, even for humans, to describe many intended meanings*. Consider the following sentences: *And he came back from the dead. Training was a way of killing myself without dying. The supporting actor has become the leading man. This is about substance. The roots that are set here grow deep.* Such examples allow for multiple interpretations, at many levels of vagueness and specificity, depending on the specific speech situation. The existence of utterances of this type are among the reasons we believe that, in building agent-oriented NLU capabilities, actionability – not exhaustive understanding – is key. But for this exercise, decision-making about actionability was outside of purview.

5. *The intended meaning can rely more centrally on discourse/pragmatic interpretation than semantic analysis*. In some cases, e.g., for personal pronouns, there is a clear progression from semantic to pragmatic meaning. However, in other cases, semantic meaning is either vague, not directly connected with pragmatic meaning, or even relatively unimportant. Space is too short to flesh out these complex eventualities, but consider the example *It takes two to tango*, which occurred in our corpus. If we were to write a lexical sense for this phrase, how would we describe its meaning? Its propositional meaning – something like "a communication cannot exist without multiple people being agentive" – is much less important than its discourse function. That is, the speaker is saying that the given situation is an example of a generalization about human relations, but the context-specific pragmatic nuances can range from being a barb during a spat (*It's your fault, too, that we're arguing!*) to being advice to a friend (*If you back off, maybe the other person will too*). It seems incorrect to lexically record, and then give a system credit for computing, semantic meanings when it is the pragmatic force that is predictably more important.

6. *Non-literal language is even more prevalent than we had expected – and we had expected a lot.* In fact, we have methods for detecting and recovering from some types of non-literal language, but not the onslaught we encountered in this exercise. For example, *Everyone was saying we won ugly last week* and *He not only hit the ball, he hammered* were imperfectly analyzed because the non-literal meanings were not correctly recovered.

7. *We need to operationalize reasoning about language via affordances*. Just as human vision is well-understood to be largely driven by expectations, so, too, is language understanding. Affordances – i.e., the knowledge of what objects can do and how they can be used – can support reasoning about language inputs, particularly if they involve difficult phenomena, such as non-literal language, unknown words, and indirect modifications. For example, we previously noted that *eyelids rose* resulted in a misinterpretation of 'rise'. It is unlikely that people encode a word sense of 'rise' that covers eyelids; however, we know that eyelids are capable of precious few actions. So a fuzzy matching between words and concepts for moving up and down is sufficient for a person to understand this. A microtheory of applying affordances to reasoning about NLU is on our team's agenda.

8. *It is unclear what credit to give semantics without implicatures*. On the one hand, semantic analysis is hard enough without requiring that NLU systems account for all a speaker's implicatures before claiming any success. On the other hand, in some cases semantics and implicatures cannot be neatly separated. Consider the example, *She's also a woman*. Reading this in isolation, we understand that the context must have been about her in some other social role – as a mother, a co-worker, etc. – and that this utterance focuses attention on her female/sexual side. It is similarly unclear what, if anything, would count as a sufficient semantic (pre-implicature) analysis of the following: *How quickly the city claimed the young. They sat by bloodline. I think he is coming into good years. Fathers were for that.*

9. *Not invoking domain-oriented expectations is more limiting that we had anticipated.* For example, unless you

realize you are in a sports context – and know sports-related lexical and ontological knowledge – the following are not fully interpretable: *The Rangers and the Athletics have yet to make it. He hit his shot to four feet at the 16th. We stole this one. I wanted the shot.*

10. *Although our system is knowledge-based and all processing apart from what is contributed by CoreNLP is fully inspectable, the computational complexity of deep NLU can make it difficult to fully predict, explain, and trouble-shoot results*. Consider the simple example *I almost never talk about it,* whose words have, respectively, 3/5/2/2/2/1 senses. The number of candidate TMRs generated is 50, with their final scores ranging from -22 to 22.9. There was only 1 highest-scoring TMR and it was correct. The CoreNLP parse happened to be correct, but since this is not always the case, our analyzer compensates by considering other syntactic analysis possibilities as well. As a result, the process of mapping syntactic dependencies in inputs to the variables in the syntactic descriptions in lexicon entries can lead to multiple sets of variable assignments for each available sense. At the semantic level, the system needs to select the best sense and set of variable assignments for each word by examining the interactions between the semantic constraints among all the words that interact with it. In the worst case, that can become a computational clique, which has exponential time requirements (we employ various techniques for reducing or sometimes eliminating this computational drain). Scoring functions are also complex – their composition is a research issue in itself. In short, even though we can configure a glassbox evaluation, the analysis process can, in certain cases, still defy complete explanation.

Conclusions

We believe that our original goal – to vet our system's domain-independent microtheories using open text – is achievable. The reason why the focus of this exercise shifted from "vetting" to "investigating lessons learned" is because the methodology for extracting examples and automatically evaluating the quality of output TMRs turned out to be insufficiently developed. The lessons learned will inform the creation of a more sophisticated methodology for future experiments. To give just a few examples of planned enhancements: (a) Including the preceding context for each extracted example to allow for coreference and lateral-constraint heuristics to be leveraged; (b) Automatically excluding excessively short inputs, direct speech, texts from jargon-intensive domains like sports, and inputs containing pronouns whose resolution strongly affects disambiguation decisions (e.g., *it, that* and *they* are more problematic than *he* or *she*); (c) Using an example-extraction methodology that identifies the highest-confidence examples of each word sense, microtheory, etc., from a much larger corpus than was used for this exercise; and (d) Including within purview high-confidence subsentential results.

Apart from lessons learned, this experiment has resulted in promising outcomes. The fact that the system correctly analyzed some inputs from the open domain – even given the shortcomings of the reported methodology and all of the challenges natural language predictably presents – suggests that deep NLU can have near- and mid-term utility, given an appropriate task formulation and improved methods of automatically judging the system's confidence in its analyses.

Lifelong learning has long been understood as a necessary foundation of AI. Even the current capabilities of the reported NLU system can support the learning of lexical units and ontological concepts, with the coverage expected to rise dramatically even with relatively (by industry standards) modest knowledge acquisition efforts.

Our system addresses the open-world problem directly and takes responsibility for all upstream processing errors (currently, from CoreNLP). In some cases, it can successfully learn new meanings and recover from upstream errors, whereas in others it cannot. However, we believe that failures under real-world circumstances are far preferable to the non-real-world experimental set-ups favored by the well-known task-oriented competitions of statistical NLP.

Although the reported exercise focused on stages of NLU that can be, to some degree, computed outside of context, the overall program of work moves toward explainable AI covering integrated agent functionalities.

Abstract

A wealth of developmental evidence suggests that children essentialise natural kind but not artifact categories, and that both adults and children use generic language less with artifacts as well (Gelman, 2003). Here we further explore the latter result using a novel model for generic identification. We apply our model to a much larger dataset than before, consisting of 26 CHILDES corpora of naturalistic speech involving children at a variety of ages and in a variety of contexts. We found no consistent preference for generic usage in animates over artifacts. Follow-up analyses indicate that this result was probably driven by our inclusion of a wider variety of nouns into our dataset than previous work.
Keywords: essentialism; generics; development; language

Introduction

Psychological essentialism refers to the intuitive belief that many categories have a hidden essence which gives the objects in those categories their identity. Essentialised categories have sharp boundaries, are discovered rather than invented, and have properties that are inherent in some way (e.g., Gelman, 2003). From an early age children behave in ways that are consistent with having essentialist beliefs. This is evident in how they use category information to support induction (Gelman & Markman, 1986) and make predictions about innate potential (Gelman & Wellman, 1991) and identity in the face of transformation (Keil, 1989), among others.

Although there is robust evidence that people essentialise natural kinds, we do not appear to essentialise artifact categories (e.g., Sloman & Malt, 2003). Artifacts do not retain their identity even when transformed (Keil, 1989), often have fuzzy category boundaries (Estes, 2003), and have different insides than animals do (Simons & Keil, 1995).

To what extent is this difference between artifact and natural kinds learned from or supported by environmental differences? One way to answer this question is by investigating one possible source of environmental influence: the use of generic noun phrases (e.g., *Owls sleep during the day* or *Books are heavy*). Generics communicate properties about categories as a whole rather than individuals, and both adults and children appear to make more essentialised inferences when generics are used (Rhodes, Leslie, & Tworek, 2012). Moreover, in a variety of experimental contexts, both children and adults produce generics more often for animals than for artifacts (Gelman & Tardif, 1998; Gelman, Coley, Rosengren, Hartman, & Pappas, 1998; Goldin-Meadow, Gelman, & Mylander, 2005; Brandone & Gelman, 2013). This is highly suggestive that environmental input in the form of generic language usage may play a role in children's early acquisition of essentialised beliefs.

However, the generality of these studies are limited somewhat because they all involved highly structured tasks, often with stimuli specifically created for the experiment. To our knowledge only one study has explored truly *naturalistic* generic language use. Gelman, Sarnecka, and Flukes (2008) hand-coded six corpora for generic language use and found the same bias toward generics in animates over artifacts.

Our work here builds on and extends this research by presenting an automatic model of generic identification. After validating its performance against several external metrics, we apply it to 26 different CHILDES corpora (including the six original ones). Our goal with this larger dataset was to learn more about the range of variation in generic usage in natural speech with children. Are generics used less with artifacts for all corpora, at all ages, and for all speakers? Do the patterns in generic usage support the possibility that psychological essentialism may reflect (or lead to) the statistics of generic speech in the linguistic environment?

Method

The first contribution of our work is the creation of a novel model that can automatically identify generic noun phrases based only on syntactic information. We describe it here.

Model

Although several models for the automatic identification of generic noun phrases exist, they are not ideal for our purposes. For instance, Reiter and Frank (2010) use a Bayesian Network model that relies on a feature set consisting of a large range of both the syntactic and semantic features of the noun itself as well as the clause it is contained in. Example syntactic features include COUNTABILITY, NUMBER, and PART OF SPEECH, while semantic features include SENSE and GRANULARITY. Friedrich and Pinkal (2015) use a conditional random field to label sequences but rely on a similar range of features, both syntactic and semantic.

The reliance on semantic as well as syntactic features is not a problem in general, but does pose an issue for us since our central questions focus on the semantic properties of generic nouns. Do they tend to be animates, artefacts, or something else? We cannot answer this question with a model that identifies generics using semantic features, since any results might emerge due to biases in how the model uses that semantic in-

Word	Part of speech	Dependency label
Elephants	noun	nsubj
do	verb	aux
not	adv	neg
eat	verb	ROOT
birds	noun	dobj
.	punct	punct

Table 1: Example sentence along with the two features used by our model: part of speech and dependency label, which indicates the role each word plays in the syntactic structure.

formation rather than actual distributional properties of the language. We therefore developed a new model of our own which relies only on syntactic features.

Structure Our model is a deep neural network classifier which makes decisions about noun phrases based on their syntactic properties as well as the syntactic properties of other words in the same clause. It therefore incorporates a notion of (local) context: an important consideration when identifying generics because the same word may or may not be a generic depending on how it is used. For instance, the word "dogs" in the sentence *Dogs like to bark* is generic, but the same word in the sentence *Dogs at Pat's house like to bark* is not.

Our classifier was constructed by stacking two different kinds of neural network units together. The first, Long Short-Term Memory (LSTM) units, are especially appropriate to classifying sequence-based data such as words in a sentence, and are widely used in many natural language applications (Hochreiter & Schmidhuber, 1997). We also used Gated Recurrent Units (GRUs) which are similar to LSTMs but often achieve higher performance on smaller datasets like ours. Our model consisted of seven different independently-trained architectures which varied from each other in the dimensionality of the units as well as in how they were stacked.[1]

All of the architectures had a final, fully-connected layer with a softmax activation function which performed the classification task. Each architecture yielded one decision for each noun (generic vs not-generic) and model decisions were made by taking the majority vote among the seven.

Input Our model required two kinds of syntactic information for each of the words in our corpora: the part of speech as well as the dependency label it was associated with in the dependency parse tree. Table 1 illustrates these features for an example sentence. In order to extract this information, we used a number of standard state-of-the art natural language processing tools. We first segmented each of the nouns and their corresponding clauses out of each sentence using the discourse parser SPADE (Soricut & Marcu, 2003). Each word was then assigned a dependency label using the Stanford Dependency Parser (Chen & Manning, 2014) and then tagged with the appropriate part of speech (Toutanova, Klein, Manning, & Singer, 2003).

[1]Our anonymised supplementary materials describe the structure of the architectures: `https://tinyurl.com/ybwg88h5` .

Model	Accuracy	F-score
Reiter and Frank (2010)	71.7	72.3
Friedrich and Pinkal (2015)	79.1	78.8
Our model	76.4	79.3

Table 2: Cross-validation performance on the WikiGenerics dataset. Our model achieves similar performance to the state-of-the-art. Accuracy reflects the total percentage of correct predictions (generics classified as generics, and non-generics as non-generics) while F-score is the harmonic mean of precision and recall, as calculated in Friedrich and Pinkal (2015).

Pronouns posed an interesting dilemma, because they make up a reasonable proportion of all nouns yet cannot be accurately classified for their genericity without determining their referent. For instance, the word "they" in the sentence *Watch out for the piranhas in that fish tank; they bite* is not generic, whereas the word "they" in *I hate mosquitoes; they bite* is generic. We addressed this issue by resolving the coreference of each pronoun using a standard coreference resolution system (Clark & Manning, 2016), and then assigning the genericity of the pronoun to be the same as its referent.

Using these part of speech and dependency features, we created input vectors for our model that corresponded to each noun along with the sequence of words in the clause. This means that for each noun, the model was given not just the noun but also all of the words in the NP it was part of and all of the words in the clause that contained that NP. Each input vector was a concatenation of two vectors consisting of the part-of-speech tag and the dependency label. The model thus used all of the words in the sequence to make a decision about each noun, not just the words that came before it.

Training and validation Each of our seven architectures was trained independently using a weighted categorical cross entropy loss function, which we optimised using the Adam optimiser (Kingma & Ba, 2014). Our loss function weighted the error associated with classifying a non-generic statement as generic (false positive) 1.5 times more than the error associated with classifying a generic statement as non-generic (false negative). By using such a weighted error function, we ensured that the classifier was conservative in its classification of generics, marking a noun as a generic only when it was very confident. This helped to ensure that our model was not overestimating the proportion of generic words.

Before applying our model to CHILDES corpora, we validated its performance in two ways. First we calculated its accuracy and F-score on the WikiGenerics dataset created by Friedrich and Pinkal (2015). This dataset consists of examples from 102 documents from Wikipedia covering a wide variety of topics including animals, games, medicine, music, politics, science, and people, among others. The texts were hand-annotated for genericity by three computational linguists, with contested annotations decided by majority vote. We tested our model using as leave-one-out cross validation strategy. In each cross validation step, examples from 101 of the 102 texts were used for training and the model was tested on the remaining one. The results, shown in Table 2, show

that despite relying on a much smaller range of features our model performed as well as the two best-performing models of generic identification.[2]

Although this level of performance is reassuring, it is not necessarily the case that high performance on a dataset consisting of Wikipedia articles means that the model can accurately identify generics in corpora of child with children. As a second validation of model performance, we thus tested its accuracy against the genericity judgments reported in Gelman et al. (2008).[3] The data we had access to consisted of all of the nouns (in the child speech only) in their six corpora that they coded as generic. Our model had a 88% true positive rate on this data: 88% of the items that they coded as generic were coded as generic by our model. We do not have the list of nouns that they coded as non-generic, but on the assumption that any nouns not coded as generic would have been coded as non-generic, this gives our model an accuracy of 96.8 and an F-score of 81.2 against their gold standard.

CHILDES Datasets We applied our model to 26 different corpora from the CHILDES database (MacWhinney, 2000). The corpora, which are listed in full in the supplemental materials, include the six corpora from Gelman et al. (2008) as well as twenty additional corpora made up of natural conversations between children and adults in English (American or UK). All corpora include both adult and child speech except one (Sawyer) which contained only child speech. Because we were interested in the statistics of language in naturalistic situations, we excluded studies in which children were given a structured task or played with a restricted set of toys.

The supplemental materials list all corpora in detail, but in general, the children ranged in age from less than one year to over five years of age. Given the difficulty in identifying generic usage when grammatical abilities are limited, we excluded all child speech from children less than two years old. However, we do include adult speech to these children because one of our goals with this work is to better understand the distributional properties of the linguistic input they receive at all ages. Our full corpus of child speech contained 1,057,807 utterances total and the corpus of adult speech contained 1,595,305 utterances.

Results

Our first question is about the prevalence of generic speech as a function of age. For the child corpora, we can ask when children begin producing generics. For the adult corpora, we can ask whether adult speech is rich in generics from an early age, and whether there are developmental trends in generic usage. We thus calculated the proportion of generic utterances at different age ranges, coding an utterance as generic if any noun in it was classified as generic. Our results are shown in Figure 1, plotted alongside similar data from Gelman et al. (2008). Although we show more generic usage overall than did Gelman et al. (2008), the patterns are remarkably similar. Children's production increases rapidly over the early years of development, with them producing generics as soon as they have the grammatical capacity. In the early years, adult production is consistently higher than children's, but it then levels off at later ages until they converge. We consider reasons that we estimate more generics in the Discussion.

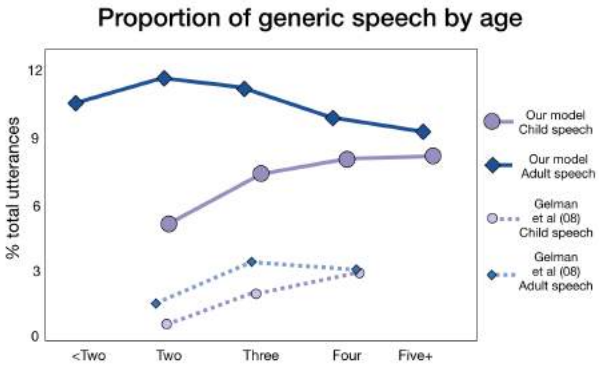

Figure 1: Proportion of generic speech by age. The overall percentage of all utterances coded as generic in our corpora (solid line), broken down by child and adult speech (purple and blue, respectively). For comparison, we plot analogous results from Gelman et al. (2008) with the dotted line. Although we estimated more total generics than they did, the qualitative patterns over development and between child and adult speech are extremely similar.

The primary question motivating this work was how generic usage differs between different kinds of nouns. Do animates, which both children and adults essentialise more, occur more often in generic speech than artefacts, which are essentialised less? In order to investigate this question we had to assign each of the nouns in our corpus to the appropriate category. We accomplished this based on the categories in WordNet, a widely-used lexical database for English. WordNet contains 22 different noun categories, including animals, artifacts, and people as well as feelings, communications, plants, motives, substances, time, and more.

We classified all of our nouns into the four categories used by Gelman et al. (2008): animates, artifacts, food, and other. The artifact and food categories correspond straightforwardly to equivalent categories in WordNet. We constructed our animates category by combining the WordNet animal and person categories, and classified everything else as other. If a word was associated with multiple WordNet categories, we used the Lesk Algorithm to determine which one to assign it to. This algorithm uses the words in the surrounding context to determine the appropriate classification. For instance, the word *fish* would be classified as an animal if it was surrounded by words like *swim* or *water* and as a food if it was surrounded by words like *eat* or *cook*.
