COGSCI'19

Creativity+Cognition+Computation

24 - 27 JULY 2019 MONTREAL, CANADA

Invited Speakers

Elizabeth Churchill | Mary Lou Maher | Takeshi Okada

Co-Chairs

Ashok Goel | Colleen Seifert | Christian Freksa

Introduction

Dear Cognitive Science Colleagues,

Welcome to the 41st Annual Conference of the Cognitive Science Society in Montreal, Canada! Our meeting brings together some of the most innovative and exciting research in Cognitive Science today, and highlights the conference theme of *Creativity + Cognition + Computation*.

In addition to the Rumelhart Prize presentation by Michelene Chi and the Carvalho-Heineken Prize presentation by Nancy Kanwisher, the program features three plenary speakers: Elizabeth Churchill (Google Research), Mary Lou Maher (University of North Carolina), and Takeshi Okada (University of Tokyo). Further, the program includes the Jacobs Foundation Symposium, *How Curious? The Need for Exploration and Discovery*, as well as an invited symposium on *Creativity in the Arts* in addition to the Rumelhart Symposium on *Translation Research in STEM Learning* and the Glushko Ph.D. Dissertation Awards Symposium.These invited symposia and talks showcase the conference theme.

The program committee for CogSci 2019 received 1110 submissions, including 810 full papers, 256 member abstracts, 13 publication-based short papers, as well as 14 proposals for symposia, 10 for workshops, and 8 for tutorials. After a rigorous review process, the committee selected 202 papers for oral presentation and inclusion in the conference proceedings (25%), 306 papers for poster presentation and inclusion in the proceedings (38%), and 163 papers for poster presentation with inclusion of abstracts in the proceedings (20%). We also selected 204 submitted member abstracts and accepted another 19 abstracts from full paper submissions as invited member abstracts. In addition, we accepted 12 publication-based talks, 10 symposia, 7 workshops, and 4 tutorials to make for a very rich and inclusive program.

We hope that you enjoy the program this year as well as the beautiful city of Montreal!

Your Program Co-Chairs,
Ashok Goel (Georgia Institute of Technology, USA)
Colleen Seifert (University of Michigan, USA)
Christian Freksa (University of Bremen, Germany)

Acknowledgements

We are very grateful to everyone who contributed to the planning and organization of this year's Cognitive Science meeting, to all authors who submitted their contributions, and to all reviewers who generously donated their expertise and time to evaluate the submissions. We thank the members of the Program Committee who coordinated the reviews and made the tough decisions about submissions, and the members of the conference organizing subcommittees who showed initiative in completing their demanding tasks. These Organizing and Program Committee members are listed below.

We are especially grateful for the assistance of a number of individuals and groups critical to handling the many organizational aspects of the meeting. We thank Michael Frank, the Chair of the Cognitive Science Society, Anna Drummey, the Executive Officer of the Society, and the entire Governing Board of the Society, for their advice and support throughout the process. Lily Chang at *International Conference Services*, Jude Ross at *Podium Conferences*, and James Stewart at *Precision Conference Solutions* have been helpful, effective, and constant partners during the long process. Chuck Kailish and Timothy Rogers, two of the Co-Chairs of last year's conference, offered help whenever we needed them. Additional help included key contributions from Thomas Barkowsky for the reviewing process, Andrea Patalano for the awards organization, and Sungeun An for creating the conference poster.

Finally, we are grateful to the Cognitive Science Society and to the sponsors of this conference, including the Robert J. Glushko and Pamela Samuelson Foundation, the Jacobs Foundation, Facebook AI, DeepMind Technologies and the Weinberg Institute of Cognitive Science for their support.

Enjoy!

Ashok Goel, Colleen Seifert, and Christian Freksa

Awards

Robert J. Glushko Dissertation Prizes

The Cognitive Science Society and the Glushko-Samuelson Foundation award up to five outstanding dissertation prizes in cognitive science each year. The goals of these prizes are to increase the prominence of cognitive science and encourage students to engage in interdisciplinary efforts to understand minds and intelligent systems. The hope is that the prizes will recognize and honor young researchers conducting ground-breaking research in cognitive science. The eventual goal is to aid in efforts to bridge between the areas of cognitive science and create theories of general interest to the multiple fields concerned with scientifically understanding the nature of minds and intelligent systems. Promoting a unified cognitive science is consistent with the belief that understanding how minds work will require the synthesis of many different empirical methods, formal tools, and analytic theories. 2011 was the inaugural year of this prize, and a new competition is held annually. The 2019 recipients of the Robert J. Glushko Prizes for Outstanding Doctoral Dissertations / Theses in Cognitive Science are:

Kirsten Adam – University of Chicago, 2018
Characterizing the Limits of Visual Working Memory

Max Kleiman-Weiner – **Massachusetts Institute of Technology, 2018**
Computational Foundations of Human Social Intelligence

Martin Maier – Humboldt University, 2018
Language, Meaning, and Visual Perception: Event-Related Potentials Reveal Top-Down Influences on Early Visual Processing

Jean-Paul Noel – Vanderbilt University, 2018
Leveraging Multisensory Neurons, Circuits, Brains, and Bodies to Study Consciousness: From the Outside-In and the Inside-Out

Katharine Tillman – University of California, 2017
Constructing the Concept of Time: Roles of Language, Perception, and Culture

Marr Prize

The Marr Prize, named in honor of the late David Marr, is awarded to the best student paper at the conference. All student first authors were eligible for the Marr Prize for the best student paper. The Marr Prize includes an honorarium of $1000 and is sponsored by The Cognitive Science Society. The winners of the 2019 Marr Prize for the Best Student Paper is:

Jose M. Ceballos, University of Washington, *The Role of Basal Ganglia Reinforcement Learning in Lexical Priming and Automatic Semantic Ambiguity Resolution*

Nicolas Oliver Riesterer, Universität Freiburg, *Modeling Human Syllogistic Reasoning: The Role of "No Valid Conclusion"*

Computational Modeling Prizes

Four prizes worth $1000 each are awarded for the best full paper submissions to CogSci 2019 that involve computational cognitive modeling. The four prizes represent the best modeling work in the areas of perception/action, language, higher-level cognition, and applied cognition. These prizes are sponsored by The Cognitive Science Society. The winners of the 2019 Computational Modeling Prizes are:

Applied Cognition:

Douglas Guilbeault, University of Pennsylvania, *The Social Network Dynamics of Category Formation*

Higher-Level Cognition:

Ardavan S. Nobandegani, McGill University, *A Resource-Rational Process-Level Account of the ST. Petersburg Paradox*

Perception & Action:

Yunyan Duan, Northwestern University, *A Rational Model of Word Skipping in Reading: Ideal Integration of Visual and Linguistic Information*

Language:

Benjamin Peloquin, Stanford University, *The Interactions of Rational, Pragmatic Agents Lead to Efficient Language Structure and Use*

Sayan Gul Award

Sayan Gul was an undergraduate at UC Berkeley studying cognitive science and computer science, and had great potential as a cognitive scientist. He died tragically while traveling to the Annual Conference of the Cognitive Science Society for the presentation of his research. This award is intended to support similarly outstanding undergraduates conducting research in cognitive science. In honor of Sayan Gul, the Sayan Gul Award supports undergraduate students with travel related costs who are presenting authors at the conference. The Sayan Gul Award includes a cash award of $500. This year's winner of the award is:

Megumi Sano, Stanford University, *Graphical Convention Formation During Visual Communication*

Diversity & Inclusion Travel Awards

Five prizes will be award to support travel to the conference for graduate students who bring diversity to the society, in particular under-represented racial/ethnic groups and citizens of under-represented countries (Zone B Society members) who are presenting at the conference. Each travel award includes a cash award of $1,000. This year's travel awards recipients are:

Jose M. Ceballos, University of Wisconsin, *The Role of Basal Ganglia Reinforcement Learning in Lexical Priming and Automatic Semantic Ambiguity Resolution*

Tania Delgado, University of California San Diego, *Differences in Learnability of Pantomime Versus Artificial Sign: Iconicity, Cultural Evolution, and Linguistic Structure*

Nianyu Li, Peking University, *A Conceptual Model of Self-Adaptive Systems Based on Attribution Theory*

Che Lucero, Cornell University, *Unconscious Number Discrimination in the Human Visual System*

Mukesh B. Makwana, Centre of Behavioural and Cognitive Sciences, Mumbai, *Hands in Mind: Learning to Write with Both Hands Improves Inhibitory Control, but Not Attention*

Guilherme Sanches de Oliveira, University of Cincinnati, *Bee-ing In the World: Phenomenology, Cognitive Science, and Interactivity in a Novel Insect-Tracking Task*

Staci Meredith Weiss, Temple University, *Individual Differences in Bodily Attention: Variability in Anticipatory Mu Rhythm Power Is Associated with Executive Function Abilities and Processing Speed*

Student Travel Awards

The Robert J. Glushko and Pamela Samuelson Foundation generously sponsored $10,000 for student travel awards. Travel awards have been provided to students whose submissions were accepted as full papers, received high rankings, and who indicated a need for travel funding. This year's travel awards went to:

Nicolas Collignon, University of Edinburgh
Douglas Guilbeault, University of Pennsylvania
Ethan Hurwitz, University of California, San Diego
Akila Kadambi, University of California, Los Angeles
Kei Kashiwadate, Deniki University
Lara Kirfel, University College London
Sang Ho Lee, Ohio State University
Ashley Leung, University of Chicago
Mahi Luthra, Indiana University
Olivia Miske, Arizona State University
Sebastian Musslick, Princeton University
Benjamin Peloquin, Stanford University
Nicolas Riesterer, University of Freiburg
Harrison Ritz, Brown University
Jennifer Sloane, University of New South Wales
Leila Straub, ETH Zurich
Karina Tachihara, Princeton University
Charley Wu, Max Plack Institute for Human Development
Yueyuan Zheng, University of Hong Kong

Heuristics, hacks, and habits: Boundedly optimal approaches to learning, reasoning and decision making

Ishita Dasgupta[1], **Eric Schulz**[1], **Jessica B. Hamrick**[2] & **Joshua B. Tenenbaum**[3]
[1]Department of Psychology, Harvard University
[2]DeepMind, London, UK
[3]Department of Brain and Cognitive Sciences, Massachusetts Institute of Technology

Humans regularly perform tasks that require combining information across several sources of information to learn, reason, and make decisions. Bayesian models provide a computational framework, and a normative account, for how humans carry out these tasks. However, exact inference is intractable in most real-world situations, and extensive empirical work shows that human behavior often deviates significantly from the Bayesian optimum. A promising possibility is that people instead approximate rational solutions using bounded available resources. In this workshop, we bring together leading researchers from cognitive science, neuroscience and machine learning to build a better understanding of bounded optimality in how humans learn, reason and make decisions.

Keywords: Heuristics; Resource rationality; Reasoning; Decision making; Reinforcement learning; Machine learning

Introduction

This workshop will cover work that casts human and machine learning, decision making and reasoning as *boundedly optimal*. In particularly, we will focus on meta-reasoning, reinforcement learning, active information acquisition, and probabilistic reasoning.

The notion that the mind approximates rational (Bayesian) inference has had a strong influence on thinking in psychology since the 1950s. However, people deviate from Bayesian ideals in several well-documented instances (6), giving rise to the idea that they rely on heuristic rules instead (5). Nonetheless, people can behave in ways that approximate Bayesian inference in complex domains such as (active) learning (2), reasoning (1) and decision making (14). How can these apparently contradictory findings be explained?

One idea is that people approximate rational solutions using limited available resources, a proposal often discussed under the terms of resource or computational rationality (4; 7). In light of limited resources, boundedly optimal solutions to complex problems can take the form of sampling-based approximations (3), simplified decision rules (13), pruning of low-value options (9), or through an adaptation of information acquisition to the structure of the task (12). However, how exactly the different approaches should be combined to produce a fully-developed theory of bounded optimality that transfer across domains and tasks is still an open question, with some researchers proposing that intelligent agents can meta-reason about which strategies to apply (10), and others stressing the connections between heuristic and Bayesian inference (11) and the role of inductive biases (8).

Goal and scope

The aim of this workshop is to bring together scientists who have a joint interest in how resource-constrained agents solve realistic problems, such as making decisions, finding rewards, acquiring information or reasoning and learning about the world. We have invited leading researchers from cognitive science and machine learning interested in the computational foundations of bounded optimality. In particular, our goal is to facilitate discussion and help build a more unified notion of rationality that takes resource and computational limitations into consideration. Key questions of discussion will include:

- How can we formalize theories of bounded optimality?
- What is a good framework and what are good domains in which to benchmark progress in developing such theories?
- What can we learn from past debates on and formalizations of rationality?
- Do agents learn different context-specific boundedly optimal strategies? How might they recognize when to apply which strategy?
- What does a bounded agent optimize, if at all? How can bounded optimality cope with the curse of dimensionality?

Target audience

This workshop fits well with this year's focus on "Creativity + Cognition + Computation". These key elements of cognition are precisely those that drive modern accounts of bounded optimality and are features of human intelligence that modern theories of rationality seek to explain. Our target audience is interdisciplinary and almost as broad as the conference as a whole — we expect this workshop to be of interest to cognitive psychologists, linguists, developmental psychologists, neuroscientists, philosophers and machine learning researchers alike. The workshop's webpage can be found at: https://hacksandhabits.github.io

Organizers and presenters

Ishita Dasgupta (Organizer) is a PhD-student at Harvard University working in Samuel Gershman's Computational Cognitve Science lab. Ishita's work explores how people and machines make resource rational approximations to difficult problems, in particular in the domains of probability estimation, hypothesis generation, and intuitive physics.

Eric Schulz (Organizer) is a Data Science Postdoctoral Fellow at Harvard University. Eric studies generalization as function learning with a particular focus on compositionality and reinforcement learning.

Jessica B. Hamrick (Organizer) is a Research Scientist at DeepMind. Her research focuses on cognitive science-inspired theories of machine learning. In particular, she focuses on the role of mental simulation and resource rational approximations.

Joshua B. Tenenbaum (Organizer) is Professor of cognitive science at MIT. Josh's lab sits at the intersection of cognitive science and machine learning, with a focus on hallmarks of human intelligence; in particular, the ability to learn efficiently and flexibly from limited data.

Paula Parpart is a postdoc at the University of Warwick working with Prof. Neil Stewart. Her research has focused on reconciling heuristic and Bayesian views of rationality in decision making.

Falk Lieder leads the Rationality Enhancement Group at the Max Planck Institute for Intelligent Systems in Tübingen. His mission is to build a scientific foundation and practical tools for helping people become more effective by supporting cognitive growth, goal setting, and goal achievement.

Tom Griffiths is a Professor of Psychology and Computer Science at Princeton University. Tom develops mathematical models of higher level cognition to understand the formal principles that underlie people's ability to solve everyday computational problems.

Özgür Şimşek is a Senior Lecturer in Machine Learning at the University of Bath. Her research is on algorithms that can learn from limited experience in complex, real-word environments, with a focus on reinforcement learning.

Neil Bramley is a Lecturer of Cognitive Psychology at the University of Edinburgh. His work focuses on how people actively construct and use causal models to guide their interactions with the natural world.

Azzurra Ruggeri is a Max Planck Research Group Leader at the MPI for Human Development in Berlin. Her research focuses on how children and adults actively search for information when making decisions, drawing causal inferences and solving categorization tasks.

Kelsey Allen is a graduate student advised by Josh Tenenbaum at MIT. She uses computational models and behavioral experiments to study the development of intuitive theories, in particular intuitive physics in planning and reinforcement learning contexts.

Peter Dayan is a director at the Max Planck Institute for Biological Cybernetics in Tübingen. His research focuses on the computational neuroscience of learning and decision making, with a focus on neuromodulation, meta-control and computational psychiatry.

Workshop structure

We propose a full-day workshop consisting of three parts. The first two parts will be a series of 20 minute talks. The final part will be a panel discussion about the limits and future of bounded optimality in cognitive science.

The morning session will consist of the following talks:

Presenter	Topic
Eric Schulz	Optimizing with confidence
Paula Parpart	Heuristics as Bayesian inference
Falk Lieder	Learning how to decide
Ishita Dasgupta	Learning to infer
Josh Tenenbaum	Computational rationality

The afternoon session will consist of the following talks:

Presenter	Topic
Jessica Hamrick	Resource-rational mental simulation
Tom Griffiths	Bridging Marr's levels
Özgür Şimşek	Exploiting the statistical properties of decision environments
Neil Bramley	Neurath's ship: Incremental active theory-building
Azzurra Ruggeri	Ecological active learning
Kelsey Allen	Hacks in intuitive theories
Peter Dayan	Slothful serial; perilous parallel processing

The final 45 minutes will be a *panel discussion*.

Guided Playful Learning: Developmental, Computational, and Educational Perspectives

Emily N. Daubert (emily.daubert@rutgers.edu)
Department of Psychology, 101 Warren Street
Newark, NJ 07102 USA

Patrick Shafto (patrick.shafto@gmail.com)
Department of Mathematics and Computer Science, 110 Warren Street
Newark, NJ 07102 USA

Keywords: guided play; computational modeling; science of learning; playful learning

Workshop Summary

Learning is a continuous process that is contingent on temporal, developmental, and social factors. Well-timed guidance is critical for successful learning. Further, the needs of learners vary with their stage of development, and the social context in which learning takes place has important implications for learning. Researchers from a variety of backgrounds, including cognitive development, computational modeling, and education have explored these various components in isolation, however, understanding learning requires the examination of the interactions between the temporal, developmental, and social factors involved.

Interactions among these factors are of critical importance in fields such as cognitive development, computational modeling, and education. Take, for example, educational settings, where didactic approaches such as direct instruction have been favored over more free-play based approaches (Stockard & Engelmann, 2008). In direct instruction, learning is not just social, it is adult-initiated and adult-led, and by its nature less responsive to temporal factors that may affect a learners performance. Free play, in contrast, allows the learner to lead, which allows greater responsivity to temporal changes. Aside from the developmental merits, the debate between direct instruction and free play is emblematic of the need for a better understanding of how the social and temporal components interact to foster learning (Yu et al., 2018). Similar issues arise in the developmental and modeling literatures.

Recently, guided playful learning has been put forth as an integrative child-led, adult-assisted approach for promoting learning. However, many unanswered questions remain regarding the interplay of factors involved in guided playful learning. The goal of this workshop is to bring together an interdisciplinary group of researchers, with expertise in cognitive development, computation, and education in an effort to merge these separate literatures, draw general conclusions, and develop directions for future research.

Research in cognitive development on the effectiveness of guided playful learning is mixed. There is some evidence that guided learning is more effective than adult-led discovery (i.e. direct instruction) and unassisted discovery (i.e. free play) for promoting learning in children (Honomichl & Chen, 2012). However, some research indicates that direct instruction is equally, if not more effective, in achieving explicit learning goals (Becker & Gersten, 1982). Others still find that there is no substitute for the wide-ranging benefits of child-initiated free play, which is intrinsically motivated (Rubin, Fein, & Vandenberg, 1983). One possible reason for the differing conclusions is different definitions of guidance, which have included questioning, modeling, enhanced materials, and feedback. Thus, it remains unclear what kinds of guidance are most effective for promoting learning. Understanding the nature of effective guidance will also help to clarify the underlying cognitive mechanisms that lead to changes in children's knowledge.

In computational modeling, there has not yet been significant progress toward an understanding of guided playful learning. Research has investigated free exploration. Two versions of this that are prominent in the literature are active learning, which is commonly formalized as maximizing Expected Information Gain of the next observation (Russo & Van Roy, 2014), and reinforcement learning which maximizes expected reward over time (Niv et al., 2015). Research has also investigated instruction. For example, models have formalized selection of data by a knowledgeable and helpful teacher as well as formalized learning from such data, where the learner reasons both about the data and the teacher's intent (Shafto, Goodman, & Griffths, 2014). Guided playful learning lies at the nexus of these three themes, where guidance aims to foster learning over time through self directed exploration. Moreover, guided playful learning requires modeling of when to provide guidance, which adds layer of complexity not considered in this previous work.

In education, researchers have asked if guided playful learning is effective in various domains of learning. Specifically, guided playful learning may be more effective in domains in which learning is promoted through child-led exploration, as with causal learning (Bonawitz et al., 2011). Similarly, guided playful learning may promote learning in domains in which child engagement is crucial, such as literacy (Lillard & Else-Quest, 2006). But it remains unclear if guided learning is effective in domains that are

traditionally associated with rote memorization, such as mathematics. In addition, educational researchers have focused on the role of individual differences in guided playful learning. The effectiveness of guidance content can be influenced by individual differences, such as children's cognitive style, background knowledge, socioeconomic status, and language learner status.

Developing a unified theoretical and empirical understanding of guided playful learning will allow for the discovery of the complex interplay of temporal, developmental, and social factors in children's learning. By bringing together researchers from traditionally distinct communities, we hope to begin to answer this foundational set of questions about the nature of cognition.

Workshop Structure

The workshop will feature well-known experts from different fields. The workshop will also invite poster submissions from the broader cognitive science community, with "poster teasers" flash talks related to guided playful learning. Additionally, the schedule has built in ample time for questions for mini-panels of each sub-area of guided playful learning, ensuring maximum opportunity for audience engagement.

Proposed Schedule

9:00-9:15: Opening Remarks (Elizabeth Bonawitz)

9:15-10:45: The Role of Play in the Development of Knowledge

Roberta M. Golinkoff *"A helping hand: Adult-infant play and infant category learning"*

Using replication studies to teach research methods in cognitive science

Joshua R. de Leeuw (jdeleeuw@vassar.edu)
Jan Andrews (andrewsj@vassar.edu)
Ken Livingston (livingst@vassar.edu)
Department of Cognitive Science, Vassar College

Michael Franke (mchfranke@gmail.com)
Institute for Cognitive Science, University of Osnabrück

Josh Hartshorne (joshua.hartshorne@bc.edu)
Department of Psychology, Boston College

Robert Hawkins (rxdh@stanford.edu)
Department of Psychology, Stanford University

Jordan Wagge (jordan.wagge@avila.edu)
Department of Psychology, Avila University

Keywords: pedagogy; replication; research methods; education

Overview

Some instructors of research methods classes are conducting authentic (i.e., publishable) replication studies with their classes (de Leeuw et al., 2018; Hartshorne et al., 2019; Hawkins et al., 2018; Leighton, Legate, LePine, Anderson, & Grahe, 2018; Wagge et al., 2019). This practice has, potentially, both pedagogical benefits for students and broader benefits for the scientific community (Frank & Saxe, 2012; Standing et al., 2014). Students experience an authentic research process from design through publication, providing opportunities for instruction on many different aspects of the research pipeline. When done with care, replications from the classroom become a valuable part of the scientific literature, and students fulfill an underserved role in science: performing direct replications (Everett & Earp, 2015).

Adding authentic replication work to a research methods class naturally raises many questions about pedagogy and implementation. What studies should be replicated? How can an appropriate sample for the replication be obtained, especially at small institutions? What can instructors do to ensure that students, who may be conducting research for the first time, are able to produce quality work that meets the standards of publication? What aspects of the research process should students contribute the most to, and what aspects should be controlled by the instructor?

There are many reasonable answers to these questions. With the growing adoption of replication studies in courses, a diverse set of classroom-tested approaches now exists. This creates the possibility for sharing, synthesizing, and improving teaching strategies, which is the goal of this workshop. This workshop brings together instructors who have conducted replication work with their research methods classes to discuss their successes and failures. These instructors have taught classes at the undergraduate and graduate level. Students in the classes have conducted behavioral studies (both in-lab and online) and EEG studies. The classes vary in structure (students may work as an entire class, in small groups, individually, or as part of a larger collaborative endeavor across many classes) and points of emphasis in the research process.

Workshop Structure

This is a half-day workshop. The first portion of the session will feature presentations from instructors (listed below) describing how replication studies have been utilized in their classes and how replication studies fit into the broader pedagogical goals of the class. In the second portion of the workshop, the presenters will discuss questions from the audience and a moderator in a panel format. Audience contributions to the discussion will be welcome.

Target Audience

The workshop welcomes anyone with an interest in teaching research methods, including both current instructors and students and postdocs who plan to teach research methods in the future. We hope that workshop attendees will leave with concrete ideas for how to incorporate replication work into their own research methods classes.

Presenters

Josh de Leeuw, Jan Andrews, & Ken Livingston (Vassar College) have co-taught undergraduate Research Methods in Cognitive Science. In their course, students begin the semester by conducting a replication study and then develop one or more novel follow-up experiments. They will discuss how conducting a replication prepares students to design and execute their own original research, and how

working with undergraduate students on drafting a manuscript for submission to a journal provides a different kind of opportunity for teaching scholarly writing.

Jordan Wagge (Avila University) is the Associate Director of the Collaborative Replications and Education Project (CREP), a project that promotes and scaffolds crowdsourced replication work through student research. She will discuss how CREP can support replication work in methods courses, including sample assignment guidelines for instructors who seek to incorporate CREP work into their courses.

Joshua Hartshorne (Boston College) has taught three iterations of his course Language Acquisition & Development. Although not a methods course, it contains a substantial lab component. Through a series of group projects, each class of approximately 10 students completes 5-6 replications. The presentation will discuss how to incorporate a lab component into a content class. It will also discuss how to use replications as a vehicle for teaching programming, statistics, and best practices.

Robert Hawkins (Stanford University) recently led a classroom replication effort as part of the graduate course "Lab in Experimental Methods". In this course, each student chooses a paper to replicate based on their own research interests and proceeds independently through a structured series of milestones with supervision from instructors. The presentation will discuss this pedagogical workflow, how the replication model can be adapted for students of different levels, and the challenges that arise in managing a wide diversity of projects.

Michael Franke (University of Osnabrück) has taught two classes that combine undergraduate/graduate levels with a dual focus: one on theoretical issues concerning reproducibility and open science, and another on conveying first practical experiences with behavioral experiments by means of a replication project. The courses required students to preregister their replication and make all analysis scripts available prior to data collection. The presentation will discuss the challenges and opportunities of making especially undergraduates appreciate solutions (e.g., preregistration & large-scale replications) to problems (e.g., abundant researcher degrees of freedom) they have not experienced first-hand yet.

Measuring Creativity - Workshop Proposal

Ana-Maria Olteţeanu (ana-maria.olteteanu@fu-berlin.de)
Human-Centered Computing, Freie Universität Berlin,
Germany

Keywords: creative cognition; creativity psychometrics; creative problem solving; computational modelling; computational creativity; creativity metrics and methods; intelligent systems; creativity assistive systems

Workshop Proposal

Various methods exist for measuring creativity, most of them in the form of creativity tests, like the Remote Associates Test [Mednick, 1962], the Alternative Uses Test [Guilford, 1956], TTCT [Kim, 2006], the Wallach-Kogan tests [Wallach and Kogan, 1965], insight problems [Maier, 1931, Duncker, 1945, Cunningham et al., 2009], etc.

However, the feasibility and dependability of various types of psychometric assessment and administration of measures, as pertaining to various creativity tasks, have recently been questioned and enriched [Beisemann et al., 2018, Hass, 2015, Hass et al., 2018, Hass and Beaty, 2018, Wilken et al., 2018]. The thought and work on the measurement of creativity are witnessing a new revival.

Recently, new methods of computationally creating stimuli for greater measurement accuracy have been developed [Olteţeanu et al., 2017, Olteţeanu, 2016, Olteteanu and Yoopoo, 2017], inspired by artificial cognitive systems that solve creativity tests [Olteţeanu et al., 2018]. Such computational psychometrics methods have already shown to provide designs with greater control [Olteţeanu and Schultheis, 2017] and the computational resurrection of tests which were initially proposed theoretically [Olteţeanu et al., 2018].

This workshop will focus on building a red thread of discussion on the current state of creativity psychometrics, integrating topics on existing classic and novel, manual and computational methods of testing and measuring creativity. The following questions will be addressed:

(i) What creativity measuring methods exist and what are their strengths and weaknesses?
(ii) Which creativity factors are measured by the existing creativity methods? Is there an overlap of measuring methods for different factors? Are they factors for which no methods exist or current methods are not yet up to the task?
(iii) What is the suitability of existing current methods for empirical testing versus computational modelling?
(iv) How can comparability be ensured across creativity test item sets?
(v) What creativity metrics and methods can be used in evaluating the computational modeling of creativity?
(vi) What is the impact of artificial cognitive systems and their evalution on creativity metrics? Of computational creativity systems and their evaluation?
(vii) What are the new computational and automatized measures of creativity, and what is their role in the ecosystem of measures?
(viii) Subjective and objective measures in creativity.

Workshop Duration and Organization

We propose a half a day workshop for the presentation, discussion and elaboration of creativity measuring methods. The workshop will involve three elements:

(i) Three invited speakers from different backgrounds (Cognitive Psychology, Cognitive Neuroscience, Cognitive Systems - Computer Science) will present existing creativity measuring methods (details below).
(ii) Short presentations of papers and posters will be accepted on the topic.
(iii) The workshop will end with a panel discussion, focused on establishing future directions for methods and systems aimed at supporting creativity and problem solving.

Publication: The papers submitted for this workshop will be published as a CEUR-WS volume. If enough high quality papers are received, a Special Issue will be proposed by the organizer to the *Cognitive Systems Research* journal, or a topic proposal will be made to TopiCS in Cognitive Science.

Topics for this workshop will be centered around, but not limited to:

- Creative cognition
- Creativity measures and Tests
- Psychometrics for Creative Cognition
- Computational methods for measuring creative cognition
- Computational modelling
- Artificial creative cognitive systems
- Creative problem solving
- Computational Creativity
- Evaluation of natural and computational cognitive systems
- Associativity and Conceptual Spaces
- Semantic networks and semantic graphs
- Ill structured problem solving and Structured representations
- Knowledge discovery
- Creativity modeling approaches and their relation to evaluation, including Case based reasoning, Neural networks, Evolutionary algorithms
- Analogy and Metaphor
- Creative assistive systems

Speakers

- **Richard Hass** – Thomas Jefferson University, US. Talk topic: *Improving Measures on Creative Object Uses*. Background: Cognitive Psychology.
- **Evangelia Chrysikou** – Drexel University, US. Talk topic: *A standardized test for creativity based on the Alternative Uses Task*. Background: Cognitive Neuroscience.

- **Ana-Maria Olteţeanu** – Head of Cognitive Systems, Freie Universitat Berlin– Talk topic: *Computational Measures of Creativity*. Background: Cognitive Systems – Computer Science.

Organizer - Short biography

Ana-Maria Olteţeanu is the Principal Investigator of the „Creative problem solving in cognitive systems" (CreaCogs) project funded by the German Research Foundation (DFG) at the Freie Universitat Berlin, Germany.

Ana-Maria has a cross-disciplinary background: she holds a PhD in Musicology (2011) and a *summa cum laude* Doctorate in Cognitive Systems and Artificial Intelligence (2016). Her thesis got nominated for the EurAI Dissertation Prize, and won the OLB 1st Prize for the best Doctoral Dissertation in Science in NW Germany in the last two years (2017).

Ana-Maria authored more than 30 papers on the topic of creative problem solving, of which five journal articles focus on developing artificial cognitive systems and computational measures for creativity psychometrics. Her book *Cogs in the Creative Machine* will be published by Springer in June 2019. Ana-Maria has reviewed more than 40 papers for over 20 international conferences and journals, and gave over 20 conference and invited talks on creative cognitive systems. Dr. Dr. Olteţeanu has been a program committee member of 15 workshops and conferences in the field. She organized and chaired 4 Symposia/Workshops/conference tracks, and is the editor of four volumes and special issues on creativity related topics. Together with Sebastien Helie, Ana-Maria will write the chapter on *Computational Models of Creativity* in the upcoming edition of The Cambridge Handbook of Computational Cognitive Sciences. Ana-Maria's interests are related to natural and artificial cognitive systems, creative problem solving, cognitive modeling, computational psychometrics, knowledge discovery and spatial reasoning.

Recent Organizing and Editorial Experience

2018 - 2021 – Editorial Board member, Cognitive Systems Research Journal.

2018 – Organizer and Chair of the workshop *Computational Methods and Systems for the Cognitive Modelling and Support of Creativity and Creative Problem Solving*, at the Cognitive Science Conference in Madison, Wisconsin, 2018 (over 50 participants)

2018-2019 – Topic Editor for *Frontiers in Psychology-Cognitive Science* and *Frontiers in Artificial Intelligence and Robotics*, for the Topic *Creativity from Multiple Cognitive Science Perspectives* (with Bipin Indurkhya).

2018-2019 – Guest Associate Editor for *Frontiers in Psychology-Cognitive Science* and *Frontiers in Artificial Intelligence and Robotics*, for the Topic *Creativity from Multiple Cognitive Science Perspectives* (with Bipin Indurkhya).

2017-2018 – Guest editor of the Cognitive Systems Research journal, for the special issue on *Problem-solving, Creativity and Spatial Reasoning in Cognitive Systems* (with Zoe Falomir).

2017 – Editor of the *Proceedings of the 2nd Symposium on Problem-solving, Creativity and Spatial Reasoning in Cognitive Systems*, CEUR-Ws vol. 1869 (with Zoe Falomir).

2017 – Co-organized the *ProSocrates - Problem solving, creativity and spatial reasoning in cognitive systems* Symposium, at the Hanse Wissenschafts-Kolleg, Delmenhorst, Germany.

2016 – Co-organized the *ProSocrates - Problem solving, creativity and spatial reasoning in cognitive systems* Symposium, at the German Cognitive Science Society conference - Space for Cognition, Bremen (Germany).

Keywords: Cognitive Modeling; Syllogistic Reasoning; Individual Modeling; Challenge

Short Summary

Most computational models of cognition are based on aggregate data. In recent years, skepticism about group-to-individual generalizability has begun to emerge (Fisher, Medaglia, & Jeronimus, 2018). Simultaneously, results have shown that the current state in modeling reasoning is approaching a ceiling caused by the focus on aggregation (Riesterer, Brand, & Ragni, 2018). The time is ripe to adopt a new perspective on the challenge of cognitive modeling: how to model the individual reasoner. In addition to explaining aggregate data from training datasets, computational cognitive models can adapt to an individual by integrating knowledge about past responses into the prediction mechanism. This workshop will tackle conceptual, computational, theoretical, and methodological challenges in modeling individual reasoning behavior. A recent methodological advancement in assessing both aggregate and individual reasoning behavior, the Cognitive Computation for Reasoning Analysis (CCOBRA) framework, will be used to propose a new competition for theory-driven computational models of individual reasoning behavior. This workshop, and its underlying theoretical challenge, invites participants from cognitive science, AI, and all related fields to learn to build computational models of individual reasoners.

Core challenge: Modeling individuals

How can cognitive scientists build robust simulations of individual reasoners? This workshop will address the theoretical and methodological challenges in developing PREdictive, individualized COgnitive models of REasoning – the PRECORE Challenge. An orthodox methodology for fitting cognitive models to a dataset concerns a two-fold procedure: a given cognitive model's parameters are set by learning to predict the outcomes from a training dataset, and then it is applied to a novel dataset that the model never encountered before. The methodology is often used to build models of aggregated behavior form multiple individuals, but in principle, it can be applied to assessing individual reasoning behavior as well. The Cognitive Computation for Behavioral Reasoning Analysis (CCOBRA) framework is a benchmarking tool implemented in Python that actively integrates the individual human into the prediction loop. At its core lies a close connection to psychological experiments. Models are expected to simulate the experimental procedure for individual participants. They are presented with the same task in the same sequence with the same response options. By providing precise responses to individual tasks, models are evaluated based on their predictive accuracies. In the CCOBRA framework, computational models are supplied with the true response, both in the training phase, as well as in the evaluation phase; in this way, models can learn a default set of parameter settings in training and then be used to detect individual strategies in reasoning in the evaluation phase to refine their predictions further. Models are allowed to train on a dataset consisting of tasks and the actual human responses of individuals not present in the evaluation data. Additionally, after predicting the response to a task, they are presented with the true response and thus allowed to adapt to an individual participant. Hence, CCOBRA extends the traditional cognitive modeling problem by moving beyond the level of aggregates. As a result, the challenge for computational cognitive models is more difficult, but the payoffs are greater, i.e., they can lean to the development of robust computational models of individual reasoning strategies and adapt to the constraints of individual reasoners.

Models are ultimately compared via their predictive accuracy on unseen data. If a model manages to hit the true response more often than another model, the CCOBRA framework assigns it a higher score. The framework operates in a domain-agnostic fashion, i.e., it is compatible with computational cognitive models based on symbolic, probabilistic, connectionist, or hybrid approaches. Hence, computational cognitive models in the CCOBRA framework are assessed and compared on a fair and neutral ground. The only requirements imposed by CCOBRA is an implementation based on Python and the capability of generating a precise prediction for a given task. The problem of overfitting will be tackled by computing the final evaluation scores on previously unreported data. Higher predictive scores in the CCOBRA framework correspond directly to a better grasp of the processes underlying an individual human reasoner's cognitive system. The project is entirely open-source and accessible via Github[1].

[1] https://github.com/CognitiveComputationLab/ccobra

Benchmarking data and example model implementations can be found in the repository. A companion website[2] exists which allows to quickly upload and evaluate model implementations without the need to install the framework.

A domain-general challenge

Cognitive scientists have built computational models that simulate a wide variety of reasoning behavior, e.g., reasoning about syllogisms, reasoning about relations, reasoning about sentences and propositions, and reasoning about causation. Theorists have built computational models of reasoning in only some of these domains – and they've constructed models of individual reasoners in only one of them. Hence, the challenge of analyzing individual reasoning behavior is acute. This workshop, and its underlying benchmarking methodology, seeks to develop domain-general solutions for developing models of individuals. Consider the domain of syllogistic reasoning, for instance. Syllogisms are problems built from categorical assertions of the form "All of the As are Bs" and "All of the Bs are Cs". Reasoners deduce conclusions from syllogisms by comprehending two premises responding to the prompt: "What, if anything, follows?" Most reasoners generate spontaneously generate a conclusion of the form "All of the As are Cs" to the two premises above. As a recent meta-analysis shows, some syllogisms are easy, and some are difficult (Khemlani & Johnson-Laird, 2012). The same meta-analysis showed that twelve theories syllogistic reasoning had difficulty explaining the variation reasoners exhibit. The problem is endemic to computational models of reasoning: many of them perform well on aggregated data, but they they are unable to account for the individual differences that become relevant when attempting to predict how individual reasoners respond to various problems (Riesterer et al., 2018). Models in all reasoning domains are presently have an upper bound by the most frequent response.

Goals and Scope

The central goal of the workshop is to encourage and enhance cognitive modeling of syllogistic reasoning on an individual level and discussions by researchers of such diverse fields of cognitive science as psychology, AI, linguistics, and philosophy. Participation is possible by any of the following: Presenting a 15 minutes talk about cognitive modeling (please send us an email by July, 1), submitting a model for the modeling task in CCOBRA, discussing statistical analysis of aggregated vs. individual reasoning, or providing any insights in the discussion for advancing the current state of modeling beyond the level of aggregate syllogistic data.

Workshop Organization

Marco Ragni is a DFG-Heisenberg fellow and associate professor at the technical faculty of the Albert-Ludwigs-University Freiburg and leads the Cognitive Computation Lab. His research interests include qualitative spatio-temporal reasoning, knowledge representation and reasoning, cognitive modeling, and complex cognition with a special focus on analyzing why and how human reasoning often deviates from classical logical approaches.

Introduction

Humans perform a wide range of everyday activities (e.g., preparing a meal, setting the table) frequently, and often without conscious thought. Despite the experienced ease with which we perform such activities, their successful completion involves a complex set of abilities and mechanisms. This becomes apparent when considering that even healthy adults exhibit occasional errors (Norman, 1981, e.g., failing to spoon coffee grinds into the filter before switching on the coffee machine) in performing the necessary actions, while mild cognitive impairment may interfere with successful performance of highly familiar everyday activities (Gold, Park, Troyer, & Murphy, 2015).

Successful performance of everyday activities taxes at least the following abilities:

- *Perception*: The environment in which the actions are performed has to be adequately perceived to properly act in it. Among others this comprises the ability to recognize largely occluded objects in cluttered environments (e.g., plates in a stack of plates or objects in a dishwasher).
- *Action Planning*: Everyday activities consist of several actions and the effectiveness and efficiency of performing activities will often depend on the order in which the actions are executed (see coffee making example above). Accordingly, planning one's actions is an important aspect of everyday activity performance.
- *Spatial Reasoning*: Spatial relations of objects to each other and to one's body are crucial for everyday activity. Without knowledge about these relations, locomotion in the environment as well as collecting and properly arranging objects would not be possible.
- *Movement Planning*: Individual (motor) actions require planning to, for example, avoid obstacles, remain in the operational range of one's effectors, and to reduce the chance for mishaps (reaching with a full cup over – instead of around – your laptop is not a good idea)
- *Controlling Action Sequences*: Action sequences not only have to be planned, but also controlled during execution to ensure that no actions are left out, actions are not executed in the wrong order, or that inappropriate (i.e., not part of the plan) actions that are habitual or appropriate given the current state of the environment are avoided.
- *Monitoring and Error Correction*: Given that slips and lapses in action execution occur, monitoring of progress towards the goal and error correction mechanisms are also need to ensure successful action completion.

Considering that the listed abilities constitute research areas in their own right, it seems clear that gaining a (more) comprehensive understanding of everyday activities is an ambitious endeavor. At the same time, everyday activities provide an opportunity to jointly research several cognitive abilities in what Newell (1973) has called *complex tasks*. Everyday activities such as "setting the table" are circumscribed enough to study them in the lab, while being complex enough to require the combination of several cognitive abilities. As such, investigation of everyday activities has the potential to not only foster our understanding of the cognitive processes involved, but also of their interaction and integration.

Gaining a deeper understanding is also of applied relevance. Given the demographic change and an aging society, the number of people unable to perform independently all necessary everyday activities is increasing (e.g., Nicholas & Smith, 2006). A deeper understanding of what drives successful everyday activities, how the underlying mechanisms develop, and how and what in the process may break down with age and cognitive impairment (dementia) can help support those who have trouble with everyday activities in two ways. First, with knowledge about which abilities may decline with age and impairment, specific training regimes can be developed to counter the decline in ability (e.g., Bettcher et al., 2011). Second, support could be given by artificial cognitive agents (e.g., robots) performing or prompting those activities that people are less able to do themselves. Currently available (household) robots are missing the flexibility and versatility to stand in for a human housekeeper (Ersen, Oztop, & Sariel, 2017), and a deeper understanding of the mechanisms that underlie learning and mastery of everyday activities may therefore inform the design of improved artificial agents.

This workshop will assemble six speakers with multidisciplinary backgrounds to discuss (a) the cognitive abilities un-

derlying everyday activities, (b) how these abilities develop ontogenetically, (c) how abilities may break down with cognitive impairment, (d) possible integration of different abilities in the scope of everyday activities, and (e) how insights from (a)-(d) could inform building artificial cognitive agents mastering everyday activities.

Speakers

Speakers have been selected to cover important areas that are relevant to the issues raised in the preceding section. Our speakers combine expertise in abilities involved in everyday activities, how they develop (Kaichi Yanaoka, Satoru Saito), how they may decline with cognitive impairment (Tania Giovannetti), how they may be formalized and integrated in computational models (Falk Lieder, Gregor Schöner, John Laird), and how cognitive principles may be transferred to artificial cognitive agents (John Laird, Gregor Schöner). Talks will address the following topics:

Falk Lieder, MPI Tübingen will present work on *discovering rational planning strategies*. To succeed in everyday life people have to quickly solve complex sequential decision problems with bounded cognitive resources. Lieder and colleagues' resource-rational analysis suggested that people's planning strategies are jointly shaped by these adaptive pressures and the structure of the environment. Lieder will present an automatic method that leverages this principle to predict which planning strategy people are going to use in a given environment and test it in a series of experiments.

Gregor Schöner, Ruhr-Universität Bochum will present *how neural dynamic architectures generate physical and mental acts*. Acting in the real world involves the coordination of perception, cognitive processes, and movement generation. Schöner will discuss how the balance between stability and flexibility that is necessary for successful coordination can be achieved in a framework of neural dynamics.

Kaichi Yanaoka & Satoru Saito, Kyoto University will present work on *the role of executive functions in routine sequential actions in young children*. They will provide an overview of research on executive functions and action control from a developmental perspective before presenting new data on learning and control of routine sequential actions in young children.

John Laird, University of Michigan will present *a cognitive architecture approach to everyday activities*. Laird will explore how the myriad of cognitive capabilities required to perform everyday activities can be supported by an integrated cognitive architecture, drawing examples from research with the Soar architecture. One capability Laird will focus on is Interactive Task Learning — how the cognitive architecture approach can support learning new tasks from natural instruction.

Tania Giovannetti, Temple University will present work on *everyday action in cognitive aging, mild cognitive impairment, and dementia*. Giovannetti will provide an overview of how deterioration of older adults' performance of everyday tasks is related to level and type of cognitive impairment. In doing so, she will also highlight the implications observed difficulties have for understanding the cognitive mechanisms that are required for accurate performance of everyday activities in healthy populations.

Schedule

The workshop is planned as a half-day event. Speakers will be allotted 25 minutes each for their presentations (20 minutes talk + 5 minutes discussion). The workshop will begin with a brief introduction by the organizers followed by the first three talks (Lieder, Schöner, Yanaoka & Saito). After the break, the two remaining talks (Laird, Giovannetti) will be delivered. The organizers will then lead a discussion of all presentations. The workshop will be concluded with a 30 min. poster session. Posters will be solicited by a Call for Posters with rolling acceptance. Poster presenters will be asked to put up their posters before the workshop to allow attendees to begin discussing them during the break.

Acknowledgments

We gratefully acknowledge support by the German Research Foundation (DFG) through the project P3 "Spatial Reasoning in Everyday Activity" as part of the Collaborative Research Center (Sonderforschungsbereich) 1320 "EASE - Everyday Activity Science and Engineering", University of Bremen (http://www.ease-crc.org/).

Beyond the Ivory Tower: Non-Academic Career Paths for Cognitive Scientists

Vanessa R. Simmering (vanessa.simmering@act.org)
ACTNext by ACT, Inc., 500 ACT Drive
Iowa City, IA 52243 USA

Carissa L. Shafto (carissa.shafto@gmail.com)
Brightfield Strategies, LLC, 575 8th Ave
New York, NY 10018 USA

Keywords: professional development; non-academic; careers; industry; non-profit; government

Objectives and Scope

Cognitive science research has far-reaching implications, but many graduate students are trained with only an academic career in mind. Academic training develops a wide range of skills in service of behavioral research, literature reviewing, data analysis, scientific publishing, grant writing, teaching, and student mentorship. These skills also have direct application in non-academic positions, but training within academia typically neglects to address how these skills translate to other work environments and career paths. As growth in the number of doctoral trainees continues to outpace permanent academic positions (Kolata, 2016; Larson, Ghaffarzadegan, & Xue, 2013; Lederman, 2016), more doctoral recipients have been seeking non-academic employment (National Science Board, 2018). Doctoral students and recipients who are interested in exploring non-academic employment options may not know where to turn for guidance. Our goal in this professional development workshop is to offer such guidance and an opportunity to network with scholars in similar situations.

The session will be led by two scholars with doctoral degrees in psychology who worked in academic positions previous to their industry careers: Carissa Shafto is a senior data scientist and data governance specialist for Brightfield Strategies; Vanessa Simmering is a senior research scientist for ACTNext by ACT, Inc. They will draw on their individual experiences navigating from academic to non-academic positions to guide the activities and discussion. Additionally, they will solicit contributions and participation from other scholars with a diverse range of backgrounds and positions to increase the breadth of experiences participants consider.

Workshop Schedule

The time for the half-day session will be divided approximately in thirds, beginning with a presentation by the leaders, followed by a set of interactive activities among participants, and closing with group discussion of the activities and questions they raised. Because the workshop will occur before the conference, we hope that participants can use this opportunity to connect with each other and continue the conversations and networking beyond the end of the workshop.

Part 1: Introduction of Contributing Scholars and Different Career Paths

The leaders will begin with an overview of the goals of the session, followed by a series of narrated slides in which scholars (the leaders plus additional contributors) describe their backgrounds and employment. Specifically, we will ask all contributors to list the discipline of their degree and the general area of their research training, followed by (when relevant) any academic and non-academic positions they held before their current position, then a description of their current job, ending with a comment on what motivated them to seek out a non-academic career. Each contributor's description will be brief (3 minutes or less) and compiled into a single presentation in advance to maximize the number of examples we can present to participants. We have agreements to contribute narrated slides from thirteen participants thus far, listed in Table 1, and will invite more contributors if needed to ensure diverse representation of participants' backgrounds, interests, and employment types. Contributors will be encouraged to attend if possible, but attendance will not be required as this may limit which types of people and careers that can be represented, since many non-academic careers do not require or fund conference travel.

Part 2: Developing Your Pitch

Participants will be given time to work individually and then in small groups on two related activities developing "elevator pitches", which are brief but persuasive speeches designed to spark the listener's interest to learn more. The first pitch will be focused on what the participant is looking for in a career. The second will focus on what the participant has to offer to an employer. The leaders will scaffold this activity by highlighting successful strategies (e.g., focusing on skills over content, considering opportunities rather than obstacles) and potential individual considerations (e.g., whether one is leaving a temporary versus permanent position, whether relocation is possible). As relevant, these activities may include brainstorming a wide range of potential employment opportunities, or focusing on a specific position the participant already has in mind. During this portion, the leaders and any contributors in attendance will circulate through the room to talk to participants and answer questions that arise.

Table 1: PhD Scholars Contributing Narrated Slides on their Backgrounds and Careers

Name	Position	Institution / Company / Agency
Dan Acheson	Data Science Manager	Uptake
Keith Apfelbaum	Research Director	Foundations in Learning, Inc.
Aimee Arnoldussen	Medical Technology Assessment	University of Wisconsin Hospital & Clinics
Megan C. Brown	Lead Decision Scientist	Consumer and Partner Insights, Starbucks
John Lipinski	Director of Client Management	Certilytics
April Murphy	Data Scientist	Tulco Labs
Maggie Renno	Research Analyst	Wisconsin Department of Children and Families
Alexa Romberg	Research Manager	Schroeder Institute at Truth Initiative
Sarah Sahni	Associate in Social & Economic Policy	Abt Associates
Matthew Schlesinger	Senior Data Scientist	ReThink Medical
Sean Taylor	Research Scientist Manager	Core Statistics Team, Facebook
Dan Vatterott	Data Scientist	Showtime
Tim Wifall	Senior User Experience Researcher	Samsung Research America

Part 3: Questions, Feedback, Discussion, Networking, and Resources

Following the activity, participants will have an opportunity to ask questions, seek feedback, and discuss concerns within the larger group. The leaders will structure the time of the final third of the session based on interest from participants, including references to resources participants may want to use as they pursue non-academic careers. For example, a number of consulting services can be found online (The Professor Is In, Cheeky Scientist, Beyond the Professoriate, Next Scientist) but each varies slightly in their scope (i.e., some cater more to "hard" sciences, others to social sciences and humanities) and therefore their potential utility for participants with different backgrounds. They also vary in the amount of information offered free of charge and services provided at a cost. Social media sites (e.g., Post-Academic Athenas, Facebook groups, and LinkedIn) also offer more informal support, through discussion and peer mentoring, and can help participants expand their networks. The leaders and contributors will be able to provide some specific experiences to help participants evaluate what approaches could be of most use to them.

At the conclusion of the event, Dr. Simmering will survey interest from participants in potentially forming a group on LinkedIn or another platform to stay connected and follow up on conversations started during the session. Participants will also be provided with contact information from any contributors who agree to offer this opportunity to connect. We hope the session will give participants an entry point to exploring a wide range of career options and the necessary resources to pursue non-academic career paths.

Acknowledgments

Thanks are owed to Alexa Romberg for help in organizing a variant of this workshop submitted to another conference, and to Shevaun Lewis for permission to adapt and use materials she developed for a professional development workshop at the University of Maryland.

Abstract

Several of the central questions in language, social cognition, and developmental research focus on the roles of input, output, and interaction on learning and communication. While it has become easy to collect long-form recordings, getting useful data out of them is a more daunting task. Across four mini-sessions, this tutorial aims to address pre- and post-data collection concerns, and provide a hands-on introduction to manual and automated annotation techniques. Attendees will leave this tutorial with resources and concrete experience for collecting, annotating, and sharing/archiving naturalistic recordings, including specific open-science practices relevant for these data.
Keywords: daylong recordings; natural language; speech technology; automated annotation; open science

Introduction

The ability to record and efficiently analyze everyday talk from a variety of different populations is crucial for many topics in language science, including: variation in children's linguistic input, distributional patterns of language in adult speech, atypical speech patterns for medical diagnosis, and more (e.g., see Casillas and Cristia (under review) for a review). However, even the most basic facts about everyday speech experience have remained elusive given the technological constraints of capturing and analyzing daylong speech for large samples of participants. In the last two decades, the LENA™ system has emerged as a potential solution to this methodological gap (see Ganek and Eriks-Brophy (2018) for a review). However, due to its costs and proprietary, aging technology, LENA™'s usefulness is increasingly limited.

In this half-day tutorial we will describe a new approach for getting the most from daylong recordings; one that uses community-based norms to support researchers at every step, from ethics review and initial data collection to automated analysis, manual annotation, and data archival. The tools and databases we include are all open-source and oriented toward usability on new populations and new technical challenges—an ideal next step to enable researchers to tackle new scientific questions about everyday language use. These tools has developed out of the ACLEW project (`http:\sites.google.com/view/aclewdid/home`).

Tutorial aims

This tutorial is focused on facilitating current research using daylong recordings while also boosting the future development of *even better* tools for the collection, annotation, and analysis of daylong recordings.

Our first aim is to **lower the barrier to using daylong recordings for language research**. Many researchers who are interested in this method are held back from doing so because there is no clear cost- and time-efficient way to annotate the data. We hope to allay some of these concerns by introducing a set of tools and techniques participants can use to extract usable data from their recordings. We will provide a hands-on training session demonstrating how to use our ACLEW audio-processing pipeline (automated tools for exploring voice activity, utterance segmentation, speaker diarization, and speech rate estimation) and manual annotation framework suitable for cross-corpus comparison. All software is free, open-source, and multi-platform.

Our second aim is to **promote an open-science framework for natural language data**, with an eye toward improving access to shared data and comparative analysis. The daylong recording community is just getting off the ground (HomeBank; VanDam et al., 2016), and there is vast potential for scientific advancement if more researchers were to participate. To demonstrate the benefits of data sharing and re-use for daylong recordings, we will show how the use of unified tools and annotation templates can lead to new breakthroughs in comparing natural language environments across cultures. Our motivation is that the long-term non-commercial success of our toolkit depends on an active community of users. Active users contribute new training data, give feedback on quality, and make requests for new functionality. We therefore hope to convince researchers that these tools can meet their immediate analytic needs while also persuading them to invest in the community so that we can establish the mega corpora necessary for continued tool improvement.

Participants

This tutorial is intended for researchers at all levels of experience who are interested in the collection, analysis, curation, and computational modeling of natural language data. While the tutorial will be accessible to a general CogSci audience, we also hope to attract participants who are interested in daylong recordings but daunted by the prospect of collecting or processing them. We also encourage participation by researchers who have already invested in daylong recordings and are looking for new ways to utilize them. Indeed, as part of DARCLE we have a commitment and track record of supporting new investigators (`http://darcle.org/newInvestigators.html`).

Learning outcomes

After this tutorial, participants will be able to (1) assess the pros and cons of using naturalistic recordings for their research questions, (2) locate, use, and adapt our online, self-guided tutorials and templates for creating machine-friendly annotations, (3) download, install, run, and interpret the output provided by the (open source) audio-processing software, and (4) understand how to gain access to and use HomeBank, a repository for daylong audio recordings.

Tutorial structure

This half-day hands-on tutorial will introduce: issues surrounding daylong recording collection, a standardized manual annotation process, the use of automated annotation tools, and best practices for data archiving. This will be organized into four sessions (separated by 5-min breaks). Participants will work with sample media file to get hands-on experience in each session.

Session 1. Pre-data collection concerns (25 min) A brief introduction to the method, its costs and benefits, and what to consider before collecting data. Topics include: how to decide whether daylong recordings are suitable for the research question, considerations when applying for ethical approval, and off-the-shelf hardware and software options. We will relate these topics to individual research interests.

Session 2. Manual annotation (55 min) A 3-part interactive training session introducing participants to manual annotation in the machine-friendly template we have developed for ELAN (Casillas et al., 2017). Part 1 focuses on the basic setup of the annotation scheme. Part 2 focuses on the use and adaptability of the annotation conventions. Part 3 focuses on the annotator training standards and reliability estimation using the automated tools provided by ACLEW.

Session 3. Automated annotation (55 min) An interactive tour of the ACLEW automated tools package. Each tool will be introduced and demonstrated with example media files. We will also take this opportunity to demonstrate the value of adding new training and testing data and will open the floor to discussion about future tool development.

Session 4. Archiving and community (25 min) A brief discussion focused on the issues surrounding the long-term storage of daylong recordings. We will also discuss efficient and accessible ways to share data, annotations, and analysis, and review the benefits of open-science practices.

Learning materials

Participants will need an Internet-connected laptop and a pair of headphones. The organizers will create an OSF page with links to all training materials and instructions for future use. Although sample data will be provided, participants are encouraged to bring their own data to demonstrate the challenges of different research questions using daylong audio.

Tutor credentials

The materials and instruction for this tutorial will come from the cognitive scientists and software developers who created the tools being covered. Collectively, they have expertise in training dozens of researchers (undergraduate to PhD) on the steps covered in sessions 1–4. That said, this tutorial will be the very first to cover the end-to-end use of this pipeline for researchers working on daylong audio recordings.

Summary of significance

The study of everyday talk is fundamental for understanding the relationship between cognition, culture, and language. Recent technological advancements afford researchers the ability to study everyday language on a much larger scale than before, but these technologies are challenging and therefore remain somewhat underutilized. We aim to further the use and usefulness of this technology by spreading knowledge of how to effectively employ it and by facilitating the continued improvement of the associated tools for language science.

Acknowledgments

This work was supported by a TransAtlantic Platform "Digging into Data" collaboration grant (ACLEW: Analyzing Child Language Experiences Around the World) and an NWO Veni Innovational Research Scheme (275-89-033) to MC.

EMHMM: Eye Movement Analysis with Hidden Markov Models and Its Applications in Cognitive Research

Janet H. Hsiao (jhsiao@hku.hk)
Department of Psychology, University of Hong Kong
Pokfulam Road, Hong Kong, Hong Kong

Antoni B. Chan (abchan@cityu.edu.hk)
Department of Computer Science, City University of Hong Kong
Tat Chee Avenue, Kowloon, Hong Kong

Keywords: EMHMM; eye movement; hidden Markov model

Significance of the Method

In many daily life activities, eye movements provide strong clues about underlying cognitive processes. For example, patients with cognitive deficits have atypical eye movement patterns. Users with different experiences show different eye movement behavior in viewing websites. Thus, eye movement has become an important measure in the broad research fields in cognitive science.

Recent research has reported substantial individual differences in eye movements during cognitive tasks. Nevertheless, most of the current analysis methods do not adequately reflect these individual differences. Also, they focus on spatial information (fixation locations), whereas temporal information (transitions among fixation locations) is typically overlooked. The most common method has been the use of predefined regions of interests (ROIs) on the stimuli. However, predefined ROIs are often subject to experimenter bias and inconsistency across studies. To address these problems, Caldara and Miellet (2011) proposed to directly perform by-pixel statistical tests on fixation heat maps (where fixations are smoothed with a Gaussian function) to determine the regions with significant difference between conditions. Nevertheless, these regions are often irregularly shaped and difficult to interpret. Also, fixation maps at different times only show the transition of overall fixation distribution and do not provide information about transitions between regions. Another method (Jack et al., 2009) is to define ROIs as regions formed by running the k-means clustering algorithm on significantly fixated regions of a fixation map. However, this approach assumes that all ROIs are circular and the same size, and the number of ROIs must be preset by the experimenter.

Thus, we have developed a novel eye movement data analysis method, Eye Movement analysis with Hidden Markov Models (EMHMM; Chuk, Chan, & Hsiao, 2014), which summarizes each individual's eye movement pattern using a hidden Markov model (HMM; a type of machine learning model for time series data), including person-specific ROIs and transition probabilities among the ROIs. Individual HMMs can be clustered according to similarities to discover common patterns (Fig. 1a), and the similarity between an individual pattern and a common pattern can be quantitatively assessed through estimating the likelihood of the individual's data being generated by the common pattern HMM. This similarity measure then can be used to examine associations between eye movement patterns and other cognitive measures (Fig. 1b & 1c). We have applied this method to face recognition research and made discoveries thus far not revealed by other methods, including how eye movements are associated with recognition performance, cognitive abilities (Chan, Chan, Lee, & Hsiao, 2018), cultural differences (Chuk, Crookes, et al., 2017), memory encoding/retrieval (Chuk, Chan, & Hsiao, 2017), sleep loss (Zhang, Chan, Lau, & Hsiao, 2019), and activations in brain regions important for top-down attention control (Chan et al., 2016). We have also recently developed new methodologies for more complex cognitive tasks, including using switching HMMs for tasks involving cognitive state changes (Chuk, Chan, Shimojo, & Hsiao, 2016), and using the machine learning algorithm co-clustering for tasks involving stimuli with different feature layouts (Hsiao, Chan, Du, & Chan, 2019).

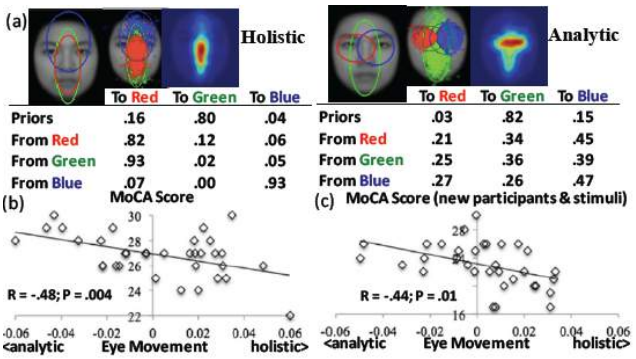

Fig. 1: (a) Analytic and holistic patterns in face recognition (Chan et al., 2018). Ellipses show ROIs as 2-D Gaussian emissions. The table shows transition probabilities among the ROIs. Priors show the probabilities that a fixation sequence starts from the ellipse. (b) In older adults, the more holistic the pattern, the lower the cognitive status (by MoCA), and (c) this correlation was replicated with new participants viewing new face images using the representative HMMs in (b).

In short, the EMHMM methodology will allow us to summarize, quantitatively assess, and compare individual eye movement patterns across stimuli and tasks, and examine how they are associated with other cognitive measures. It will lead to innovative findings not revealed by any existing methods with a lasting impact on how eye tracking is used for understanding cognition across disciplines. The Matlab Toolbox for EMHMM is available at http://visal.cs.cityu.edu.hk/research/emhmm/.

Structure and Activities

This half-day tutorial consists of 2 sessions:

1. Introduction to EMHMM and Its Applications: We will first introduce current methods in eye movement data analysis to illustrate the advantages of the EMHMM method. We will then introduce how we can apply EMHMM to research on face recognition, reading, cultural difference, ageing, sleep, information systems, decision making, scene perception, and video viewing. In the end we will provide a short demo in which attendees can come to perform a face recognition task with eye tracking, and get a personalized EMHMM report on site.

2. Tutorial and Hands-on Experience: We will first present an EMHMM simulation study (Chan & Hsiao, 2018) and provide recommendations for using EMHMM in cognitive research. We will then provide an EMHMM Matlab Toolbox tutorial with sample data for attendees to practice using the toolbox on their own laptops. We will have at least one laptop available onsite for attendees who do not have access to Matlab. Attendees may also bring their own data and ask questions on site.

Credentials of the Tutorial Organizers

The tutorial organizers have been developing the EMHMM method for 7 years. Since the first paper/talk presented at the Annual Meeting of the Cognitive Science Society (Chuk, Chan, & Hsiao, 2013), they have published 6 journal papers (including *Cognition* and *Sleep*) and 23 conference/invited presentations (including VSS and ICIS) using this method with collaborators from the UK, the US, Germany, and Australia, etc. on various topics.

Janet Hsiao is a world-leading expert in using eye tracking and computational modeling methods to understand human cognition. She has published in several high-profile cognitive science journals including *Psychological Science* and *Cognition*. She is currently an Associate Editor for *Cognitive Science*, and has been served on the Program Committee for the annual meetings of the Cognitive Science Society since 2016.

Antoni Chan is a world-leading expert in probabilistic models for time series data analysis and pattern recognition. He has published in several high-profile machine learning and computer vision journals, including *IEEE Trans. on Pattern Analysis and Machine Intelligence* and the *Journal of Machine Learning Research*. He is currently a Senior Area Editor for *IEEE Signal Processing Letters*, and served as an Area Chair for ICCV'15, '17, and '19.

Optimizing the Design of an Experiment using the ADOpy Package: An Introduction and Tutorial

Jay I. Myung (Myung.1@osu.edu)
Mark A. Pitt (Pitt.2@osu.edu)
Department of Psychology, Ohio State University
Columbus, OH 43210 USA

Jaeyeong Yang (urisa12@snu.ac.kr)
Woo-Young Ahn (wahn55@snu.ac.kr)
Department of Psychology, Seoul National University
Seoul, 08826 KOREA

Keywords: computational cognition; Bayesian active learning; autonomous experimentation; adaptive design optimization; Python software package

Introduction

Experimentation is one of the cores of cognitive science, whether one is interested in understanding the mechanisms underlying cognitive control or the neural basis of decision-making. Through accurate measurement in a well-thought-out experimental design, the goal is to obtain sufficiently noise-free data to make inferences about processing. The design of an experiment can be especially tricky, requiring consideration of many factors (e.g., what levels and how many levels of a variable should be presented, how many stimuli per level, etc.). The final design can sometimes result in only a subset of the design space (i.e., conditions) yielding interesting results, with the remaining data being minimally informative.

Advances in Bayesian statistics and machine learning offer algorithm-based ways to generate optimal and efficient experimental designs so as to minimize uninformative and wasted experimental trials (e.g., Cavagnaro, Myung, Pitt, & Kujala, 2010; Lesmes, Lu, Baek, & Dosher, 2010). In an optimized experiment, stimuli are selected adaptively and optimally (i.e., in an information theoretic sense; Lindley, 1956) on each trial by real-time data analysis of observed responses from earlier trials. What is being optimized is the values of the design variables that can be manipulated experimentally, such as the intensity of a stimulus in a psychophysics experiment or the monetary rewards and probability of occurrence in a preferential choice experiment. This is unlike a traditional experiment in which the design is fixed for all participants and stimulus presentation is either random or follows a predetermined schedule.

One such approach is referred to as Adaptive Design Optimization (ADO; Cavagnaro et al., 2010). ADO derives from optimal experimental design in statistics (Atkinson & Donev, 1992; Chaloner & Verdinelli, 1995) and active learning in machine learning (Cohn, Atlas, & Ladner, 1994; Settles, 2012). ADO is a general-purpose, algorithm-based method for autonomously conducting adaptive experiments that lead to rapid accumulation of information about the phenomenon of interest with the fewest number of trials. ADO can improve significantly the informativeness and efficiency of data collection (e.g., Cavagnaro et al., 2011 & 2016).

ADOpy

Expertise in statistics and computational modeling is required to use these machine-learning methods. To improve their accessibility to a wide range of researchers, we have developed an open-source Python package. The package, dubbed ADOpy, implements ADO for optimizing experimental designs. ADOpy is currently available on GitHub (https://github.com/adopy), with three pre-installed adaptive experimental tasks as of January 2019: (a) the slope and threshold estimation of the psychometric function (Kontsevich & Tyler, 1999); (b) the delay discounting experiment (Cavagnaro et al., 2016); and (c) the choice under risk and ambiguity experiment (Levy et al., 2010).

ADOpy is written using high-level semantic-based commands in a such way that the whole ADO procedure is broken into a set of meaningful function calls that can be easily edited and modified by users. Further and importantly, the package is user-friendly in that users can use the package without having to understand the computational details of the ADO algorithm. Additionally, the package is modular so that new models and/or experimental tasks can be easily added. Thus, only a modest amount of programming and modeling experience is required to use ADOpy.

The purpose of the proposed tutorial is to introduce ADOpy to cognitive scientists in a hands-on training environment, first providing a conceptual introduction to optimal experimental design and then walking through examples that demonstrate how to use methodology. The tutorial will be based on a manuscript (in preparation) to be submitted for publication in the near future.

Tutorial Format

This half-day tutorial will be organized into two 1.5-hour sessions with a 30-min coffee break between them. The first part, given by the first two authors, will consist of a general

overview of the conceptual and statistical foundations of ADO (1 hour) and then 30 minutes to answer questions and set up for the tutorial session. After the break, the second 1.5 hours will be a tutorial on the ADOpy package, with hands-on training using concrete, work-through examples, run jointly by the third and fourth authors.

There will be a website with a program, a web link to the GitHub site, the abstracts and slides of all presentations, supplementary Python code to be used in the hands-on session and recommended readings.

Target Audience

Graduate students, postdoctoral researchers, and scientists, who are new to ADO and have workable knowledge of Bayesian statistics on a graduate level and also of basic Python programming.

Organizers/Presenters

Jay I. Myung is Professor of Psychology at the Ohio State University. He received a PhD in 1990 in psychology at Purdue University. His research interests in the fields of cognitive and mathematical psychology include computational cognition, optimal experimental design, Bayesian modeling, and model comparison. Homepage: https://faculty.psy.ohio-state.edu/myung/personal/

Mark A. Pitt is Professor of Psychology at the Ohio State University. He received his PhD in 1989 in psychology at Yale University. In addition to researching computational approaches to improving inference in experimentation, he researches questions in psycholinguistics, such as how listeners recognize spoken words. Homepage: http://lpl.psy.ohio-state.edu/.

Jaeyeong Yang is a second-year graduate student of psychology in the Department of Psychology at Seoul National University. He received a double major B.S. in psychology and computer science, and he wrote the *ADOpy* package in Python.

Woo-Young Ahn is Assistant Professor of Psychology at Seoul National University. He received a PhD in 2012 in clinical psychology at Indiana University and has published over 20 papers in journals such as *Cognitive Science, Proceedings of the National Academy of Sciences, Current Opinion in Behavioral Sciences, Journal of Mathematical Psychology,* and *Computational Psychiatry*. His research interests include decision neuroscience and computational psychiatry, and he developed the Bayesian modeling package *hBayesDM* (https://github.com/CCS-Lab/hBayesDM).

Acknowledgments

This research is supported in part by National Institute of Health Grant R01-MH093838 to JIM and MAP, and also by Basic Science Research Program through the National Research Foundation of Korea (NRF) funded by the Ministry of Science, ICT, & Future Planning (2018R1C1B3007313) to WYA.

Keywords: quantum probability theory; classical/ Bayesian probability theory; Markov processes; contextuality; decision making; memory; similarity.

Introduction

Even though the generally acknowledged normative and descriptive standard for modeling human inference is classical/ Bayesian probability theory (CPT), there have also been several reports which challenge CPT's universal applicability. Some of the most influential empirical demonstrations of such so-called fallacies have been reported by Kahneman, Tversky and their collaborators. For example, consider the evocative conjunction fallacy. In the Tentori et al. (2004) demonstration of the conjunction fallacy, participants are quite happy to consider it more probable to randomly select a Scandinavian person with both blue eyes and blond hair, than just blond hair. Even though we can imagine a line-up of Scandinavian individuals (making the set theoretic structure of CPT explicit and so the impossibility of a conjunction fallacy), there just seems a persistent feeling that somehow the conjunction is more likely than the marginal (cf. Gilboa, 2000). How can our intuition be so much at odds with CPT prescription?

We call quantum probability theory (QPT) the rules for how to assign probabilities to events from quantum mechanics, without any of the physics. QPT is in principle applicable in any situation where there is a need to formalize uncertainty. In psychology, one way to motivate QPT is as a bounded rationality approach to CPT: whereas in CPT we require conjunctions/ disjunctions across all possible questions (and the underlying logical structure is a Boolean algebra), in QPT (classical) conjunctions/ disjunctions are possible only for so-called compatible questions, while for incompatible ones they are undefined (they have to be computed with sequential operations; the underlying logical structure is a partial Boolean algebra).

Where incompatible questions are concerned, QPT provides a radically different perspective on probabilistic inference, compared to CPT, characterized by, for example, interference effects, violations of the law of total probability, supercorrelations, and constructive influences from judgments. These characteristics have provided a rich modeling framework for accommodating behavioral results superficially at odds with classical structure, across several areas including decision making, memory, similarity, perception, and logical reasoning, to mention but a few (overviews in Bruza et al., 2015; Busemeyer & Bruza, 2012; Haven & Khrennikov, 2013; Pothos & Busemeyer, 2013).

The purpose of the tutorial is to provide a comprehensive introduction to the QPT techniques commonly employed in cognitive modeling and illustrate the breadth of cognitive findings for which successful QPT models have been proposed.

Presenters

Emmanuel Pothos is a Professor of Psychology at City, University of London. He has been involved with the quantum cognition research programme since its inception, more than 10 years go. James Yearsley is a mathematical psychologist, originally trained in quantum theory. He has provided one of the most compelling a priori behavioral predictions of QPT (Yearsley & Pothos, 2016). Zheng (Joyce) Wang is a Professor at The Ohio State University. She was Co-Editor for a special issue on quantum cognition that appeared in *Topics in Cognitive Science,* 2013, Vol. 5). Peter Kvam is a postdoctoral researcher at Indiana University, who has published many articles on quantum cognition including in top journals such as PNAS. Finally, Jerome Busemeyer is Distinguished Professor of Cognitive Science at Indiana University and fellow of the Cognitive Science Society. He is one of the instigators of the quantum cognition research programme.

Previous Tutorials and Symposia

The tutorial has been presented at the Cognitive Science meetings in Nashville (2007), Washington DC (2008), Amsterdam (2009), Sopporo (2012), Berlin (2013), Quebec City (2014), Pasadena (2015), Philadelphia (2016), and Madison (2018), with about 30 to 50 participants each time. The ratings from participants after the tutorial were all very positive. In 2017, we held a workshop on quantum cognition supported by the Estes Foundation to 60 participants at a joint meeting of

the Society for Mathematical Psychology and the International Conference on Cognitive Modeling at the University of Warwick, UK. Also, this tutorial follows a symposium on quantum cognition at the Cognitive Science meeting 2011, whose papers appeared as a special issue in *Topics in Cognitive Science* (2013).

Assumptions about Participants Background

Most of the techniques we will cover involve elementary linear algebra and should be accessible to participants with minimal mathematical background. Note, no knowledge of physics is required and, with the exception of providing some historical context, no references to physics will be made.

Material to be Covered

We intend to organize the tutorial in three sessions, but with multiple speakers per session and short breaks, to make presentations more engaging for the audience. We note below how each session will be broken up into parts, with an approximate indication of time per part.

Introduction and background (2 hours)

Why employ QPT in cognitive modeling? Busemeyer will provide a brief introduction to the tutorial (0.25 hours). We will then consider a simple QPT model for the conjunction fallacy, explaining how the representations can be set up, how are probabilities computed, and how the interference term necessary to accommodate the conjunction fallacy emerges. We will also discuss the way the QPT prediction of a CF can be interpreted in rational terms (Pothos, 1 hour). We will then provide an overview of empirical findings which have been modeled with QPT, with a focus on other decision findings (e.g., disjunction effect; disjunction fallacy), questionnaire response biases (e.g., order effects), memory (e.g., the overdistribution effect), similarity, and perception (e.g., violations of the law of total probability; Wang, 0.75 hours).

Dynamical models; advanced techniques (2 hours)

We will discuss how dynamical cognitive processes can be modeled with QPT and introduce related technical concepts, e.g., unitary operators and Hamiltonians, side by side with classical counterparts, in the context of well-known empirical results from decision making (Busemeyer, 0.75 hours). We will then introduce some more advanced QPT methods. Notably QPT includes a sophisticated formalism for noise in probabilistic inference (with the formalism of POVMs), that is relevant in psychological processes where noise is assumed to play a substantial role. Additionally, the standard dynamical formalism in QPT can be extended to situations where there is an interaction (information exchange) with the environment (cf. open system dynamics; Yearsley, 0.75 hours). Finally, we will consider Bayesian model comparisons between QPT and matched CPT models and discuss their relative complexity in general terms and in relation to specific examples (Yearsley & Kvam, 0.5 hours).

Generative value (2 hours)

We will consider the generative value of the quantum cognition research programme, with emphasis on explaining the techniques and allowing insight into the thought process leading to model creation. Kvam (1 hour) will present a research programme on modeling heuristics within QPT. In particular, he will demonstrate how several fast and frugal heuristics can be reconstructed by integrating them with a quantum logic structure, introducing qubits, U-gates, and quantum information theory more generally. He will consider several applications including regarding expertise, game theory, and the hindsight bias. Wang (0.75 hours hours) will present one of the most surprising and robust predictions from QPT, the so-called QQ equality, which is a parameter free constraint on how order effects in question pairs ought to add up to zero (Wang et al., 2014). Yearsley (0.25 hours) will discuss the prediction of the Quantum Zeno effect, that the density of intermediate judgments slows down opinion change; this prediction relates to one of the most distinctive properties of QPT, the collapse postulate, which entails state changes from measurements. Pothos (0.25 hours) will illustrate this in a simpler paradigm, leading to a prediction of a novel decision bias. And finally, Busemeyer (0.5 hours) will outline the future directions of the quantum cognition research programme.

Acknowledgments

EMP was supported by ONRG grant N62909-19-1-2000.

Individual Differences in Spatial Representations and Wayfinding

Navigation is a well-specified computational problem, and solving it is vital for survival. Given these constraints, we might expect that humans differ minimally in their wayfinding capabilities. Indeed, a lack of variation is often implicitly assumed when cognitive scientists debate the existence of cognitive maps or when cognitive neuroscientists search for the neural substrates of navigation. However, in everyday life, we frequently discuss how some people get lost with some frequency, or how women ask for directions while men use maps. Indeed, it is increasingly apparent in the scientific data on navigation (and other cognitive domains) that the study of normative functioning needs to be integrated with the study of human variation, with its attendant challenges regarding experimental design and use of psychometrics. The four papers in this symposium gather together current work in cognitive science and neuroscience that aim to integrate the study of variation into the more common normative approach.

Mechanisms of Differences in Cognitive Mapping and Navigational Ability: Explorations Using Virtual Reality Manipulations

Thackery I. Brown[1], Qiliang He[1], Timothy P. McNamara[2], Jon Starnes[1], Sarah Goodroe[1]
[1]Georgia Institute of Technology [2]Vanderbilt University

Daily function depends on an ability to mentally map our environment. Environmental visibility and complexity can increase this challenge. Importantly, people vary dramatically in their ability to navigate flexibly and overcome such environmental challenges. In this paper, we will present experimental work targeting the mechanisms that underlie different navigational abilities, and how objective and introspective measures of ability interact to influence navigational strategy use. Using virtual reality, we manipulated environmental visibility and complexity. Participants then performed wayfinding, pointing, and route following tasks to probe cognitive map memory and navigational flexibility. Our findings reveal that individual differences in metacognition - such as perceived sense of direction - and in navigational strategy preference powerfully impact how environmental features affect spatial memory. We also gathered data on the neurocognitive foundations of these differences. Importantly, our methods highlight individualized interventions that can improve spatial learning and specify the mechanisms through which they operate.

A Meta-analysis of Sex Differences in Human Navigation Skills

Alina Nazareth[1], Lucy Huang[2], Nora S. Newcombe[1], Daniel Voyer[2]
[1] Temple University [2]University of New Brunswick

Popular sources often assume the existence of a male advantage in navigation, but the scientific data are inconsistent. This meta-analysis evaluates the literature on behavioral sex differences in human navigation. We quantify the overall magnitude of sex differences in a variety of paradigms and populations and examine potential moderators in large-scale navigation skills, using 694 effect sizes from 266 studies and a multilevel linear modeling approach. Overall, we found that male participants outperform female participants, with a small to medium effect size (d= 0.34 to 0.38). The type of task, the type of dependent variable and the testing environment significantly contribute to variability in effect sizes. Pointing and recall tasks show larger sex differences than distance estimation tasks or learning to criterion; among the dependent

variables, the deviation scores associated with pointing tasks show larger effect sizes. The largest estimate was d = .55 for tasks than required coordinating indoor and outdoor views. Interestingly, studies with children younger than 13 years showed very small effect sizes (d = .15) as compared to older age groups. We discuss the implications of these findings for the study of sex differences and identify avenues for future navigation research.

Measuring Spatial Perspective Taking:
Analysis of Four Measures using Item Response Theory

Maria Brucato[1], Andrea Frick[2], Alina Nazareth[1], Nora S. Newcombe[1]
[1] Temple University [2] University of Fribourg

Research on spatial thinking needs reliable and valid measures of individual differences in skills. Visuospatial Perspective Taking (PT)—the ability to mentally maintain and transform spatial relationships between objects within an environment—is one kind of spatial skill that is especially relevant to navigation and building cognitive maps. However, the psychometric properties of various PT tasks have yet to be examined. The present study examines three main psychometric properties of PT tasks: 1) the reliability of two tasks developed for children but adapted in difficulty level for use in adult populations, 2) item difficulty and discriminability within and between four tasks using item response theory, and 3) relation of scores with general intelligence, working memory, and mental rotation. Results showed that two of the four PT tasks have promising psychometric properties for measuring a wide range of PT ability based on item difficulty, discriminability, and efficiency of a test information function.

Genetics and Experience Modulate Individual Differences in Navigation

Veronique Bohbot
McGill University

Different memory systems, dependent on separate parts of the brain, can sustain successful navigation. The hippocampus is implicated in spatial memory strategies used when finding one's way in the environment, i.e. it is allocentric and involves remembering the relationship between landmarks. On the other hand, another strategy dependent on the caudate nucleus can also be used, i.e. the response strategy, which relies on making a series of stimulus-response associations (e.g. right and left turns from given positions). Participants who use the response strategy are faster at learning navigation tasks lending themselves to using a single specified route. Young adult response learners have increased fMRI activity and grey matter in the caudate nucleus, but decreased fMRI activity and grey matter in the hippocampus. Research in my laboratory has shown that specific navigation strategies are associated with several genes, such as BDNF and ApoE, as well as hormones, such as cortisol and progesterone, but not estrogen and progesterone. Experiences dependent modulators such as age, habit, stress and rewards also modulate strategies dependent on the hippocampus and caudate nucleus. These results have important translational implications because a larger hippocampus has been associated with healthy cognition in normal aging and with a reduced risk of numerous neurological and psychiatric disorders such as Alzheimer's disease, Schizophrenia, Post-Traumatic Stress disorder and Depression.

Keywords: Explainability; Artificial Intelligence; Philosophy of Artificial Intelligence; Psychology; Cognitive Science

Explainability is assumed to be a key factor for the adoption of Artificial Intelligence systems in a wide range of contexts (Hoffman, Mueller, & Klein, 2017; Hoffman, Mueller, Klein, & Litman, 2018; Doran, Schulz, & Besold, 2017; Lipton, 2018; Miller, 2017; Lombrozo, 2016). The use of AI components in self-driving cars, medical diagnosis, or insurance and financial services has shown that when decisions are taken or suggested by automated systems it is essential for practical, social, and increasingly legal reasons that an explanation can be provided to users, developers or regulators.[1]Moreover, the reasons for equipping intelligent systems with explanation capabilities are not limited to user rights and acceptance. Explainability is also needed for designers and developers to enhance system robustness and enable diagnostics to prevent bias, unfairness and discrimination, as well as to increase trust by all users in *why* and *how* decisions are made. Against that background, increased efforts are directed towards studying and provisioning explainable intelligent systems, both in industry and academia, sparked by initiatives like the DARPA Explainable Artificial Intelligence Program (DARPA, 2016). In parallel, scientific conferences and workshops dedicated to explainability are now regularly organised, such as the 'ACM Conference on Fairness, Accountability, and Transparency (ACM FAT)' (Friedler & Wilson, n.d.) or the 'Workshop on Explainability in AI' at the 2017 and 2018 editions of the International Joint Conference on Artificial Intelligence.

However, one important question remains hitherto unanswered: *What are the criteria for a good explanation?*

Explainable Artificial Intelligence

While Explainable Artificial Intelligence (XAI) has recently received significant attention, its origins stem from several decades ago when AI systems were mainly developed as knowledge-based or expert systems, such as in MYCIN (Buchanan & Shortliffe, 1984) and NEOMYCIN (Hasling, Clancey, & Rennels, 1984). In these systems, explanations were conceived mainly as reasoning traces of the system — at first resulting in a very technical notion of what an explanation is, with only limited regard to cognitive aspects on the user's side. Still, in the context of REX (Wick & Thompson, 1992), there was already a discussion of how to adapt explanations to different user groups and the trade-offs involved. While interest in XAI subsided after the mid-1990s, recent successes in machine learning technology have brought explainability back into the focus. This has led to a plethora of new approaches for both autonomous and humans-in-the-loop systems, aiming to achieve explainability, as defined by respective system creators, without sacrificing system performance.

Many systems focus on interpretable *post-hoc* approximations of black-box models (Guidotti et al., 2018), using symbolic representations such as decision trees (Craven, 1996; Sarkar et al., 2016) or decision rules (Ribeiro, Singh, & Guestrin, 2018), feature importance (Lou, Caruana, & Gehrke, 2012), saliency maps (Selvaraju et al., 2017), or local regression models (Ribeiro, Singh, & Guestrin, 2016). On the other hand, there are efforts to design intelligent systems to be interpretable by design, e.g., in recommender systems (Zhang & Chen, 2018), or in a recently started project developing the concept of *perspicuous computing*.[2]

In these heterogeneous origins and developments of XAI, a discussion is still to be had on what precisely the roles of explanations are and, in particular, what makes an explanation a good explanation. To this end, we will bring together several experts of different aspects of the phenomenon "explanation" in this symposium, to analyze the notion of explanation in the context of artificial intelligence from different cognition-related perspectives.

What Makes a Good Explanation?

Starting out from the cognition of explanations, this symposium will foster scientific discourse about what

[1]As a case in point, the European Union's General Data Protection Regulation (GDPR) stipulates a right to "*meaningful information about the logic involved*"— commonly interpreted as a 'right to an explanation'— for consumers affected by an automatic decision (Parliament and Council of the European Union, 2016).

[2]https://www.perspicuous-computing.science

functions an explanation needs to fulfill and the criteria that define its quality. Some of the aspects to be addressed are:

- Objective and subjective value of explanations
- Dimensions of explanations: complete vs compact, abstract vs concrete, reduced vs simplified, ...
- Anchoring to known concepts
- Counter-factual explanations and actionability
- Personalisation
- Legal requirements
- Grounding in personal and social experience and intuition

A panel of recognised scholars and researchers will bring insights and expertise from different points of view, including psychology, cognitive science, computer science, and philosophy, and will foster knowledge exchange and discussion of the multiple facets of explanation:

- Kathleen Creel will talk about 'Understanding Machine Science: XAI and Scientific Explanations', drawing on the literature on scientific explanation in philosophy and cognitive science, and arguing that for scientific researchers, good explanations require more access to the functional structure of the intelligent system than is needed by other human users.
- Tania Lombrozo will talk about 'Explanatory Virtue & Vices', considering the multiple functions and malfunctions of human explanatory cognition with implications for XAI. In particular, she will suggest that we need to differentiate between different possible goals for explainability, and that doing so it highlights why human explanatory cognition should be a crucial constraint on design.
- Shane Mueller will talk about 'Ten fallacies of Explainable Artificial Intelligence', reviewing some of the assumptions made until now about what properties lead to good explanations, and describing how each constitutes a fallacy that might backfire if used for developing XAI systems. He will then describe a framework developed for the DARPA XAI Program for measuring the impact of explanations that incorporates cognitive science theory related to mental models, sensemaking, context, trust, and self-explanation that can provide a principled approach for developing explainable systems.
- Patrick Shafto will talk about 'XAI via Bayesian Teaching', raising questions about the use of modern machine learning algorithms in societally important processes, and theoretical questions about whether and how the opaqueness of these algorithms can be ameliorated, in the framework of Bayesian teaching.
- Roberto Confalonieri and Tillman Weyde will talk about 'An Ontology-based Approach to Explaining Artificial Neural Networks', addressing the challenges of extracting symbolic representations from neural networks, exploiting domain knowledge, and measuring understandability of decision trees with users both objectively and subjectively.

Introduction

The past decade has seen remarkable progress in artificial intelligence, with such advances as self-driving cars, IBM Watson, AlphaGo, Google Translate, face recognition, speech recognition, virtual assistants, and recommender systems. Ray Kurzweil and others think that it is only a matter of decades before AI surpasses human intelligence. This symposium will evaluate the extent to which AI currently approximates the full range of human intellectual abilities, and critically discuss the prospects for closing the gap between artificial and human intelligence. Participants will combine the perspectives of computer science, psychology, and philosophy.

The Comparative Cognition of Humans and Machines

Ken Forbus and Dedre Gentner

While there has been great progress in both cognitive science and artificial intelligence, both would benefit from better communication between them. The comparative study of cognition in humans and intelligent machines can shed light on both kinds of systems. In the last decade, the confluence of massive computational resources, massive data sets, and several decades of incremental advances has led to a substantial increase in the ability to build applications with neural networks. Deep learning systems have shown impressive performance in image classification and game learning. However, they still fall far short of capturing human abilities such as explanation and inference, and they require orders of magnitude more data than humans do. We argue that a fundamental lack in these systems is their lack of explicit relational representations. The ability to represent and reason about relational patterns is central to our human ability to explain and predict, and to learn rapidly via analogies with prior knowledge. Fortunately, many of the same factors that have led to gains in deep learning systems are also acting to increase our ability to build large-scale systems with relational representations, which reason and learn in human-like ways. We discuss examples from recent experiments in which analogical learning over relational representations leads to far more humanlike and data-efficient learning than deep learning.

AI and Cognitive Architecture

John E. Laird

There is more talk than ever about general AI, but all the emphasis appears to be on recognition, classification, or reactive decision making with very little on cognition. The emphasis seems to be on only slices of System 1. Within those slices, we see human-level or even super-human performance, but these are very thin slices. Each system is focused on one phenomenon, and given the emphasis on learning from large data sets; it leads to overfitting, not necessarily to specific data, but to the specific problem to the exclusion of developing anything that can work on another problem, or even interact with another cognitive capabilities. In contrast, humans are defined by their flexibility – they can work on many different problems, switching effortlessly from one task to another. They also can learn from many sources of knowledge, on line and in real time, and using a variety of learning techniques. Moreover, they can learn new tasks from scratch in real-time from natural language instruction. A growing field

called Interactive Task Learning has developed an AI system that is embodied in a variety of robotic platforms and that can learn over 50 games and puzzles as well as navigation tasks. It integrates natural language processing, planning, perception, motor control, and learning within a cognitive architecture. Christian Lebiere, Paul Rosenbloom and I have proposed the Common Model of Cognition (CMC) to unify the theoretical underpinnings of many cognitive architectures, starting with Soar, ACT-R, and Sigma. CMC has a vastly different structure than current AI approaches, including procedural and declarative memories, working memory, multiple learning mechanisms. Although these components are common in cognitive science, they are the exception in current AI systems, in large part because of the emphasis on System 1, and off-line batch learning. Until AI takes cognitive architecture, as exemplified by the CMC, seriously, it will not achieve the flexibility, breadth, and adaptability we associate with human intelligence.

Close the Gap and Cooperate

Thomas Shultz and Ardavan Salehi Nobandegani

We will argue that attempts towards achieving artificial general intelligence (AGI) should pay more attention to human intelligence and its neural underpinnings. Having to interact with humans, AGI will need an adequate grasp of human judgment and decision-making and moral principles. Human intelligence not only surpasses current AGI systems, but, importantly, it does so in a resource-efficient way, setting a gold standard for future AI systems. Many of the important AI algorithms originated in psychology, and that strategy is still worth pursuing. A current shortcoming of many AI systems is their limited capacity for generalization – the ability to transfer knowledge from a newly or previously learned task to other relevant tasks. AI could also benefit tremendously from cognitive and developmental psychology to better understand the developmental stages that human infants go through on their way toward adult-level intelligence. To illustrate, we'll focus a bit on the significance of autonomous learning (aka active learning) for bridging the current gap with humans. Even infants take an active role in their own learning by selecting what to work on, what to abandon, and perhaps which examples would be most useful. There is a key role here for learning cessation, the ability to give up on impossible learning tasks, identifiable by lack of continued progress. This paves the way for focusing on tasks in which progress and mastery are more likely. We can suggest ways of implementing these important human capacities in future AI systems. Finally, we want to stress the importance of a cooperative relationship between humans and machines. The notion of gap between us and them that can be closed or even surpassed suggests a more competitive relationship than there perhaps needs to be. The results of mutual cooperation between humans and machines could be much more interesting and desirable to achieve.

How AI Can Understand Causality

Paul Thagard

Causality is important for operating in the world and explaining how it works. Yoshua Bengio and others have pointed out that deep learning and other AI systems lack a human-level understanding of causality. Thagard (2019) argues that human understanding of causality originates with sensory-motor-sensory schemas found in infants as young as 2.5 months. For example, a baby can see a rattle, hit it with hands, and see the rattle move and make a noise. Learning robots could potentially form such schemas, but would have to go beyond current AI systems in several ways. First, they would need *modal retention*, the capacity to save and work with sensory and motor representations. This capacity is found in the Semantic Pointer Architecture of Chris Eliasmith (2013), but not in other cognitive architectures or AI systems. Second, they would need the capacity to learn dynamic patterns that capture changes in series of events. Third, they would need to be able to expand the rudimentary sensory-motor appreciation of causality to cover advanced elements that included regularities, probabilities, and manipulations.

In Vivo Studies of Solo and Team Performance

Ray Perez (Co-Organizer)
Office of Naval Research (ray.perez@navy.mil)

Wayne D. Gray (Co-Organizer)
Rensselaer Polytechnic Institute (grayw@rpi.edu)

Jerad H. Moxley
Weill Cornell Medicine (jhm2006@med.cornell.edu)

David Mendonça
Rensselaer Polytechnic Institute (mendod@rpi.edu)

Jamie C. Gorman
Georgia Institute of Technology (jamie.gorman@psych.gatech.edu)

We bring together four researchers who study expertise in team or in solo (i.e., individual) performance. Team research tends to either collect a lot of questionnaire data after performance or a little data, in real-time, by human observers. Studies of solo performers are often restricted to convenience samples of task novices, who often spend less than an hour learning and performing the task. In contrast, the research of all four of our panelists is notable for using tasks which require days-to-years of practice and for the quantities of data collected. Discussions will emphasize the contributions these approaches are making to theoretical cognitive science.

Jamie C. Gorman – *Theory of Interactive Team Cognition*

By recreating environments for Drone pilots or Submariners, Jamie Gorman and colleagues collect communications and responses among team members in real-time longitudinal studies. These data allowed researchers to apply the power of nonlinear dynamical systems theory to further develop the theory of Interactive Team Cognition (ITC, Cooke, Gorman, Myers, & Duran, 2013). The approach has been extended to teams composed of humans and machines.

ITC proposes that team cognition: (1) is an activity, not a property or product; (2) must be measured and studied at the team level; and (3) is inextricably tied to context.

ITC Prop 1 maintains that team cognition is dynamic and context dependent. ITC Prop 2 leads to a systems perspective in which models and metrics are focused at the team level, with individual cognition and behavior viewed as emergent team dynamics. Team member behavior and cognition are dynamically reorganized (or rearranged) in real time (ITC Prop 1) to maintain functionality as the team adapts to changing task environments to achieve its goal. Hence, teams with high cognitive skill achieve their goal even if environmental context varies and roadblocks to team effectiveness are encountered (ITC Prop 3).

Unlike individual cognition, there are no standard tests to measure the general cognitive skill or ability of a team. One theoretical and methodological development has been to determine a generalizable way to identify and measure team cognitive skill through a team's "general adaptive response".

Our research on team cognition has shown that teams that achieve their goals have (a) a faster general adaptive response, (b) adapt their responses to the variability in obstacles they encounter, and (c) generate responses appropriate to the particular roadblocks they encounter. For examples, I will draw on research with medical teams, submarine crews, UAV teams, as well as in vitro, laboratory, team coordination tasks. This variety of teams illustrates the concept of the *general adaptive response* as an ITC-based measure of team cognitive skill. These teams also illustrate the real-time dynamical system modeling techniques that we use to track team cognition in dynamic environments.

David Mendonça – *Adaptation in Adversarial Games*

David Mendonça's prior research has focused on intensive studies of teams in high-stakes, time-constrained environments. His most recent work is an extremely retrospective analysis of "An historical perspective on community resilience: The case of the 1755 Lisbon Earthquake" (Mendonça, Amorim, & Kagohara, 2018).

In addition to being the most played game in the world (with approximately 10M active users), *League of Legends* (LoL) is an adversarial game (similar to "capture the flag") in which teams must adapt to (and even precipitate) unplanned-for contingencies. Elite players (such as those we study), have played thousands of such matches, with the average match consisting of two teams, each of 5 players, battling for 30 min.

Our work explores the relationship between (i) prematch composition of a team, (ii) decision processes within the match, and (iii) match outcomes in LoL. Respective methodological challenges include (i) characterizing team capabilities, (ii) quantifying adaptation, and (ii) validating measures of performance.

In contrast to traditional work on teams, we utilize no psychometric instruments, instead deriving measures that are validated against salient theoretical constructs and instantiated with gameplay data. And while these data are freely available, their allure is offset by some hard realities: researchers have no influence over either the data stream or the game architecture, and the formulas used to benchmark individual and team expertise are

held as trade secrets. Matches are scheduled by the developers on a rolling basis and–unlike in "regular" sports–are designed so that opponents are closely matched.

After briefly summarizing results to date, we explore within-match performance of teams whose members have weaker or stronger histories of working together, focusing specifically on behavioral responses to the temporary loss of one or more team members. We present data on how the experience of "playing shorthanded" translates (or fails to translate) into longer-term behavioral adaptations.

The talk concludes with issues and implications for the design and/or modification of open-source, team-based games and the data associated with them. ïż£

Jerad Moxley – *Chess: The Once & Future Paradigm*

The distinction of having studied more types of gameplay by solos or teams, than any other researcher on this panel may go to Jerad Moxley. His studies have spanned crossword puzzles, chess, basketball, elderly game players, videogames, as well as gender differences among SCRABBLE players.

For researchers interested in skilled performance, an important feature of chess is the reliability of the chess rating system and the fact that one experimental task (the choose the *best move task*), can measure skill and age effects about as well as tournament play, thereby making Chess ideal for studying domain-specific performance. Complimentary, another common task, the *recall task*, diverges from tournaments in ways that make it useful for studying a mixture of domain specific and domain-general abilities.

Applying the *best move task* and *the recall task* across the lifespan of chess players has increased our understanding of how domain-specific processes and domain-general abilities develop. Research on older adults and children now converges to show strong aging effects of chess tasks that tap into both specific and general abilities. In contrast, the best move tasks captures relatively small aging effects consistent with tournament performance.

As noted, performance on the best move task shows developmental trends in both youth and older adults that mirror tournament performance. Importantly, however, process tracing shows clear differences between the growth of skill in youth and the decline of skill with aging. Although skill development is broadly consistent with what we expect based on tournament performance, the age-related decline of prior skill levels shows process differences that dissociate from skill. In particularly, the age-related declines are not uniform. On easy problems, better players immediately gain an advantage over weaker players.

In contrast, on difficult problems, process tracing has shown that better players initially resemble weaker players but as problem solving continues, better players massively improve their move selection. In contrast, more time does not improve the performance of the weaker players. Methodologically, these conclusions follow from the combination of verbal protocol analysis and the traditional behavioral measures.

We view chess not as a standalone domain, divorced from the rest of human cognition but, rather, as a viable paradigm for studying the big questions in cognitive science. Indeed, the tasks and domains discussed here can easily be used by researchers who have no interest in chess itself to answer their questions of interest.

Wayne D. Gray – *Plateaus, Dips, & Leaps to Expertise*

After several years of working in applied labs, Wayne Gray became concerned that basic researchers were not working on the types of theory he needed to do his job. That concern led him to shift to academe where he has since attempted to pursue theories and research applicable to problems of interactive behavior.

Learning a new task can be hard but, apparently, learning and using a new procedure for an old task can be even harder. That is the message from work on *stable suboptimal performance* from the early 2000s. Wai-tat Fu and I demonstrated time and again that people who knew the optimal procedures would fail to apply them, falling back on older ways of doing things.

Although that battle is still being fought (e.g., Lafreniere, Gutwin, & Cockburn, 2017), the focus in my lab has shifted. After a few years of looking at learning curves for individuals, we realized that none of our curves were close to being picture-perfect power law curves. All of our curves showed plateaus, dips, and leaps. Indeed, what we had thought of as noise was, in fact, the message; namely, that learning a real-time, complex, dynamic task entails a series of explorations and discoveries, trials and errors, in search of methods or strategies that will move performance forward.

We now refer to complete mastery of a task as *asymptotic performance* and to stable suboptimal behavior as performance *plateaus*. However, the most interesting parts of the curve are those periods in which performance dips and, sometimes, leaps. The talk will provide several examples of the use of dips and leaps to identify periods of method discovery or invention.

Ray Perez – Basic Research for Complex Problems

For the last 3 decades, Ray Perez has been pursuing applied problems by finding or encouraging others to find theory-based solutions. Most recently, Ray has been the Program Officer of the Office of Naval Research's Cognitive Science of Learning program.

Ray Perez is co-organizer of this symposium as well as its moderator and discussant. In each of these three roles, Ray is focused on how complex tasks, sometime performed by a single person and other times performed by teams, are learned and executed.

Cognitive Network Science: Quantitatively Investigating the Complexity of Cognition

*** - Organizer**

Keywords: cognitive networks; aging; learning; network science; multiplex networks; complexity

Cognition is complex. This complexity is related to multiple, distributed neurocognitive processes dynamically operating across parallel scales, resulting in cognitive processing. A major challenge in studying this complexity, relates to the abstractness of theoretical cognitive constructs, such as language, memory, or thinking in general. Such abstractness is operationalized, indirectly, via behavioral, measures or in neural activity. In the past two decades, an increasing number of studies have been applying network science methodologies across diverse scientific fields to study complex systems.

Network science is based on mathematical graph theory, providing quantitative methods to investigate complex systems as networks (Baronchelli, Ferrer-i-Cancho, Pastor-Satorras, Chater, & Christiansen, 2013; Siew, Wulff, Beckage, & Kenett, 2018). A network is comprised from nodes, that represent the basic unit of the system (e.g., concepts in semantic memory) and links, or edges, that signify the relations between them (e.g. semantic similarity). While the application of network science methodologies has become an extremely popular approach to study brain structure and function, it has been used to study cognitive phenomena to a much lesser extent. This, despite classic cognitive theory in language and memory being highly related to a network perspective (Collins & Loftus, 1975; Siew et al., 2018). Already, network science in cognitive science has enabled the direct examination of the theory that high creative individuals have a more flexible semantic memory structure, identified mechanisms of language development through preferential attachment, shed novel light on statistical learning, shown how specific semantic memory network parameters influence memory retrieval, and provided new insight on the structure of semantic network of second language in bilinguals (Siew et al., 2018).

The aim of the current symposia is to demonstrate the potential and strength of applying network science methodologies to study cognition. This will be achieved by bringing together leading researchers that apply such methods to study various aspects of cognition, including language, learning, aging, and creativity. The presentations will describe state-of-the-art progress and perspectives that are achieved in applying these methods to study cognition. Importantly, these talks aim at stimulating discussion of the fruitfulness of such an approach and how such an approach can powerfully and quantitatively study the complexity of cognitive phenomena. Finally, this symposium aims to demonstrate how network science in cognitive science can be used to quantitatively bridge across different levels of analysis, spanning the computational, behavioral, neural, and social.

Yoed Kenett: Introducing cognitive network science

In recent years, network science has become a popular tool in the study of structure and dynamics at the neural level of the brain. Despite its rich potential, this has been the case to a lesser extent to the study of cognitive phenomena. This, despite classic cognitive theory in domains such as memory and language being heavily based on a network perspective (Collins & Loftus, 1975; Siew et al., 2018). In this talk, I will argue for the potential of applying the quantitative language of networks to study cognition. I will first describe methodological approaches to estimate cognitive networks and relevant network science measures. I will then briefly describe how cognitive network research can be applied to study the structure, processes, and dynamics of cognitive domains. These examples will focus on semantic memory and relate to aspects of creativity, spreading activation, and semantic memory restructuring. Finally, I will argue that cognitive network science can be used to quantitatively bridge across multiple domains of analysis, spanning the neural, cognitive, and social.

Nichol Castro: Capturing the aging lexicon using network science techniques

Word findings problems increase with age, even in the absence of disease or impairment. Although some accounts attribute word finding problems to changes in domain general cognitive processes, the prominent explanation is a deficit in accessing phonology due to weakened connections between lexical items and their phonological constituents between lexical items and their phonological constituents (Burke, MacKay, Worthley, & Wade, 1991). In other words, there is a change in the structure of the mental lexicon that occurs with age. However, quantifying structural change in the mental lexicon has remained understudied. This talk will show how the tools of network science can be used to identify key structural changes in phonological and semantic networks occurring across adulthood (e.g., Dubossarsky, De Deyne, & Hills, 2017). A discussion of how structural change could impact language processing will ensue, followed by a brief foray into the implications of aging lexicon networks in clinical populations. In particular, it's important that we consider how aging impacts the lexicon of not just "healthy" adults, but also those who have suffered brain insult (e.g., in the case of stroke-induced aphasia).

Elisabeth Karuza: Probing the level at which learners track co-occurrence patterns

Humans are highly attuned to the clustering of elements in their surroundings. For example, when learners are confronted with novel sequential input, their element-by-element processing times have been shown to reflect the community structure (i.e., multi-element patterns of co-occurrence) underpinning those sequences. In this talk, I will detail recent developments in a framework for examining learners' sensitivity to the network structure of their environment. Prior applications of this framework have generally involved assigning a handful of unnatural stimuli (e.g., fractal images) to nodes in a small network and generating sequences by walking along its edges (Karuza, Kahn, Thompson-Schill, & Bassett, 2017; Schapiro, Rogers, Cordova, Turk-Browne, & Botvinick, 2013). Here, I will describe the expansion of this approach to encompass the study of larger temporal networks comprised of more naturalistic stimuli (e.g., manipulable objects and phonotactically legal pseudowords). Finally, I will examine how the collection of off-line measures might serve to clarify the previously observed relationship between on-line processing times and network architecture.

Michael Vitevitch: Connecting the MIND and the BRAIN with multiplex networks

Poeppel and Embick (2017) describe two problems researchers face when trying to bring together the mind and the brain: (1) granularity mismatch problem, and (2) ontological incommensurability problem. In the granularity mismatch problem, the elemental concepts and operations of Cognitive Science doesn't match the elemental concepts and operations of Neuroscience. In the ontological incommensurability problem, the fundamental elements of Cognitive Science cannot be reduced to or matched up with the fundamental biological units of neuroscience. Poeppel and Embick (2017) suggest that computational models may overcome these problems and provide the desired bridge between mind and brain. As an alternative to bridging the mind and brain, I discuss the possibility (and potential problems) of using multiplex networks to bridge mind to brain, and to bridge the individual mind-brain to the mind-brains of others.

Keywords: Jeff Elman, simple recurrent networks, prediction, TRACE, language development, event knowledge

Introduction

Jeffrey Locke Elman (1948-2018) devoted his career to studying human language. He investigated how people use language flexibly and productively, and how these abilities are learned from linguistic and other input. Jeff was a faculty member at the University of California, San Diego from 1977 until he passed away in 2018. His early research focused on phonetics and phonology. This work began his theoretical journey that resulted in the ideas for which he is best known: seemingly discrete combinatorial units of language, such as phonemes, may best be understood as emergent properties of underlying continuous multidimensional representations, such as phonetic input.

In the early 1980's, Jeff was a key part of transformative developments at UCSD in connectionist modeling, working with Jay McClelland, Dave Rumelhart, Geoff Hinton, and Liz Bates. With McClelland, he developed the TRACE model of speech perception. In TRACE, speech perception is seen as a constraint satisfaction process in which prior and subsequent context combine with incoming sensory evidence to determine how humans perceive speech.

Jeff then turned his attention to a central but often neglected aspect of cognition: time. Jeff's work on Simple Recurrent Networks, beginning with his classic 1990 article *Finding Structure in Time*, proposed that time-evolving continuous hidden-state representations are fundamental to language processing, and enable prediction-based learning of language. This work remains among the most influential in the history of Cognitive Science. Jeff's subsequent work explored the initial conditions under which a simple recurrent network would recover grammatical structure. He then led a collaborative project to rethink the nature of what must be built in as a foundation for language, and more generally for cognition (Elman et al., 1996). In later work, he focused on the relationship between language and event knowledge. He argued that words do not have meanings, but instead provide clues that a listener uses to understand language. He also focused on event knowledge as a basis for prediction during language comprehension (Elman, 2009; Metusalem et al., 2012). Jeff's final major contribution was a model of how event knowledge is learned. He argued that knowledge of the components and temporal structure of events emerges as a consequence of prediction-based learning (Elman & McRae, 2019).

Jeff also played a major role in advancing Cognitive Science as a field. At UCSD, he and colleagues co-founded the interdisciplinary Center for Research in Language in 1985. In 1986, Jeff was a major part of the first Cognitive Science department, which he chaired from 1995 to 1998. Jeff also served as Dean of Social Sciences, and a founder of both the Kavli Institute for Mind and Brain and the Halicioğlu Data Sciences Institute. Finally, Jeff provided guidance for the field by serving as President of the Cognitive Science Society, and a highly respected Chair of the NIH Language and Communication study section.

This symposium honors Jeff's memory. The introduction and discussion will be led by the organizers (McClelland & McRae). In between, four speakers whose work reflects the legacy of Jeff's contributions will present research from the perspectives of cognitive neuroscience, cognition and perception, language development, computational modeling, and deep learning in simulated embodied agents.

Talks

Gina R. Kuperberg
Language prediction over time and space: Evidence from multimodal neuroimaging studies

In his seminal paper, *Finding structure in Time*, Elman argued that predictions are based not just on input from the world, but on the ever-changing state of the cognitive system. He emphasized the idea that these predictions are

non-deterministic, implicit, and inevitable. He also pointed out that prediction error not only provides feedback to the system (to learn and maximize its performance), but that it also provides valuable clues for the scientist: it can tell us about the structure of the input and the nature of cognition. These ideas have far-reaching implications for thinking about what neural measures can tell us about the architecture of language comprehension. I will discuss evidence from multimodal neuroimaging studies (ERP, fMRI and MEG) that, during comprehension, spatiotemporally distinct neural signatures reflect neural prediction error and updating at multiple time scales. I will argue that they point to a language comprehension system in which probabilistic predictions are generated and incrementally updated over time, at multiple levels and grains of representation, with the ultimate goal of inferring the latent cause that best explains the full set of inputs encountered — the message that the communicator intended to convey. Consistent with Elman's ideas, I also will argue that the neural responses evoked by prediction violations play a crucial role in triggering us to rapidly adapt to the statistical structure of our ever-changing communicative environments so that we can predict more efficiently in the future.

Arielle Borovsky
Prediction in a changing world

This talk connects with several of Elman's contributions, including his perspective on prediction, learning over time, and event knowledge in language learning and processing. Numerous language processing models emphasize the importance of listeners' ability to predict upcoming information for efficient language comprehension and learning. Much of the evidence for these models is derived from studies of comprehension in well-known or familiar (i.e. predictable) contexts. However, speakers are pressed to prioritize novel information, suggesting that everyday conversation does not typically rehash redundant events. In developmental and learning contexts, this problem may be compounded by the fact that listeners may still be learning about the language and the world. Therefore, they may not have sufficient knowledge to generate predictions. In all of these circumstances, prediction might be counter-productive for comprehension. I will discuss recent studies of how adults and children engage in prediction while learning about new events. The findings illustrate that while adult listeners can rapidly modify their predictions in the face of change, children develop this flexibility gradually over a protracted period. By incorporating developmental insights and learning paradigms into studies of linguistic prediction, we can develop richer models of how predictive mechanisms support everyday communication and learning.

James S. Magnuson
Elman's agenda for the cognitive science of language processing

I will review the remarkable breadth and depth of one of Elman's major contributions: the TRACE model of speech perception and spoken word recognition (McClelland & Elman, 1986). I then will apply one of his other major contributions – the simple recurrent network (SRN; Elman, 1990) – to the same domain. Remarkably, SRNs have not been applied deeply to problems in spoken word recognition. Even more remarkably, despite seemingly large differences in architecture, TRACE and SRNs make extremely similar predictions, including item-specific predictions for large sets of items. I will conclude by considering how deeply Elman's ideas and work have shaped the cognitive science of language processing.

Felix Hill
Embodied neural network agents that learn language in a simulated world

I will describe a neural network 'agent' that is situated in a fully-navigable simulated 3D world as a model of early child word learning. The agent perceives its world via first-person continuous raw visual input and must learn to respond, with appropriate sequences of fine-grained motor actions, to symbolic language-like stimuli that describe simple goals. Recurrent components inspired by Jeff Elman's work play an important part in this architecture both for processing language word-by-word and for making sense of experience timestep-by-timestep. I explain how, under certain training conditions, the agent learns to reflect some known aspects of human word learning, including the emergence of semantic classes, vocabulary spurts, curriculum effects and word-learning biases. I further demonstrate how word learning can be sped up by incorporating an offline experience replay mechanism. Finally, I discuss the strengths and weaknesses of modelling early word learning with deep reinforcement learning agents in this way.

Introduction

Research in cognitive control investigates how cognition and behavior get tailored to suit behavioral goals in particular task contexts. The work often focuses on mechanisms that adjudicate competition amongst simultaneously active but mutually incompatible representations. The objects of control—the competing representations—are often cast as fixed entities: control influences interactions among these but does not shape the representations themselves. Conversely, research into the origins of mental representations (perceptual, linguistic, semantic, etc.) often neglects questions central to theories of control: whether and how the acquired representations support flexible task-dependent behaviors, the degree to which learning produces representations that compete or cooperate within and across tasks, or the extent to which learned representations require task-dependent potentiation to operate effectively.

Recent work within each tradition suggests, however, that control, learning, and representation are tightly interconnected. First, the degree to which control is required for any given task and stimulus domain depends critically on the nature, structure, strength, and compatibility of the underlying representations, which in turn arise from learning and experience. Second, when the same items are engaged in a variety of different tasks, it may be useful to exploit a common representation across tasks, or to learn different representations for each, or to find some middle ground—thus learning must produce a flexible set of representations suited to control demands and capturing shared structure within and across task contexts. Third, since control shapes the flow of activation within sensory, motor, and associative systems, it must also constrain activation-dependent learning within and between these systems—that is, the representations acquired must depend to some degree upon control.

This symposium brings together four perspectives on the mutual constraints existing among systems of control, learning, and representation. In each case, consideration of these mutual influences leads to new and often surprising resolutions to long-standing questions across seemingly disparate domains of cognitive neuroscience.

The rational boundedness of cognitive control: Shared versus separated representations

Sebastian Musslick, Abigail Hoskin Novick &
Jonathan D. Cohen, Princeton University

A fundamental and striking limitation of human cognition is the constraint on the number of control-dependent processes that can be executed simultaneously, which forms one of the most basic and influential tenets of cognitive psychology: controlled processing relies on a central, limited capacity processing mechanism that imposes seriality on control-dependent processes. We present a challenge to this view that distinguishes control-dependent and automatic processing by their reliance on shared vs. separated representations. Specifically, we propose that: task performance relies on sets of representations that may be shared with others; the inability to perform more than one task at a time may reflect conflict that arises when the tasks involved make use of the same set of representations for different purposes; and the purpose of control is to prevent such conflict by restricting use of such shared sets of representations to just one task at a time. That is, constraints associated with control-dependent processing reflect a rational response to sharing of representations, rather than limitations in the control mechanism itself. We use graph-theoretic methods to formalize this theory, and analyze the multitasking capability of two-layer neural networks when representations are shared/not shared across tasks. The multitasking capability of a network drops precipitously with an increase in shared representations, and is virtually invariant to network size.

Why then should a network use shared representations at all? In computational simulations and behavioral experiments we demonstrate a tradeoff between learning efficiency, promoted by shared representations, and multitasking, best achieved via separated representations. The commonly-observed trajectory from controlled to automatic processing may therefore reflect an optimization of this tradeoff: shared representations initially afford a bias toward efficient learning in novel task environments at the expense of seriality and control-dependence; but experience in environments where multitasking affords sufficient advantage ultimately promotes acquisition of separated, task-dedicated representations.

Canonical representations for generalization in relational reasoning

Taylor Webb, Steven Frankland, Alexander Petrov[1], Randall C. O'Reilly[2] & Jonathan D. Cohen, Princeton University, Ohio State[1], and U. Colorado-Boulder[2]

The preceding talk suggests that capacity limits on control-dependent tasks fundamentally arise from the use of shared representations across tasks. Why then should cognitive systems employ shared representations? The answer may lie in the remarkable human capacity to generalize far beyond the scope of experience. By contrast, state-of-the-art neural network algorithms tend to do well at interpolating between data points in their training corpora, but generally fail to extrapolate beyond the scope of those data points.

We propose that one way to enable human-like generalization in neural networks is by giving them access to a basis set of canonical, general-purpose representations that capture the abstract relations inherent in common structural motifs (e.g. lines, rings, or trees). We present a method for transforming domain-specific representations into a canonical form, and show that these transformed representations enable robust extrapolation to data points far from the training domain — that is, out of domain generalization. Such broad generalization requires, however, that processes within and across task and item domains share use of the canonical representations, thus making them dependent on control. Understanding the conditions under which canonical representations arise thus provides insight into both the human capacity for generalization and the relationship of this ability to cognitive control.

Toward a neural architecture for controlled semantic cognition

Rebecca J. Jackson, Timothy T. Rogers & Matthew A Lambon Ralph, Cambridge University

We consider how opposing demands of task-specific control versus broad generalization might constrain the architecture of the networks that support semantic cognition—the remarkable human ability to flexibly deploy conceptual knowledge across a variety of behavioral contexts. The semantic system must acquire context-invariant representations that express conceptual structure by abstracting over episodes, time, and modality (sensory, motor, linguistic, and affective), while also dynamically tailoring representations to produce context-appropriate similarity structures and behaviors. How should a semantic system be structured to promote both functions?

We report simulations with models varying in five architectural features, representing different hypotheses about the influence of control on semantic processing and the structure of the semantic network itself. We compared model variants in their acquisition of both context-invariant conceptual structure and context-dependent tailoring of representations and outputs. The system's functioning was best served by an architecture employing a single, deep multimodal hub containing sparse long-range connections from modality-specific inputs, and with control systems operating on peripheral modality-specific representations without affecting the hub. This architecture creates regions of relative specialization for control and representation, explaining distinct patterns of semantic dysfunction arising from temporal versus fronto-parietal pathology. The simulations thus suggest that the cortical anatomy of semantic cognition can be understood as balancing demands of representation and control.

Learning, control, and modularity in lexical semantics.

Lang Chen, Stanford University
Timothy T. Rogers, University of Wisconsin-Madison

A central goal for cognitive approaches to language has been to understand whether various sub-processes operate independently or are mutually interdependent. In accordance with the preceding talks, we suggest the tension between views can be resolved by considering how cognitive control and task-specific experience jointly impact learning in lexical semantic systems, taking visual word recognition as a well-studied example of the controversy. On one hand, patients with acquired semantic impairments typically show difficulty recognizing low-frequency words with unusual orthography, suggesting an interdependence between lexical and semantic representations. On the other, a handful of cases show serious semantic impairment with normal word recognition, suggesting that recognition and semantic processes are independent. Similar patterns in other aspects of language have produced fundamentally different perspectives: one in which all varieties of linguistic representation mutually constrain one another, and another in which different representations are modular and independent.

We show that lexical and semantic representations in a recurrent neural network can become modular when (1) words appear in task-contexts requiring independent activation of each representation and (2) a context-dependent control signal strongly constrains activation in the network. This model suggests that individuals with strong executive control and unusually frequent experience with orthography may develop relatively independent lexical and semantic representations. We tested this hypothesis using dual-task studies to assess semantic interference on word recognition. Most participants showed degraded recognition with concurrent semantic processing but a small percentage showed no such effect. These exceptions uniformly showed exceptional orthographic knowledge and no interference in a Stroop task—suggesting that strong control and practiced orthography jointly promote independent lexical and semantic processing. The results offer a middle ground between fully modular and fully interactive perspectives, and suggest that control and learning play critical roles in shaping the degree to which various linguistic representations interact.

Beyond number: Towards a unified view of dimensional reasoning in perception, cognition, and language

Keywords: quantitative scales; analog magnitude systems; transitive inference; ordinality; comparative reasoning; animal behavior; conceptual development; language; psychophysics;

Introduction

Natural number concepts play a fundamental role in abstract human thought, being central to mathematics, science and measurement, as well as pervasive in our everyday reasoning. A major turning point in our understanding of the psychological bases of number came with the discovery of an approximate, analog system for representing numerical magnitude found to underlie our numerical intuitions in tasks ranging from relative numerosity judgments, to addition, subtraction, and ordering, among others. Crucially, such analog magnitude representations are involved not just for number, but for all other kinds of dimensions as well, from *physical size*, *loudness, brightness*, and *duration* (e.g. Fias et al. 2003; Cordes & Brannon, 2008), to more evaluative dimensions like *likelihood* (Wellman, Kushnir, Xu & Brink, 2016). Based on extensive studies on human adults, children, pre-verbal infants and non-human species, we now understand the systems underlying the mental representation of scalar dimensions to be best characterized as approximate, analog representations with signature ratio limits (obeying Weber's Law), operational in humans from birth and throughout the lifespan, and shared with a wide range of other animal species.

The primary goal of this symposium is to bring recent developments from infant and comparative psychological research pertaining to our understanding of analog magnitude systems to a broader audience of cognitive scientists, to discuss their implications for human cognition. With a more complete picture of the kinds of inferential capacities afforded by analog magnitude and other systems in non-human animals and preverbal infants, we are in a better position to understand the interplay between language and non-linguistic systems in the human mind.

Recent developments

A wealth of research in developmental and comparative cognition in recent years has revealed previously unexpected inferential capacities in infants and non-human animals that are evidently supported by analog magnitude representations.

Cross-dimensional mapping in infancy

It is well-known that adults and children readily map analog magnitude representations to one another (e.g. Stevens & Marks, 1965), but it is a more recent discovery that this tendency in fact begins in infancy. For example, given evidence for a correspondence between numerosity and line length in a visual habituation task, human newborns expect shorter lines to correspond to smaller numerosities, and longer lines to correspond to larger numbers (de Hevia & Spelke, 2010). That newborn infants spontaneously map between number and space, as well as duration (de Hevia et al., 2014), suggests that at least some kinds of scalar mappings may precede experience. Importantly, older infants have been shown to learn more arbitrary mappings in a context-specific manner as well (Lourenco & Longo, 2010), raising the possibility that tracking correspondences between environmentally co-occurring variables may be one way in which infants learn about their physical (and social) worlds in infancy, before access to language.

Transitive inference in animals

Yet another reasoning strategy implicated to be subserved by the analog magnitude systems is transitive inference (TI), the ability to infer from $A > B$ and $B > C$ that $A > C$. Extensive and well-controlled studies of non-human animals in recent decades have revealed a pervasive capacity for transitive inference in species ranging from fellow primates and mammals, to birds, amphibians, and fish. The capacity to represent ordinal relationships is a prerequisite for transitive inference, and as such, TI can be considered a kind of order-based reasoning. Cantlon and Brannon (2006) find behavioural evidence for shared systems for ordering numerical magnitudes in humans and monkeys, and moreover that both groups exhibit semantic congruity effects, signalling a common mental comparison process (Cantlon & Brannon, 2005). The preponderance of evidence for successful non-symbolic TI and order-sensitivity in the animal literature has important implications for human reasoning that are yet to be fully explored by the cognitive scientific community. Such evidence should be of particular interest to those investigating the conceptual foundations of symbolic thought, given the implication that the binary *more than* relation ('<') in language and mathematics may have its basis in analog magnitude systems.

Scalar phenomena in language

In linguistics, conceptual and pragmatic scales are invoked in explanations of linguistic phenomena ranging from gradable adjectives ('*tall*', '*fast*', '*large*', '*ambitious*') and comparative and superlative constructions ('*Ben is taller*

than Dan'; '*Ben is the tallest*'), to scalar implicature (Horn 1972; Hirschberg 1985), to name a few. That classic behavioral signatures of analog magnitude systems --- the symbolic distance effect (e.g. Moyer & Landauer, 1967) and semantic congruity effects (e.g. Banks, Clark & Lucy, 1975) --- arise in tasks involving gradable adjectives, provides some support for links between these linguistic labels and underlying analog format representations. But most well-studied in this regard are the bidirectional linkages between natural numbers (<'*one*', '*two*', '*three*', …>), and corresponding analog magnitude representations in the numerate human mind (Odic, Le Corre & Halberda, 2015). Given that both the number scale as well as scales comprised of gradable adjectives give rise to scalar implicatures, it is worthwhile to consider whether similar mechanisms to those supporting dimensional inference in infants and animals, may also be involved in scale-based reasoning in humans. As it happens, there is recent evidence for the use of parallel strategies for scalar inference by children and adults in non-linguistic tasks (Kampa & Papafragou, 2019; Gweon & Asaba, 2018) lending credence to this possibility.

The pervasiveness of scalar phenomena cross-linguistically, in light of the developments highlighted above, raises the following questions: First, taking for granted that conceptual scales are indeed psychologically 'real', how should they be characterized in psychological terms? What is the precise nature of the relationship between conceptual and/or pragmatic scales, and associated analog magnitude representations? Finally, are there deeper connections between the inferential capacities afforded by analog magnitude systems in preverbal infants and nonverbal animals, and the widely-studied phenomena of scalar and quantity-based inference in linguistically-savvy humans? More specifically, might there be shared neural and cognitive mechanisms for the computation of dimensional inferences in the linguistic, cognitive, and perceptual domains?

Linguists in the 1980's and 90's theorized the existence of 'scalar models' that map between two or more correlated dimensions to support implicit inferences arising with scalar language (e.g. Fauconnier, 1975; Kay, 1990; Israel 1996). Although such cognitive accounts subsequently fell out of favor within mainstream linguistic theory, the empirical clarity provided by psycholinguistic findings in recent years has convinced some that a better understanding of the conceptual structures that language links up to "under the hood" may be essential to account for the distribution of various classes of linguistic inference (Paul, 2018). The superficial similarity of the early theoretical models of scalar linguistic reasoning to the recent empirical results from the infant literature (i.e., bidirectional mappings between statistically correlated properties), suggests the former may be ripe for revisiting. The different disciplines studying phenomena involving the representation of dimensional attributes stand to gain from sharing insights across disciplinary boundaries, something we hope to foster with this symposium. Moreover, this symposium has the potential to inspire renewed efforts towards a more psychologically informed model of scalar reasoning in language, and possibly even a unified model of dimensional reasoning in human and animal cognition.

Speakers:

Stella Lourenco will represent the perspective from infant cognition, specifically her research on cross-dimensional mappings in infancy, as well as some brand new cognitive neuroscientific results from her lab supporting a generalized system of magnitude representation.

Jessica Cantlon will discuss the comparative cognitive perspective, including findings of parallel behavioral patterns in human adults and monkeys in numerical ordering and other tasks, and what this reveals about our shared mental processes for magnitude comparison.

Anna Papafragou will focus on the development of scalar implicature, and present new work showing that adults and children's behavioral patterns in non-linguistic and linguistic versions of a task eliciting scalar implicature are guided by a common principle.

Pooja Paul will employ her background in linguistics and developmental psychology to disentangle the contributions of extra-linguistic domains from that of language in scalar reasoning. Her presentation will synthesize the different strands of research presented during the symposium, and paint a picture of what a unified theory of dimensional reasoning might look like.

Fallacies?

Since antiquity, we have wondered about the foundations of our (apparent) intellectual superiority. A way to approach this issue is to seek rational standards in decision making and examine convergence between such standards and behavior. However, establishing a rational framework is not straightforward. One of the most unique contributions of cognitive science is the varied perspectives it has provided for rationality. With many recent advances in decision theory (including novel techniques in probabilistic inference and sophisticated frameworks for heuristics-driven reasoning), it is particularly timely to reevaluate rational standards and our assumptions regarding rational behavior. This is the purpose of this interdisciplinary symposium, bringing together expertise in psychology, computer science, mathematics, physics, and philosophy of mind.

Cognitive science research has already instigated major shifts in our perception of rationality and optimality. For most of our history, it has been considered that classical logic is the source of human rationality and the appropriate normative standard against which to assess decisions. Wason sought a general test of whether natural reasoning is consistent with classical logic, by asking participants to select which evidence was best suited to test a given rule. Logic prescribes selections which can definitely falsify the rule (a falsificationist mentality which has had a pervasive influence in scientific reasoning, including in frequentist statistics), but instead participants selected evidence with potential to confirm the rule. Oaksford and Chater (1994) proposed that participants prefer the cards which minimize the information-theoretic uncertainty regarding the validity of the rule, employing Anderson's (1990) idea of optimal adaptation. Classical probability theory (CPT) thus revealed an alternative perspective for the 'correct' selections in Wason's task.

CPT is currently recognized as the right starting point for understanding rational decision making, benefiting from powerful formal justifications and excellent descriptive coverage. Equally, it has been increasingly appreciated that a *baseline* CPT framework is unlikely to provide either a complete descriptive framework for cognition or indeed an appropriate normative framework, without suitable extensions (e.g., Tenenbaum et al., 2011). One influential source of indication that this is the case concerns reports of persistent apparent violations of CPT principles, usually called fallacies. Tversky, Kahneman and their colleagues have produced some of the most evocative examples, for example, the conjunction fallacy, according to which naïve observers are quite happy to accept that *Prob*(A&B)>*Prob*(A) (Tversky & Kahneman, 1983). The most telling instantiation of this result involves the probability of a Scandinavian person having blue eyes and blond hair vs. just having blond eyes (Tentori et al., 2004). Imagining a line-up of Scandinavian individuals makes it immediately obvious why the conjunction fallacy is, well, a fallacy, and yet the conjunctive statement still feels natural – it is this persistence that makes fallacies so puzzling. There are several similar results. For example, a famous Gallup poll study showed a *Prob*(Clinton is honest) of 50% when this question was first but 57% after a similar question for Gore (Moore, 2002); in another famous study, a mixture of weak and strong evidence had less impact than just the strong evidence (the dilution effect; Nisbett et al., 1981).

Such findings appear to challenge our expectation of rationality. But do they have to? Over the last decades, new, sophisticated techniques and ideas have emerged, which require drastic revision to our perception of applicability of *baseline* CPT frameworks in thought. In this symposium we explore four approaches, some of which directly extend baseline CPT ideas while others are motivated from baseline CPT ideas to develop in more alternative directions, with sometimes surprising implications for empirical coverage and normative evaluation.

Resource-rational analysis: Griffiths, Lieder

Baseline CPT inference is expensive, and practical models often involve some kind of sampling-based approximation to posterior probabilities. In the tradition of bounded

rationality, the resource-rational analysis is about finding the optimal balance between the accuracy of probabilistic approximations and resource allocation, with the latter formulated in terms of computational cost (Griffiths et al., 2015). This approach can recover previously-identified heuristics and discover new ones, as well as shed light in the way resource limitations can lead to apparent deviations from CPT prescription.

Quantum: Busemeyer, Pleskac, Yearsley, Pothos

Another way in which CPT probabilistic inference can be made more tractable is by limiting the size of the probabilistic space. The logical structure of CPT is a Boolean algebra, but for Quantum probability theory (QPT) it is a partial Boolean algebra, which means a collection of smaller (simpler) parts, which are classical individually, but inconsistencies/ contextuality/ apparent fallacies arise when reasoning between parts. We think that QPT representations are more likely when e.g. participants are unfamiliar with a problem or unwilling to engage thoughtfully. We show how QPT can reveal rational perspectives to established fallacies (Pothos et al., 2017) and further consider whether QPT can shed light on rational status of behavior in strategic games, in situation when decisions appear inconsistent with the Nash equilibrium or sub game perfect equilibrium.

Heuristics: Hertwig, Pachur, Leuker

Rather than simplify or approximate CPT inference through e.g. more efficient sampling procedures, an alternative, influential possibility is that the mind adopts heuristics. Heuristics can be as accurate and sometimes even more accurate than strategies that employ the greatest possible amount of information and computation. Can such advantages generalize to situations involving interactions with other intelligent, competitive actors? We will explore the effectiveness of heuristics in stationary games against nature and in strategic games and show that heuristics are particularly competitive when the level of epistemic uncertainty is high. We will also consider in general the ecological structures that heuristics can harness, and how theories of heuristics can be integrated with other frameworks of human choice.

Probabilistic language of thought: Tenenbaum, Goodman, Tessler

An important extension to baseline CPT frameworks concerns incorporating language-like properties (such as compositionality), representations, and pragmatic reasoning in probabilistic inference. The probabilistic programming language (PPL) / probabilistic language of thought (PLoT) can more naturally apply to richer forms of reasoning, including everyday reasoning under uncertainty (e.g., Goodman et al., 2015). Furthermore, enriching these models with an understanding of natural language pragmatics can explain apparent fallacies in classical reasoning tasks (e.g., Tessler & Goodman, 2014). Assuming a communicative context to a task involving language allows a reasoner in a PPL/PLoT model to incorporate the goals of a speaker (e.g., assuming the speaker intends to be informative), so providing a rational perspective on reasoning fallacies. We will also consider the way resource limitations guide practical models in PPL.

Discussion: Shiffrin

The discussion part of the symposium will address these varying perspectives on rationality and bring together the themes raised in the presentations. The overarching questions concern what is rationality, and whether 'bounded rational' approaches capture enough of what humans mean by this concept. The discussion will be open to all presenters and the audience.

Insight and the Genesis of New Ideas

Frédéric Vallée-Tourangeau
(f.vallee-tourangeau@kingston.ac.uk)
Department of Psychology, Kingston University
Kingston upon Thames, UNITED KINGDOM, KT1 2EE

Linden J. Ball
(lball@uclan.ac.uk)
School of Psychology, University of Central Lancashire
Preston, Lancashire, UNITED KINGDOM, PR1 2HE

Keywords: insight, creativity, working memory, phenomenology, first-order problem solving

Research on insight problem solving focuses on the genesis of new ideas and aims to identify underpinning processes that turn an initially unproductive problem representation into one within which the solution offers itself in the agent's mental look-ahead horizon. To address this aim, researchers typically create laboratory-based tasks designed to encourage an incorrect representation of an ostensibly simple problem or riddle such as "how do you throw a ping pong ball in such a way that it travels a certain distance, comes to a dead stop and then reverses direction" (Ansburg & Dominowski, 2000). Such riddles are created to encourage an incorrect interpretation and engender an *impasse*. Researchers can then observe how this impasse is overcome by: (i) examining the phenomenology of insight; (ii) analysing strategic processing (e.g., via protocol analysis); and (iii) exploring brain areas that are active when insight arises (e.g., using neuroimaging).

The current debate in insight research (e.g., Gilhooly, Ball, & Macchi, 2015; Gilhooly & Webb, 2018) pitches the *business-as-usual* view against the *special-processes* view. The latter has roots in Gestalt ideas: insight is the result of a swift change in the way a problem is represented in the mind. The sudden awareness of the solution suggests that insight is not the product of a conscious, incremental, deliberate analysis of the problem helping the agent formulate a solution gradually over time. The 'special' in special processes underscores insight as the product of non-routine cognition largely operating non-consciously (Ohlsson, 2018). If routine cognition, in turn, is in the business of helping an agent plan and solve problems, then the business-as-usual view holds that insight is the product of conscious, deliberate, and incremental effort to solve a problem. From this perspective, a breakthrough may yield a *eureka* moment, but this distinct phenomenological signature does not imply that something other than routine cognition is involved in insight.

Insight research has laboured a fertile ground of methodological and theoretical development in the past 20 years. When the important edited volume by Sternberg and Davidson (1995) was published, research was predicated on a dichotomy whereby problems were deemed to be either *analytic* (e.g., the Tower of Hanoi) or *insight* problems (e.g., the 9-dot problem). This missed the critical point that insight and analysis are underpinning *processes* rather than solution outcomes. Developments in theory (e.g., Weisberg's, 2018, integrated framework) have underscored this point, as has the introduction of new problem types that can be solved either by insight or analysis, as reflected in self-reports (Bowden, Jung-Beeman, Fleck, & Kounios, 1995; Salvi, Costantini, Bricolo, Perugini, & Beeman, 2015; Threadgold, Marsh, & Ball, 2018). Such problems have facilitated investigations of the neural correlates of insight (Abraham, 2018; Kounios & Beeman, 2014) and associated biomarkers (e.g., eye blinks; Salvi, Bricolo, Franconeri, Kounios, & Beeman 2015). Individual differences approaches have also revealed the role of working memory capacity in insight (Chuderski & Jastrzębski, 2018). This symposium will showcase important aspects of current insight research, with presentations by Anna Abraham, Carola Salvi, Ut Na Sio, Margaret Webb, Frédéric Vallée-Tourangeau and Linden Ball (discussant).

Abraham will explore how the study of the brain informs the workings of the human mind as it arrives at insights. Functional neuroimaging studies have revealed key brain regions and networks of relevance, also highlighting the intimate roles played in insight by creative processes such as analogical reasoning and conceptual expansion. EEG studies using event-related potentials indicate a unique neural activity pattern when processing creative associations that are personally experienced as being novel and fitting, as distinct from processing associations that are merely novel or merely fitting. In addition, neuropsychological studies indicate that disruptions at the level of brain structure can both aid and impede creative thinking. The former occurs in contexts where distractibility facilitates creative ideation, a finding indirectly supported by personality-based studies of schizotypy and creativity. These results highlight the value of the neuroscientific approach in advancing an understanding of how creative insights come to pass.

Salvi will present her findings on the "accuracy effect" (i.e., insight solutions have a higher probability of being correct than analytic solutions when tested using convergent thinking problems) and will discuss the model behind this result. The effect is explained by the fact that insight processing yields no partial solution information because of subthreshold processing prior to the suddenly available solution. In contrast, analytic processing can yield better-than-chance guessing based on processing of suprathreshold activation candidates. Further**,** Salvi will present her latest results on the neural correlates and biomarkers associated with insight solutions and the underlying cognitive processes.

Sio will focus on the circumstances that promote creativity. Despite the common belief that distraction will cause productivity loss and that individuals should focus on a single task to achieve optimal performance, recent studies have demonstrated that distraction (e.g., incubation and multitasking) can enhance performance for problems requiring creative thinking. Different potential mechanisms for this distraction effect will be discussed. Sio will also

present findings of recent studies aimed at identifying moderators of the effect to help explain why the positive effect of distraction might emerge and to identify the conditions under which distraction becomes facilitating.

Webb will present research on individual differences associated with insight phenomenology. Investigating individual differences in possible biases in reporting insight is constrained by the "problem of problems", that is, problem-solving skills (e.g., working memory) are required for insight problem solving itself. These individual differences may not be the same as those associated with a bias towards insight experiences. In her recent work, Webb has explored divergent thinking tasks, in which subjective accuracy is high. Participants completed a form of the alternative uses task, reporting on their insight phenomenology ("aha!" experiences) in a trial-wise manner. They were then presented with various solutions to the previous task and also completed a measure of schizotypy (the O-LIFE) to assess whether positive schizotypy (associated with the tendency to perceive meaning in noise) predicted a tendency to report feelings of insight. Findings indicate that generating a use is significantly more likely to result in an "aha!" experience than being presented with a use; positive schizotypy is also a positive predictor of feelings of insight.

Vallée-Tourangeau will outline an ecological perspective on insight, critically reflecting on how insight research often proceeds in the laboratory and how the psychometric methodology validates and reinforces a model of problem solving in which working memory plays a central role. His reflections draw on a distinction between *first-order* versus *second-order* problem solving (Vallée-Tourangeau & March, forthcoming). Research typically assumes the world is represented *inside* a person's head, with mental representations being transformed by rules and operators. It is, therefore, not surprising that individual differences in working memory capacity explain a substantial proportion of the variance in problem solving performance, as working memory underpins a person's ability to construct, maintain and transform mental representations. Crucially, the standard methodology requires participants to think about short vignettes (a few words or sentences) that describe (ambiguously) some state of the world. In other words, participants are not embedded in the *physical* world to solve a problem (first-order problem solving) but are instead processing representations of the world based on abstractions of varying complexity (second-order problem solving). First-order problem solving is impossible as participants cannot interact with a *physical* problem presentation. Second-order problem solving carries a representational toll and, as a result, individual differences in the ability to maintain and transform mental representations—gauged in terms of working memory capacity—correlate with problem solving performance.

Logicist Computational Cognitive Modeling of *Infinitary* False Belief Tasks

Selmer Bringsjord (selmerbringsjord@gmail.com)
Rensselaer AI & Reasoning Lab, Dept of Cognitive Science, RPI; Troy, NY 12180 USA

Naveen Sundar Govindarajulu (naveensundarg@gmail.com)
Rensselaer AI & Reasoning Lab, Dept of Cognitive Science, RPI; Troy, NY 12180 USA

Abstract

We synoptically describe having achieved the unprecedented logicist cognitive computational simulation of quantified versions of any n-level (FBT_n, $\forall n \in \mathbb{N}$) false-belief task, and hence of what we call the *infinitary* false-belief task (FBT_ω); the achievement is enabled by the automated reasoner ShadowProver. Logicist cognitive computational simulation of the level-one (or, as it's currently known, "first-order") false-belief task (FBT_1) was achieved circa 2007 by Bringsjord et al. But subsequently cognitive science has seen the arrival such modeling and simulation successfully applied to the *second-order* false-belief task (FBT_2); see e.g. (Blackburn & Polyanskaya, forthcoming). (This is the level-two FBT in our hierarchy of tasks.) But now, courtesy of what we report, logicist cognitive computational simulation of any FBT_n is accomplished for the first time, and hence the infinitary false-belief task (FBT_ω) is reached as well.

Keywords: logic; cognitive modeling; false-belief task; sally-anne task; infinitary reasoning

The Level-1 and Level-2 False-Belief Tasks Many readers will be familiar with the standard false-belief task (FBT_1; a.k.a. the Sally-Anne task), first introduced by Wimmer and Perner (1983). But to ensure self-containedness we recapitulate: A subject (in an experiment carried out by e), agent a, perceives two agents a_1 and a_2 in front of two boxes b_1 and b_2. Agent a_1 puts an object o into b_1 in plain view of a_2. Agent a_2 then leaves, and in the absence of a_2, a_1 moves o from b_1 into b_2; this movement isn't perceived by a_2. Agent a_2 now returns, and a is asked by the experimenter e: "If a_2 desires to retrieve o, which box will a_2 look in?" If younger than four or five, a will reply "In b_2" (which of course fails the task); after this age subjects respond with the correct "In b_1." While some refer to this task as the "first-order" version of the false-belief task, we refer to it as the "level-one" version of the task.[1]

Table 1 lists some of the key epistemic propositions that hold of FBT_1^P after the switch happens, paired with their obvious symbolizations in our multi-operator quantified cognitive calculus used for handling false-belief tasks. We use the superscript 'P' to indicate that the task in question is passed; we reserve superscript 'F' to indicate that the task is failed.

[1]Use of the locution "n-order" is quite infelicitous, because this locution is long established in formal logic as a way to pick out the expressive power of extensional logics within a hierarchy of them. For instance, there is first-order logic, second-order logic, and so on. Since which of these logics is used to model and simulate a given false-belief task is a key parameter in the logicist modeling in question, we judge it to be wise to refer to such tasks at a given *level*, not an order, so as to avoid confusion that will otherwise obtain.

Table 1: Table for Level-1 (L1) FBT = FBT_1

Label	English Declarative Content	Formula
L1.1	a_1 believes a_2 believes o is in b_1.	$\mathbf{B}_{a_1}\mathbf{B}_{a_2}I(b_1)$
L1.2	a_1 believes o is in b_1.	$\mathbf{B}_{a_1}I(b_1)$
L1.3	a believes a_2 believes o is in b_1.	$\mathbf{B}_{a}\mathbf{B}_{a_2}I(b_1)$
L1.4	a bel. a_1 bel. a_2 bel. o is in b_1.	$\mathbf{B}_{a}\mathbf{B}_{a_1}\mathbf{B}_{a_2}I(b_1)$

The level-two (or "second-order") FBT is easily captured, as follows.[2] First, when agent a_2 leaves, he/she secretly perceives a_1 move o to box b_2. Formally, the key adjustment is an *addition* to (adjustments of) the lines seen in Table 1: e.g.

L2 a_2 believes a_1 believes a_2 believes o is in b_1.

Prior Relevant Achievements Circa 2007, cognition associated with the *false-belief task* (FBT_1, including both FBT_1^P and FBT_1^F) was modeled in formal logic expressive enough to handle quantification, and computationally simulated (Arkoudas & Bringsjord, 2008, 2009).[3] This type of research falls under what Bringsjord (2008) calls *logicist computational cognitive modeling* (LCCM). As far as we are aware, this work in 2007 marks the first robust logicist modeling and simulation of both passing and failing cognition in FBT.[4] Here is the crucial takeaway from study of prior work: No one, before now, has achieved logicist computational cognitive modeling of quantified false-belief tasks at level 3, 4, ..., even in the non-quantificational case; and no one has reached the infinitary case.

Level-k ($k \geq 3$) False-Belief Tasks In the level-three false-belief task, agent a_1 secretly views a_2's secretly viewing into the room from outside it. (All of this is easily visualized with help from iterated, hidden cameras that feed information to the agents. Because of space limitations we forego visual depictions.) For FBT_3, the characteristic formula is:

$$\mathbf{B}_{a_1}\mathbf{B}_{a_2}\mathbf{B}_{a_1}\mathbf{B}_{a_2}I(b_1) \tag{1}$$

[2]A nice place to start reviewing the literature on FBT_2 is (Baron-Cohen, O'Riordan, Stone, Jones, & Plaisted, 1999), which has complete references to the earliest introduction of FBT_1 and FBT_2 in the (empirical) literature. (In this regard, we certainly recommend that interested readers review (Perner & Wimmer, 1985).) There is no discussion in this literature of level-3-and-above FBTs, let alone of infinitary FBTs such as FBT_ω; and we haven't found any formal/mathematical literature on these more demanding FBTs either.

[3]While formal but certainly declarative, very impressive computational cognitive modeling of FBT_1 was achieved earlier by Wahl and Spada (2000). Stenning and van Lambalgen (2008) provide informal declarative notation for modeling false belief, but have no implementation/simulation.

[4]Bello, Bignoli, and Cassimatis (2007), as in the aforecited (Wahl & Spada, 2000), achieve computational cognitive cognitive modeling of FBT_1 that makes use of declarative representations, but not of any logics.

Quantified False-Belief Tasks The sub-formulae $I(b_n)(n \in \{1,2\}$ is expressible within the formal language of only the propositional calculus. If instead of a single object o being used, a given FBT involves a *group G* of, say, n objects, then the correlate to this sub-formula will require the machinery of at least the quantificational machinery of first-order logic. We are able to model and computationally simulate in this more demanding case, so that even if subjects have beliefs about a quantity m from G ($m \leq n$) being placed in the box, their cognition can't be captured.

FBT_ω: An Infinitary Quantified False-Belief Task Our inference system leverages a computable version of an infinitary inference rule to prove FBT_ω given that we can prove FBT_n $\forall n$ (N. Govindarajulu, Licato, & Bringsjord, 2013).[5]

Automation We use an automated reasoning system, ShadowProver, to model FBT_n and FBT_ω. ShadowProver is a quantified modal logic theorem prover that has been used to model, in LCCM fashion, intricate reasoning tasks, e.g. ethical reasoning in (N. Govindarajulu & Bringsjord, 2017; N. S. Govindarajulu, Bringsjord, Ghosh, & Peveler, Forthcoming in 2019) and self-consciousness in (Bringsjord, Licato, Govindarajulu, Ghosh, & Sen, 2015). Since characteristic statements for FBT_n and FBT_ω are structurally similar to common knowledge, we leverage ShadowProver's ability to use the operator ($\mathbf{C}$) for such knowledge.[6]

Objections We mention here only that while it might be objected that humans have trouble with even third-order belief, many of our college-level subjects on the contrary have little trouble proving correct answers for any FBT_n.

Acknowledgments The "late-breaking" achievements described herein have been enabled by generous support from ONR and AFOSR, for which we are deeply grateful.

PUBLICATION-BASED PRESENTATION: Modeling Human Creative Cognition using AI Techniques

Steve DiPaola
School of Interactive Arts and Technology, Simon Fraser University
250-13450 102nd Avenue, Surrey, B.C., Canada V3T 0A3 sdipaola@sfu.ca

Keywords: computational creativity; fine art painting; creativity; empathy; artificial intelligence; deep learning; evolutionary programming

DiPaola's research endeavors to build top down Artificial Intelligence (AI) models of human creativity, empathy and expression for both use in new forms of computation systems as well as analysis of how the creative mind works. In doing so he has interviewed hundreds of artists, writers and musicians on how they perceive their creative talent and its originals. Combined with research from neuro-aesthetics and computer modelling, DiPaola notes that while many creative individuals report that they believe new insights as coming into them from an external source during creative flow, that evidence point to these new creative ideas and interpretations often more likely have internal roots from the individual's, mid and long term past experiences and processes. DiPaola attempts to model this and other human creativity processes in computational form often as AI systems such as deep learning, reinforcement learning and evolution programming. Two efforts underway in DiPaola's research lab are mapping out the creative process of a fine art portrait painter using 5 hierarchical AI systems, as well as modelling an empathetic embodied character agent who can understand emotions from those she talks with and construct creative narrative or quote like responses.

The common view that our creativity is what makes us uniquely human suggests that incorporating research on human creativity into Artificial Intelligence (AI) based generative deep learning techniques might be a fruitful avenue for making their outputs more compelling and human-like, especially in arts such as the creative arts. Using our labs original AI systems such as our deep learning convolutional neural networks and cognitive based computational art rendering systems, we attempt to show how human creativity can be implemented/modelled computationally, and demonstrate their impact on the resulting digital generative art. Conversely, he will discuss how explorations in creativity AI can inform our understanding of human creativity and its foundations.

DiPaola will discuss and demonstrate his lab's approach (ivizlab.sfu.ca) to cognitively modeling a fine art painter process by integrating Deep Learning AI with novel computational novel NPR approaches. This interdisciplinary (cognitive science / arts / AI) work brings cognitive creative fields together with Deep Learning neural networks. DiPaola will demonstrate and discuss the lab new work as well as the applications spaces in interactive arts, health and a recent Google / Knight Foundation granted project using creative painterly emulation as a new approach to anonymize interviewees in documentary videos where the study data shows improvement to overall empathy and engagement compared to current techniques.

Steve DiPaola, past Director of the Cognitive Science Program at Simon Fraser University (SFU), is currently is a Professor and lab director of the iVizLab, a PhD based lab on Artificial Intelligence using human cognition theories of creativity, empathy and expression. He came to SFU from Stanford University where some of his creative AI systems were used in generative game creation including the best-selling game of that year, "The Sims". DiPaola has over 100+ peer reviewed papers in AI/cognition and $2 million in past/current funding in AI related areas of cognitive creativity and expression. As both a scientist and artist, DiPaola has written code for his AI "creative on its own" artworks that has been shown in major galleries and museums including The Whitney, The Smithsonian, Tate, and gallery's in NYC, London and LA.

A Cultural Evolution Framework for Human Creativity

Liane Gabora (liane.gabora@ubc.ca)
Department of Psychology, University of British Columbia, Kelowna BC, V1V 1V7, CANADA

Keywords: concepts; convergent thinking; contextual focus; creativity; cultural evolution; divergent thinking; representational redescription; self-organized criticality

Introduction: Honing Theory of Creativity

Other species perceive, make decisions, take action, and even create. However, our species is exceptional with respect to our predilection to adapt ideas to our own needs, tastes, and perspectives, and express ourselves through language, technology, art, and other means. I will present ongoing theoretical and empirical research on how the creative process works and how human creativity evolved. What makes this research program unique is that it examines creativity from the perspective of its role in fueling the evolution of culture, and includes both studies with human participants and computational models.

Creativity research has emphasized the generation of multiple ideas over *honing*—recursively reflecting on a question or idea by viewing it from different perspectives (Gabora & Kauffman, 2016; Gabora, 2017). Just as a single object may cast separate shadows when lit from different directions, the mental representation of a creative work-in-progress may be a single entity with the potentiality to be articulated as different prototypes, sketches, or story ideas.

Honing does not encompass additions or modifications to an idea that are tacked on willy-nilly; it refers specifically to modifications that arise in response to an overarching conceptual framework that is shepherding[1] the creative process. The structure of this overarching framework reflects the individual's *worldview:* their self-organizing web of understandings about their world and their place in that world (in other words, the creator's mind as experienced 'from the inside').

The term *psychological entropy* has been used to refer to arousal-provoking uncertainty, which can be experienced not just negatively as anxiety but also positively as a wellspring for creativity (or both) (Gabora, 2017). It is proposed that psychological entropy—a macro-level variable acting at the level of the worldview as a whole—generates emotions that play a role in guiding and monitoring creative tasks. Thus, honing continues until psychological entropy decreases to an acceptable level. In Piagetian terms, during honing the individual assimilates each new understanding of the idea, and the individual's worldview changes to accommodate this new understanding. Insight is then explained in terms of *self-organized criticality* (SOC) (Gabora, 2017), a phenomenon wherein, through simple local interactions, complex systems tend to find a critical state poised at the cusp of a transition between order and chaos, from which a single small perturbation occasionally exerts a disproportionately large effect. Thus, while most thoughts have little effect on one's worldview, an idea we call *insightful* is one for which one thought triggers another, which triggers another, and so forth in a avalanche of conceptual change.

Convergent thought has been defined and measured in terms of the ability to perform on tasks where there is a single correct solution, and *divergent thought* in terms of the ability to generate multiple different solutions. I will explain why *honing theory* (HT) leads us to redefine convergent thought as thought in which the relevant concepts are considered from *conventional contexts,* and divergent thought as thought in which they are considered from *unconventional contexts* (Gabora, 2018).

Implications for Cultural Evolution Theory

I propose that creativity fuels worldview transformation, and that worldviews are what evolve through culture, in a piecemeal fashion, through a process of *Self-Other Reorganization* (SOR) involving (internal) self-organization and (external) interaction with other worldviews (Gabora, 1999, 2013, 2019). SOR solves dilemmas associated with the high degree of human cooperation (Voorhees, Read, & Gabora, in press), which enables the cumulative building of ideas on one another. I will present a set of agent-based model experiments which show, in different ways, that the effectiveness of this cumulative building depends on the balance between continuity (via imitation) and novelty (via creativity) (Gabora & Tseng, 2017).

I propose that creative outputs merely provide evidence concerning the evolutionary states of worldviews (just as shadows provide evidence concerning the shape casting the shadow). This stands in contrast to the traditional view that behaviors, artifacts, or memes, are the objects of cultural evolution, i.e., they are *what* evolves through culture.

Cross-Domain Influence

The view that it is worldviews that evolve through culture follows naturally from studies of *cross-domain influence,* wherein a creative output in one domain (e.g., art) is influenced by another domain (e.g., music). I will report on a set of studies in which creative individuals in multiple disciplines were asked to list as many influences on their creative work as they could. Results indicate that cross-domain influences are surprisingly ubiquitous, particularly in the arts, where they appear to be even more widespread than within-domain influences (Scotney, Weissmeyer, & Gabora, 2018). The discontinuities in cultural lineages that result from cross-domain influence (e.g., Led Zeppelin's use of Tolkien's *Lord of the Rings* as inspiration for the song

[1] This word is chosen deliberately because it implies that the process is neither entirely top-down nor entirely bottom-up.

"Battle of Evermore") are difficult to account for without resorting to the view that it is not the outputs themselves but the worldviews generating them that evolve through culture.

The Origins of Creative, Cultural Evolution

Like the origin of life, the origin of the kind of integrated worldview needed for cultural evolution has been modeled using an *autocatalytic framework* (Gabora & Steel, 2017). In an autocatalytic network, for each component there exists a means to catalyze the reaction that generates it. Although no component can catalyze its own formation, the network of components as a whole is collectively autocatalytic. In culture, the role of catalysis is played by association and reminding events, and the 'reactions' are between, not catalytic molecules, but concepts and ideas. As parents and others share knowledge with children, an integrated understanding of the world takes shape in their minds, such that they become able to reframe new information in terms of existing mental structure, and become themselves creative contributors to cultural evolution.

I propose that two key steps toward cognitive modernity were (1) onset of *representational redescription* (RR) in *Homo erectus* 2 MYA, and (2) onset in the Middle/Upper Paleolithic of *contextual focus* (CF): the ability to shift between convergent and divergent modes of thought (Gabora & Smith, 2018). In terms of the autocatalytic model, representational redescription entails an interaction or 'catalysis event' between different representations or perspectives, and CF entails the capacity to vary the 'reactivity' of the network. CF may have originated with mutation of the FOXP2 gene, which is known to have undergone human-specific mutations in the Paleolithic (Gabora & Smith, 2019). FOXP2, once thought to be the "language gene", is not uniquely associated with language. In its modern form, FOXP2 may have enabled fine-tuning of the neurological mechanisms underlying the capacity to shift between convergent and divergent processing modes by varying the size of the activated region of memory.

Computer-generated Art and Music

Finally, I will discuss ongoing applications of HT to the development of computer-generated art and music (Bell & Gabora, 2016; DiPaola, & Gabora, & McCaig, 2018; McCaig, DiPaola, & Gabora, 2016). I will show how such efforts are useful for bringing to light the strengths and limitations of our understanding of the creative process.

From Design Cognition to Design Neurocognition

John S Gero (john@johngero.com)
Department of Computer Science and School of Architecture, University of North Carolina at Charlotte
Charlotte, NC 28223 USA

Keywords: design cognition, design neurocognition, protocol analysis, EEG, fNIRS

Introduction

Design is one of the most profound acts of humans and is the way in which we intentionally change both the physical and virtual worlds around us. Design is mentioned in the earliest extant writings of humans. It appears in *The Epic of Gilgamesh,* which dates back over 4,000 years. The first mention of design appears around the same time as the earliest writings about mathematics, philosophy and science. Design is one of the ways a society increases its economic and social wealth. Given its longevity it is surprising that the formal study of design dates back only to the twentieth century. The scientific study of design, design science, commenced only about 60 years ago.

In English the word "design" is used both as a noun and a verb and its use is disambiguated by its context. We will, in general, use the word "design" to mean the outcome and "designing" to mean the process of producing a design.

There are many designers and teachers of designing who claim that designing cannot be studied scientifically since its results are not reproducible. Whilst designs can be studied what we are interested in when studying designing are the processes that go to make up the acts of designing. It is assumed that there is some regularity exhibited by those processes and it is those processes and that regularity that is being studied. The scientific study of designing borrows it methods directly from the scientific method. It carries out controlled experiments in laboratories and in-situ studies in the field.

Designing was initially studied within the framework of information processing before moving to an artificial intelligence frame. However, when designing was treated as cognitive processes, it used the frame of cognitive science and the field of research became known as "design cognition".

The talk will present recent advances in the study of design cognition and the extension of those studies into the study of brain behavior while designing – "design neurocognition" in the Gero lab. The Gero lab is a disaggregated lab with projects in locations in multiple countries including Australia, Croatia, France, Italy, Sweden, Switzerland and the USA.

Design Cognition Through Protocol Analysis

Protocol analysis (Ericsson & Simon, 1993) has become the preferred research method for the elicitation of design cognition. Around it a range of analysis methods have been developed (Kan & Gero, 2017) that form the basis of new results. The results presented in the talk are derived from a newly developed model of co-design in teams by Gero & Milovanovic (unpublished) based on the situated version of the FBS ontology, sFBS, (Gero & Kannengiesser, 2014). The model provides for fine grained behavior of individuals in teams.

Results from a protocol study of cohorts of two-person homogeneous and heterogeneous teams, where the heterogeneity is due to gender, are presented in Figure 1 (Milovanovic & Gero, submitted). The cohorts were undergraduate mechanical engineering students at a state university in Utah and were given the same design task. In Figure 1, each ellipse contains the sFBS behavior of team members, where the top ellipses represent team member A activations and the bottom ellipses represent team member B activations. For a detailed development of the situated Function-Behavior-Structure ontology consult Gero & Kannengiesser (2004). The links between the activation variables are a measure of the cumulative occurrences of cognitive design processes. The variables outside the team members' individual spaces are externalizations in the forms of verbalizations, sketches or gestures. The externalization of thought through verbalization, gestures and sketching provides the basis for co-designing. The Gero & Milovanovic (submitted) model of co-design uses the notion that co-design occurs when designers cross the externalization boundary.

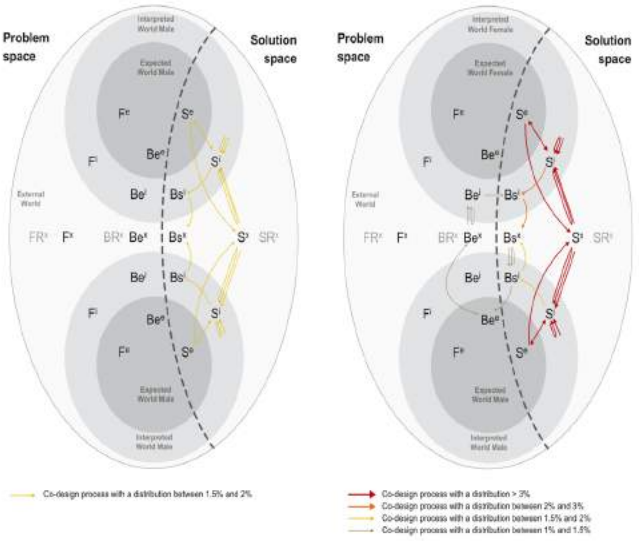
The results in Figure 1 show that heterogeneous teams containing one female and one male member exhibit more co-design processes than do homogeneous all-male teams. Further, such mixed-gender teams distribute more of their cognitive effort between the problem and the solution than do all-male teams, who expend more of their cognitive effort on the solution.

The presentation will show results of studying the design cognition of students and tutors in a studio pedagogy setting. It will present the change in student-student design cognition interaction over multiple studio sessions.

From Design Cognition to Design Neurocognition

The drop in the cost of non-invasive brain measurement has opened avenues of research into design neurocognition. In particular EEG and fNIRS, which collect temporal data, are both well suited for design neurocognition studies since design is a temporal activity. fMRI is less suited to study the

temporal behavior of designing. It is well suited where high spatial resolution is required.



(a) (b)

Figure 1: (a) Dominant sFBS co-design processes for homogeneous, all-male, teams; (b) dominant sFBS co-design processes for heterogeneous, mixed-gender, teams (Milovanovic & Gero, to appear).

The presentation will report on using a 14 channel EEG block experiment to measure the effect of design task on brain behavior. The tasks range from highly constrained to unconstrained. The total task related power of measured signals is presented in Figure 2 for the pre-task and the four design tasks for 58 participants covering multiple domains. Results for individual domains indicate significant differences due to domain and task.

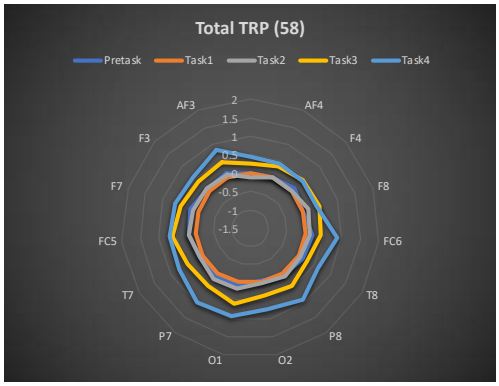


Figure 2: Total TRP for each of 14 channels across all participants for Pre-task, Task 1, Task 2, Task 3 and Task 4 (Vieira, Gero, et al, unpublished data).

While EEG measures electrical signals at the surface of the brain with high temporal resolution, functional near infrared spectroscopy (fNIRS) measures BOLD demand with medium temporal resolution. The presentation will report on an fNIRS experiment that repeats a previous protocol study for which we have cognitive results. The results of dominant hemisphere activation over time are presented in Figure 3 showing an unexpected pattern of behavior. Additional results cover other concept generation techniques.

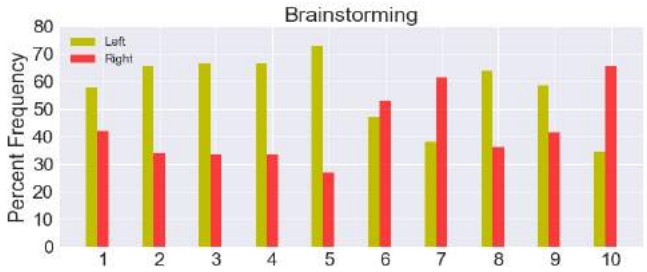

Figure 3: Percent frequency across time deciles of dominant hemisphere during brainstorming (Shealy & Gero, submitted).

These three exemplary results from there different measuring approaches, protocol analysis, EEG and fNIRS, demonstrate the expanding capacity to measure design cognition through measurement of the mind and indirectly through measurement of the brain. Until recently, only measurement of the cognition through the behavior of the mind was reliably available. The development of relatively inexpensive tools for non-invasive brain measurement has opened novel approaches to the measurement of design neurocognition. Bringing cognitive studies of the mind and neurocognitive studies of the brain together offers opportunities to both increase our understanding of designing and to provide the foundation for the development of tools to aid designing and the development of curricula to improve design education.

Towards emotion based music generation: A tonal tension model based on the spiral array

Keywords: Tension; Tonal tension, Music, Computational modelling; Music and emotion; Music structure

Introduction

Tension is an integral part of the music listening experience, closely connected to the sensing of emotions. We have explored how a particular aspect of tension, tonal tension, can be modelled and used to guide for automatic music generation.

A model was developed for extracting three aspects of tonal tension (Herremans & Chew, 2016b) from a musical score. The model is based on the spiral array, a three-dimensional model for tonality developed by Chew (2014). This was then integrated in an online interactive system, for easy visualisation, in sync with audio and score. Finally, the tension model was included in a state-of-the-art music generation system called MorpheuS, whereby we use tension to guide the underlying tension fabric of the generated music.

Spiral Array Model

In order to model tonal tension, we first need to be able to model pitches in a meaningful way. This was achieved through the three-dimensional model of tonality called the spiral array (Chew, 2014). The spiral array consists of three sets of helices: one that represents pitch classes, a pair for major and minor triads, and a pair for major and minor keys. The pitch spiral is the one we use for modelling tension. The triads are generated as convex combinations of their member pitches, and keys are represented as convex combinations of their defining chords.

Three new indicators of tension

Tension is a composite characteristic. There are many factors that contribute to the listener's feeling of tension, including loudness, timbre, dissonance, and harmonies. We chose to focus on tonal tension, and propose three characteristics, that are calculated for each time window, or cloud, of notes:

Cloud diameter Calculated as the largest distance between different notes in a cloud, thus capturing the dissonance of a note cluster.

Cloud momentum Calculated as the position change or movement between two adjacent clouds of notes, capturing the amount of harmonic change from one time slice to the next.

Tensile strain Computed as the distance between the centroid of the current slice and that of all pitches, representing the global key.

Figure 1 shows an example of the Tristan chord in the spiral array, a famous tense chord from Wagner's opera Tristan and Isolde. One can immediately see that it spans a large region in the pitch helix, which results in a high cloud diameter.

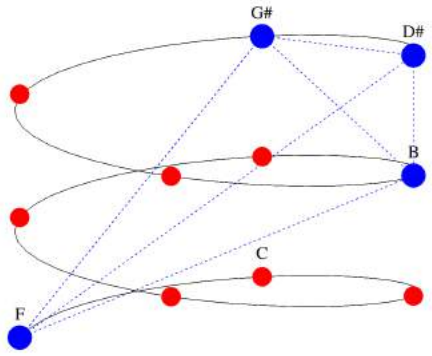

Figure 1: The Tristan chord in the Spiral Array pitch helix.

For a more complete overview of the proposed novel tonal tension model, the reader is referred to (Herremans & Chew, 2016b).

The model can be used for musicological or cognitive science purposes, as we have created an interactive online platform that visualises both tension (Herremans & Chuan, 2017) and arousal valence data (Herremans, Yang, et al., 2017) in sync with musical scores and audio.

Scaffolding music generation

In recent years, automatic music generation systems have become ever more popular due to advances in deep learning. There is a wide range of music generation systems available, e.g. for generating music that matches computer games, harmonizing a melody, etc. For a complete overview, the reader

Figure 2: Excerpt (bars 1-8) of MorpheuS' piece based on the first of Stravinsky's *Three Pieces for String Quartet*

is referred to the survey paper by Herremans, Chuan, & Chew (2017). In this paper, the current challenges for music generation are identified as generating music with long term structure, and music that communicates certain emotions.

We developed a music generation system, called MorpheuS, which uses combinatorial optimization techniques to generate music with specific tension values over time (i.e., a given tension profile) and recurring pattern structure (Herremans & Chew, 2016a, 2017). MorhpeuS takes as input an existing musical score in MusicXML format. From this piece, the tension is calculated using the model described above. Secondly, recurring note patterns are extracted using the SIA algorithm by Meredith et al. (2002). The user can then use this original tension profile and the detected recurrent pattern structure, or create a new version of these, to scaffold the music generation process.

In the first step of the music generation process, all pitches of the original template piece are erased, but the rhythm is kept intact. A variable neighborhood search algorithm then populates the rhythm template with random pitches, while preserving the repeated pattern structure. The pitches are then optimized to maximize the fit between the current tension profile and the desired tension. For a more in depth explanation, the user is referred to Herremans & Chew (2017).

Figure 2 shows an example of one of the generated pieces by MorpheuS, based on Stravinsky's *Three Pieces for String Quartet*, composed for performance by members of the Singapore Symphony Orchestra on Channel News Asia.

Conclusions

The MorpheuS music generation system tackles one of the biggest remaining challenges in automatic music generation: generating music with structure and with the goal of communicating particular emotions over time. MorpheuS pieces have been performed internationally; recordings of selected pieces can be found online[1].

Cognitive Chrono-Ethnography (CCE): A Behavioral Study Methodology Underpinned by the Cognitive Architecture, MHP/RT

Keywords: cognitive architecture; action selection; multidimensional memory; ethnography

Introduction: MHP/RT and CCE

At the 0-th order approximation, a person interacts with his or her environment by running an endless cycle of perceiving the external and internal environment through five senses via sensory neurons as parallel processing, and acting to the external environment through body parts via motor neurons as serial processing. As s/he perceives the results of movement of his/her body parts as well as the changes of the external environment as time goes by, the next cycle of Perceptual–Motor should occur. Interneurons in-between the sensory neurons and motor neurons convert the input patterns to the output patterns – these constitute a Perceptual-Cognitive-Motor process (PCM process). Starting from this basic cycle, we (M. Toyota and the author) constructed a comprehensive theory of action selection and memory, Model Human Processor with Realtime Constraints (MHP/RT), that should provide a basis for constructing any models for users interacting with ever-changing environments, and an accompanying behavioral study methodology, Cognitive Chrono-Ethnography (CCE) (Kitajima, 2016; Kitajima & Toyota, 2013) to be used to utilize, validate, and/or refine MHP/RT. MHP/RT and CCE are two wheels for conducting cognitive behavioral sciences, that complement each other from theoretical and experimental perspectives, respectively. Visit `http://oberon.nagaokaut.ac.jp/ktjm/organic-self-consistent-field-theory/index.html` for more information for the entire project.

Model Human Processor with Realtime Constraints (MHP/RT)

MHP/RT is an extension of Model Human Processor developed by Card, Moran, and Newell (1983). The purpose of MHP/RT is to implement at a higher level the facts that the fundamental processing mechanism of brain is Parallel Distributed Processing (PDP) (McClelland & Rumelhart, 1986), that human behavior emerges as the results of competition of the dual processes of System 2, slow *conscious* processes for deliberate reasoning with feedback control, and System 1, fast *unconscious* processes for intuitive reaction with feedforward control for connecting perception and motor movements, called Two Minds (Kahneman, 2003), and that human behavior is organized under happiness goals (Morris, 2006), on the assumption that the processing involved in action selection is truly dynamic interaction that evolves in the irreversible time dimension. The extension is done by considering that the endless PCM cycle continues from his or her birth to death in the ecological system that consists of the person and the environments, and it is a periodic circulation system.

MHP/RT consists of two parts. The first part is the cyclic PCM processes, in which PDP for those processes is implemented in hierarchically organized bands having their respective characteristic times for operations, i.e., biological, cognitive, rational, and social bands (Newell, 1990) by associating relative times (not absolute) to the PCM processes that carry out a series of events. The second part is memory, which supports the PCM processes. It is implemented as a distributed memory system and at the same time it serves as a mechanism to establish synchronization among multiple PCM processes.

Cognitive Chrono-Ethnography: CCE

Equipped with the cognitive architecture, MHP/RT, how can we study people's behaviors, characterized by Two Minds working dynamically along the time dimension? We came up with a solution in the form of a study methodology, called CCE. Cognitive Chrono-Ethnography combines three concepts. "Cognitive" declares that CCE deals with interactions between consciousness and unconsciousness in the PCM cycles. "Chrono(-logy)" is about time ranging from $\sim$100 msec to days, months, and years, and CCE focuses on such time ranges. "Ethnography" indicates that CCE takes ethnographical observations as the concrete study method because in daily life people's Two Minds tends to re-use experientially effective behavioral patterns, which is called "bias". Ethnographical field observations are essential for understanding each person's bias in his/her daily life.

CCE Procedure

Figure 1 shows the seven steps to conduct a CCE study:
1) Ethnographical Field Observation: Use the basic ethnographical investigation method to clarify the outline of the structure of social ecology that underlies the subject to study.
2) Mapping the Observed Phenomena on Cognitive Architecture: With reference to the behavioral characteristics of people which have been made clear so far and MHP/RT, consider what kind of characteristic elements of human behavior are involved in the investigation result in (1).
3) Identifying Study Parameters through Model-Based Simulation: Based on the consideration of (1) and (2), construct an initial simple model with the constituent elements of activated memories, i.e., meme, and the characteristic PCM processing to represent the nature of the ecology of the study space.
4) Design a CCE Study: Based on the simple ecological

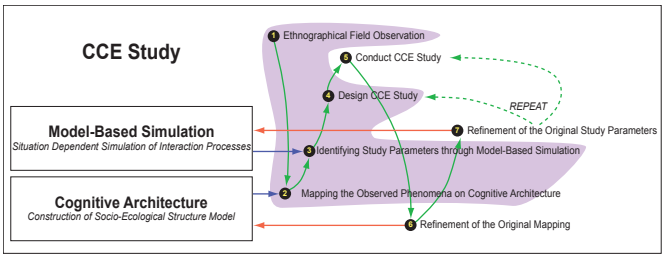

Figure 1: The CCE procedure (Kitajima, 2016, Figure 5.1).

model, identify a set of typical behavioral characteristics from a variety of people making up the group to be studied. Then formulate screening criteria of elite monitors who represent a certain combination of the behavioral characteristics, and define ecological survey methods for them.

5) Conduct CCE Study: Select elite monitors and conduct an ethnographical field observation.

6) Refinement of the Original Mapping: Check the results of (5) against the results of (2) for appropriateness of the mapping. If inappropriate, back to (2) and redo from there.

7) Refinement of the Original Study Parameters: If the result of (5) is unsatisfactory, go back to (4) and re-design and conduct a revised CCE study, otherwise go back to (3) to redo the model-based simulation with a set of refined parameters.

Completed CCE Studies: A Few Examples

Navigation in a train station by following signs: With the focus of action selection processes involved in slow navigation, Kitajima and Toyota (2012) reported a CCE study to investigate how elderly people use guide signs at train stations when they have to transfer lines, in addition to use some facilities such as restrooms, lockers, and so on. The results showed: 1) persons with inferior planning function with normal attention function did not use guide signs when they had mental models, whereas they did not gather task-relevant information but irrelevant one when they had no mental model, and 2) persons with inferior planning function and inferior attention consistently had problems in gathering task-relevant information by using guide signs because of vague description of behavioral goals. The interactions between planning and attention functions and the existence of mental models are consistent with MHP/RT's simulation results.

Sightseeing in a hot spring resort: Hot spring resorts are popular tourist attractions in Japan. However, little is known about why they are popular destinations. To answer this question, Kitajima, Tahira, Takahashi, and Midorikawa (2012) conducted a CCE study. Forty-three groups participated in the study as elite monitors. Each group arrived at Kinosaki-Onsen and were asked to tour the place. They were instructed to carry a GPS and a digital camera for recording their activities. By analyzing the results of the interviews, we identified six types of tourist activities including: bathing, staying, eating, exploring, touring, and shopping, each of which corresponds to a different set of happiness goals.

On-Going CCE Studies

Designing Memorable Events: People live in the environment filled with artifacts, part of which is real and the rest is virtual. Kitajima, Shimizu, and Nakahira (2017) conducted initial steps of CCE to understand how the PCM processes along with the memory process result in memorable experiences. Preliminary experiments were conducted to see how omnidirectional movies in virtual reality augmented with audio-guide made the experience memorable by timely provision of multi-modal information as designed by MHP/RT.

Designing Immersive Events: Immersive virtual environments are distinct from other types of multimedia learning environments. Dinet and Kitajima (2018) reported initial steps of CCE that focused on the conditions necessary to produce "immersive experience" for the user. The CCE study will continue in the context of developing a multimodal interface to help young pedestrians acquire necessary skills for safe navigation in dangerous traffic environments.

The WARP Model of Category Learning

Research on categorization and classification learning has greatly benefitted from the use of computational modeling which requires making all theoretical assumptions explicit and provides a direct means of theory evaluation by *fitting* behavioral data. The field has advanced notably through model comparison relative to benchmark data on human category learning performance. Exemplar theory has become a leading psychological explanation largely due to the success of its formal models in fitting human data across a number of tasks (Kruschke, 1992; Nosofsky & Palmeri, 1997).

The exemplar view casts categorization as based on an explicit calculation of similarity between the to-be-categorized stimulus and instances stored in long-term memory (exemplars) associated with each category. The similarity is computed as an inverse exponential function of distance between psychological representations in a multidimensional space. This representational space can be transformed by stretching or shrinking dimensions using selective attention. The category with exemplars of greater similarity (less distance) to the stimulus is activated. This account has been extended in the ALCOVE model (Kruschke, 1992) which implements adaptive learning of attentional weights on the stimulus dimensions and association weights between each exemplar and category.

While exemplar models have shown a high degree of success in fitting behavioral data, they do not provide an account of representation learning. These models generally assume that each item in the input domain has a unique psychological representation (estimated via multidimensional scaling) that remains fixed throughout the category learning process. Further, a strict correspondence holds between the category representation and the stimulus items known to be members of that category (note: reference point models can also use centroids of clusters of exemplars).

This is in strong contrast to feedforward artificial neural networks that gradually learn representations to optimize task performance (Rumelhart, Hinton, & Williams, 1986). In standard connectionist models, each stimulus gets recoded at a "hidden" layer based on a set of optimized synapse-like weights that yield a distributed representation across the hidden nodes—which can be seen as a point in a constructed multidimensional space. A second set of weights connects these hidden nodes to an output layer of class nodes. The internal representations are incrementally repositioned in weight space via gradient descent to optimize accurate prediction at the output layer.

The Weights-as-Adaptive-Reference-Points (WARP) model is designed to bridge the reference point similarity-based approach of exemplar models with the flexibility and psychological plausibility of learned representations in neural networks. This merger of design principles is achieved by replacing the localist exemplar node representations (as in ALCOVE) with a layer that follows the foundational connectionist design principles of: 1) a forward pass that computes activation based on a function of the 'net input,' i.e., the input activations multiplied by their weights; and 2) a backward pass that modifies the weights to minimize task error and estimate the function to be approximated.

On the connectionist view, the hidden nodes are constructed dimensions that usefully transform the values of a stimulus in input space to a set of values in another representational space. On the exemplar view, each hidden node is a reference point to the location of a training item in input space and its activity indexes the proximity of that point to a stimulus. We propose a new formulation that allows the hidden nodes to function according to connectionist mechanics and yet act as reference points. The result is that the model discovers its own reference points using task-driven error minimization as opposed to making a commitment to the inputs themselves as the basis for the reference points.

The WARP model functions by taking the encoding weights to each hidden node as its "address" or reference point location in input space. As the weights change via learning by backpropagation, each node follows a trajectory in weight space from its initial random location toward a place where its task is functionality optimized. The 'net input' is the vector multiplication between the input activations and the incoming weights to a node. This is a dot product or linear algebraic measure of similarity (i.e., the angle between the vectors) as opposed to a spatial distance metric. The critical similarity computation between stimulus and reference point occurs implicitly in the forward pass. To

make this work as intended, a simple, novel activation function at the hidden layer is used which takes the form of Equation 1:

$$exp[(a \cdot b) - k] \quad (1)$$

where a is the vector of input activations, b is the vector of incoming input->hidden node weights, and k is a constant value set to the number of dimensions in the category structure. The key property of this function is this: the more closely the incoming weight vector for a hidden node approximates the values of an input vector, the greater the activation of the hidden node. Over the course of training, different hidden nodes will be repositioned to parts of weight space that allow them to respond to particular regions in input space: to get better at classifying is to move the adaptive reference points to useful positions. A standard association layer connects the hidden nodes to class nodes and a softmax output layer is used to determine the class probabilities

WARP utilizes a set of connectionist-style free parameters: learning rate, number of hidden nodes (i.e., density of the implicit covering map), and range of random initialization for incoming weights; and can also incorporate a set of reference point model-style free parameters: degree of sensitivity of reference points and a response mapping constant for determining class activations.

Preliminary testing has shown promising fits to the classic behavioral benchmark of the Shepard, Hovland, and Jenkins (1961) six types of elemental category structures (dataset from Nosofsky et al., 1994). This investigation also revealed that the WARP model discovers more parsimonious reference points when available: instead of always dedicating each hidden node to a single input, WARP can develop reference points that respond strongly to particular feature correlations or unidimensional rules. In conjunction with classic exemplar-style nodes, these feature detector-style nodes allow the model to efficiently handle various and complex category structures. The use of this multi-strategy toolkit mirrors the diversity and flexibility of human category learning (Ashby, Alfonso-Reese, & Waldron, 1998).

In addition to modeling human behavior, WARP has also been initially tested for potential application as a classifier in the domain of machine learning. Different parameterizations of the model, while inappropriate for capturing the pace and nuance of human learning, show highly rapid and efficient performance on the iris flower benchmark dataset. Interestingly, the model solves the classification problem using *discriminative prototypes* that maximize distance to competing classes while minimizing distance to the target class. Continued investigations of the model are underway to better reveal the nature and diversity of the solutions WARP discovers for different types of classification problems; and to determine the power of the model in addressing the goals of psychological explanation and advancing AI.

Concept Learning with Energy-Based Models

Igor Mordatch (mordatch@openai.com)
OpenAI, San Francisco, CA

Keywords: concepts;meta-learning;imitation learning

Introduction

Many hallmarks of human intelligence, such as generalizing from limited experience, abstract reasoning and planning, analogical reasoning, creative problem solving, and capacity for language require the ability to consolidate experience into *concepts*, which act as basic building blocks of understanding and reasoning.

Examples of concepts include visual (*"red"* or *"square"*), spatial (*"inside"*, *"on top of"*), temporal (*"slow"*, *"after"*), social (*"aggressive"*, *"helpful"*) among many others (Rosch, Mervis, Gray, Johnson, & Boyes-braem, 1976; Lakoff & Johnson, 1980). These concepts can be either identified or generated - one can not only find a square in the scene, but also create a square, either physical or imaginary. Importantly, humans also have a largely unique ability to combine concepts compositionally (*"red square"*) and recursively (*"move inside moving square"*) - abilities reflected in the human language. This allows expressing an exponentially large number of concepts, and acquisition of new concepts in terms of others. We believe the operations of identification, generation, composition over concepts are the tools with which intelligent agents can understand and communicate existing experiences and reason about new ones.

Crucially, these operations must be performed on the fly throughout the agent's execution, rather than merely being a static product of an offline training process. Execution-time optimization, as in recent work on meta-learning (Finn, Abbeel, & Levine, 2017) plays a key role in this. We pose the problem of parsing experiences into an arrangement of concepts as well as the problems of identifying and generating concepts as optimizations performed during execution lifetime of the agent. The meta-level training is performed by taking into account such processes in the inner level.

Specifically, a concept in our work is defined by an energy function taking as input an event configuration (represented as trajectories of entities in the current work), as well as an attention mask over entities in the event. Zero-energy event and attention configurations imply that event entities selected by the attention mask satisfy the concept. Compositions of concepts can then be created by simply summing energies of constituent concepts. Given a particular event, optimization can be used to identify entities belonging to a concept by solving for attention mask that leads to zero-energy configuration. Similarly, an example of a concept can be generated by optimizing for a zero-energy event configuration. See Figure 1 for examples of these two processes.

The energy function defines a family of concepts, from which a particular concept is selected with a specific concept code. Encoding of event and attention configurations can be achieved by execution-time optimization over concept codes. Once an event is encoded, the resulting concept code structure can be used to re-enact the event under different initial configurations (task of imitation learning), recognize similar events, or concisely communicate the nature of the event. We believe there is a strong link between concept codes and language, but leave it unexplored in this work.

Description of events we consider and video results of our model learning on these events are available at: `sites.google.com/site/energyconceptmodels`

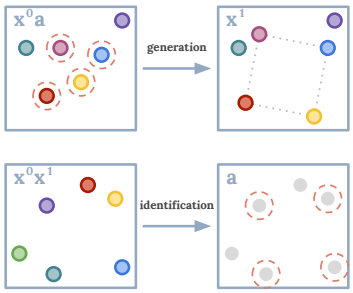

Figure 1: Examples of generation and identification processes for a *"square"* concept. a) Given initial state $\mathbf{x}^0$ and attention mask $\mathbf{a}$, square consisting of entities in $\mathbf{a}$ is formed via optimization over $\mathbf{x}^1$. b) Given states $\mathbf{x}$, entities comprising a square are found by optimization over attention mask $\mathbf{a}$.

Method

Existence of a particular concept is given by energy function $E(\mathbf{x},\mathbf{a},\mathbf{w}) \in \mathbb{R}^+$, where parameter vector $\mathbf{w}$ specifies a particular concept from a family. $E(\mathbf{x},\mathbf{a},\mathbf{w}) = 0$ when state trajectory $\mathbf{x}$ under attention mask $\mathbf{a}$ over entities satisfies the concept $\mathbf{w}$. Otherwise, $E(\mathbf{x},\mathbf{a},\mathbf{w}) > 0$. The conditional

probabilities of a particular event configuration belonging to a concept and a particular attention mask identifying a concept are given by the Boltzmann distributions:

$$p(\mathbf{x}|\mathbf{a},\mathbf{w}) \propto \exp\{-E(\mathbf{x},\mathbf{a},\mathbf{w})\} \quad (1)$$

$$p(\mathbf{a}|\mathbf{x},\mathbf{w}) \propto \exp\{-E(\mathbf{x},\mathbf{a},\mathbf{w})\} \quad (2)$$

Given concept code $\mathbf{w}$, the energy function can be used for both generation and identification of a concept implicitly via optimization (see Figure 1):

$$\mathbf{x}(\mathbf{a}) = \underset{\mathbf{x}}{\operatorname{argmin}} E(\mathbf{x},\mathbf{a},\mathbf{w}) \quad \mathbf{a}(\mathbf{x}) = \underset{\mathbf{a}}{\operatorname{argmin}} E(\mathbf{x},\mathbf{a},\mathbf{w}) \quad (3)$$

To learn concepts from experience grounded in events, we pose a few-shot prediction task. Given a few demonstration example events and initial state for a new event, the task is to predict attention $\mathbf{a}$ and the future state $\mathbf{x}$ of the new event. We

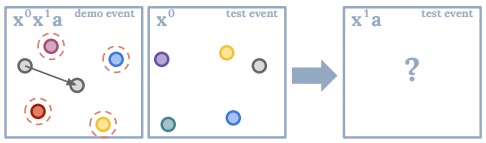

Figure 2: Example of a few-shot prediction task.

follow the maximum entropy inverse reinforcement learning formulation (Ziebart, Maas, Bagnell, & Dey, 2008) and assume demonstrations are samples from the distributions given by the energy function E and find energy function parameters θ via maximum likelihood estimation over future state and attention given initial state. The resulting loss for a particular dataset X is

$$\mathcal{L}_p^{\mathrm{ML}}(X,\mathbf{w}) = \mathbb{E}_{(\mathbf{x},\mathbf{a})\sim X}\left[-\log p\left(\mathbf{x}^1,\mathbf{a} \mid \mathbf{x}^0,\mathbf{w}\right)\right]$$

Where the joint probability can be decomposed in terms of probabilities in (1) and (2) as

$$\log p\left(\mathbf{x}^1,\mathbf{a} \mid \mathbf{x}^0,\mathbf{w}\right) = \log p\left(\mathbf{x}^1 \mid \mathbf{a},\mathbf{w}_x\right) + \log p\left(\mathbf{a} \mid \mathbf{x}^0,\mathbf{w}_a\right)$$

We use two concept codes, $\mathbf{w}_x$ and $\mathbf{w}_a$ to specify the joint probability. The interpretation is that $\mathbf{w}_x$ specifies the concept of the action that happens in the event (i.e. *"be in center of"*) while $\mathbf{w}_a$ specifies the argument the action happens over (i.e. *"square"*). This is a concept structure or syntax that describes the event. The concept codes are interchangeable and same concept code can be used either as action or as an argument because the energy function defining the concept can either be used for generation or identification. This importantly allows concepts to be understood from their usage under multiple contexts.

Experimental Results

We introduce a simulated environment and tasks for a two-dimensional scene consisting of a varying collection of entities, each processing position, color, and shape. We observe the following properties:

Concept inference in multiple contexts: An important property of our model is ability to learn from and apply it in both generation and identification contexts. We qualitatively observe that the model performs sensible behavior in both contexts. For example, we considered events with proximity relations *"closest"* and *"farthest"* and found model able to both attend to entities that are closest or furthest to another entity, and to move an entity to be closest or furthest to another entity.

Transfer between contexts: When our model trained on both contexts it shares experience between contexts. Knowing how to act out a concept should help in identifying it and vice versa. We perform an experiment where we train the energy model only in identification context and test the model's performance in generation context (and conversely). We observe that even without explicitly being trained on the appropriate context, the networks perform much better than baseline of two independently-trained networks.

Sharing codes across contexts: Another property of our model is that codes $\mathbf{w}_x$ and $\mathbf{w}_a$ for identifying concepts are interchangeable and can be shared between generation and identification contexts. For example, either turning an entity red would or identifying all red entities in the scene would ideally use the same concept of *"red"*. We indeed observe that events which involve recognizing entities of a particular color, the codes $\mathbf{w}_a$ match the codes $\mathbf{w}_x$ for setting entities to that color and find similar correlation in the other events as well.

Conclusion

We believe that execution-time optimization plays a crucial role in acquisition and generalization of knowledge, planning and abstract reasoning, and communication. In the current work we used a simple concept structure, but more complex structure with multiple arguments or recursion would be interesting to investigate in the future. It would also be interesting to test compositionality of concepts, which is very suited to our model as compositions corresponds to the summation of the constituent energy functions.

The creative role of performativity

In our project the performance is a product of performativity. Performativity is the cognitive ability to produce physical or mental actions. Studying performance and studying performativity sets different scientific activities. Studying how to enhance performance belongs to the behavioral science. On the contrary, studying performativity belongs to a general cognitive procedure that must not be confused with the description of behaviors, requiring instead a specific theorization in the cognitive sciences. The aim of this research project is to focus on the hypothesis that performativity is not a property confined to certain specific human skills, or to certain specific acts of language. Instead, the executive and motor component of cognitive behavior should be considered an intrinsic part of the physiological functioning of the mind and as endowed with self-generative power (Pennisi A., 2019; Pennisi A.-Falzone, 2016).

We believe that performativity has evolved alongside with those natural selection processes which have led the human species to develop articulated language and the embodied simulation (Pennisi A.-Falzone, 2016; Falzone 2018). In such framework, cognition is a form of mediated action rather than the link between inner thought and overt behavior. According to our model, thus, action is not the mere externalization of a mental process, but is the process itself (Pennisi A., 2018 and 2019; Pennisi A.-Falzone, 2019; Gallese, 2019). Since such process is carried out through the body, we think that the species-specificity of the bodies occurring in nature paves the way for every individual's knowledge of reality.

Performativity as a physiological tool of cognitive creativity has precise neural correlates and procedural properties.

From the point of view of procedures, performativity is a cognitive property that arises from the absence of an algorithm designed to carry out a given performance. Acting in a non-planned way, learning by trial and error, applying familiar behavioral patterns to new situations: these are just a few examples of what is performativity and of how it works.

Thus, performativity is intrinsically creative because its nature is to face situations that cannot be solved by the application of already known algorithms. In a nutshell, performative creativity is a procedural system that is somewhere between what Chomsky called "rule governed creativity" and "rule-changing creativity". Performativity however bears a peculiar kind of creativity, which is different from the one generated by the competence but still shares some features with the latter: in fact, it is a fully embodied and free-from-rules process that is carried out through trial and error, that is to say it depends on the bodily practice (locomotion, language, perception, etc.) made in everyday experience (Pennisi A., 2019; Pennisi A.-Falzone, 2016; Gallese 2018; Matteucci, 2018; Montani 2018). In functional terms, hence, the brain is a powerful biological instrument which permits continuous reorganization of the activity of organisms. An incessant activity of biological agents that move and act, that perceive and explore the world around them through a network of sensors and nerves, whose complexity of articulation is directly dependent on the species-specific structure. This activity relentlessly stimulates the rewiring of sensorimotor networks and remodeling of cognitive interactions. Our mind is the result of this close cooperation between the performative competence triggered by sensory-motor systems and the readjustment of the computational procedures of our deep brain to allow the survival and growth in the fitness of individuals and the entire species within environmental variation.

Insights from neurolinguistics

A large amount of literature has been devoted to the aforementioned mapping process, carried out through both brain imaging (Monchi et al. 2001, 2006; Nagano-Saito et al. 2008) and the study of the biochemical reactions involved in the plasticity of synaptic processes (Thivierge et al. 2007; Ko et al. 2013; Tamburrini-Prevete, 2018). Such researches have demonstrated "that the caudate nucleus and the putamen are particularly important, respectively, in the planning and the

execution of a self-generated novel action, whereas the subthalamic nucleus may be required when a new motor program is solicited independently of the choice of strategy" (Monchi et al. 2006, 257). Examining the biolinguistic aspects of these discoveries in depth, Lieberman and his team have shown that the neural circuits connecting different brain parts during human speech exploit the putamen for neuromotor control, changing "on the run" - that is, during verbal action performance - "the direction of our thought processes based on new stimuli such as the understanding of meaning conveyed by the syntax of language" (Lieberman & McCarthy 2007, 16).

Furthermore, a similar activation of brain motor components is registered when language data are processed in the absence of grammatically well-tested algorithms, such as when a second language is learned (Klein et al. 1994), or when a subject switches from listening to informal speech to a more formal one (Abutalebi et al. 2007).

In short, the management of neurocerebral performative strategies seems to be responsible for the most dynamic processes of linguistic behavior. This kind of behavior needs an attempt, or an active effort, that cannot be accomplished only through the mechanical application of already known and stabilized rules because it requires "the execution of a self-generated action among competitive alternatives" (Lieberman 2013, 80): an activity that is prolonged virtually forever, after the first acquisition step of ontogenetic speech, moving from mechanical physiology to the physiology of thought.

This overall framework also explains why the paths of speech often follow the hesitational phenomena of breaking up, recomposition, reunion, syncretism, propositional chiselling, semantic and lexical refinement: that is, all that is stigmatized by Chomsky's idea of performance as the deposit of cognitive junk produced by externalization devices (to repeat his words: "numerous false starts, deviations from rules, changes of plan in mid course, and so on", 1960, 530). On the contrary, the most advanced neurolinguistic research reveals the close interconnection between motor performativity and the continuous reorganization of propositional and abstract thinking: "the cortico-striatal regions that regulate language comprehension also regulate many aspects of behavior such as motor control and abstract reasoning" (Simard, Monchi et al. 2010, 1092). Evolutionarily, in fact, the performative motricity of thought could have been decisive for understanding the subsequent development of human language, "because it indicates that our modem brains may actually have been shaped by an enhanced capacity for speech motor control that evolved in our ancestors" (Lieberman & McCarthy 2007, 16).

Schizophrenia as the realm of anti-performativity

Another field of research which supports our idea of performativity is phenomenological psychopathology. Authors like Sass (1992), Stanghellini (2004) and Fuchs (2005), in fact, claim that one of the core symptoms of schizophrenia is a sort of "disembodiment", the onset of a problematic relationship between the patient and his own body in which the parts of the latter become heavy, distorted and even "stranger". This peculiar kind of corporeity is reflected in a total lack of fluidity in any patient's performance: "patients frequently experience a disintegration of habits or automatic performances, a «disautomation». Instead of simply dressing, driving, walking, etc., they have to prepare and produce each single action deliberately, in a way that could be called a «Cartesian» action of the mind on the body" (Fuchs & Röhricht 2017).

Such schizophrenic tendencies might be described as the attempt to apply procedural rules - algorithms - to the everyday and well-mastered situations that make up our "being in the world", as the following words by a schizophrenic patient show: "If I do something like going for a drink of water, I've to go over each detail – find cup, walk over, turn tap, fill cup, turn tap off, drink it" (Chapman 1966, 239). As we have already claimed (Pennisi G. 2018), schizophrenia might be read as the disruption of the mechanisms that make a performance efficient, namely the selective target control, the softly conscious monitoring of one's bodily configurations and the implicit sense of body-as-subject (Gallagher 2018).

Instead of having this tacit, self-transparent and immediate relationship with their own bodies, patients often exercise a thematic control on the latter that goes from repetitively touching their own body parts – as if they try to verify if their body still «belongs» to them – to the fragmentation of every goal-related movement in many sub-movements, like in the previous example. Schizophrenics' inability to get in the flow of the action is what makes such illness "the realm of anti-performativity" (Pennisi G. 2018): this is why we think that the study of the role of performativity on human cognition cannot be separated from the phenomenological analysis of psychopathologies.

Conclusion

In the light of the above, we will define performativity as a constituent component of the cognitive processes. The actions that we perform in the environment, in fact, allow us to know both the surrounding world and our physical possibilities. In such model, the body is not only the means by which the individual explores and acts on the environment, but the precondition for the development of any cognitive ability.

Our intention is to validate our ideas on the role of the body and on performativity by applying the interdisciplinary methods of Cognitive Science. The issues we have raised, in fact, not only are the subject of a debate between the embodied/extended mind models and the mentalist hypotheses carried out by cognitive psychology and computationalism, but can only be clarified by providing an overview of the scientific literature on psychopathology and on cognitive neuropsychology.

Introduction

As human beings we are social. All of us had to be included in a group to survive; most of us highly desire to live and collaborate with others on a daily basis. In this paper we will try to show how our sociality (considered as the inclination to live and collaborate with other co-specifics) affects our creativity.

How sociality affects creativity

Creativity, in fact, means being yourself, seeing the world in a way that is different from that of others. Each time that we perceive the world, we collect or ignore some data, we focus on something and neglect something else. Each perception is a creative act and this is showed not only by the Kanizsa's triangle or other similar optic illusions, but even by our spontaneous impulse to build our reality. When we are in love, for example, we are more inclined to interpret the gestures of our object of love in the direction that we would like to be the real one. In this condition we could easily mistake a wink aimed at the expulsion of a hair from the other's eye with a wink towards us. The thirst makes us see the water even where it is not there. What we call reality is an interspecific bargaining of the meaning of a perception.

Our sociality can push us to creativity in many ways: inviting us to solve problems, providing new information, criticizing one of our acts of creation or even inviting us to brainstorm. Societies also often reward creativity. But the *eureka,* the act of creating a different way of thinking something will take place only if we are able to go beyond the conformity of our perceptions with those of others.

Working definition for "creativity"

Creativity is a very heterogeneous concept. Here we will consider "creativity" as the ability to generate multiple solutions to a problem.

This definition encompasses in the same category the divergent thinking, insights and artistic creativity[1].

[1] This last can be seen as the essay of the artist to resolve the problem of representing his subjects.

Creativity in autism

Autism is a neurodevelopmental disorder characterized by persistent deficits in social communication and interaction and restricted and repetitive patterns of behaviour, interests or activities (APA 2013). Among the numerous consequences of the disorder, there are the lack of spontaneous symbolic play (Jarrold et al. 1993); anomalies in imagination (Low et al. 2009); difficulties to understand metaphors (Hobson 2012; Rumblad & Annaz 2010); very poor dreamlike activity (Daoust et al. 2007). For these reasons, subjects with autism are frequently considered less creative than subjects without autism. I.e. Craig and Baron Cohen (1999) described autistic creativity as a reality-based creativity and opposed it to the imaginative creativity of people without autism (Craig & Baron Cohen 1999).

The artistic productions of some savants with autism are famous for their proximity to reality – i.e. Stephen Wiltshire's productions, or Nadia's drawings (Selfe 2011). However a lot of other productions of autistic subjects show that the disorder doesn't affect the imaginative creativity: see i.e. Tammet (2008) or fig.1, which is a drawing made a 7 years autistic child.

Figure 1

Moreover, also among those who show the reality-based style of creativity described Craig & Baron Cohen (1999), subjects frequently solve problems in non-conformist ways. I.e., Temple Grandin managed to solve a major technical problem in the slaughtering of cows thanks to her style of thought which is indeed based on a reality-based form of creativity that is impossible to artlessly catch for people without autism (Grandin 1995).

As we will try to show in the full paper, the lacking of social affordances in subjects with autism greatly enhance their creativity, making their professional or artistic contribution very original for many fields of studies.

Subjects with autism, in fact, can think and imagine things in different ways than that of the most part of the population because they are less subject to perceptive and psychological biases linked to human sociality. I.e. their ability to make physical causation inference is superior than that of the most part of the population; on the contrary

emotional and intentional inferences are more difficult for subjects with autism than for the rest of the population (Pennisi 2016).

Why not all subjects with autism are creative?

Unfortunately, neurodevelopmental disorders are frequently associated with a low QI. Below a certain IQ, it is rarely possible to express one's creativity in a way that is comprehensible to others. Some talents sometimes manage to emerge, such as in the case of Nadia (Selfe 2011), but normally too low intellectual quotients do not allow the expression of the creativity of one's own creativity.

For all those subjects with autism who have an average or above average IQ, creativity is probably hidden where we are not used to looking for it. The absence of social motivation (Chevallier et al. 2012) turns into the habit of not asking others to help solve their problems and not to receive requests for help in solving problems. But in a world where the rules of sociability are a far-off buzz, the need to solve everyday problems requires the use of creativity. I.e., a child with autism who wants to open a door handle too high for him could easily take the adult's hand next to him and use it as a tool to open the door, rather than explicitly asking for help. Certainly this is a not very conventional way of "using" the adult's arm. Italian journalist Gianluca Nicoletti, father of a boy with autism (Tommaso), tells how his son, interested in not losing his favorite cassette during a move, was able to find a way to identify the right tape in a mountain of identical boxes (Nicoletti 2015). Nobody knows exactly what strategy the boy used, but certainly it hides an attitude to think and perceive the mountain of boxes in a totally different way from the rest of the family. An ordinary child would have simply asked the mother to remember for him and she would have drawn something on the outside of the box.

The point is that creativity is always linked to something pre-existing. It is likely that, in the eyes of people without autism, many tactics used by individuals with autism are creative, whereas for Tommaso, the ability to locate the cassette in the box was not an act of creativity, but just the result of having followed his normal flow of thought, which simply has characteristics different from that of most of the population.

We all have a creative mind, but the pressure of sociability pushes us to inhibit part of our potential in order to better understand others and be better integrated into social groups.

İn the full paper we will try to prove our hypothesis by providing a wider analysis of numerous case studies.

Conclusions

The study of autistic cognition is a precious source of information on the usual functioning of human cognition. In fact, it shows the link between attitude to sociality and all the rest of cognitive processes. Autistic cognition teaches us that creativity is not an empyrean concept and that we are always creative with respect to something else.

Creativity with respect to the usual ways of thinking is the active effort to alter our usual flow of thought in order to solve a problem that we are not able to solve with previously used methods. Creativity with respect to society, on the other hand, is a style of thought that deviates from the one that is accepted by the rest of the group. In most people the two things often coincide; but at any moment we have the possibility of exerting an active effort to get rid of a habit of thought and to create one that has not yet been explored yet.

Language and event recall in memory for time

Introduction

We remember and talk about events as unfolding over time. When recalling a recent past event, we are often able to recollect its duration and mentally reproduce its component actions, as if replaying the event in our mind. However, key aspects of duration memory are poorly understood, in particular, how event memories map onto clock time and how this mapping is modulated by language. Indeed, we do not perceive and remember objective clock time, unless we pay attention to clocks. Instead, we build event representations that are not replicas of our experiences but are rather temporally compressed, and thus do not often coincide with the real time it took these experiences to unfold.

Here, we investigate the relationship between time, memory and language by examining how people recall and mentally reproduce (replay) events that were conceptualized through language. We specifically ask two main questions. First, what determines the duration and clock accuracy of event reproductions from memory. Second, how these reproductions are modulated by linguistic descriptions, thus potentially leading to distorted reproductions.

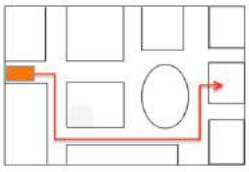

Figure 1: Stimulus example. The arrow indicates path.

In four studies, participants were first asked to study cartoon-like animations accompanied by descriptive phrases for a later memory test. The animations varied in duration from 3-9s and showed geometric figures moving in a familiar setting. Each animation was paired with one of two possible descriptions implying either fast or slow-motion speed, for example, *grandma taking the bus to the hospital* vs *an ambulance taking someone to the hospital* (cf. Fig. 1). Thus, the two phrases implied a shorter or longer event duration. The descriptions provided critical information to understand the animation, which would otherwise be unspecific as to the nature of the moving object. After learning, participants were asked to replay the animations in their minds *exactly as they occurred in their original time course* when prompted with either an animation frame or the corresponding description. Participants clicked the mouse at the start and finish of their mental replays. The reproduced or replayed duration was measured. Finally, they were asked to verbally recall as many details as they could about each animation when prompted.

We hypothesized following Ornstein (1969) recall-based account that the amount of information recalled would explain duration memory over and above the influence of stimulus duration and number of stimulus segments (Faber & Gennari, 2017). Importantly, when the amount of exposure to the same stimuli increases (as in Exps. 2 & 4), we expected that more event information should be learned, and thus, the reproduced duration should lengthen particularly for the stimuli where reproduction accuracy could be improved. Under this hypothesis, memory biases previously reported (Roy & Christenfeld, 2008), such as the tendency to shorten long events and lengthened short ones should emerge from the information recalled: people remember proportionally more information per time unit for short events, leading to lengthened duration reproductions, whereas they remember proportionally less information per time unit for long events, leading to shortened reproductions.

Additionally, we hypothesized following interactive-encoding accounts (Lupyan, 2008; Feist & Gentner, 2007) that if verbal encoding distorts the initially encoded memory, events described with slow-phrases should be mentally reproduced as longer than those described with fast-phrases, even when a visual-cue prompts event replay. Alternatively, retrieval-based accounts (Alba & Hasher,1983) argue that language should only play a role at retrieval, i.e., the effect of descriptions should be observed only when descriptions prompt replays.

Experiments 1 & 2: visually-cued event replays after one and three stimulus viewings

Participants learned 21 animations alongside descriptions either once in random order (exp. 1) or three times (3 runs through the stimuli in random order, exp. 2). Mental replay and verbal recall were cued by a visual frame. Separate pre-tests determined stimulus characteristics (implied motion speed, familiarity, number of segments, etc.).

Results indicated no influence of language on duration reproductions. However, the event information recalled (as measured by the number of words used in verbal recall) modulated reproduced duration. As the number of words recalled increased, so did the reproduced duration, over and above the influence of stimulus duration and the number of stimulus segments. Moreover, the extent to which reproduced duration deviated from the clock stimulus duration (deviation index = reproduced duration/stimulus duration) were

lengthened for shorter animations but were shortened for longer animations, as previously reported (Fig. 2). A deviation index of 1 indicates accurate reproductions, with smaller or larger indices indicating under- or over-reproductions. Moreover, more accurate reproductions (closer to 1) were obtained in Exp. 2 compared to Exp. 1, particularly for longer animations, where more details could be learned with more exposure. This suggests that the number of details recalled underpins duration reproductions. Critically, the density of the details recalled (the number of words recalled per seconds in an animation) explained deviation indices. Thus, shorter animations were reproduced as longer because more details were proportionally recalled for them compared to longer animations, thus providing a possible explanation for the temporal bias observed.

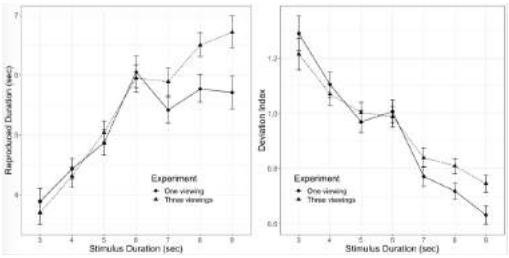

Figure 2: Reproduced duration and deviation index as a function of the stimulus duration

Experiment 3 & 4: verbally cued event replays after one or three stimulus viewings

These studies used the linguistic descriptions to prompt event replays and verbal recall, instead of a visual cue. Note that language may influence reproductions because participants are unsure of what they saw after a single viewing. Thus, testing deeper learning may reveal whether weak memory traces play a role in language effects.

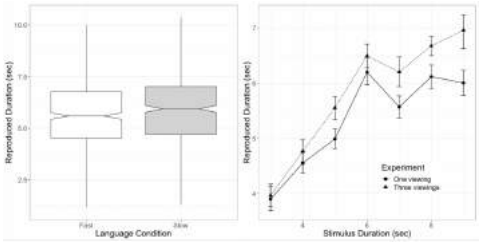

Figure 3: Reproduced duration as a function of language condition and stimulus duration in Exp. 4

Results indicated that for one and three stimulus viewings, there was a language effect. Slow-phrases led to longer reproductions whereas fast phrases led to shorter ones across all stimulus durations. This suggests that the memory representation retrieved is combined with top-down conceptual information present at retrieval, leading to a biased reproduction. In addition, the density of the information recalled predicted deviation indices (temporal bias), replicating exps. 1 & 2. Thus, both language and event recall influenced replays, leading to linguistically and temporally distorted retrieval.

Discussion

We investigated how event reproductions from memory were modulated by event descriptions and the event information recalled. Visually cued event reproductions did not vary as a function of language, suggesting that language did not modulate the way the animations were encoded or subsequently retrieved. Instead, event memory was the main source of information guiding duration reproductions, as evidenced by the predictive role of the number of words used in recall, over and above stimulus duration and segments. Critically, irrespective of cue type, better learning led to longer event reproductions for animations where accuracy could be improved, consistent with the recall-based view.

Verbally-cued reproductions led to shorter or longer reproductions according to the phrases, even after extensive learning. The concurrent influence of recalled information and language, therefore, suggests that the retrieved episodic event representations were combined with linguistic concepts, leading to hybrid event reproductions modulated by both event memory and language.

In all experiments, shorter stimuli were lengthened, and longer stimuli shortened, despite modulations by learning and language. The deviation index in all studies was explained by the information density recalled (the number of words recalled per second). We argue that information density and temporal biases stems from event perception and encoding mechanisms: Information at event boundaries is recalled better than within-event information (Zacks et al., 2007). In longer events, which tend to have longer segments, more within-segment information is forgotten, whereas for short events, which have relatively short segments, more information is proportionally retrieved.

Taken together, these results are consistent with both a recall-based view of memory for duration and a retrieval account of the role of language in memory.

Keywords: language evolution; color naming; efficient communication; information theory

Many theories hold that languages acquire new color terms with time, resulting in finer-grained color naming systems (e.g. Berlin & Kay, 1969; MacLaury, 1997; Levinson, 2000). More recently, it has also been claimed (e.g. Lindsey et al., 2015; Regier et al., 2015; Gibson et al., 2017) that this historical evolutionary process, and color naming more generally, are shaped by the need for efficient communication — that is, the need to communicate accurately, with a simple lexicon. Zaslavsky et al. (2018) [henceforth ZKRT] showed that an independent information-theoretic principle of efficiency, the Information Bottleneck (IB) principle (Tishby et al., 1999), explains much cross-language variation in color naming, and they hypothesized that color naming systems evolve under pressure to remain near the theoretical limit of efficiency. However, most research concerning the evolution of color naming, including ZKRT, has been based on synchronic cross-language comparisons, rather than on diachronic data.

Here, we examine color naming evolution using diachronic data for a single language: Nafaanra, a Senufo language spoken in Western Ghana. Color naming data for Nafaanra were first collected in 1978 in the village Banda Ahenkro, as part of the World Color Survey (WCS, Kay et al., 2009). The data revealed a 3-term system with terms for light/white, dark/black and red. ZKRT found that 93% of the WCS systems, including this one, are near-optimally efficient in the IB sense. Nafaanra data were collected again in Banda Ahenkro by one of us (K.G.) in summer 2017, and revealed a 7-term system. The three terms from 1978 are still used but they now name smaller categories, and there are also new terms for (roughly) yellow, green, blue and purple. These findings are consistent with the claim that languages add new color terms with time. To investigate whether Nafaanra had changed under pressure to remain efficient, we analyzed the 2017 system in the same way ZKRT had analyzed the 1978 system. We found that the 2017 Nafaanra system, like the 1978 system, lies near the theoretical limit of efficiency, and that this outcome would be unlikely without pressure for efficiency. To our knowledge, this is the first evidence that directly supports the proposal that color naming evolves under pressure for efficient communication. How broadly this finding generalizes across languages and domains (Regier et al., 2015), and how efficiency interacts with other factors such as language contact, are questions for future research.

Abstract

People spontaneously collaborate to solve a common goal. What factors affect whether teams are successful? Due to lack of large-scale naturalistic data and methods for investigating scientific questions on such data, previous work has either focused on very concrete cases, such as surveys of business teams, or abstract cases, such as GridWorld games, where agents coordinate their movement so that each agent can get to their own goal without obstructing other agents. We propose a computational framework based on the multivariate Hawkes process and a novel algorithm for parameter estimation on large data sets. We demonstrate the potential of this method by applying it to a large database of programming teams, public GitHub repositories. We analyze factors known to influence team performance, such as leader organization style and team cognitive diversity, as well as other factors, such as the burstiness of effort, that are difficult to test using existing methods.
Keywords: Collaborative cognition; Hawkes process; Organizational psychology; Bayesian nonparametrics

Introduction

People naturally form groups to collaborate towards a common goal. We coordinate to navigate the world (Ho et al., 2016), to protest inequalities (Korkmaz et al., 2018), to increase efficiency and well-being (Simon, 1991), to solve problems (Miller, 1951) and crises (Militello et al., 2007), to conduct science (Wuchty et al., 2007) and for many other goals. Previous work on *collaborative cognition* tends to either focus on case studies, such as using surveys of company employees (Kozlowski & Ilgen, 2006), or abstract situations, such as game-theoretic analyses of whether to cooperate or defect in the Prisoner's Dilemma (Rand & Nowak, 2013). Although these methods have been drastically increased our understanding of collaboration and competition (e.g., what mechanisms promote cooperation in competitive scenarios; Kleiman-Weiner et al. 2016; Rand & Nowak 2013), there is a need to bridge this gap. In this paper, we propose a large-scale natural data set and computational framework for analyzing human collaboration.

Technical approaches for theoretical development, conceptualization, and modeling of collaborative cognition come in many forms, each with specific strengths and weakness. For example, agent-based simulation can represent individuals interacting in dynamic network structures, but suffer from issues, such as computational difficulties in scaling the number of agents to realistic numbers, the number of free parameters (whether in model choice or explicit parameters), what the right level of abstraction should be, and how to evaluate them with respect to empirical data. This methodology has been extremely powerful, for example, it is unclear we would have discovered without these models that cooperation in the Prisoner's Dilemma can emerge from natural selection when the agents play according to how they are networked (Ohtsuki et al., 2006). But due to the simplifications, it is unclear whether this approach can be applied to any phenomena of interest (Louie & Carley, 2008).

In this paper, we focus on one aspect of collaborative cognition: how teams act as if they are a single mind when solving a common task (Searle, 1995; Bacharach et al., 2006). There are two major challenges facing collective cognition research on this perspective: (1) a lack of naturalistic data of real-world problems in the process of being solved and (2) a lack of formal methods for evaluating such data, which are richly-structured discrete data over continuous time (Kozlowski et al., 2016). For example, recent work has explored how pairs of agents can learn to coordinate and generalize their coordination in "Grid Worlds" – an environment consisting of a grid, two circle avatars in the grid, and two goals that the avatars try to get to without impeding each other (Austerweil et al., 2016; Ho et al., 2016). To address the first problem, we propose analyzing projects (called repositories) on GitHub, an online social coding platform, as a source of large-scale, naturalistic data of humans self-organizing towards solving a common goal. To address the second problem, we propose using the multivariate Hawkes process (Hawkes, 1971), a Bayesian nonparametric process, that, unlike Poisson processes, can capture the bursty nature of work on GitHub. To do so, we derive a novel approximation technique that can estimate parameters for a set of richly structured discrete data.

Introduction to GitHub

GitHub is an online social coding platform. Users can create projects, called repositories, which are publicly accessible. It is built on the decentralized software version control platform `git`. Each `git` user of a repository has a full-fledged version of the project and full control of their local version. They then can share their changes to others working on the project who can decide whether to merge them into their own repository.

Given how decentralized projects managed by `git` are and the importance of clear leadership for project success in some tasks from empirical research in Industrial and Organizational Psychology (Kozlowski & Ilgen, 2006; D. Wang et al., 2014), one may be surprised that GitHub is one of the most popular platforms for collaborative programming projects. This is because GitHub affords coordination with other team members in a few ways. (1) Only some members are "owners" of the repository, who are allowed to accept proposed changes to the project (any owner can make another member an owner – the original creator is the first owner of the repository), (2) a set of `Events` that keep track of actions taken by each member to global repositories, and (3) conversations through different media, such as e-mail lists or Reddit. Although the third method of coordinating is important, we leave it for future research. We will focus on repository ownership and events to analyze collaborative cognition on GitHub.

There are six main types of `Events` that we focus on: `CreateEvent`, `ForkEvent`, `DeleteEvent`, `PullRequestEvent`, `PushEvent`, `IssueEvent`, and `WatchEvent`. Every event is stored with the time when it occured. Some event types have subtypes that enable team members to discuss the event. A `CreateEvent` occurs when someone creates a new repository or (more commonly) creates a new "branch", which is a copy of the project attached to the main one. Branches are often used to prototype new features. Sometimes the prototype works and a team member proposes incorporating it back into the main project, which is a `PullRequestEvent` (an owner then either accepts or rejects the merger, sometimes after comments from different members). Sometimes the prototype does not work, in which case it gets deleted, which is catalogued by a `DeleteEvent`. A `PushEvent` occurs when someone updates a file in the main public repository. Team members that discover problems or want to raise other issues can do so with an `IssueEvent`. Finally, anyone interested in a project can get regular updates to any changes by "watching" the repository. Whenever a new person watches the repository, a `WatchEvent` occurs. Although these events do not catalogue all work by a team, they provide a lot of information about how team members collaborate and develop a project. We will analyze them to test theories of collaboration, but first we present our computational framework.

A Computational Framework for Teamwork

We formulate our model as a Bayesian nonparametric Point Process. It is a multivariate Hawkes process, where the dimensions correspond to the different types of Events and marks correspond to the properties of the Event. For example, an IssueEvent will be one dimension in the multivariate Hawkes process, and values of the IssueEvent (such as the user, the repository, etc) are all part of the mark.

In this section, we first define Stochastic Marked Non-Homogeneous Poisson Point Processes. Next, we define the univariate Hawkes process with a simple mark. Then, we formulate a multivariate Hawkes process. Throughout, we will introduce notation that will become increasingly catered to the special case of modeling GitHub.

Stochastic Marked Non-Homogeneous Poisson Point Processes

A *Marked Point Process* is a sequence of marked random points, where each point $H_i = (t_i, e_i)_{i=1,\dots}$ is composed of a continuous-valued time value ($t_i \in \mathcal{R}_+$, positive real numbers) and a *mark* ($e_i \in \mathcal{E}$, an arbitrary event space $\mathcal{E}$). For the specific case of modeling GitHub, marks are multivariate points taking values in the space, $\{1,2,\dots,E\} \times \{1,2,\dots,U\} \times \{1,2,\dots,R\}$, where E is the number of Event Types, U is the number of agents, and R is the number of repositories.[1] The framework allows for observed mark types to influence the rates of EventTypes, which will be important for capturing dependencies betweeen EventTypes. For example, a PushEvent is more likely after a CreateEvent then a WatchEvent.

A *Non-homogeneous Marked Poisson Point Process* is a special case of a Marked Point Process, where the number of points in a period of time $[a,b]$ is Poisson distributed with parameter $\int_a^b \lambda(t)dt$. $\lambda(t)$ is an intensity function or the instantaneous rate for points to arrive at time t. To capture relations between EventTypes, agents, and repositories, $\lambda_\theta(t)$ will be dependent on $\theta = (e,u,r)$, which corresponds to the rate of users u producing events of type e in repository r. The interactions between the stream of events for users in different repositories can be distributions other than *Possion*. They are defined as appropriate for the domain, which is how we will include psychologically-based representations in future work. For this article, we assume each repository, event types, and users are marked processes with empirical distributions extracted from real repository data.

Multivariate Hawkes Process with Agent Types, Repositories, and Communities

In the models discussed above, all events arrive independently, either at a constant rate (for Poisson process) or governed by an intensity function (for the non-homogeneous Poisson processes). In both cases, they are independent of events that previously occurred. However, in social environments, the arrival of an event increases the likelihood of observing events in the future. To model this phenomena we use a *Hawkes Point Process* with a *self-exciting* kernel in which an event arrival explicitly depend on past events (Hawkes, 1971). A *Point Process* is a *Hawkes Process* if the conditional intensity function $\lambda_r(t|H_i = (t_i, e_i)_{i=1,\dots})$ is:

$$\lambda_r^*(t) = \lambda_r(t|H_1,\dots,H_n) = \lambda_{r,0}(t) + \sum_{i:t>t_i} \phi(t-t_i;\beta) \qquad (1)$$

[1] Technically, the number of users and repositories are random variables themselves. Then the second and third dimension of the mark would each be counting processes. $U(t)$ could encode the number of users at time t and the probability of a point having a value on the second-dimension beyond $U(t)$ is null. The same can be done for repositories.

where $\lambda_{r,0}(t)$ is the repository intensity based on prior or exogenous information. The events generated from $\lambda_{r,0}(t)$ are called *immigrant* events. Note that when $\phi = 0$, we recover a *Poisson Process*. $\phi(t;\beta)$ is a kernel function and typically decays with increasing t and β are its parameters. The most common decay function is the scaled exponential taking the following form: $\phi(t;\alpha,\omega) = \alpha\omega\exp\{-\omega t\}$, where $\beta = (\alpha,\omega)$, $\alpha \geq 0$ and $\omega > 0$ and $\alpha < \omega$. Another widely used kernel for modeling social behavior is the power-law function: $\phi(t;\alpha,\eta,\gamma) = \alpha(t+\gamma)^{-(\eta+1)}$, where $\alpha \geq 0$, $\gamma > 0$, $\eta > 0$ and $\alpha < \eta\gamma^{\eta}$.

After observing an event, the intensity is large for some time and then decays to zero. Thus, more recent events influence the current event's intensity more than older events. This results in a *self-excitatory* process, where bursts of points in a small time period lead to a large increase in intensity in that region. By defining $\phi(t)$ differently, it is also possible to capture *self-inhibiting* processes (Yang et al., 2015), which will be important in capturing an user waiting for other users (e.g., respond to an `IssueEvent`). Both properties violate the *memoryless* property, and thus, Hawkes processes capture a broader set of Point Processes then standard nonhomogeneous Possion Processes.

As our model is multi-user, multi-event and multi-repository we will use the *multivariate* formulation of the Hawkes process. The basic assumption behind the multivariate Hawkes process is that the arrival of an event in one dimension can affect the arrival rates of events in other dimensions according to some generative process. The specification of the generative process can be as richly structured as appropriate for the domain. This enables analysis of structured discrete data over continuous events. We model this dependence in the following manner: each repository is a Hawkes process, the Hawkes processes for repositories are interdependent, and the event types and users as marks. In this paper, we use pairwise correlations to capture repository interdependence and the joint probability of pairs of Event Types is estimated from our data set.

Using an exponential kernel function, the conditional intensity $\lambda_r^*(t)$ is:

$$\lambda_r^*(t) = \lambda_{r,0}(t) + \sum_{i:t>t_i} \alpha_{r_i,r}\omega_{r_i,r}\exp(\omega_{r_i,r}(t-t_i)), \qquad (2)$$

where $\alpha_{r_i,r}$ is an interactivity matrix defining how the r_i dimension influences the r dimension given the values of features across the different dimensions at time t. We approximate this matrix via maximum likelihood estimation. The likelihood of repository r with parameter set $\beta = (\alpha,\omega)$ and λ_0 is (Ozaki, 1979):

$$l_r = \exp\left\{-\int_0^T \lambda_r(t|\{t_j\}_{j=1}^N)dt\right\}\prod_{i=1}^N \lambda_r(t_i|\{t_j\}_{j=1}^{i-1}) \qquad (3)$$

and the log-likelihood, with some simplification, is:

$$\log l_r(\{t_i\}|\eta_r) = -\lambda_{r,0}T + \sum_{i=1}^N \alpha_r(\exp(-\omega_r(T-t_i))-1) + \sum_{i=1}^N \log(\lambda_{r,0} + \alpha_r\omega_r\Omega_r(i))$$

where $\Omega_r(i) = \sum_{t_j<t_i}\exp(-\omega_r(t_j-t_i))$, $\forall i \geq 2$ and $\Omega_r(1) = 0$.

Unfortunately we cannot optimize the log-likelihood directly, because the curvature vanishes. So, we estimate the parameters by extending a version of *Maximum a Posteriori Expectation Maximization* (Zipkin et al., 2016). Let $\tau = (t_i)$ be the sequence of actions performed on a repository and $M = M_{ij}$ be a branching matrix of an immigrant event, where $M_{ij} = 1$ if event i is an offspring of event j. M is the causal cascade structure of sequence of actions performed in a repository. Let $p(\Upsilon;F)$ be a prior on $\Upsilon = (\eta,\lambda_0)$ with hyperparameter F. We perform *MAP* estimation using the EM algorithm to maximize the event stream posterior, $p(\Upsilon|\tau,M) \propto p(\tau,M|\Upsilon)p(\Upsilon|F)$. Let $\log P(\tau,M|\Upsilon,F) = \log p(\tau,M|\Upsilon) + \log p(\Upsilon|F)$ be the event stream probability. We decompose the first term in the following manner: $\log p(\tau,M|\Upsilon) = \mathfrak{L}_1(\lambda_0,\tau) + \mathfrak{L}_2(\eta,\tau) + \mathfrak{L}_3(\eta,\tau)$ where

$$\begin{aligned}
\mathfrak{L}_1(\lambda_0,\tau) &= -\lambda_0 T + b(\log\lambda_0 + \log T) - \log m! \\
\mathfrak{L}_2(\eta,\tau) &= -n\Phi(\eta) + \sum_i d_i\Phi(\eta) - \log m_i! \\
\mathfrak{L}_3(\eta,\tau) &= \sum_{ij} M_{ij}[\log\phi(t_i-t_j;\theta) - \log\Phi(\theta)]
\end{aligned}$$

where $m = \sum_i M_{ii}$, $m_i = \sum_j M_{ij}$, and $\Phi(\eta) = \int_0^\infty \phi(t;\eta)dt$.

$$\log p(\tau,M;\Upsilon) = -\lambda_0 T + m\log\lambda_0 + b\log T - \log(m!) + \sum_i[-\Phi(\eta) + m_i\log\Phi(\eta)\log(m_i!)] + \sum_{ij} M_{ij}\log\phi(t_i-t_j;\eta) - \log\Phi(\eta)$$

In the E-step of the MAP EM algorithm, we compute the current distribution over M. As M is a matrix of branching variables, each is Bernoulli and so M can be expressed as the expected branching matrix $P = [p_{ij}]$ based on the data τ and our current parameter estimate Υ^k. The expected branching matrix at each iteration is $P^{k+1} = \mathbb{E}[M|\tau,\Upsilon^k]$. In the M-step, we update our parameter estimate to maximize the expectation of the event stream posterior log-likelihood:

$$\begin{aligned}
\Upsilon^{k+1} &= \arg\max_\Upsilon \mathbb{E}[\mathfrak{L}(\tau,M;\Upsilon,F)|M = P^{k+1}] \\
&= \arg\max_\Upsilon (\mathbb{E}[\log p(\tau,M;\Upsilon)|M = P^{k+1}] + (\mathbb{E}[\log p(\Upsilon,F)])
\end{aligned}$$

We use a Gamma prior on α and ω, with parameters (s,t) and (u,v), respectively. Extending the method in Zipkin et al. (2016), the EM update steps can be derived using the immigrant/offspring interpretation. The ith event is either an immigrant or an offspring of one of the previous events. The probability that the ith event is an immigrant event is proportional

to λ_0^k, while the probability that it is an offspring of event j for $j < i$ is proportional to the kernel function $\phi(t_i - t_j; \alpha^k, \omega^k)$. The E-step update then is

$$P_{ij}^{k+1} = \begin{cases} \frac{1}{\Lambda^k(i)} & \text{for } i = j \\ \frac{1}{\Lambda^k(i)} \phi(t_i - t_j; \alpha^k, \omega^k) & \text{for } j < i \\ 0 & \text{otherwise} \end{cases} \quad (4)$$

where the normalization factor is $\Lambda^k(i) = \lambda_0^k + \sum_{j<i} \phi(t_i t_j; \alpha_k, \omega_k)$. Finally the M-step is

$$\mu^{k+1} = \frac{1}{T} \sum_i P_{ii}^{k+1} \quad \alpha^{k+1} = \frac{1}{n+l} [\sum_{j<i} P_{ij}^{k+1} + s - 1] \quad (5)$$

$$\omega^{k+1} = \frac{\sum_{j<i} P_{ij}^{k+1} + s - 1}{\sum_{j<i} P_{ij}^{k+1} (t_i - t_j) + v} \quad (6)$$

Analyzing Teamwork on GitHub

We now present how GitHub can be used as a naturalistic, large-scale data set and the Hawkes process to analyze the dynamics of collaborative cognition. We used a data set of events from public repositories on GitHub at the start of midnight on March 1st 2017 to 11:59pm on August 31st 2017. We retrieved 456,195 events across 8,083 repositories.

One issue is that not all repositories are collaborative projects. For example, many repositories are used for web pages, software tutorials (e.g., learning how to fork repositories), and other personal usage. Further, many projects become inactive and abandoned without being deleted. We follow best practices for studying GitHub repositories from previous work in computer science (Kalliamvakou et al., 2016) by filtering repositories according to the following criteria: (1) there are at least 10 Events (not counting `WatchEvent`) in the data set, and (2) at least three unique "active" users. We define an active user of a repository to be someone who had at least one `CreateEvent` or `PushEvent` with it. Using these criteria, our filtered data set was comprised of 390,277 events across 1,235 repositories. This leaves us with 86% and 15% of the total events and repositories, respectively.

Are Hawkes Processes Really Necessary?

Before testing collaborative cognition hypotheses, we provide some justification for using a more complex process, a Hawkes process, rather than a standard Poisson process. From a qualitative perspective, Figure 2 shows the stream of events over time from a representative project and the best fits from a Poisson process and a Hawkes process using an exponential and power-law kernel. Due to its memorylessness property, the Poisson process is simply unable to recreate the bursty dynamics of the event stream. For our data, the Hawkes process with an exponential kernel provides the best qualitative and quantitative fit. Thus, for the remainder of the paper, we only consider the Hawkes process with an exponential kernel. A quantitative comparison of the model fits is computationally challenging due to the large number of repositories. Thus, we approximated by calculating the root

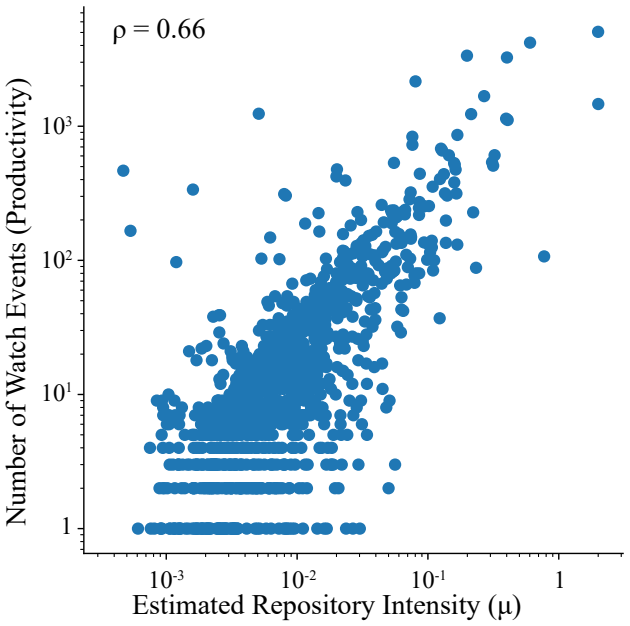

Figure 1: The repository intensity (μ) of the Hawkes Process as estimated from the GitHub data. It corresponds closely to the productivity of the repository.

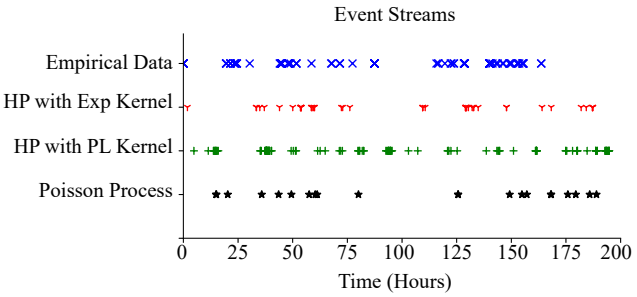

Figure 2: A representative GitHub event stream and samples from a best-fit Poisson Process and Hawkes Processes with an exponential and a power-law kernel.

mean squared error (RMSE) of 200 randomly sampled repositories and then 200 randomly sampled events within each of those repositories. The approximate RMSE for the Hawkes and Poisson processes were 7.27 and 11.81. Further, Figure 1 the number of watch events is closely related to the estimated repository intensity ($\rho = 0.66, p < 0.001$), validating our novel estimation procedure.

.

Testing collaborative cognition

We now turn to testing three different phenomena in collaborative cognition and assess how they affect performance: leadership organization style, diversity, and event dynamics. There is no clear definition of what makes a repository successful on GitHub (especially one that can be automatically applied to all repositories). We use the number of

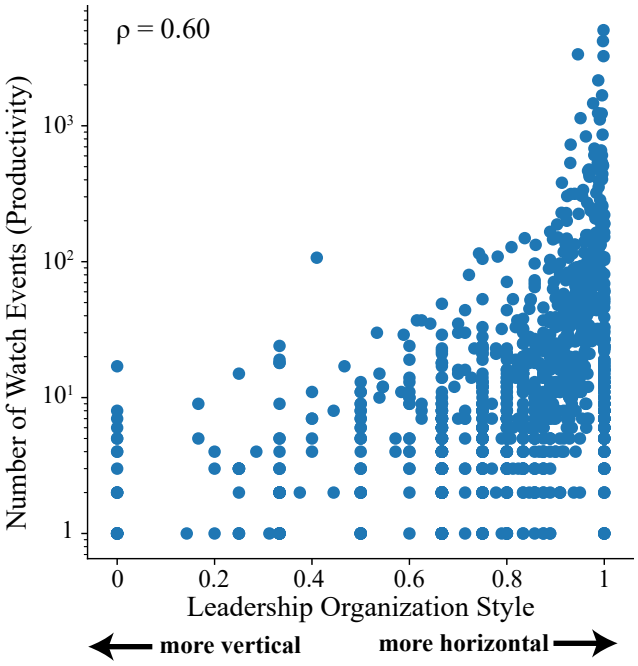

Figure 3: Shared leadership is more successful.

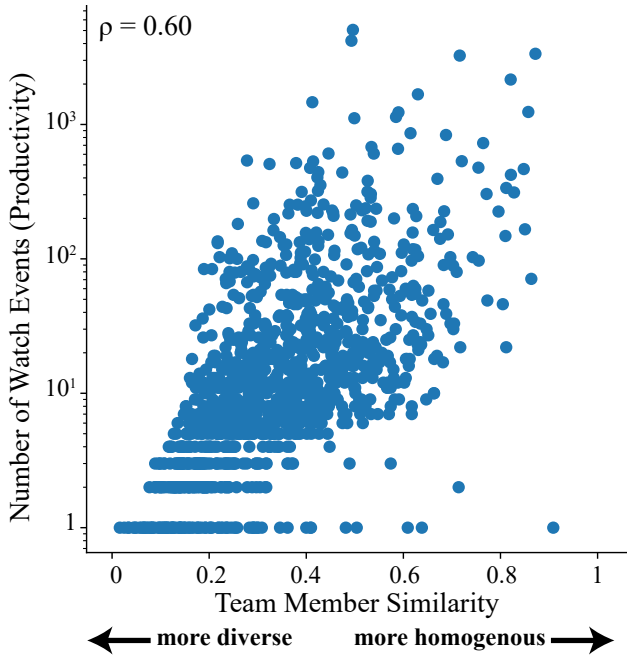

Figure 4: Teams with less cognitive diversity are more productive. The cognitive role of a team member was quantified as the distribution of event types that they produced.

`WatchEvents` for a repository in the six month period as a measure of project success. When a person chooses to *watch* a repository, it means they receive regular updates on any changes to the repository. These are people who are interested in the progress of a project, but do not necessarily contribute to it. In fact, they probably do not, as previous work found that only about 5% of people who watch a repository end up contributing to it (Sheoran et al., 2014).

Leadership organization style. Previous survey studies and meta-analyses of them have found that shared leadership (what we call "horizontal") is positively associated with group performance (D. Wang et al., 2014). We test whether this relationship holds in our large-scale, naturalistic collaboration data set. Team members in a repository are split into two groups: *owners* and *users*. Users can create their own version of a project and build on it on their own. However, they can only propose changes to the global repository (or the team's project). We define leadership style as the percentage of active users who are not owners that work on the project. Lower scores imply a vertical leadership style, where only a few team members are leaders. Larger scores imply a horizontal leadership style, where most team members are leaders. As shown in Figure 3, most teams are horizontally organized and there is a strong positive relation between horizontal organization and performance ($\rho = 0.60, p < 0.001$).

Cognitive Diversity. How does the diversity of roles within a team affect performance? Recent work found that diversity of roles (cognitive diversity) is positively related to team creativity when there are leaders that serve as role models for other team members, but negatively associated otherwise (X.-H. Wang et al., 2016). Given that we found higher performance in programming projects when the leadership style was more distributed, we expect that cognitive diversity may hurt productivity on GitHub, rather than enhance it.

To assess the role of cognitive diversity in team performance on GitHub, we quantified the similarity between two users as the inner product of the distributions of events produced by each user across all repositories. The diversity score of a repository was defined to be the average pairwise similarity of active repository users. Due to computational constraints, for repositories with many users, we approximated the quantity by averaging 10,000 randomly selected pairs of users. Figure 4 shows that teams with less diverse roles performed better ($\rho \approx 0.60, p < 0.001$).

Bursts. Are particular leadership organizations related with differences in how bursty the team's progress is on the project? Is burstiness related to performance? Thanks to the Hawkes process formalism, we can address this question by examining the relation between leadership style and the fit α parameter associated with the repository. Interestingly, Figure 5 shows that more centralized leadership organization is associated with burstier progress ($\rho = 0.39, p < 0.001$). However, burstiness has only a very weak effect on performance ($\rho = -0.13, p < 0.001$). Note that this analysis was only possible to conduct due to the computational formalism for analyzing teamwork presented in this paper.

Discussion, Limitations, and Conclusions

In this article, we proposed, validated, and used a novel computational framework for analyzing large-scale real-world

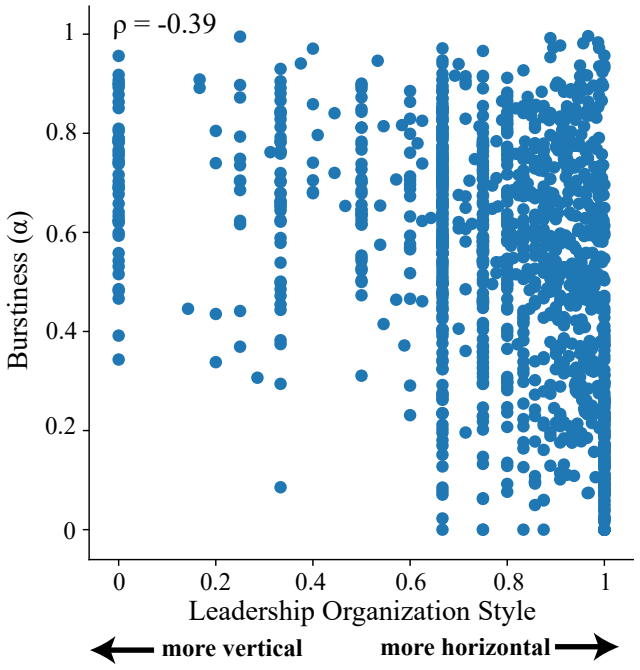

Figure 5: More vertically organized leadership styles are burstier.

collaboration data: The Multivariate Hawkes Process. We demonstrated how it can be used to test constructs in collaborative cognition. For example, we found that horizontal leadership structures were more successful. This may be specific to programming projects that naturally break into different pieces that can be worked on individually and integrated later. Future work will need to follow up on this and the other findings

As a proof of concept, we made a number of assumptions and simplifications. We assumed the only relation between events and teams are pairwise correlations. Further, we ignored an event's content, focusing on statistical patterns. In future work we plan to extend our work to address these limitations and incorporate social and cognitive principles (e.g., scripts for how events usually occur on GitHub; Schank & Abelson 1977), and examine whether the framework generalizes to analyzing other social domains (e.g., Reddit). Recent work suggests cognitive structures, such as shared memory, are essential for understanding team performance (DeChurch & Mesmer-Magnus, 2010). Additionally, we assumed that our results generalize to all task types solved by teams. However, psychologists have organized task types into ontologies (Wildman et al., 2012), and we plan to examine whether our results generalize across tasks. Shared programming projects may lend themselves more naturally to distributed, horizontal leadership structure, whereas a clear leader or established organizational identity may be needed to solve other tasks, such as putting out a fire (Mesmer-Magnus et al., 2018).

Our computational framework is built using probabilistic modeling. This enables us to conduct principled analyses that would otherwise be difficult or impossible in other frameworks. Recent work has analyzed determining automated interventions on social media using a similar probabilistic modeling framework (Farajtabar et al., 2017). For example, using point processes and Markov decision processes, Farajtabar et al. (2017) created a method for mitigating the spread of Fake News through online social networks. We are excited to adapt these techniques into our framework, which would enable us to see how intervening on GitHub repositories (e.g., stopping support for TensorFlow) or counterfactual questions (e.g., how would machine learning applications be affected if TensorFlow were never made public).

Measuring Programming Competence by Assessing Chunk Structures in a Code Transcription Task

Noorah Albehaijan[1,2] (N.albehaijan@sussex.ac.uk, naalbehaijan@iau.edu.sa)

Abstract

In a simple transcription task in which sections of Java program code are copied by freehand writing, it is demonstrated that chunk related temporal signals are sufficiently robust to permit the measurement of programming competence. An experiment with 24 participants revealed that the number of views of the stimulus per trial and the duration of writing per stimulus view are both strongly correlated with independent measures of Java competence.

Keywords: Chunking, program comprehension; competence measurement; transcription.

Introduction

Chunking (Miller, 1956; Cowan, 2001) underpins cognition in tasks that involve information of any complexity. Many phenomena are explained by the notion. For instance, at a long timescale, chunk acquisition explains many of the elevated abilities of experts over novices (e.g., Chase & Simon, 1973; Egan & Schwartz, 1979). At medium timescales, learning relies on the acquisition of chunks (Gobet et al., 2001). The organization of chunks changes during learning with the accretion of new chunks and the restructuring of networks of chunks. At short timescales, the structure of chunks in memory is one substantial factor in the control of routine sequential behaviour, such as the writing of memorised sentences (Cheng & van Genuchten, 2018) or the drawing of geometric diagrams (Obaidellah & Cheng, 2015).

All this suggests that it should be feasible to assess a learner's understanding or competence in a particular knowledge domain by evaluating behavioral measures that are dependent on the underlying structure of that learner's chunk network. And that such assessments can be done using simple production tasks, such as the written transcription of text or formulas, or the copying of diagrams.

Various studies have shown that certain measures of the distribution of the durations of inter-stroke pauses provide feasible measures of competence (Cheng, 2014, 2015; Cheng & Rojas-Anaya, 2007; van Genuchten et al., 2009; Zulkifli, 2013). An *inter-stroke pause* is the time that the pen is off the paper between written strokes, which provides measures at times scales in the range of 100 ms to 1 second . These studies typically used simple transcription tasks, in which the participants copied simple stimuli in each trial, such as a mathematical equations or one English sentence. Strong correlations with independent measures of domain comprehension were found. Further, the relative difficult of stimuli were clearly related to the magnitude of the pause measures. These findings were obtained across diverse domains (algebraic formulas and natural language), classes of users (children and adults) and interface media (pen on paper and on screen mouse driven symbol selection).

Pause measures in typewriting, keystroke logging, have been used extensively to study writing behaviour and performance (e.g., Spelman Miller & Sullivan, 2006), but this requires the aggregation of relatively large amounts of data in order to find effects. Also, our pilot experiments have shown that individual differences, such as variations in typing strategy and skill, tend to obscure the temporal chunk signals. So, inter-keypress pause measures do not appear to be reliable.

What other behaviors might provide strong and robust temporal chunk signals that can serve as a measure of comprehension? Can the scope of chunk-based measures of comprehension be extended to other domains beyond mathematics and natural language? The present experiment addresses these questions.

As chunking is important in the doing and learning of programming (e.g., Shneiderman, 1976; McKeithen, et al., 1981; Pennington, 1987), here we will focus on the assessment of learners' comprehension of programming code, specifically Java. Some studies have used response times to study programming comprehension in whole tasks, such as sets of multiple choice questions, lasting minutes (e.g., Adelson, 1981, 1984; Ye & Salvendy, 1996). Here, the focus is on the time required for component activities within a task, rather than overall task time, and the examination of process durations that may directly depend upon the chunks possessed by participants.

Again we will use a transcription task, as in the experiments cited above. In those experiments, typically, the stimulus was presented on a card or computer-screen placed near a writing tablet, so that the participants could switch their gaze between the stimulus and the tablet. In this experiment we will record when the participant switches between the stimuli and tablet using a participant-driven "hide-show" interaction method. The stimulus appears on the computer screen when the participant holds down a special button. To write the participant must release the button and the stimulus is masked. This extends the repertoire of techniques that may be used to assess chunk structures with a method that targets the processing of several chunks, at a 10 s timescale, which contrasts to the previous methods that analyse elements within a single chunk.

This method makes available various measures: (a) *view-numbers* – the total number of views of the stimulus in a trial;

(b) *writing-times* – the time spent writing between two successive views; (c) *view-times* – the duration of each look at the stimulus.

Various predictions can be derived for these measures. Experts perceive the stimuli using larger chunks than novices. Assume that working memory capacity for chunks does not vary substantially with expertise, which is plausible given that transcription is a relatively complex task (Cowan, 2001) rather than a simple decision making or capacity test (Miller, 1956). So, as the size of a stimulus is fixed, we predict:

H1) View-numbers*: the number of views of the stimulus in a trial will be less for more competent participants.*

As more competent participants' chunks contain more content, we predict:

H2) Writing-times*: the duration of written responses after each stimulus view will be longer for more competent participants.*

This assumes that writing speed is independent of expertise in the target domain, which is plausible for adult participants. Now, as the time to perceive a chunk is approximately constant (Chase & Simon, 1973), and if the number retained per view is independent of competence, then we predict:

H3) View-times*: the time spent on each separate view of the stimuli will not be directly related to competence.*

Frequently used components of Java are introduced earlier during instruction, so we predict:

H4) The performance on basic stimuli will be superior to advanced stimuli, with fewer view-numbers and longer writing-times, but no impact on view-time.

Note that H3 is framed negatively, so care is required to interpret data that might support it. In particular, the magnitude of other effects must be strong so that the likelihood of the absence of an overall view-time effect is not merely due to lack of statistical power. The underlying pattern of view-time data can also be examined for supporting evidence.

Clearly, the predictions depend on some strong assumptions, so unless the effects of chunking produce substantial temporal signals, no effective measures of competence will be obtained.

Method

The experiment was conducted at the University of Sussex with approval from the Science School's ethics committee.

Design

The experiment is a within participant design with each person transcribing basic and advanced sections of Java program code. The order of these trials was counter-balanced. The trials were preceded with two practice stimuli.

(Originally, the experiment was a counter-balanced 2X2 design with a fixed stimuli factor to provide pause distribution measures for comparison. Unfortunately, an obscure software-hardware interaction on the experimental computer was found during analysis. As the original counterbalancing does not appear to have affected the reported conditions, for clarity, the experiment is presented just as single factor.)

Participants

The participants were 24 adults from the School of Engineering and Informatics. Recruitment spanned first year undergraduate students through to members of faculty, to obtain good range of programming expertise. Age ranged from 19 to 59 years (*mean*=25, *SD*=8.51), and 15 were male and 9 females. They received £8 for participating.

```
#
public class Person{
    public String name;
    public int age;}

public void Balance(){
    System.out.println("#");
    Total += balance;}

int h=0;
while(h<hCount.length){
  System.out.println(h+hCount[h]);h++;}
```

Figure 1: Stimulus sample (basic).

Materials

The two practice stimuli consisted of series of simple statements, such as 'Computer Science', 'Programming Course', 'JAVA Programming Language'. Each of the four Java program code stimuli consisted of nine lines of code divided into three separate blocks. Each stimulus had an equal number of lines and the total number of characters differed by less than 5%. Figure 1 shows an example of one stimulus. Two *basic* and two *advanced* versions of the stimuli were created by consulting the course content of the student participants. The expressions in the basic stimuli were a core part of their JAVA instruction in their first year. The expressions in the advanced stimuli are more specialist items that would only have been seen by the better performing students.

The experiment was conducted using a standard graphics tablet (Wacom – Intuous3) connected to a PC running a logging program specially written in our lab. Participants wrote with an inking pen on a response sheet. The response sheet was printed with a grid of 17 lines; each consisting of 42 spaces for the writing of separate characters. The sheet was designed for non-cursive writing in order to provide rich inter-stroke pause data (see parenthetical note in the Design section). Participants adjust to this style of writing quickly and it does not appear to adversely affected other aspects of their performance (Cheng, 2014; Zulkifli, 2013).

Following the trials, the participants completed a questionnaire with four parts (on an internet survey platform). Part 1 included biographic questions relating to educational level. Part 2 assessed programming experience in general with five graduated rating items, such as 'I can develop programs using more than one object-oriented programming language". Part 3 assessed Java programming expertise level using eight graduated items, such as 'I am familiar with both objects and classes in Java'. Part 4 measured the participants' familiarity with the four specific Java stimuli that they were presented with during the trial. Participants were asked to judge what

their degree of familiarity would have been for each item *prior* to the experiment, on a 5 point Likert Scale.

Procedure

Participants were asked to hold the pen in their preferred hand and trained to: start writing at the beginning of each line, even for indented code; start writing as soon as the stimulus is revealed; copy the code as quickly and as accurately as they can; continue writing without correcting if they made a mistake; draw an upside down triangle symbol (inverted capital delta) in place of spaces; to start each trial with a hash (#); to hold down the special key to reveal with stimulus, with their preferred hand, which ensures that they write only when the stimulus key is released. The participants easily complied with these requirements and quickly became fluent in the practice trials. (Several of these conditions were needed for the pause measurements.) Similar trial requirements were successfully used in our previous experiments, so it is clear that they do not, on their own, undermine the reliability of the results.

For each trial, the response sheet was taped to the tablet. The participants finished the experiment within an hour.

Table 1: Correlation between competence measures. (N=24, Pearson correlation, 1 tail, critical value is 0.472 at $p<.01$)

	Education level	General programming	Java	Familiarity
Education level	–	0.366	0.183	0.181
General programming		–	0.759	0.734
Java			–	0.849
Familiarity				–

Results

Independent measure of competence

Questionnaire responses were coded to obtain independent competence measures against which to compare the chunk-based measures. Education level was scored on a scale from one to six (1=1st year undergraduate student, 6=faculty member). General programming and Java experience were scored by giving one point for each positive answer related to the measure, so had scales from zero to five and zero to eight, respectively. Ratings of the familiarity were scored from 0 (low) to 4 (high), so with the four stimuli, the overall scale runs from zero to twelve. Table 1 presented correlations between all combination of the measures, and is unsurprising. Education level is only weakly (and not significantly) correlated to the other measures. General programming experience has a strong positive relation to both Java experience and familiarity. The correlation between Java experience and familiarity are particularly strong. All this suggests that both Java experience or familiarity are specific to Java, rather than wider programming competence, and that either is suitable to serve as an independent measure. As the actual pattern of results is equivalent with either measure, just the analyses using familiarity are reported here.

Behavioural measures

The dependent behaviour measures were computed from the logs of each participant. The median writing-times and view-times were calculated for each trial. View-numbers is a count of interface switches to the stimuli (button presses). (We also computed a view related measure that discounted views of a stimulus without any accompanying writing before the next view, as some participants occasionally made such repeated views. The pattern of results using this measure is essentially the same as that with view-numbers.)

Figures 2, 3 and 4 show the total view-numbers, median writing-times and median view-times for participants rank ordered by their familiarity scores. Figures 5, 6 and 7 aggregate the data across low and high competent participants by showing the mean of the total view-numbers, the mean of the median writing-times and the mean of the median view-times. A binary split of participants' familiarity scores conveniently creates two equal size groups, with low scores exclusively below 6 or and high score exclusively above 8.

The first thing to note is that the total view-numbers, Figure 5, for the practice items is considerably lower than for the Java stimuli, but that the value is essentially equal at low and high competency (6.6 and 5.7, respectively). Similarly, the mean of the median writing-times, Figure 6, for the practice items is substantially longer than the Java stimuli, and although the value is greater for higher than lower competence (means of 14.2 and 12.1 s), it is not significantly so (by a *t* test; t=1.09, df=22, 1 tail, p=.24). These results reassuringly suggest that an effect of transcribing the Java stimuli exists beyond the act of merely transcribing any stimuli.

Consistent with prediction H1, Figure 5 shows that the high competence participants required fewer views than those with low competence, which is significant at both levels of stimuli (basic: 16.3 vs. 25.2, t=4.40, p=.0002; advanced, 20.0 vs. 28.5; t=4.05, p=.0005; both df=22, 1 tail).

Consistent with prediction H4, the basic stimuli demand fewer views than the advance stimuli across all participants (20.8. vs. 24.3; t=4.05, p=.0003; df=22, 1 tail). Further, for high competence participants the view-numbers is still significant despite the small group size (19.2 vs. 22.2; t=2.88, p=.016; df=10, 1 tail).

Consistent with prediction H2, Figure 3 and 6 show that the high competence participants had longer writing-times than those with low competence, which is significant at both levels of stimuli (basic: 10.7 vs. 6.5 s, t=3.86, p=.0008; advanced, 8.0 vs. 5.7; t=3.14, p=.005; both df=22, 1 tail).

Consistent with prediction H4, the advanced stimuli had shorter writing-times than the basic stimuli across all participants (6.9. vs. 8.6 s; t=3.29, p=.002; df=22, 1 tail). Further, for high competence participants the writing-time is still significant despite the small group size (8.0 vs. 10.7 s; t=3.7, p=.003; df=10, 1 tail), but not for the low competence participants (5.7 vs. 6.5 s, t=1.8, p=.1, df=10, 1 tail).

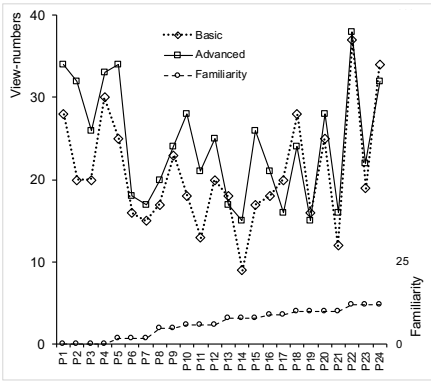

Figure 2. Total view-numbers for participants across basic and advance stimuli.

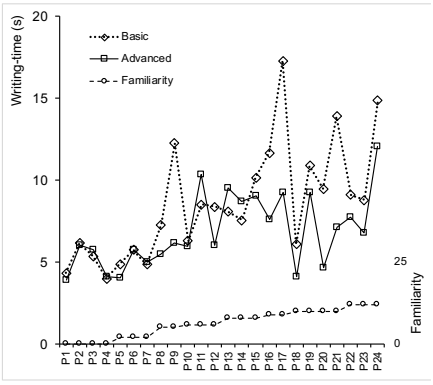

Figure 3. Median writing-times for participants across basic and advance stimuli.

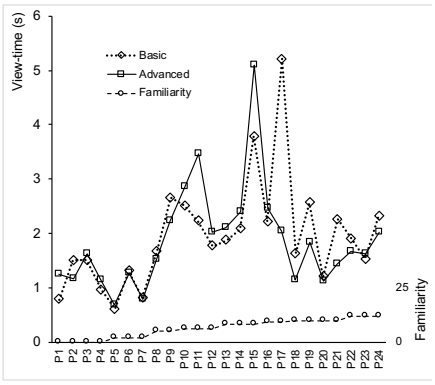

Figure 4. Median view-times for participants across basic and advance stimuli.

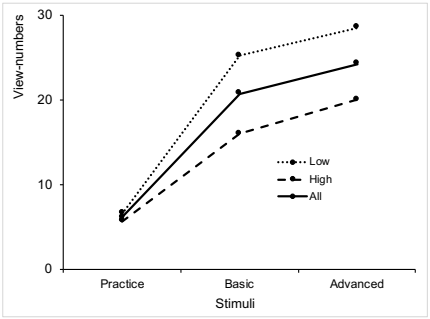

Figure 5: Mean view-numbers across stimuli type and level of competence.

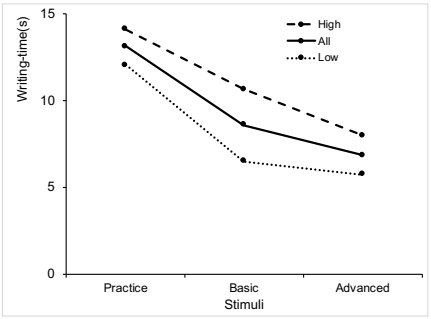

Figure 6. Mean of median writing-times across stimuli type and level of competence.

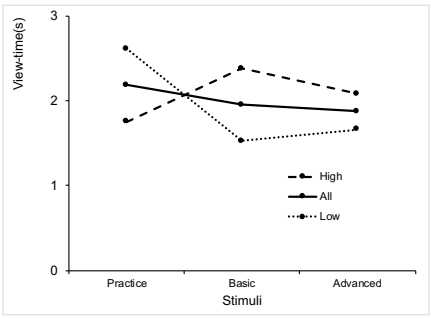

Figure 7. Mean of median view-times across stimuli type and level of competence.

Turning to H3, which concerns the absence of an overall effect of view-times, Figure 4 does not show a clear overall upward or downward trend in view-times, for both levels of stimuli difficulty. If anything, the overall pattern is an inverted 'u', in contrast to the trends in Figure 2 and 3. Figure 7 reveals that high competence participants have longer view-times than those with low competence, but this is not significant for the advanced stimuli (2.1 vs. 1.7 s; t=1.50, p=.15, df=22, 1 tail), but is marginally significant for the basic stimuli (2.4 vs. 1.5 s; t=2.62, p=.02, df=22, 1 tail). Further, comparing the view-times on the practice stimuli with the Java stimuli view-times we see they are similar, whereas for view-numbers and for writing-times the practice values are quite different to the Java stimuli values, as noted above.

Consistent with prediction H4, Figure 4 shows that nearly equal numbers of participants had longer view-times for basic stimuli or for advanced stimuli. In terms of the means across all participants, Figure 7, no significant differences occur for the basic stimuli (1.5 vs. 1.7, t=1.03, p=.3, df=22, 1 tail) nor the advanced stimuli (2.4 vs. 2.3; t=1.21, p=.25; df=22, 1 tail).

In summary, with respect to total view-numbers, means writing-times and view-times, all the predictions are supported.

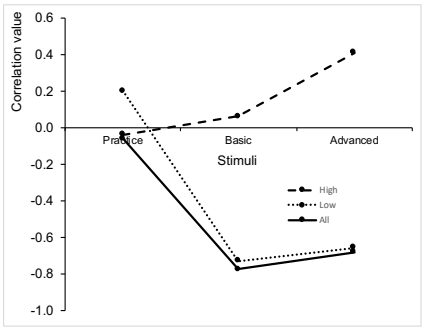

Figure 8: Correlation of view-numbers with familiarity across stimuli and competence.

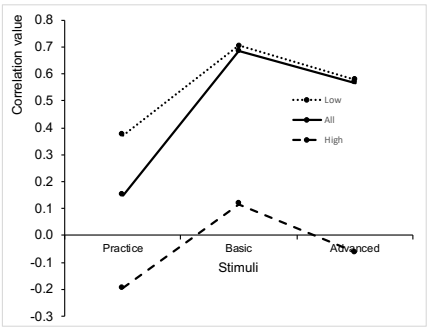

Figure 9: Correlation of writing-times with familiarity across stimuli and competence.

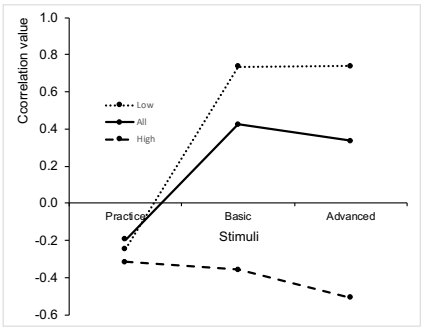

Figure 10: Correlation of view-times with familiarity across stimuli and competence.

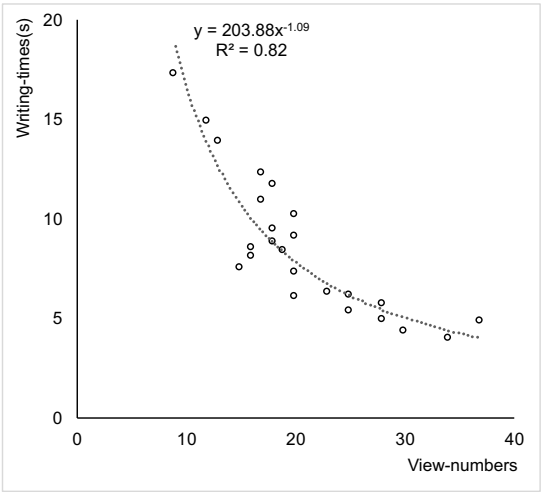

Figure 11: Relation of writing-times to view-numbers (basic stimulus)

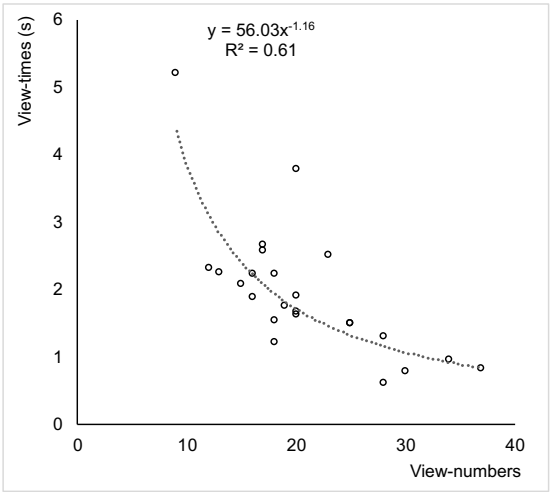

Figure 12: Relation of view-times to view-numbers (basic stimulus)

Correlation values for various measures

The correlations between view-numbers, writing-times and view-times versus familiarity were computed in order to further examine our four predictions. Figures 8, 9 and 10 show the Pearson correlations of familiarity score with, respectively, view-numbers, writing-times and view-times. The scale ranges are not the same. For correlations over all participants (solid line in Figs. 8-10) the critical value is 0.344 for significant correlations at $p<.05$, and 0.472 at $p<.01$ (1 tail, df=22). For correlations with just high competence or low competence participants (dashed or dotted lines) the critical value is 0.497 at $p<.05$ and 0.658 at $p<.01$ (1 tail, df=10).

As expected, none of the correlations for the practice items are significant. With view-numbers, Figure 8, across all participants the negative correlations are strong and significant: numbers of views decrease with competence (H1). The result is similar when just the low competence group is considered, but correlation for the high competence participants is positive but not significant. For writing-times the pattern of results is similar but the direction of the correlations are reversed, Figure 9: writing-time increases with competence (H2). For the whole group and the low competence subgroup the correlation for advanced stimuli is less than for the basic stimuli.

The view-times correlation, Figure 10, for the whole group and the high competent sub-group are not significant, but the correlations of the low competence participants are strong for both Java stimuli.

In summary, correlations for the view-numbers, writing-times and view-times are consistent with our four predictions, overall, but with some divergence in detail. In particular, view-numbers and writing-times did not differentiate high competence participants. Also, view-times did unexpectedly differentiate low competence participants, who needed more view time with increasing competence.

View-numbers vs. writing-times and view-times

The relation between our three main behavioural measures are examined because a systematic relation between them could provide further support for the hypotheses and more precise chunk-based explanations of the results. View number and writing-time are both predicted to be dependent upon chunking processes, so there should be some consistent and systematic relation between them. View-time is not expected to be chunk dependent, so no regular relation between it and view-numbers (or writing-duration) is anticipated. Scatter plots of these variables were drawn for all the participants in all the conditions of the experiment. Figure 11 plots writing-times versus view-numbers for the basic stimuli and Figure 12 is similar but for view-times. The pattern of data in Figure

Table 2. Parameter of best-fit power relation for writing-times and view-times to view-numbers

	Writing-times vs. view-numbers			View-times vs. view-numbers		
	Practice	Basic	Advanced	Practice	Basic	Advanced
Index, *i*	-0.95	-1.09	-0.97	-1.05	-1.16	-1.24
Constant, *C*	57.9	203.9	136.5	8.9	56	83.7
R-squared	0.459	0.818	0.747	0.603	0.615	0.623

11 has a particularly distinctive form, which is also apparent in the graph for the advanced stimuli. Thus, a power law curve for an inverse proportional relation was fitted to the data: the parameters of the best fit equations are given in Table 2, along with the R^2 values. The quality of fit for other equation forms (e.g., linear) were worse than a power law.

The power law for writing-time versus view-numbers is noteworthy, across both stimuli: the index is close to minus one and the R^2 values are large. This implies that the data is governed by a direct inverse proportional law. The relation between the view-times and view-numbers is less clear, with an absolute value of the index further from unity and lower R^2 values.

In other experiments, as yet unpublished, we have found similar patterns in view-numbers and writing-times data that closely fit an inverse proportional power law, so we are confident that the pattern is not accidental.

In summary, there appears to be a simple relation between the view-numbers and writing-times: a participant who takes twice the view-numbers of another will use half the time each time they write. But this simple relation does not hold for view-times.

Discussion

Previous studies have shown that measures of the distribution of inter-stroke pauses, captured in a simple transcription task, appear to reflect the different chunk structures of learners and hence may be used to assess the competence of the learners (Cheng, 2014; 2015, van Genuchten & Cheng, 2010; Zulkifli, 2013). This experiment extends those findings, in three ways.

First, allowing the user to reveal the stimulus at will, and hiding it during writing, allows two alternative temporal chunk measures to be captured: view-numbers — the total number of views of the stimulus in a trial; writing–times – the median duration of writing time between views. Predictions H1, H2, and H4 associated with these measures are well supported by converging evidence. The measures strongly correlated with our independent measures of competence. Further, no support for view-times as a suitable measure of competence was obtained, as predicted in H3, despite the relative strength of the effects for the other two measures.

Second, the experiment has shown that measures based on temporal chunk signals are applicable beyond mathematics (algebraic formula) and natural language, in a domain that happens to share some characteristics of both those domains.

Third, in contrast to the single line stimuli used in the previous experiments mentioned above, the present stimuli were larger (nine lines). The greater amount of data per trial means that single trials can yield strong usable correlations with competence, without the theoretical problems of deciding how to aggregate data from multiple trials or the practical problems associated with switching between multiple trials.

The overall correlations of view-numbers and writing-times with competence are strong, and this also holds for the low competence group. However, we must consider two qualifications. First, it is clear from Figures 2 and 3, that there is considerable variability between participants, such that some of the best low competence participant have better scores than many of the high competence participants, and vice versa. Clearly the development of a real educational test of programming competence must address the accuracy and sensitivity of the measures, perhaps by combining measures. Second, the curves in Figure 2 and 3 suggest that the view-numbers and writing-times may have plateaued for the high competent participants; in other words the difficulty of the advance stimuli may be insufficient to differentiate those within that group. This seems plausible, in hindsight, as the range of difficulty captured in the stimuli design was based on the undergraduate Java programming curriculum, but a proportion of the participants were drawn from more senior groups. This plateauing was also seen in previous studies (Cheng, 2014, 2015). One implication of this is the importance of designing stimuli with a sufficient range for the target test group.

The clear inverse proportional relation between writing-times versus view-numbers (Figure 11, Table 2) supports the chunk based explanations underpinning the predictions H1 and H2, and the poor fit of such a power law for view-times versus view-numbers is consistent with prediction H3. In particular, this implies that assumptions made for the predictions concerning the variability in participants working memory capacity and speed of writing are relatively small effects in comparison to chunk size variability with competence. In other words, the primary process in the transcription tasks appears to be the selection of chunks from the stimulus, with more competent participants retaining more characters – because they possess larger chunks – and this determines that time required for writing is in a direct proportion to the number of characters. Nevertheless, Figure 2 and 3 show much individual variability, so a useful line for future work is to investigate the possibility of separately measuring working memory capacity and writing speeds of participants in order to consider whether there is a need to devised methods to normalize for them.

Two observed effects might be spurious results, but they are sufficiently striking to deserve fuller investigation in further work. The first is the positive correlations of view-times with competence, specifically for low competence participants, is counter to prediction H3, Figure 10. The second is the increase in view-times with decreasing view-numbers, Figure 12: theoretically, there ought to be little relation between the two. One approach to study these effects is to probe the contents of participants' individual sets of chunks, which we are currently doing by extracting the locations of onset of views from the written logs in order to identify the precise content of participants' chunks. Our current hypothesis is that view-time variations may be due to differences in stimuli encoding strategies that fluctuate with content type.

This paper contributes a method for evaluating competence in a programming using a transcription task and measures with timescale of 10 s. This extends the range of techniques beyond the pause distribution measures of previous work (e.g., Cheng, 2014, 2015; Cheng & Rojas-Anaya, 2007).

Uses of the technique in education are readily imagined that exploit the relative simplicity, short trial times and the potential for fully automated scoring. Simply, such transcription tasks might be administered as a component of summative end-of-course evaluations or as standalone screening tests at the outset of a course. More interestingly with appropriately designed test items, the approach might be used as a form of formative assessment to provide tutors with information about individuals' growing understanding of targeted programming concepts. We are planning work on the development of the approach as a tool for use in computer-based tutoring systems.

Abstract

Proficient readers typically fixate near the center of a word, with a slight bias towards word onset. We explore a novel account of this phenomenon based on combining information-theory with perceptual constraints in a connectionist model of visual word recognition. This account posits that the amount of information-content available for word identification varies across fixation locations and across languages. These differences contribute to the overall fixation location bias in different languages, make the novel prediction that certain words are more readily identified when fixating at an atypical fixation location, and predict specific cross-linguistic differences. We tested these predictions across several simulations in English and Hebrew, and in a behavioral experiment. The results confirmed that the bias to fixate closer to word onset aligns with reducing uncertainty in the visual signal, that some words are more readily identified at atypical fixation locations, and that these effects vary across languages.

Keywords: visual word recognition; computational modelling; connectionism; information theory; fixation location

Introduction

The fundamental aim of visual word recognition is to identify a word based on its constituent letters. Considerable computational and behavioral evidence from studying isolated visual word recognition, which typically involves seeing a single word presented at the center of visual fixation, suggests that a graded constraint satisfaction process selects a candidate that fits with the lower-level (visual/orthographic) and higher level representations (e.g., lexical information, McClelland & Rumelhart, 1981). In contrast to this methodology, in more naturalistic studies of reading via eye-tracking, considerable evidence suggests that readers tend to fixate more frequently near the middle of words, typically with a bias towards beginning of a word, with some variation across languages (see Figure 1, for example distributions from initial fixations during natural reading in English and Hebrew Siegelman et al., 2019).

A key question from considering this body of work, then, is how and why the visual system of a proficient reader tends to fixate at particular positions in a word, and on a related front, why these fixation distributions vary as a function of the language. Classic accounts focused on the low-level operations of the occulomotor system do not appear to offer a ready explanation of these effects, particularly in terms of cross-linguistic differences (see McConkie, Kerr, Reddix, Zola, & Jacobs, 1989 for a review of occulomotor theories; also Reichle, Rayner, & Pollatsek, 1999; Engbert, Nuthmann, Richter, & Kliegl, 2005). Accounts that hold more promise in this regard consider higher-level factors (e.g., morphology; Deutsch & Rayner, 1999).

Here, we explore an alternative more general account based on information theory in the visual signal and how it maps onto lexical representations. This work shares some conceptual similarity with prior work by Brysbaert and Nazir (2005), although the latter did not quantify information in the formal terms that we do, which may, as outlined in the discussion, explain some discrepancies between their results and ours. In our first study we examined the differences in information distributions as a function of fixation location in Hebrew and English, and found that these distributions shared key characteristics of the human fixation location distributions. In our second study, we instantiated a feed-forward connectionist model with a psychophysically-derived constraint on letter identification as a function of distance (eccentricity) from the target fixation. This model allowed us to examine how different amounts of information content can be extracted at different fixation locations in different languages during word recognition. If it succeeded in doing so, it could explain why there is a preferred fixation location in different languages due simply to how low-level constraints interact when identifying a word, in the absence of higher-level constraints (e.g., morphology, semantics). This model also served as a test-bed for probing whether words exist in different languages that, due strictly to the information content available at different fixation locations, are, perhaps counter-intuitively, more efficiently recognized by looking at fixation locations other than the overall preferred location in the language. These predictions were corroborated in a pilot behavioral experiment. Taken together, this research highlights how maximizing information in the visual signal could be a major driver of many behaviors observed within and between languages. It also offers specific predictions for broadening this account in future work, for instance, in maximizing information across words

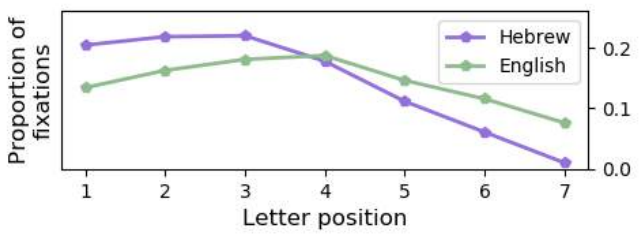

Figure 1: Distribution of fixation locations for 7-letter words in English and Hebrew. 1=start of word (left in English, right in Hebrew)

rather than within the processing of single words.[1]

Study 1: Information-content in the early visual-orthographic representation.

In our first study, we explored how much information-content was available for word recognition in the early visual-orthographic signal when fixating at different locations in the word. This was achieved computationally by passing the visual representation of a word at a particular fixation location through a visual filter that reflects how more visual information is extracted from the fixated location in a word and less information is extracted as a function of eccentricity (distance) from this location. We applied this procedure to samples of words from English and Hebrew, which belong to different language families, to gain insight into the language-specific versus language-general nature of the results.

Data We analyzed the 50,000 highest frequency words from the OpenSubtitles translated movie subtitle database (Tiedemann, 2012)[2]. We removed all words that contained foreign alphabet characters. For simplicity, we selected for our study only 7-letter words, because we predicted that strong effects of fixation location and information content would be more readily detected in longer words that could nevertheless be perceived with a single fixation. The resulting lists contains 5565 words in Hebrew, and 8145 in English.[3]

Architecture To simulate the constraints on visual perception imposed by the early visual perception system, we passed the representation of each word in each language through perceptual filters adapted from McConkie et al. (1989). In the original formulation of this model of perceptual filtering, the fixated letter was perceived with 100% accuracy, and the likelihood of successful perception fell off linearly as a function of eccentricity (see Figure 2, for examples from fixating letter 2 or letter 6 in a 7-letter word). The exact slope of this function, as exemplified by the $drop = 0.1$ and $drop = 0.25$ lines in the figure, leads to an initial linear change in the amount of extracted information, which eventually reaches floor.

In the original paper, the authors noted that the optimal value of the *drop* parameter remained to be determined. Thus, for this initial work, we opted to use a *drop* parameter of 0.25. This value was selected so as to capture most but not all the letters in a word when perceived from the start or end of the word, which we predicted would lead to relatively high, but below ceiling, recognition rates (confirmed and described in a later section) and substantial differences in information as a function of fixation location.

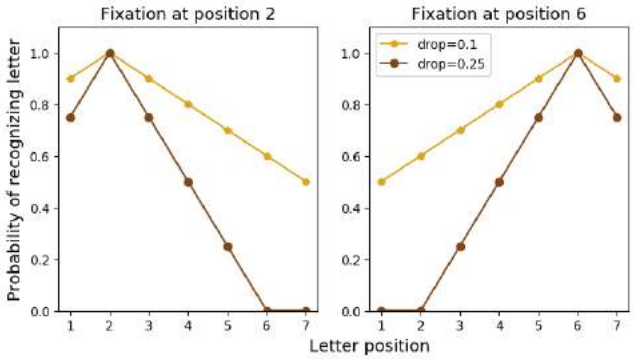

Figure 2: Probability of recognizing the constituent letters in a word when fixating letter position 2 (left) and letter position 6 (right) in a word according to the McConkie model.

Procedure We tested for how the fixation location could impact the information content extracted from the perceived word. For simplicity, and to test for strong modulations in word recognition due to the perceived information, here we focused on the information content extracted from a fixation near the beginning of a word (at the second letter position) and near the end of a word (at the sixth letter position). After passing each word through the McConkie filter, for each word, we calculated the remaining amount of uncertainty on the identity of the word *after* fixating at each of these fixation locations (a proxy of the information content in each location[4]). The measure of uncertainty we used was *entropy*, as proposed in Shannon (1948). Concretely, given the letters retrieved after fixating on a word, we computed the remaining entropy as $H = -\sum_{w=1}^{m} p_w log_2(p_w)$, where the words w belonged to the set of words m that have a perfect match with the identified letters, both in letter identity and letter position (e.g. the word 'therapy' would be in the set of matching words for the recognized letters 'ther - - -'). The probability of a matching word p_w was estimated as its relative frequency

[1]The code for our models and analyses is released at https://github.com/rgalhama/nnfixrec_cogsci2019.

[2]From https://github.com/hermitdave.

[3]We ruled out the possibility that vocabulary size drove any of our simulated behavioral effects by down-sampling the English corpus to be the same size as the Hebrew corpus in our simulations.

[4]Note that, throughout our paper, we use the term "information content" of a fixation location to quantify the contribution of the observed letters in minimizing the uncertainty *on the identity of the word*. This should not be confused with the *surprisal* conveyed by the letters in a fixation location. The former concerns a probabilistic models for words (based on word frequency and component letters), while the latter would be based on a probabilistic model of letter strings.

in the corpora.[5] To test whether information was distributed evenly across the beginning and end of all words in each language, we subtracted the entropy for each word at fixation location 2 from that at fixation location 6. If entropy were evenly distributed, these values should cluster around 0.

Additionally, from the distribution of entropy difference scores, we identified 100 words with the most extreme positive (50 words) and negative (50 words) values.[6] We refer to the words with more information content when fixating at position 2 (i.e. negative entropy differences) as the $maxIC(2)$ words, and the words with more information content at position 6 (i.e,. positive entropy differences) as the $maxIC(6)$ words. These words served as test items in Study 2.

Results

The difference in entropy values when a word was perceived at fixation location 2 versus fixation location 6 are plotted in Figure 3. It clearly shows that entropy information is not uniformly distributed across words, as in both English and Hebrew there are more negative scores. It also shows a relatively wide range of entropy values, with both languages containing words with entropy difference scores ranging from approximately -5 to 3. Further, the Hebrew scores tend to be more negative than the English scores.

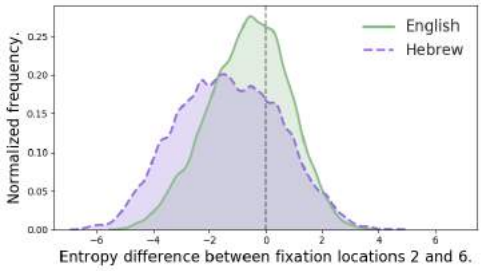

Figure 3: Distribution of entropy differences for 7-letter words.

To give a more concrete intuition into the magnitude of the difference scores and their relationship to successful visual word recognition, consider the case of the word "zooming", which has an entropy difference score of -5.1. If the fixated letter and the two letters on either side of this letter are preceived correctly, there is a 100% likelihood of successful recognition of this word when fixated at position 2 (i.e. when perceiving 'zoo-'). However, there is only a 3% success rate when fixated at position 6 (i.e. when perceiving '-ing').

Next, we selected 100 words per language with "extreme" entropy difference scores for use in Study 2. These items had mean difference scores, for $maxIC(2)$, of -2.68 in English and -3.32 in Hebrew, and for $maxIC(6)$, it was 2.19 in English and 2.58 in Hebrew.

In additional simulations, not reported in detail due to space constraints, we also confirmed that varying the exact shape of the McConkie function and the value of the *drop* parameter did not qualitatively alter these trends unless only the nearest items to the fixation location, or nearly all the words in the word, were perceived with 100% accuracy.

Discussion

The first simulation substantiated our predictions that different amounts of information content can be extracted by fixating at different locations in a word. Overall, there appears to be more information content present at the start of words in both languages, providing initial evidence for a language-general trend. Thus, the fixation distributions in different languages may at least be partially attributed to a system that attempts to minimize entropy in the visual signal in service of word recognition. This claim is further bolstered by the fact that the Hebrew distribution was even more shifted to contain more information when fixating at the beginning of a word, consistent with the stronger preference to fixate earlier in Hebrew words in behavioral data (see Figure 1). The broad distribution of values in each language also enabled us to select items with "extreme" entropy difference scores across fixation locations. This enabled us to test whether some words are more readily identified by fixating at a location other than the overall preferred fixation of the language (which is off-center, nearer to the beginning of the word).

Having thus established that the perceptual input to the word recognition system contains major differences in entropy based on fixation location, we next explored how these inputs could shape processing in a connectionist model of word recognition.

Study 2: A perceptually-constrained connectionist model of visual word recognition

The previous study focused on the distribution of information contained in the languages. In this study, we employed a connectionist model and a coordinated pilot behavioral experiment to investigate whether a learning model of word recognition is sensitive to these information patterns. This allowed us to develop new predictions about how performance in different fixation locations evolves in relation to reading proficiency: although it is beyond our goals to align model training (in epochs) with human reading experience —which is a non-trivial question–, our learning model provided us with insights into novel emergent processing dynamics that are not visible from an information-theoretic approach. In particular, we focused on whether the model and the human participants displayed an interaction between fixation location and the location of maximum information content in our "extreme" items selected in Study 1. Because some of the implementational decisions for the model were made to increase

[5] An alternative approach is to compute these values over word types rather than word tokens. Control simulations showed that both of these approaches were highly correlated in both languages, $r > .72$, and that the correlations between entropy differences over types or tokens and word frequency were extremely small, $|r| < .04$

[6] We filtered some items to avoid the over-representation of letter combinations like "-ing" and to eliminate extremely low and high frequency items.

the similarity between the simulated task and the pilot behavioral task, we provide a brief overview of the behavioral task and findings before turning to the details of the simulation (for the complete report of this experiment, see Siegelman et al., 2019).

Overview of the behavioral task. A total of 23 native speakers of Hebrew (14 females, age range: 22-30, mean: 24.9) were presented with the a set of words including the 100 words with extreme information differences described previously, and an additional selection of 100 words (also of length 7)[7] with intermediate entropy differences, which we treat as fillers for the purpose of this paper.[8] In the task, participants first focused on a fixation cross for 1000 ms, and then were presented with a word for 100 ms. This brief presentation prevented multiple fixations and was expected to lower performance below ceiling. Critically, the word was presented in different locations, including cases wherein the letter at position 2 or position 6 appeared at the same location as the fixation cross (i.e., the word was left- or right-shifted from screen center where participants were fixating). Participants were then instructed to say or guess the word that had been presented. Responses were coded either as correct or incorrect. All words were presented in both fixation locations simulated in the model (i.e., fixation at position 2 vs. position 6). Words were presented in a random order.

The results are presented in Figure 4. The pattern of results indicated that accuracy was highest when a word was fixated at the location which contained the most information content, and lower at the location which contained less information content. Critically, this was true not only for words that had more information content early in the word, but also for words that contained more information content near the end of the word: a logistic mixed-effect model (with condition, fixation location, and their interaction as fixed effects, trial number and log-transformed frequency as control variables, by-subject and by-item random intercepts, and by-subject random slope for condition) revealed a significant interaction (B = 0.59, SE = 0.05, $p < 0.001$ and a significant main effect of fixation location (B = -0.23, SE = 0.05, $p < 0.001$). Thus, these findings do not simply reflect a preference to process words in the more frequently fixated location in a given language, which our prior study showed contains, on average, more information content. The presence of numerically larger differences across fixation locations for words

[7] All the words we use are multisyllabic. This could create confounds in the modelling work if we mapped the input with phonological representations, but we intentionally focused only on orthographic factors, since our goal is to find out what structure exists in the orthographic signal alone in the absence of phonological considerations. Future work may investigate how these visual representations interact with phonological representations, similar to a classic "triangle" model (Seidenberg & McClelland, 1989).

[8] Although we did not test these items in the model, the behavioral results indicated that items with intermediate entropy difference scores were relatively unaffected by whether they were fixated near onset or offset, as predicted by the account.

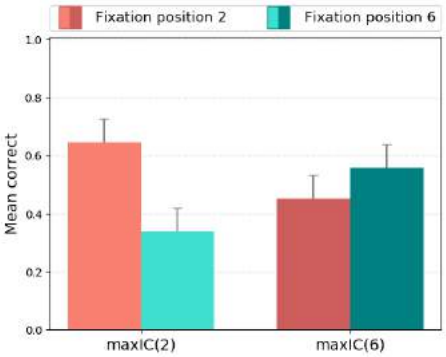

Figure 4: Mean correct responses of participants in the four conditions. Error bars = SEM.

with more information content near the start of a word relative to near the end of a word may suggest a more subtle interaction between information content and frequency of exposure to different locations, however. Additionally, averaging across the four experimental conditions, overall accuracy was significantly below ceiling.

Simulating the behavioral experiment

Model Architecture We implemented a feed-forward connectionist model that mapped perceptually-constrained distributed input of a word's constituent letters onto a localist representation of each word in the training vocabulary, as illustrated in Figure 5. There were 7 letter input slots, one for each position in a 7-letter word. Each of these slots had one unit for every letter in the alphabet and coded for the presence (1) or absence (0) of a given letter in that position (i.e., a binary one-hot coding). The distributed representation of the visual word was then input to a McConkie filter set to perceive the word at a particular fixation location (the procedure for specifying fixation locations is described later). Thus, the one-hot vectors would be down-scaled (using a drop parameter, d, of 0.25) to reduce the activity of having perceived a given letter as a function of eccentricity from the fixation location, as quantified in Equation 1:

$$x(i) = x(i) * max(0, 1 - eccentricity(i) * d) \quad (1)$$

Thus, the activity of the fixated letter remained unchanged, the activity of letters more than four slots distant from the fixated letter was set to 0, and activity in each letter-slot would decrease linearly between these two bounds.

To simulate the noisy nature of perceptual inputs in the human visual system, we next injected normally-distributed random noise ($\mu = 0.2$, $\sigma^2 = 0.05$) into the unit activations (clipping activations to $[0, 1]$). We assumed that the activity after these processing steps was analogous to what would be available in an early visual-orthographic representation ("perceived input" in the Figure).

Next, we mapped the perceived input onto a one-hot log-softmax target output representation for each word in the vocabulary through a pool of 125 hidden units. The output of

the hidden units was determined first by computing the sigmoidal function of their net input, followed by the injection of uniform random (output) noise (mean = 0, range = 0.05). All the weights in the network were randomly initialized from a uniform distribution in the range $[\frac{-1}{\sqrt{fan\_out}}, \frac{1}{\sqrt{fan\_out}}]$, where fan_out was the number of units in the subsequent layer of the model.

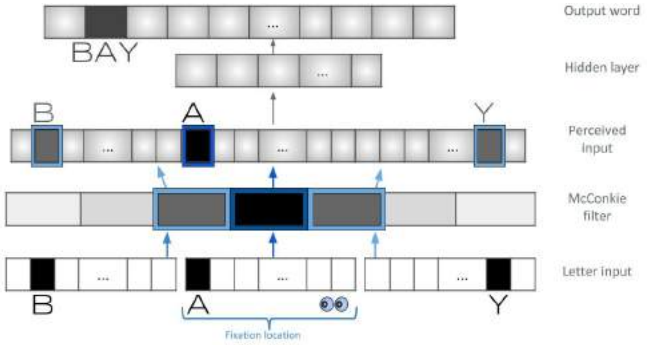

Figure 5: Model architecture. The implemented model perceived 7-letter words; here, we illustrate the model processing a 3-letter word (BAY) for simplicity. Full (1) and no (0) activity are shaded in black and white; intermediate values are shaded in grey.

Determining fixated locations in a word We evaluated several methods for selecting how often a word was perceived from a different fixation location, which we term "fixation location distribution schemes". One model sampled each fixation location equally (hereafter, the *uniform* fixation model). This provided an estimate of the impact of the entropy at different fixation locations that was unconfounded with how often humans typically fixate at each location, and how those distributions varied across the two languages under study. Another model employed the language-specific behaviorally-derived fixation distributions illustrated in Figure 1 (hereafter, the *behavioral* fixation model). A third model averaged these two fixation distribution schemes (hereafter, the *50/50* model). This "blended" model allowed us to interpolate between these two previously described schemes and simulated a case where a model was sensitive to frequency of exposure, but not necessarily to the raw values. The logic here was that a good model might standardize frequency information to ensure low-frequency information is also learned.

Training The model was trained by presenting a 7-letter word at a particular fixation location and computing the cross-entropy error between the output and the target representation. Error was accumulated in batches in which every seven-letter word in the target language was presented 20 times, with the likelihood of fixating at a particular location determined by the fixation distribution sampling scheme. Error was then backpropagated to adjust the weights between the perceived input and the output layer (learning rate = .005; weight decay = .0001) using stochastic gradient descent for the first 10 epochs, and the Adam algorithm thereafter (Kingma & Ba, 2014). The model was trained for 200 epochs (runs through each batch).

All models reached a stable high level of overall word recognition accuracy (near 80%) for approximately the last 50 epochs of training. The vast majority of the incorrect responses originate from words perceived at a suboptimal—and where applicable, less frequent—fixation location. Figure 6 provides representative data for the Hebrew words with extreme entropy values using the *uniform* model. (space constraints prevented the inclusion of plots from the other models, which were broadly similar). The presence of different effects during early training than at the end of training also makes novel predictions for future developmental studies.

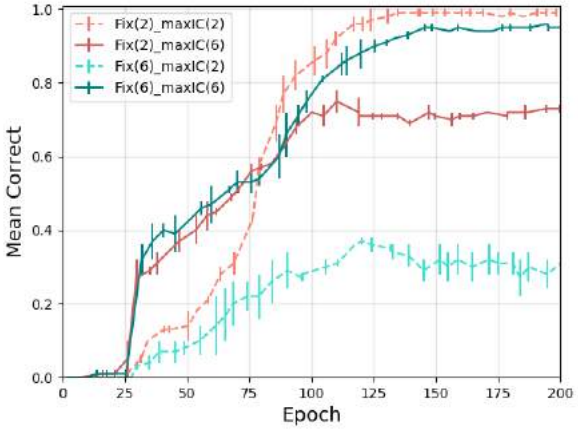

Figure 6: Accuracy for the *uniform* model trained on Hebrew for the words with extreme entropy difference scores. Error bars = SEM.

Testing We froze the weights on the trained models before testing them in a manner analogous to the behavioral experiment. In the test, we presented all the *maxIC*(2) and *maxIC*(6) words at both fixation location 2 and fixation location 6. We also tested several methods of bringing performance in the task below ceiling as in the behavioral experiment, including dimming model inputs (multiplying all input letter activations by a value less than 1), and increasing variance of the noise applied to the perceptual input (cf. Lambon Ralph, Lowe, & Rogers, 2007). These methods yielded similar overall results, so here we report only the results of dimming (dimming parameter = .35). We ran this simulation twice on models initialized with different random weights and report the average results.

Results

The results for the *uniform*, 50/50, and *behavioral* fixation models of English and Hebrew are presented in Figure 7. First, in contrast to the non-dimmed model at the end of training (see Figure 6), our testing procedure clearly succeeded in

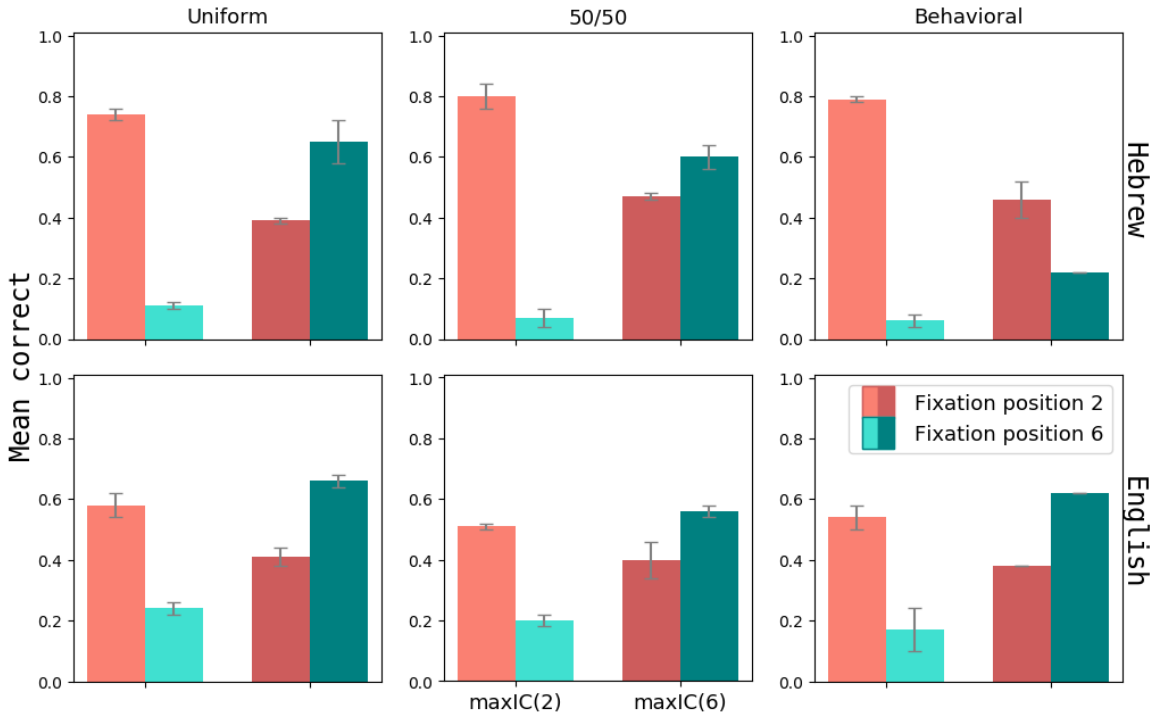

Figure 7: Results of testing the different fixation location distribution models in Hebrew [top] and English [bottom]. Error bars = SEM.

lowering overall accuracy to a level similar to that in the behavioral experiment.

The most critical finding was that, with the exception of the Hebrew *behavioral* fixation model, every one of these models produced a qualitatively similar interaction between fixation location and whether more information content was located at the beginning or end of a word, as in the behavioral results. The Hebrew simulations also show more pronounced effects for the $maxIC(2)$ items overall, as in the behavioral data. The reduced effects in English make for novel predictions for an experiment in that language.

Moving from the $uniform$ model through the $50/50$ model to the *behavioral* model, the effects of the behavioral fixation sampling scheme, which fixates words at position 2 more of then than position 6, is more apparent in Hebrew than in English. This is reflected by the fact that $max(IC2)$ words are perceived more accurately when fixating at position 2 in Hebrew and less accurately when fixating at position 6 when moving toward the behavioral fixation scheme.

The exceptional Hebrew *behavioral* fixation model appears to be an exaggerated extension of the effects of fixation location frequency outlined above. In the case of this model, even the $maxIC(6)$ words were responded to more accurately when fixating earlier in the word. The presence of this pattern only in Hebrew is at least partially explained by the more extreme differences in fixation location sampling distributions in Hebrew than in English. These results also suggest that the human visual recognition system may at least partially normalize the effects of fixation location frequency, given that the $50/50$ and $uniform$ fixation models produced qualitative results more similar to those in the behavioral experiment.

Discussion

The results of the second set of simulations largely paralleled those of the behavioral experiment, with both exhibiting an interaction between fixation location and the location with most information content. The simulations also showed the influence of the behavioral fixation location distributions in enhancing the perception of words at the most frequent fixation location, and suggest that the word recognition system normalizes the fixation location distribution to some degree. Further, although the qualitative findings were similar across languages, suggesting that a general principle is at play, at a quantitative level there were some differences between the two target languages. These differences align with the relatively higher information content at the beginning of Hebrew words and the greater likelihood of fixating at the beginning of words. Collectively, this work therefore indicates that the word recognition system is sensitive to the information content in different locations in a word, as constrained by the perceptual system.

These results are only in partial agreement with past work (Brysbaert & Nazir, 2005). In that work, participants were presented with partial word information for 5-letter words and asked to "guess" the word. The distribution of "guesses" relative to the correct response was then taken as their measure of uncertainty. Their results showed similar effects as in our study at word onset, but no effects at word offset. These

findings were interpreted as suggesting that the effects of information content were only present at the preferred fixation location. A combination of factors likely explain the discrepancy between their claims and ours, including a more adequate formal quantification of information content and the use of longer words that may be more sensitive to perceptually-constrained information content effects.

The success of this work at the individual word level also points to important directions for future work. One major question raised by this work is how these principles could generalize to the multi-word level. Can a preceding word provide top-down context and reduce the uncertainty (i.e. the average information content) on the set of upcoming words so as to not only facilitate processing, but also alter the location of an upcoming fixation? If so, this result could help explain the relatively broad fixation distributions obtained in different languages, because the optimal location to fixate in a word may deviate from the average location from the language as a function of context. The somewhat broad overall fixation location distributions may therefore in actuality reflect the averages of narrower fixation location distributions that are conditioned by the preceding word.

Our work shows that the observed behavioral effects in word recognition can be explained based on low-level information structures in the visual signal, without the need to resort to higher-level morphological structures. Higher-level structures can enter the visual-orthographic system in two ways: first, in shaping the word forms of a language, and second, as representations that mediate word recognition. The former is subsumed in our information-theoretic approach, which encompasses all the constraints that provided word forms with their actual shape, providing us with a quantitative comparative framework for a crosslinguistic perspective. The latter cannot be completely ruled out: although our model does not require morphological representations to succeed, the contribution of these representations should be assessed with more targeted experiments that aim to tease apart the visual/orthographic from morphological (e.g. looking at performance for regular and irregular morphemes such as *brothel/broth, corner/corn, farmer/farm*, Rastle, Davis, & New, 2004).

To sum up, this work offers a language-general and parsimonious account of how a specific type of statistical information drives performance in the perceptually-constrained word recognition system, complementing accounts based on the operation of the occulomotor system, as well as complementing or or subsuming accounts based on higher-level information. In so doing, this work reinforces the importance of studying how the structure of language itself interacts with the perceptual constraints of the visual/orthographic system (Lerner, Armstrong, & Frost, 2014) in shaping reading behaviors, and opens new avenues for combining isolated word and naturalistic reading research.

Abstract

We introduce a new problem solving paradigm: solving physical puzzles by placing tool-like objects in a scene. The puzzles are designed to explicitly evoke different physical concepts such as support, blocking, tipping, and launching, and are typically solved in a handful of trials. We study human participants' problem solving strategies, including what they try first, how they update their actions based on failed attempts, and how many attempts they eventually take to solve the puzzles. We introduce the 'Sample, Simulate, Remember' model that incorporates object-based priors to generate hypotheses, mental simulation to test hypotheses, and a memory and generalization system to update across simulations and real-world trials, and show that all three components are needed to explain human performance. Abstract

The division of labor phenomenon has been observed with respect to both manual and cognitive labor, but there is no clear understanding of the intra- and inter-individual mechanisms that allow for its emergence, especially when there are multiple divisions possible and communication is limited. Situations fitting this description include individuals in a group splitting a geographical region for resource harvesting without explicit negotiation, or a couple tacitly negotiating the hour of the day for each to shower so that there is sufficient hot water. We studied this phenomenon by means of an iterative two-person game where multiple divisions are possible, but no explicit communication is allowed. Our results suggest that there are a limited number of biases toward divisions of labor, which serve as attractors in the dynamics of dyadic coordination. However, unlike Schelling's focal points, these biases do not attract players' attention at the onset of the interaction, but are only revealed and consolidated by the in-game dynamics of dyadic interaction.

Keywords: Group cognition; Divergent behavioral norms; Focal points; Cooperation.

Introduction

An individual can often benefit from participating in a group when (s)he can perform just one component of the group's task while other individuals take care of other parts. When the other individuals also benefit from this arrangement, we speak of an efficient division of labor. For example, two roommates can choose between (a) preparing their lunch for themselves every day, and (b) dividing the days of the week on which one prepares lunch for two. In the latter case, both roommates benefit from not having to cook every day.

The benefits of division of labor have been studied not only with respect to manual labor (Smith, 2008), but also with respect to cognitive labor (Sloman & Fernbach, 2017; Kennedy, Eberhart, & Shi, 2001). For instance, one study showed that the puzzle of assigning categories to the nodes of a network such that no adjacent nodes have the same category could be efficiently solved as a self-organized, collective task if each individual is assigned to a single node and is only concerned about the acceptability of their local sub-network (Kearns, Suri, & Montfort, 2006).

In some collective groups, such as ant colonies or beehives, the division of labor occurs as a genetically designed organization (Weitekamp, Libbrecht, & Keller, 2017; Robinson, 1992). However, it can also emerge as a self-organized process, without leaders or explicit negotiations (Heylighen, 2013). For example, when a group of individuals has to collectively guess a target number, where the collective guess is the sum of their individual guesses, and the only feedback they receive is for how much their collective guess is greater or lesser than the target, individuals spontaneously differentiate their behaviors to either react or not react to the feedback, and the extent to which role differentiation occurs is predictive of group performance (Roberts & Goldstone, 2011).

What are the cognitive mechanisms that facilitate the self-organized division of labor? One possibility is that it arises from the principle of maximization of expected utility. In our previous example of the two roommates, successful division of the days of the week might be said to arise because it constitutes a Nash equilibrium, that is, a combination of choices in which no roommate can obtain a higher payoff by changing only their choice—fixing the other roommate's choice (Ross, 2018). However, as it turns out, maximization of expected utility is not sufficient to explain why roommates act in accord with a particular Nash equilibrium instead of another (Arthur, 1994; Colman, 2003). Some scholars have suggested that games with multiple Nash equilibria are not solved on the basis of maximization of expected utility, but rather by means of rough-and-ready rules of thumb based on limited knowledge and time. This approach is known as 'bounded rationality' to emphasize that people frequently have memory, attentional, and calculation limitations that prevent them from employing perfectly rational strategies (Holbrook, 2002; Simon, 1957). It could be claimed, returning to our roommates example, that the division of labor according to which Roommate A prepares lunch only on weekdays and Roommate B only prepares lunch on the weekend is achieved because they cannot think of a different division, or because this division is the most natural for both of them, even though there are many other possible divisions. This is an example of the focal point approach, according to which the set of all possible Nash equilibria is reduced to just a single point that is psychologically salient for all players (Mehta, Starmer, & Sugden, 1994; Schelling, 1960). Another possible proposal is that individuals possess a small set of simple strategies that they can apply in their search for a division. For example, they may stick to one strategy for as long as it provides acceptable results, and when it fails, they would swap it for another in their strategy set (a win-stay, lose-shift heuristic). There are cooperative scenarios, such as the famous El Farol problem

(Arthur, 1994), in which this heuristic works well. Another strategy could be to adapt one's own reactivity to the task based on how much the whole group is contributing. Indeed, as pointed out by Roberts and Goldstone (2011), there may be situations in which an individual helps the collective effort by refraining from acting or reducing their activity, allowing the other players to dominate the task.

We studied this phenomenon by means of an iterative two-person game where multiple divisions are possible, but no explicit communication is allowed. Our results suggest that there are a limited number of biases toward divisions of labor and that they work as attractors in the negotiation dynamics. Unlike Schelling's focal points, these biases do not attract players' attention at the onset of the interaction, but are only revealed and consolidated by the in-game dynamics of the dyadic interaction. In other words, these biases do not determine players' *a priori* actions, via some sort of iterative reasoning, for dividing up their task. Rather, the attractors only become salient as a result of the interaction.

Materials and methods

Participants and procedure

Participants were 90 undergraduate students at Indiana University in Bloomington who received course credits for approximately 1 hour of participation. Participants were run in 10 experimental sessions, each one requiring an even number of participants to be grouped into dyads. If an odd number of participants turned up to the session, one of them was randomly chosen and sent home. The number of dyads in each session were as follows: 4, 5, 3, 6, 4, 2, 6, 3, 8, and 4. Participants sat in a university computer lab, each at a sound- and sight-isolated personal computer running a version of the game implemented in the nodeGame platform (Balietti, 2017). The computer randomly paired participants into dyads and each dyad participated in 60 rounds of the game. Participants were instructed not to talk to each other and were not informed about who was paired with whom.

The task

The task is a two-player game, which we dub "Seeking the unicorn," in which players interact with 64 tiles arranged in an 8×8 grid (see the top panel in Figure 1). The grid can either hide a unicorn beneath one of the tiles or else the unicorn can be absent from the grid, either event can occur with equal probability. At the beginning of each round, the computer chooses with equal probability whether or not there is a unicorn, and if there is one, it randomly chooses a tile in which to hide it, each tile having an equal probability of being chosen. Then, players seek for the unicorn by uncovering tiles one at a time, with both players uncovering tiles simultaneously, in order to see what lies beneath them. What tiles have been uncovered and whether there is or not a unicorn is only known to the player that uncovers these tiles. Tiles uncovered by both players instantly change their color and both players can see this. At any time during the round, each player can guess whether the unicorn is present or absent. The other player will know this player's decision and can use it to inform their own guess. The round ends when both players announce that their guess is a final decision, and then they are shown their scores (see the bottom panel in Figure 1). The score depends on whether the player's guess is correct (32 points) or incorrect (-64 points), subtracting the number of tiles that were uncovered by both players.

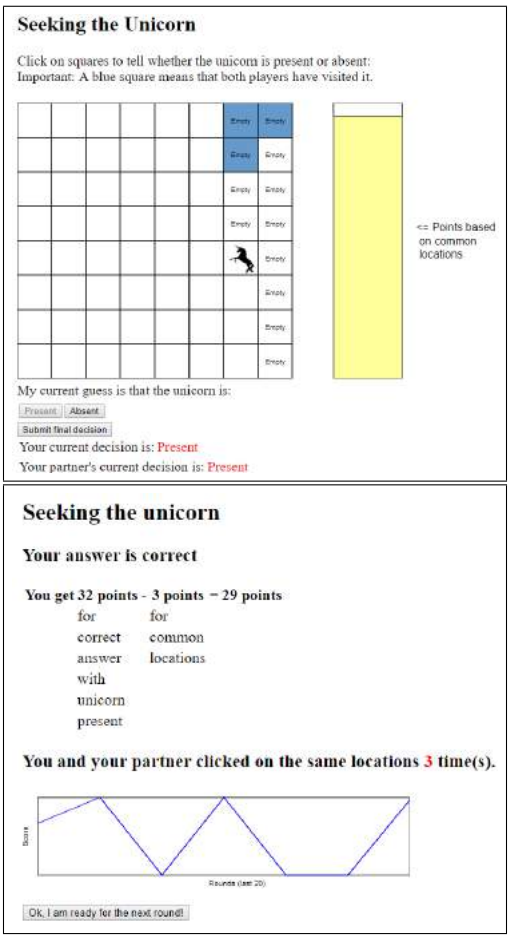

Figure 1: The experimental task. The top panel shows the grid as displayed to each player. By uncovering a tile, they know whether it is empty or contains the unicorn. Such information is private for the player. Tiles uncovered by both players have a blue background and both can see this coloration. They also have access to each other's guesses. The yellow column on the right decreases as the number of overlapping tiles increases. The round ends when both players submit their final decision. In the bottom panel we show the screen displaying the score and the score history over the last 20 rounds.

Measures

The following measure, which we call the Division of Labor Index (DLINDEX), determines the extent to which

players split the grid into complementary regions:

$$\text{DLINDEX} = \frac{\text{Tiles uncovered by one or both of the players} - \text{Overlapping tiles}}{\text{Tiles in the grid}}$$

This measure instantiates the intuition that it is beneficial if a dyad collectively uncovers all of the tiles (first term) and does not overlap in any tiles uncovered (second term). Observe that it ranges from 0 to 1 with 1 being ideal division of labor and 0 being least efficient. There is only one way of being ideal, namely, when both players uncover the entire grid and do not overlap at all. Additionally, we measure how consistently a player uncovers tiles from one round to the next:

$$\text{Consistency}_n = \frac{\text{Overlapping uncovered tiles from Round } n-1 \text{ to Round } n}{\text{Tiles uncovered in either of the two rounds}}$$

This number ranges from 0 to 1 with 1 meaning that the player uncovers the same tiles on both rounds, and 0 meaning that the player uncovers a completely different set of tiles from one round to the next. We also define the distance and the similarity between two regions a and b in the grid in the following way:

$$\text{dist}(a,b) = \sqrt{\sum_{t \in \text{Tiles}} (a_t - b_t)^2}, \quad \text{sim}(a,b,\varepsilon) = e^{-\varepsilon * \text{dist}(a,b)}$$

Here, t represents the t-th tile in the 8×8 grid (represented as the list $[1,\ldots,64]$), and a_t and b_t can be either 1 or 0, representing whether or not tile t belongs to a and b, respectively. The parameter ε in the definition of sim determines the extent to which the distance between two regions determines the similarity between them and, unless explicitly stated otherwise, we assume that ε=1.

Results

We should note at the outset that we have not used the entire dataset in our analysis. The reason is that rounds on which the unicorn is present provide us only with partial information as to how players split the grid, because on those rounds players do not have to uncover every tile. Once they find the unicorn, they will say that the unicorn is present and finish the round. Therefore, unless explicitly stated otherwise, we are only reporting results for trials on which the unicorn is absent.

For each dyad we created a figure displaying two grids, one for each player. In this figure we magnitude-coded each tile according to the number of times the player selected it through 60 rounds of the experiment in such a way that the darker the tile, the more times it was selected. Figure 2 shows the types of regions that were obtained. There were only four stable, successful pairs of complementary regions in the grid: the Left-Right, Top-Bottom, All-Nothing, and Inside-Outside splits. We call them the focal splits. Only dyads in the focal splits obtained an above-average DLINDEX, except for one dyad with no discernible stable region that nevertheless has

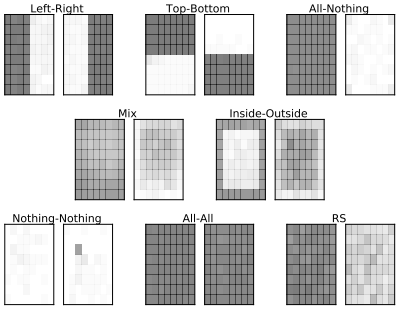

Figure 2: The seven types of splits of the grid that could be observed from our data. Each panel shows two grids, one for each player, with the regions uncovered through 60 rounds. The darker the tile, the more rounds the player uncovered it.

an average DLINDEX of 0.82 (this is over 0.45 standard deviations above the average of the 45 dyads; this dyad determined the Mix type of split in Figure 2). We conclude that 26 out of 45 dyads successfully split the grid. This represents over 57% success in self-organizing division of labor.

If our paradigm were a one-shot task in which players had to converge on a split of the grid on only one round, our data show that the average DLINDEX would be close to 0.43 (s.d.$\approx$ 0.32). By comparison, in our iterated task, the average DLINDEX rose up to almost 0.68 after 60 rounds (s.d.$\approx$ 0.32). The difference between these averages is statistically significant ($p< 0.001$). This shows that an efficient division of labor does not emerge on the first round, and that the iterated nature of our task facilitates its emergence.

But how did the division of labor emerge? We observed that, in general, dyads moved from lower to higher levels of DLINDEX, and that players in a low-level dyad tended to more frequently change their tile selection strategy from one round to the next with respect to players in a high-level dyad. Moreover, we found a positive correlation between a player's consistency on Round n and their score on Round $n-1$ ($\beta \approx 0.51$; $p < 0.001$). This supports the hypothesis that players used, at least to some extent, a win-stay, lose-shift heuristic (WSLS). That is to say, if their score is relatively high, which often occurs when the dyad splits the grid into complementary regions, each player tends to re-select their previously selected tiles; but if their score is low, they will be more likely to shift to different tiles.

However, WSLS does not seem to account for all the characteristics of the dyadic interaction. When we predict DLINDEX as a function of consistency, we see that, perhaps not surprisingly, dyads consisting of individuals who are relatively consistent in their tile selection strategies tend to divide labor better ($\beta \approx 0.36$; $p < 0.001$). However, we also observe an interaction such that dyads with players that differ in their consistencies tend to divide labor better than predicted when players have a large amount of overlap in their selected tiles. That is, if both players overlap considerably, it is best if one player is consistent and the other player is not. The evidence

for this claim comes from comparing the linear regression model above with a model that includes the interaction between, on the one hand, the absolute difference in consistency between players on a given round and, on the other hand, the number of overlapping tiles on the previous round:

$$\text{DLINDEX}(n) \sim \alpha + \beta_1 * \text{Consistency}(n) + \beta_2 * \text{difConsist}(n) + \beta_3 * \text{Overlap}(n-1) + \beta_4 * \text{difConsist}(n) * \text{Overlap}(n-1)$$

Our data show that this interaction is positive ($\beta_4 \approx 0.01$; $p < 0.001$). Moreover, an analysis of variance test ($p < 0.001$) confirms that this interaction effect accounts for significantly more variance in performance relative to the main effects. These results indicate that dyads eventually tend to most effectively divide labor despite initially overlapping in their tiles when one player is consistent/stubborn and the other player is inconsistent/flexible, giving rise to complementary degrees of reactivity to occasions of overlap (Roberts & Goldstone, 2011). But why did one of the players become more stubborn? We found that if a player tends to select tiles consistent with a focal region (that is, one half of a focal split), they tend to be more consistent. In other words, the closer a player's tile selection strategy is to a focal region, the more stubborn they become, presumably because they believe that they are forming one half of a viable division of labor. The regression model of consistency with respect to distance to closest focal region confirms this effect ($\beta \approx -0.12$; $p < 0.001$). The interesting question now is how the other player figured out that they have to select tiles in the appropriate complementary region, given that a player only had access to their own uncovered tiles and not the other player's uncovered tiles. The key seems to lie in the fact that players do have access to overlapping tiles, from which the other player's selected tiles can be inferred with reasonably high validity.

One mechanism that can account for many players' shifts in selected tiles is based on a measure of the similarity between a focal region and the overlapping tiles. If one player's selected tiles are sufficiently close to a focal region, then this can be used as a signal for the other player to select the corresponding, complementary region. In Figure 3 we take a closer look at an actual game play from a dyad in which this mechanism is prominent, as exhibited by Player B's transition. On Round 23 the overlapping tiles are similar to the focal region RIGHT, which inclines B to select every single tile in the complementary LEFT region. Observe that B not only re-selected the left region's tiles from the previous round, but uncovered the whole LEFT region. More generally, the player's attention is attracted toward a focal region k when the region that is complementary to k is sufficiently similar to the overlapping tiles. To be sure, even though the process seems to be gradual and there are other factors at play, these complementary focal regions have attraction power. Last but not least, observe that the overlapping tiles are the same for both players, so Player A's attention is also attracted by LEFT. Nevertheless, given that A has uncovered the focal region RIGHT, they tend to become "stubborn" in the sense of resisting substantial change to their uncovered tiles. The combination of this retention and the attraction powers of a focal region informs a decision process that we call the Focal Regions as Attractors heuristic (FRA).

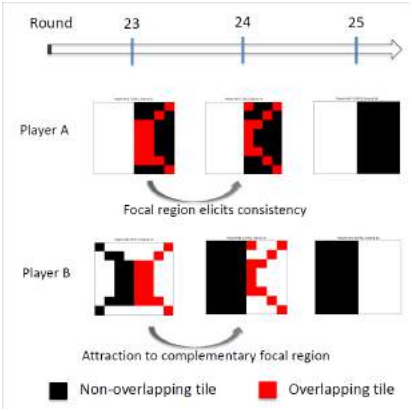

Figure 3: Evidence in favor of Focal Regions as Attractors (FRA). We see the transition from one round to the next, taken from an actual game play. In each grid, black tiles represent uncovered tiles and red tiles were uncovered by both players. Player A's transition illustrates 'stubbornness' and Player B's illustrates the attraction exerted by the complement of A's focal region, which is also a focal region. See details in the text.

Computational models

We put our previous explanations to the test by providing a computational model for each one of these two heuristics. The first model is an implementation of WSLS. To motivate it, suppose that on round n the player uncovered tiles determining BOTTOM. We want to determine the probability of choosing each region k in $\mathcal{K}$ on round $n+1$, where k in $\mathcal{K}$={RS, ALL, NOTHING, BOTTOM, TOP, LEFT, RIGHT, INSIDE, OUTSIDE}. $\mathcal{K}$ contains the focal regions, plus the type of region we call RS, which represents all remaining regions in the grid. Now, if the player is in a win situation, we should increase the probability of choosing again BOTTOM. This effect can be obtained by means of a threshold function (see Figure 4). More formally, the model defines a probability function, determined by the following formula:

$$P(k) = \frac{\text{attract}(k)}{\sum_{r \in \mathcal{K}} \text{attract}(r)} \quad (1)$$

The attract(k) function represents the extent to which a player is inclined to choose region k, given the current state of the game. For the WSLS model, we assume that this state is represented by the vector (i,s), where i is the region explored on the previous round and s the obtained score. The attract function for the WSLS model is defined in the following way:

$$\text{attract}(k,i,s) = \text{bias}_k + \alpha * \text{thresh}(s_n, \beta, \gamma) * \text{I}(k,i) \quad (2)$$

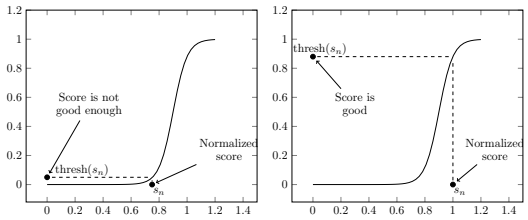

Figure 4: The thresh(s_n) function representing how good the score was. The left panel illustrates a situation where the score is not good enough, which is captured by the low value of thresh(s_n). The right panel illustrates a good situation, captured by the high value of thresh(s_n).

Here, the term bias$_k$ represents how inclined the player feels toward k, all other things being equal, and is expected to be higher for more pre-experimentally salient regions. The second term contains the functions thresh and I, which are defined in the following way:

$$\text{thresh}(s_n,\beta,\gamma)=\frac{1}{1+e^{-\beta(s_n-\gamma)}},\quad \text{I}(k,i)=\begin{cases}1, & \text{if } i=k\neq \text{RS}\\ 0, & \text{otherwise}\end{cases}$$

Here, s_n is the normalized score, which takes values between 0 and 1. The function thresh(s_n,β,γ) has an S shape and takes values in the open interval $(0,1)$. It goes from values near 0 to values near 1 when s_n is near γ, and the steepness of this transition is determined by β (see Figure 4). The second term in Equation 2 contains the parameter α, which determines the extent to which the score increases the player's tendency to choose k, when the normalized score is greater than γ. The effect of I(k,i) in this expression is that the only region that has its bias modified is region i (i.e., the region explored on the previous round) and only if this region is a focal region. The value of attract(k) for the remaining regions is equal to bias$_k$.

The model defined by FRA extends the previous model. To motivate it, suppose that on round n the player uncovered tiles in the i region as defined in Figure 5. Now, we should consider the overlapping region, j, and consider its similarity to each focal regions (see right panel of Figure 5). The more similar to k, the more attractive *the complement* of k becomes. In our example, the overlapping region is more similar to UP, so the probability of choosing BOTTOM on round $n+1$ is increased. More formally, we assume that the current state of the game is represented by the vector (i,s,j), where i is the region explored on the previous round and s the obtained score, and j the area formed by the overlapping tiles. The attractiveness of k is defined in the following way:

$$\begin{aligned}\text{attract}(k,i,j,s)=&\ \text{bias}_k+\alpha*\text{thresh}(s_n,\beta,\gamma)*\text{I}(k,i)\\&+\delta*\text{sim}(j,\bar{k},\varepsilon)*\text{Focal}(k)+\zeta*\text{I}(k,i)\end{aligned}\qquad(3)$$

Observe that the first two terms in Equation 3 are the same as in Equation 2. The third and fourth terms are new. In the third term, the function sim$(j,\bar{k},\varepsilon)$ determines the similarity

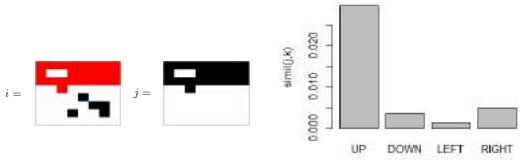

Figure 5: An example of a region visited, i, the overlapping tiles, j, and the similarity between j and other regions.

Model	θ_1	θ_2	θ_3	θ_4	α	β
WSLS	0.14	0.0674	0.0123	0.0009	39	405
FRA	0.077	0.048	≈ 0	≈ 0	48	402

Model	γ	δ	ε	ζ	Dev.	AIC
WSLS	0.933	0	0	0	3060	3074
FRA	0.99	1.57	0.94	3	2709	2709

Table 1: Best parameters and deviance for each model. The first four parameters correspond to the biases in the model: θ_1=bias$_{\text{ALL}}$, θ_2=bias$_{\text{NOTHING}}$, θ_3=bias$_{\text{BOTTOM}}$=bias$_{\text{TOP}}$=bias$_{\text{LEFT}}$=bias$_{\text{RIGHT}}$, and θ_4=bias$_{\text{IN}}$=bias$_{\text{OUT}}$. Moreover, bias$_{\text{RS}}$ is defined as 1 minus the sum of the other biases, and we require that the sum of all biases adds to 1.

between j and the complement of k, denoted as $\bar{k}$. The function Focal(k) is defined in the following way:

$$\text{Focal}(k)=\begin{cases}1, & \text{if } k\notin\{\text{RS, ALL}\}\\ 0, & \text{otherwise}\end{cases}$$

The parameter δ in Equation 3 determines the extent to which the similarity between j and $\bar{k}$ modifies attract(k), but this only occurs when k is a focal region and is different from ALL. This effect is obtained by multiplying δ by Focal(k). Finally, the parameter ζ determines the extent of the player's stubbornness when i is a focal region.

Note that the extra parameters from FRA with respect to WSLS are δ, ε, and ζ, and that Equation 2 for WSLS can be obtained from Equation 3 when $\delta=\zeta=0$. That is, WSLS is a nested model within FRA.

Using maximization of log likelihood of the multinomial distribution of the observed transition frequencies and the respective predicted probabilities given by the model, we found the optimal parameters and the *deviance* of the two models, summarized in Table 1. Both the Likelihood Ratio Test ($\chi^2=351$; 3 d.o.f.; p<0.001) and the ΔAIC=365 provide quantitative evidence that the additional parameters contributed by FRA provide a better account of the underlying choice process and that this model's better fit to the data is not due to overfitting.

We simulated our game in the same conditions as the experimental task. For each model, we ran 100 simulations of 60 rounds of the game, obtaining two collections of simulated data. In the two top panels of Figure 6 we can observe

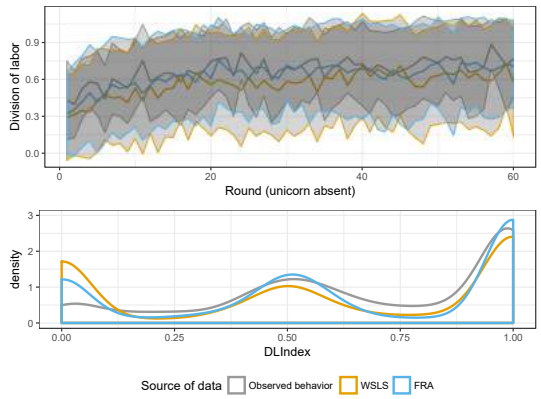

Figure 6: Comparison between observed and simulated behavior. The top panel shows the behavior of DLINDEX through all rounds. The vertical axis represents, for each round, the average DLINDEX. Shadow regions represent an error margin of one standard deviation. The bottom panel shows the kernel density estimate of DLINDEX for observed and simulated data, where each observation is the DLINDEX of a dyad at the end of a round.

the behavior of DLINDEX through all rounds. The vertical axis represents, for each round, the average DLINDEX with respect to all dyads in the respective set (45 for humans; 100 for each model). In the three cases we observe that the indexes are within the error margins of the others, and that the three sets of data show the same positive trend through rounds. However, in the case of WSLS, the t-test of mean difference ($p \approx 0.01$) does not provide conclusive evidence to assert that the means are the same, whereas the t-test of mean difference of DLINDEX ($p \approx 0.3$) determines that there is no statistical evidence to claim that the means are different, which means that FRA is better at capturing the tendency of DLINDEX in human subjects.

In the bottom panel of Fig. 6 we can see the kernel density estimate of DLINDEX for observed and simulated data. When the density curve is high (y-axis) for a given value of DLINDEX (x-axis), it means that there were many rounds for which a dyad obtained a DLINDEX close to x. Observe that, for humans, high values of DLINDEX are more frequent than medium and low values—representing the fact that many dyads split the grid satisfactorily. However, in WSLS there is a considerable tail on the left, indicating many more trials on which dyads did not split the grid into complementary regions, as compared to humans. Moreover, in WSLS the frequency of low values is higher than that of medium values, which is not in accordance with the observed data. For FRA, the frequency of low values is not greater than that of medium values, which is closer to what is observed in human data. To sum up, it seems that WSLS predicts a less efficient division of labor than exhibited by people, whereas FRA and people show a comparable degree of division of labor.

Discussion

57% of human dyads finished 60 rounds of game play with an efficient division of labor. The results from our experiment and our computational models allow us to explain how most dyads managed to split the grid without being able to engage in explicit negotiations. First of all, even though there are 2^{64} ways to split the grid, dyads split it in only four different ways. In some sense, these splits are focal points because they have a certain psychological salience (Schelling, 1960). One might have thought that these individual cognitive biases (focal points) would exert an early (in terms of rounds) influence on choices exactly because they are *a priori*, so that agents would have started on Round 1 with strategies of selecting all tiles on the left, top, bottom, or right. If agents understand that these are natural attractors, then through engaging in many levels of iterated thinking based on common knowledge (Lewis, 1969), these would be logical starting points. However, players do not generally start with strategies that resemble focal points. Humans are far more idiosyncratic and exploratory in their initial selections of tiles. It is only through repeated interactions that players manifest their *a priori* predispositions/biases toward certain focal points. In other words, a *priori biases* do not entail that the biases are manifest at the onset of play. It is only through dyadic interaction that these biases are revealed (Kaush ML, Griffiths TL, & Lewandowsky S, 2007). Returning to our two roommates example, there are 128 different ways to divide the days of the week in order to alternate one roommate cooking for two. We suppose that not every possible division is equally salient for them, and that only a handful of divisions will actually attract and retain their attention, such as the division between weekdays or weekend, or a division based on the idea of cooking every other day. If the roommates cannot explicitly negotiate a division but are given the daily chore of preparing lunch(es), one roommate will eventually follow one of these psychologically salient divisions and will tend to persist in the strategy because it is a focal point. To the extent that the other roommate wants to avoid overlapping days, soon they will be attracted to the psychologically salient strategy of choosing complementary days of the week. Interacting individuals, both human and algorithmic, can often arrive at efficient coordinating solutions in a paradigm that incorporates two challenging conditions – individuals cannot explicitly communicate, and there are multiple coordinating solutions that are initially equally salient. The human and computational results indicate that agents solve this coordination task by beginning with a set of possibly incompatible focal points. Then, via iterated interactions they adjust their behaviors to move toward focal points when they are not at a focal point, stay in a focal point once reached, and shift to a complementary focal point relative to the other player. In this way, the coordination that a group forms results from the interplay over time between their *a priori* cognitive biases and the dynamics of their interpersonal interaction (Hawkins, Goodman, & Goldstone, in press).

A friend or a toy? Four-year-olds strategically demonstrate their competence to a puppet but only when others treat it as an agent

Abstract

Others' beliefs about the self can powerfully influence our everyday interactions with others. Recent work suggests that even preschool-aged children are sensitive to what others think of the self and actively attempt to manage these beliefs (Asaba & Gweon, 2018). What cognitive capacities underlie these early self-presentational behaviors, and in what contexts do these behaviors emerge? Here we show that preschoolers strategically demonstrate their competence to even a *puppet*, but only when an adult treats the puppet as an agent and specifically asks which toy the child wants to "show" to the puppet (Exp.1). However, they do not show such strategic demonstration of their competence when the same puppet is treated as an object (Exp.2). These results suggest that self-presentational behaviors can emerge even in the absence of any immediate prospect of social evaluation insofar as children consider the target entity as capable of holding beliefs. Furthermore, whether or not children ascribe a belief about the self to the target is heavily modulated by how an entity is treated by others. We discuss the relevance of these findings to early reputation management behaviors, and more broadly, the use of make-believe agents in developmental research.

Keywords: cognitive development; social cognition; Theory of Mind; reputation management; agency

Introduction

What others think of us – our competence, kindness, fairness – is central in our minds. Others' beliefs about the self have the power to influence our social interactions, well-being, and even long-term life outcomes. Fortunately, we have some control over how others think of us: We can change our behaviors in the presence of others (e.g., act more generously; Novak & Sigmund, 2005) or actively disclose information about the self (Hicks, Liu, & Heyman, 2015). Knowing how to manage others' beliefs about us, or our reputation more broadly, can help us better navigate the complex social world and build healthy relationships with others. Despite the ubiquity of self-presentational behaviors, however, the ontogenetic origins of the ability to represent and modulate others' beliefs about the self remain poorly understood. What cognitive capacities underlie self-presentational behaviors, and in what contexts do these behaviors manifest?

Recent developmental work has provided some initial insights into young children's sensitivity to others' evaluations of them. Young children attempt to promote a positive reputation by sharing more and cheating less in the presence of others (e.g., Engelmann, Hermann, & Tomasello, 2012; Leimgruber, Shaw, Santos, & Olson, 2012) and try to maintain a positive reputation of being "smart" or "nice" (e.g., Fu, Heyman, Qian, Guo, & Lee, 2014). Their behaviors are further modulated by the potential social consequences; they share more when the observer could reciprocate their good deeds in the future than in one-time interactions (Engelmann, Over, Hermann, & Tomasello, 2013). These findings suggest that children care about others' evaluations and engage in behaviors to manage their reputations.

The ability to represent and reason about others' beliefs – Theory of Mind (ToM) – may be particularly important for effective self-presentational behaviors (Asaba & Gweon, 2018; Engelmann & Rapp, 2018; Silver & Shaw, 2018). By using an intuitive theory of others' minds, children can not only infer what others think of them, but also figure out what evidence could improve or maintain these beliefs. Surprisingly, however, there is little empirical support for ToM as a potential mechanism underlying self-presentational behaviors. Prior work in early reputation management behaviors has primarily manipulated whether or not children were being observed by another person. Thus, the role of ToM in self-presentational behaviors remains unclear; some self-presentational behaviors may only require the mere presence of others while more complex interactions may involve sophisticated inferences about the observer's beliefs.

A recent study provides suggestive evidence that preschoolers' self-presentational communicative behaviors depend on the content of others' beliefs about the self, rather than the mere experience of being observed by others (Asaba & Gweon (2018). Findings from this study suggested that 3- and 4-year-old children strategically presented their own competence depending on the observer's prior observations of their failures and successes, even when doing so meant foregoing an opportunity to teach new information to the observer. When the observer had seen the child's failures as well as their final success on a toy (i.e., believing the child can make the toy go), given a chance to demonstrate either the same toy or a toy she had never seen, children strongly preferred to demonstrate the novel toy. However, when the observer left before the child's final success (i.e., believing the child cannot make the toy go), children were more likely

[*] These authors contributed equally to this work.

to demonstrate their success on the same toy rather than the novel toy. Such selective demonstration of one's competence might require the ability to understand how others' observations of the self can generate certain beliefs in others' minds (i.e., "She thinks I cannot operate the toy") and the capacity to infer how additional evidence can change these beliefs (i.e., "demonstrating my success on this toy will make her think I can operate the toy").

These results suggest that children are sensitive to more than the mere presence of others; rather, their self-presentational actions can be *modulated* by representations of others' beliefs about the self. Following prior work on the early development of reputation management, Asaba & Gweon (2018) used a human confederate as the agent who observed children's failures and successes. However, if the process of ascribing beliefs to an observer can elicit reputation management behaviors, the target of such actions should not be limited to other human beings; these behaviors may also manifest in children's interactions with non-human entities, even if there are no real-world consequences to protecting or promoting one's reputation in front of them. If so, even the presence of *a puppet* in the room as children repeatedly fail to activate a toy would lead children to demonstrate their success (i.e., to "change the puppet's belief"), but only in contexts in which children would readily attribute beliefs to the puppet. In other words, the results from Asaba & Gweon (2018) should replicate even when the human confederate is replaced with a hand puppet, specifically when children consider the puppet as a social entity capable of holding a belief.

Decades of work on ToM provide reasonable support for this hypothesis. A large meta-analysis (Wellman, Cross, & Watson, 2001) has shown that children's responses in classic false-belief tasks do not systematically vary depending on the nature of the protagonist (i.e., a drawing, a hand puppet, or a real person); children are willing to attribute perceptual, epistemic, and emotional states to non-human, make-believe entities insofar as they are described and treated as sentient agents that think, feel, and act like humans. These classic ToM tasks usually require children to predict someone's action (e.g., Sally will go to where she thinks the ball is), but would children be motivated enough to share information about their own competence over novel information about a toy in such settings? Such results might attest to the power of mental-state reasoning that encourage children to engage in rich social interactions even with make-believe entities.

What factors may influence children's willingness to ascribe agency to various non-human entities? Prior theoretical work has proposed that children may evaluate an entity's *cognitive property* (Leslie, 1994) – that agents hold certain attitudes (e.g., desires, beliefs) to the truth of propositions. Interestingly, empirical work on children's understanding of agency suggests that children's agency attribution not only relies on the observable features of an entity (e.g., whether or not it has eyes; Johnson, Slaughter, & Carey, 1998) but also can be informed by how others communicate about it (e.g., how often parents talk about psychological property of nonliving kinds; Jipson, Labotka, Callanan, & Gelman, 2018). Critically, adults often *depict* make-believe or imaginary scenes, objects, or agents to children as if they were real, and children readily understand such communicative intent and "play along" with them (Clark, 2016). Thus, children may ascribe agency to a puppet to the extent that other adults treat or depict it as an agent, especially one holding certain beliefs.

The main objective of the current work is to bridge prior work in Theory of Mind and reputation management by clarifying the role of belief-attribution in young children's self-presentational behaviors. To this end, our primary goal was to replicate the findings of Asaba & Gweon (2018) using a puppet that was introduced as the experimenter's "friend" and treated as such (Experiment 1). We predicted that children would go as far as demonstrating their competence to a puppet to change its "belief" about their competence when the adult experimenter treats the puppet as if it were an agent with mental capacities (i.e., with the *cognitive property*). We then provide additional evidence that such behavior is selective to contexts where children have reasons to consider the puppet as a social being capable of holding beliefs (Experiment 2).

Experiment 1: Puppet as Agent

In Experiment 1, we replicated Asaba & Gweon (2018) with 4-year-olds using the same design except that children were "observed" by a puppet rather than a human confederate. Importantly, the experimenter treated this puppet as an agent, calling the puppet her "friend" and referring to the puppet's mental states (i.e., ignorance) about the toys, similarly to how the confederate was treated in Asaba & Gweon (2018).

Methods

Participants 50 4-year-olds (M_{Age}(SD)= 4.49(.29), range = 4.01–4.99; 30 females) were recruited from a university preschool and randomly assigned to the Present (N=25) or Absent (N=25) condition. An additional 14 children were recruited but excluded due to failure on a memory check question (N=13) or technical error (N=1).

Materials We designed two distinct novel toys with different causal mechanisms that each lit up when activated (see Figure 1). The blue toy had two green buttons on the top; pressing the two buttons at the same time would make a rubber frog on the top of the toy light up. The yellow toy had two gray knobs on the left and right sides; turning the two knobs at the same time would make a rubber owl on the top of the toy light up. In reality, the toys were not actually functional but were activated by the experimenter with a remote control switch

Figure 1: Schematic of the toys used in Experiments 1 and 2.

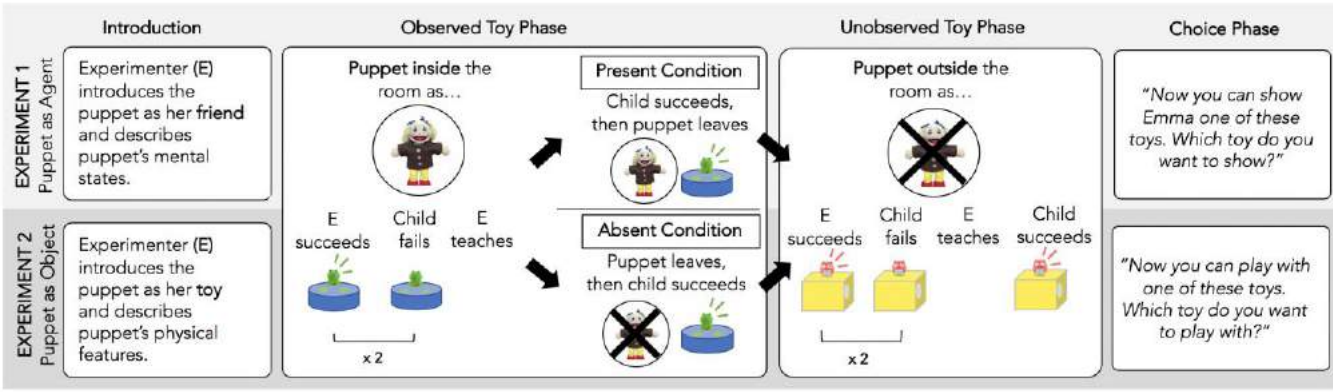

Figure 2: Procedures for Experiments 1 and 2.

underneath the table hidden from the participants' view. A girl hand puppet and a 3" x 4" picture of the puppet was used.

Procedure Children were tested individually in a quiet room at their preschool. The child sat across from an experimenter at a rectangular table. The experiment consisted of the Introduction, Observed Toy, Unobserved Toy, and Choice Phases; only the Observed Toy Phase differed between conditions (see Figure 2).

Introduction Phase: The experimenter showed the child the two toys and said that her *friend* "Emma" (a hand puppet) would watch them play. The experimenter put the puppet on the table facing the child and asked the child to say hello to Emma. Critically, the experimenter described the puppet with respect to its mental states: "Emma has never seen these toys before, and she doesn't know anything about them."

Observed Toy Phase: The puppet "watched" as the child and the experimenter played with one of the two novel toys (i.e., the Observed Toy; blue and yellow toy counterbalanced across participants). The experimenter successfully activated the toy by pressing the two buttons simultaneously (blue toy) or turning the two knobs simultaneously (yellow toy). The child then attempted to operate the toy (i.e., the child pressed the buttons of the blue toy or turned the knobs of the yellow toy) but failed, and the experimenter acknowledged the failure by saying "Hm." The experimenter then succeeded on the toy again and the child failed again. Then, the experimenter instructed the child how to activate the toy: "You have to push this button and this button at the exact same time" (blue toy) or "…turn this and this at the exact same time" (yellow toy). Then, the child was given another chance and succeeded. The experimenter acknowledged the success by saying "Now you know how to play with this toy!"

The critical manipulation between conditions was when the puppet was in the room. In the Present condition, the puppet "watched" the child's initial two failures and final success, then the experimenter brought the puppet outside the room. In the Absent condition, the puppet "watched" the child's initial two failures but was then brought outside the room after the experimenter's instruction on the toy; next, the child succeeded. In both conditions, the experimenter said that "Emma has to go now," before bringing the puppet outside.

Unobserved Toy Phase: The child and experimenter played with the other toy (i.e., the Unobserved Toy) while the puppet was out of the room. The sequence of failures and successes and the experimenter's instruction were identical as in the Observed Toy Phase. The child first failed to activate the toy twice, the experimenter taught the causal mechanism, then the child succeeded. Then, the child successfully activated both the Observed Toy and Unobserved Toy twice more, ensuring that the child was confident in operating both toys.

Choice Phase: With the puppet still outside the room, the experimenter positioned the two toys equidistant from the child. The experimenter placed a photo of the puppet in front of the child and asked, "Now you can show Emma one of these toys. Which toy do you want to show?" Children responded by touching or pointing to one of the toys. Then, children were asked a memory check question, "Did Emma watch when you were playing with this toy or this toy?" Only children who correctly responded to this question (i.e., selecting the Observed Toy) were included in the final sample. At the end, the puppet was brought back into the room, and children demonstrated the chosen toy.

Results and Discussion

In the Absent Condition, the puppet only observed the child's failures, whereas in the Present Condition, the puppet observed the child's failures *and* success. Thus in the Absent Condition, the puppet had an *incorrect* belief about the child's ability on the Observed Toy. We predicted that children would choose the Observed Toy more often in the Absent Condition than in the Present Condition if they were able to track the puppet's beliefs about their abilities and wanted to improve these beliefs.

We ran a generalized linear model (family = binomial) with Condition (dummy coded; Present = 0, Absent = 1), Observed Toy Type (dummy coded; Blue Toy = 0, Yellow Toy = 1), and Age (continuous) as predictors: Toy Choice ~ Condition + Age + Observed Toy Type. We found that Condition significantly predicted children's choice of toys (β = 1.839, z = 2.762, p = .006), but Age (β = .618, z = .519, p = .604) and Toy Type (β = -.268, z = -.400, p = .690) did not. Follow-up analyses confirmed that participants chose the

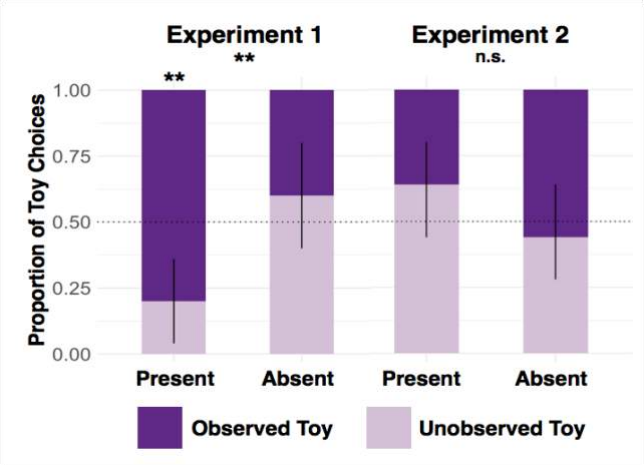

Figure 3: Results from Experiments 1 and 2. Error bars represent 95% confidence intervals. $^{**}p < .01$.

Observed Toy more often in the Absent Condition than in the Present Condition (% choosing the Observed Toy: 60% (Absent) vs. 20% (Present), $p = .009$, Fisher's Exact Test; see Fig.3). In the Present Condition, children strongly preferred to show the Unobserved Toy (80%, $p = .004$, Binomial Test), suggesting that they wanted to show the puppet a novel toy. In the Absent condition, however, children did not show a preference for either toy ($p = .424$, Binomial Test).

These results are in line with our main hypothesis that young children may go so far as to demonstrate their competence to a puppet when it is treated as an agent who is capable of holding beliefs. Specifically, when the puppet had only "observed" (i.e., was on the table facing the child) their failures but not their final success at operating a toy, children were motivated to demonstrate their competence by choosing the same toy to show the puppet, foregoing the opportunity to show a novel toy. These results are consistent with the literature on false-belief reasoning in preschoolers using puppets instead of human experimenters. However, it is nevertheless striking that children went as far as showing off their competence to a *puppet* that is incapable of any real-world social evaluation.

One critical prerequisite for such behaviors is the attribution of a belief state to the puppet. In Experiment 1, we provided a number of contextual cues to encourage children to consider the puppet as an agent, such as introducing the puppet as a "friend", verbally describing its mental states, and asking children to choose a toy to "show" the puppet. However, such behaviors would fail to emerge in the absence of any contextual support for ascribing agency to puppet, such that the puppet is no longer considered as an agent that is capable perceiving the environment or holding a mental state. In Experiment 2, we test this idea by asking whether the pattern of results in Experiment 1 would go away in a context where the puppet is treated as an object (i.e., the experimenter's toy) and children are asked to simply choose a toy to play with (rather than "showing" a toy to the puppet). Note that this is a control experiment where we expect a *failure to replicate* Asaba & Gweon (2018); critically, we also predicted an interaction of condition (Present vs. Absent) and experiment (Exp.1: Agent vs. Exp.2: Object); this would provide additional support that children's representation of the puppet (as an agent vs. an object) modulates the pattern of results.

Experiment 2: Puppet as Object

Methods

Participants 50 4-year-olds ($M_{Age}(SD) = 4.59(.31)$, range = 4.01–4.98; 27 females) were recruited from a university preschool and randomly assigned to the Present (N=25) or Absent (N=25) condition. An additional 28 children were recruited but excluded due to failure on the memory check.

Materials The same materials from Exp.1 were used.

Procedure The procedure was nearly identical to Exp.1, except for three critical modifications as described below, aiming to minimize the perceived agency of the puppet.

Introduction Phase: After introducing the two novel toys, the experimenter told the child that she had another *toy* (the puppet, which was introduced as a "friend" in Exp.1) and that she would put the puppet on the table as they were playing. Rather than referencing the puppet's ignorance about the toys, here the experimenter only described the puppet's physical features: "My puppet has blond hair and brown eyes. I also got the blue ribbons to tie my puppet's hair."

Observed Toy Phase: Children failed twice and succeeded once on the Observed Toy, and the Present and Absent conditions varied by whether the puppet was present for children's final success. In contrast to Experiment 1, the experimenter stated that someone else needed the puppet, rather than that the puppet needed to go. Additionally, the puppet's presence was emphasized at the beginning ("Now the puppet is on the table") and children helped bring the puppet outside the room to ensure that children were paying attention to the puppet. These changes were included to help children remember when the puppet was in the room.

Unobserved Toy Phase: Same as in Exp.1.

Choice Phase: The experimenter brought the puppet back onto the table. Importantly, the test question used in Experiment 1 (and in Asaba & Gweon, 2018; "Which toy do you want to show my friend?") implies that the puppet should be treated as an agent; using the same question would provide a strong signal to the child that the experimenter wants the child to "communicate" to the puppet. Thus, in Experiment 2, the experimenter asked instead: "Now you can play with one of these toys. Which toy do you want to play with?" while the puppet (instead of a photo of the puppet) was placed on the table, facing the child. We come back to the role of the final question in the General Discussion. However, we did use a similar memory check as Exp.1 by asking: "Was the puppet here on this table when you were playing with this toy or this toy?" Only children who correctly responded to this question were included in the final sample.

Results and Discussion

Here, the experimenter treated the puppet as her toy, and we predicted that if children's strategic self-promotion was sensitive to the nature of their "observer", then children would not strategically communicate to a puppet depicted as an object. Specifically, we predicted that there would be no difference in children's choices across conditions.

We ran the same generalized linear model as in Exp. 1 and found that Condition (β = -.747, z = -1.259, p = .208), Age (β =1.28, z = 1.232, p = .214), and Observed Toy Type (β = .603, z = .997, p = .319) did not predict children's choice of toys. Indeed, children chose the Observed Toy at similar rates in the Absent Condition and the Present Condition (% choosing the Observed Toy: 44% (Absent) vs. 64% (Present), p = .256, Fisher's Exact Test). Further, children did not selectively choose a toy in either condition (Present: p = .23, Absent: p = .69, Binomial Tests). Given the high rate of exclusion, we ran analyses including participants who failed the memory check question and found the same pattern of results: 53.4% (Present) vs. 38.9% (Absent) of participants chose the Observed Toy (p = .259, Fisher's Exact Test). As predicted, in this study, the results did not show a clear pattern for children's choice of toys as in Asaba & Gweon (2018).

The critical difference between experiments was whether the social context encouraged children to consider the puppet as an agent (capable of holding a belief) or an object. This allowed us to test the additional hypothesis that children would strategically choose which toy to show the puppet in a context where children had reason to attribute beliefs to the puppet (Exp.1), but not when it was treated as an object (Exp.2). To compare across experiments, we ran a generalized linear model (family = binomial) with Condition, Experiment, and Age (continuous) as predictors: Toy Choice ~ Condition * Experiment + Age. As expected, we found a significant Condition x Experiment interaction (β = -2.709, z = -2.709, p = .007), as well as significant main effects for Condition (β = 1.937, z = 2.608, p = .009) and Experiment (β = 2.013, z = 2.702, p = .007), but not Age (β = .816, z = 1.06, p = .289). The significant interaction between condition and experiment provides additional support for the idea that children's self-promotional behaviors are driven by the belief that children ascribe to the observer rather than the mere presence of an observer.

General Discussion

Across two experiments, we found that young children readily demonstrated their competence to a puppet, and that their self-promotional communication was modulated by the social context in which children interacted with the puppet.

As our primary goal, Exp. 1 provided a conceptual replication of Asaba & Gweon (2018). Remarkably, when a puppet had only observed their failures on a toy, four-year-olds demonstrated their success on the same toy to the puppet (rather than demonstrating a novel toy they played with in the absence of the puppet). This suggests that they attributed beliefs to the puppet about their own competence when the puppet was present for their failures, and they wanted to demonstrate their success to revise the puppet's (arguably false) beliefs. However, this pattern of results was found only in Experiment 1, when the experimenter treated the puppet as an agent and asked the child to demonstrate a toy to it; we did not find this pattern in Experiment 2 when the experimenter treated the puppet as an object and asked the child to choose a toy to play with.

Collectively, these results suggest that children are willing to engage in self-presentation behaviors to a non-human agent. Even though "losing face" in front of a puppet could not bear any foreseeable, real-world social consequences, children nonetheless tried to present positive information about the self (i.e., their success on the Observed Toy) instead of information about a novel toy (Unobserved Toy). Note that the puppet's belief was never explicitly mentioned; children inferred the belief from its "observations" of their own failures and successes and selectively provided evidence that might improve the puppet's beliefs. As irrational as these behaviors might seem, children were not indiscriminately showing off their competence to any entity; in the absence of any contextual cues to ascribe mental capacities to the puppet, children did not show these behaviors.

What makes children *want* to have a positive impression, even to a puppet? A large literature documents strong human desires to make positive impressions in the minds of others, regardless of age, gender, or culture. One perspective suggests that these attempts reflect a desire to build a shared reality with others (Harris, 2017); when children perceive gaps in knowledge or understanding between themselves and other people, they are motivated to remedy them by providing additional information. Our results provide additional support for this idea, and further show that the process of belief attribution (about the self) may be a key modulator of the motivation to preserve (good) or improve (bad) images of ourselves. Another theoretical perspective is that this motivation comes from the desire to be selected by others as social partners (Engelmann & Rapp, 2018). From this view, without the social pressure to be seen as desirable social partners, reputation management behaviors would not emerge. Our results do not necessarily contradict this view. Though there are no clear consequences to showing off to a puppet, children may still consider the pragmatic demands communicated by the experimenter or they may be motivated to practice self-promoting. Further, the desire to be accepted by others may be a more basic instinct even when people are not explicitly aware of them (Dweck, 2017).

More specifically, our task might have encouraged such behavior by asking children to "show" one of the toys to the puppet (although this was an ambiguous request either to show off or to teach novel information). By contrast, Experiment 2 provided little contextual support for these motivations to manifest. Although the two experiments were well matched in children's experiences with the toy and the time children spent in the presence of the puppet, Experiment 2 differed from Experiment 1 in two ways: the experimenter did not provide agency cues about the puppet and also asked the child to choose a toy to play with (rather than asking to

choose what to "show" to the puppet). Although this was an important design decision to prevent children from retrospectively attributing agency to the puppet ("showing" implies the ability to perceive), these results do not allow us to tease apart the relative importance of others' treatment of the puppet versus the nature of the final question.

An intriguing possibility is that even in contexts where adults initially treat the puppet as a toy, children might retrospectively ascribe a belief to the agent (see Király, Oláh, Csibra, & Kovács, 2018) when the experimenter asks which toy children want to "show" to the puppet. Such results might suggest that children are picking up subtle cues that reflect the ways adults communicate about the sentience of nonhuman entities (Weisman et al., 2017). Conversely, prior work in reputation management (e.g., Engelmann et al., 2012) suggests that children exhibit self-presentational behaviors even in the absence of explicit requests to communicate with their observer; thus, given clear evidence that adults treat the puppet as an agent (as in Exp.1), children might have still show similar self-presentational behaviors even when they are simply asked to choose a toy to play with. Future work might test the idea that adults' explicit treatment of the puppet and the nature of the final question might independently contribute to these behaviors.

Interestingly, the exclusion rate was noticeably high in Exp.2. It is possible that children may have not paid much attention to the puppet and subsequently had difficulty answering the memory question because of the social context. Understanding how children's memory might depend on the social context of their interactions is an area for future work.

Note that children were split between the Observed and Unobserved Toys in the Absent Condition in Exp. 1, as in Asaba & Gweon (2018). This might reflect genuine conflict between the desire to provide new information with the Unobserved Toy versus demonstrate their abilities on the Observed Toy; however, one might wonder if children were not considering the puppet's *beliefs* about their abilities, but simply wanted to show a success on either toy. While this still requires attributions of ignorance, ongoing work shows that when the confederate is fully knowledgeable about the toys in the Absent Condition, children selectively choose the Observed Toy, suggesting that they want to specifically revise the confederate's beliefs about their ability on that toy.

Broadly, these findings are consistent with the hypothesis that belief-reasoning capacities play a role in children's reputation management behaviors. Although work in Theory of Mind has traditionally focused on reasoning about others' beliefs about observable, objective physical states of the world (e.g., Wimmer & Perner, 1983), our work suggests that young children can also reason about beliefs concerning unobservable, subjective qualities of the self. Just as young children understand that others' observations (e.g., Anne *sees* the ball in the box) lead to others' beliefs (e.g., Anne *thinks* the ball is in the box, Wellman et al., 2001), they also understand that others' observations of their failures and successes informs others' beliefs about the self. Further, just as young children provide information to improve others' beliefs about the world (e.g., Gweon, Shafto, & Schulz, 2018), children in this study actively provided information about the self given others' beliefs about the self.

However, although belief attribution was critical for children's strategic communication in our task, not all reputation management behaviors may require rich psychological reasoning abilities. Rather, some behaviors may be a response to the mere presence of others, and mental-state reasoning may be involved only in certain contexts where belief attribution is necessary to motivate the behavior (e.g., when children are attempting to *revise* others' beliefs about them). If this is the case, even among children who clearly employ some reputation management behaviors (e.g., cheating less when others are present), the individual differences in their ability to select appropriate information or action to change others' beliefs about their competence might positively correlate with their performance on standard measures of Theory of Mind.

Here, we took advantage of prior work suggesting children's willingness to attribute mental states to puppets (Wellman et al., 2001). Critically, whereas prior work has manipulated the physical features of an entity (e.g., Johnson et al., 1998), we manipulated how the experimenter *treated* it. Our findings suggest that children differentially perceived the puppet depending on the experimenter's interactions with it. Along with recent work suggesting that children attend to agency cues and interact with non-human entities accordingly (Breazeal et al., 2018), the ways in which adults *treat* entities (e.g., other humans, toys, pets, deities) might have deep consequences for how young children subsequently treat them. Further, it is possible that young children might use graded levels of agency (see Weisman et al., 2017) to determine what to communicate to others. Whether children might prioritize their reputations for those with greater mental capacities (e.g., robots over puppets, or adults over babies) is an open area for future work. Further work could also consider directly asking children to evaluate the perceived agency of the interlocutor that has varying degrees of cues to agency, and investigating how this perceived agency influences children's behaviors.

These findings may also be useful to researchers in cognitive development whose work utilizes puppets in their methodology. For many studies, puppets are more than just logistically convenient stand-ins for human experimenters; they are often a necessary piece of the methodology, especially for studies that must present properties of agents that are implausible in human adults (e.g., someone who does not know labels of simple household objects) or tricky to convey with human actors in experimental contexts (e.g., someone who attempts to climb a hill). A useful takeaway from the current results is that just as children attribute beliefs about the external world to puppets (e.g., location of Sally's ball, see Wellman et al. 2001), they also attribute rich beliefs about abstract qualities of the self such as competence or abilities; Four-year-olds readily attempted to change a puppet's beliefs as if it was human. Importantly, their tendency to treat a puppet as an agent may be critically

modulated by the ways in which the experimenter had treated it. One open question is whether children genuinely believe that the puppet is an agent, or whether they are perceiving the experimenter's communicative intent (i.e., the experimenter wants to communicate to the child that the puppet is a friend of hers) and therefore following along by engaging in a pretend play with the experimenter. Although the current work does not directly address this question, it is possible that children's reasons for attributing beliefs to a non-human entity depends on age (e.g., younger children may treat it as an actual agent, whereas older children are aware that they are make-believe but still engage in pretense).

What others think of us is deeply important for our everyday interactions with others, and the ability to reason about others' minds might allow us to reason about others' beliefs about us in savvy, sophisticated ways. Our findings suggest that children's strategic self-presentational behaviors are specific to the social context. Children do not promiscuously show off to anyone or anything; rather, they are sensitive to cues about the object's agency and specifically communicate about the self to other agents.

Abstract

At first glance, humans extract social judgments from faces, including how trustworthy, attractive, and aggressive they look. These impressions have profound social, economic, and political consequences, as they subconsciously influence decisions like voting and criminal sentencing. Therefore, understanding human perception of these judgments is important for the social sciences. In this work, we present a modifying autoencoder (ModifAE, pronounced "modify") that can model and alter these facial impressions. We assemble a face impression dataset large enough for training a generative model by applying a state-of-the-art (SOTA) impression predictor to faces from CelebA. Then, we apply ModifAE to learn generalizable modifications of these continuous-valued traits in faces (e.g., make a face look slightly more intelligent or much less aggressive). ModifAE can modify face images to create controlled social science experimental datasets, and it can reveal dataset biases by creating direct visualizations of what makes a face salient in social dimensions. The ModifAE architecture is also smaller and faster than SOTA image-to-image translation models, while outperforming SOTA in quantitative evaluations.

Keywords: neural networks; generative models; face recognition; social perception; image modification

Introduction and Related Work

Humans quickly form subjective impressions of faces, judging traits like facial attractiveness, trustworthiness, and aggressiveness (Todorov, Olivola, Dotsch, & Mende-Siedlecki, 2015). Despite the continuous scale and subjective nature of these social judgments, there is often a consensus among humans in how traits are perceived (e.g., human raters agree that certain faces appear relatively more trustworthy) (Falvello, Vinson, Ferrari, & Todorov, 2015; Eisenthal, Dror, & Ruppin, 2006). Social judgments of faces have a significant impact on social outcomes, ranging from electoral success to sentencing decisions (Dumas & Testé, 2006; Oosterhof & Todorov, 2008). Modeling is one way to understand these critical split-second impressions. Another way is through explicit human-judged experiments, which require carefully controlled datasets (e.g., building a dataset of faces which vary in "trustworthiness" while remaining consistent across age, gender, and "attractiveness"). In this work, we develop a system to model these impressions, visualize human perceptual biases, and create isolated image modifications for experimental datasets.

Choosing a subset of social impressions for modeling, we look to the 10k US Adult Faces Database (Bainbridge, Isola, & Oliva, 2013a). Bainbridge et al. (2013a) investigated what social attributes influence the memorability of a face. They compiled a list of 20 spontaneous social judgments and the corresponding opposite traits. Then, they assembled a human-judged dataset of trait ratings on 2,222 faces from the 10k US Adult Faces Database. Among the 40 traits, "aggressive," "attractive," "intelligent," "emotional," and "trustworthy" were frequently used in human-written face descriptions, played a significant role in face memorability, and had high rating agreement levels between human judges. Therefore, we choose them as the subset of social impressions for modeling in this paper.

To create controlled face datasets and visualize perceptual biases, a generative model is needed. Recent generative image models have been successful in creating high-resolution, high fidelity, and diverse images (Brock, Donahue, & Simonyan, 2018; Karras, Aila, Laine, & Lehtinen, 2017; Choi et al., 2017). However, in the face space, most generative models have focused on editing or modifying categorical and objective attributes, such as expression, gender, hair color, and identity (Choi et al., 2017). These categorical changes are referred to as "image to image translation." Here, we focus on modifying continuous attributes of an image, which we refer to as "continuous image modification" (Isola, Zhu, Zhou, & Efros, 2016). Regarding continuous image modification, there has been work on modifying the memorability (Khosla, Bainbridge, Torralba, & Oliva, 2013), and attractiveness of a face (Leyvand, Cohen-Or, Dror, & Lischinski, 2008), but these models do not generalize to wider sets of social impressions. Also, some researchers have generated fake faces with particular social impressions, but these models cannot modify real face images (Vernon, Sutherland, Young, & Hartley, 2014; Oosterhof & Todorov, 2008). So, no prior work has attempted to automatically modify general continuous social impressions of real face photographs.

Conditional generative adversarial networks (GANs) (Goodfellow et al., 2014) have become the most popular tool for the image to image translation task, so we compare against a recent GAN as a state-of-the-art (SOTA) reference point (Isola et al., 2016; Mirza & Osindero, 2014; Lee & Seok, 2017). StarGAN (Choi et al., 2017) is a SOTA conditional GAN that can modify multiple binary categorical traits at once, maintaining identifying traits of the original image using "cycle consistency" (Zhu, Park, Isola, & Efros, 2017). StarGAN consists of two networks: a generator and discrim-

inator. The generator takes an image and a set of desired categorical traits, producing a modified image. The discriminator takes an image and makes a prediction about its realism and categorical traits. By comparing the fake images to genuine images, the discriminator gives feedback to the generator about how to make the image and desired traits appear more realistic.

Despite the success of GANs in categorical image-to-image translation, they cannot perform continuous image modification without binarizing the task and have architectural downsides. GANs typically have many parameters and long training times. They are also sensitive to hyperparameter selection and the delicate balance between generator and discriminator training. Therefore, they can be difficult to train compared to a single-network model. Finally, they suffer from a lack of interpretability, offering no means of visualizing or understanding why the model makes the modifications it does.

In this work, we address these architectural concerns while designing a neural network to model and automatically modify continuous-scale face traits (rated from 1 to 9) in real face images. We create a sufficiently large dataset for training a generative model by combining CelebA images with a SOTA face impression predictive model (Liu, Luo, Wang, & Tang, 2015). Enabling interpretable bias visualization and controlled dataset creation for human face impressions, we introduce ModifAE. ModifAE (pronounced "modify") is a single-network image modification autoencoder.

Subjective Judgment Face Dataset

Building a Large Scale Facial Impression Dataset

To train a generative model on continuous face traits, we need a large and diverse dataset. We start with images from the CelebA dataset (Liu et al., 2015), which are annotated with binary categorical labels such as "wearing a hat" but lack continuous ratings of social impressions.

To generate continuous social impression ratings of these faces, we use our previous social impression predictive model (Song, Li, Atalla, & Cottrell, 2017). The model was trained on a smaller dataset (2,222 faces from the MIT 10k US faces dataset (Bainbridge, Isola, & Oliva, 2013b)) that had been annotated with ratings of 40 social traits on a scale from 1 to 9 by 15 raters for each face. Now, we focus on the subset of traits with the highest correlation between human judges: emotional, aggressive, trustworthy, responsible, attractive and intelligent. We apply this predictive model to about 190,000 faces from the CelebA dataset. Example faces and their predicted ratings are shown in Figure 1. Note that 6-8 are high ratings, and 2-4 are low ratings.

Validating the Algorithm-Augmented Dataset

Evaluating the effectiveness of this algorithm-augmented dataset, we collect human judgments of the model's predictions in two ways: pairwise comparison and single image ratings. All participants were recruited from Amazon Mechanical Turk (AMT).

Figure 1: CelebA faces and their predicted traits.

Table 1: Validation of the impression prediction model

Attribute	Accuracy	Attribute	Correlation
Aggressive	0.95	Aggressive	0.76^{***}
Emotional	0.92	Attractive	0.90^{***}
Trustworthy	0.88	Trustworthy	0.73^{***}
Responsible	0.78	Intelligent	0.62^{***}

For pairwise comparison, we test four attributes: aggressive, responsible, trustworthy and emotional. For each trait, we compose 40 pairs of images. Within each pair, one is from the 40 faces of highest scores, and the other is from the 40 faces of lowest scores, as predicted by the model. We then ask human participants which face better exemplifies the predicted trait. Each trait's 40 pairs are evaluated by 30 AMT workers. We then calculate the overall likelihood that the face of higher predicted score is chosen, which we call "accuracy." The results are shown in the left side of Table 1. The attributes predicted by the model align well with human judgments.

For the single-rating experiment, we examined four traits: attractive, aggressive, trustworthy and intelligent. For each trait, we chose 80 faces whose predicted scores are evenly spread across a range of predictions (i.e., from 2 to 8). Each participant is presented with a random sequence of 80 faces, and is asked to give each face a rating on a 1-9 scale for the specified trait. Every face is rated by 15 subjects, and we compute the average. Lastly, we compute the Spearman rank correlation between the average human ratings and the model's predictions of the same set of faces for each trait. For all four traits, human average ratings are significantly correlated with model predictions (*** indicates $p < 0.001$), as seen in the right side of Table 1.

Given the pairwise and single image rating results, we consider the predicted scores as roughly equivalent to human judgments. Hence, in the next section, we train our face mod-

ification model with these ratings.

ModifAE

ModifAE is a single network autoencoder which implicitly learns to modify continuous face impression traits in images (illustrated in Figure 2). Here, we elaborate on the architecture, training procedure, and mechanism of the ModifAE model.

Model Architecture

The ModifAE architecture consists of a single autoencoder with two (image and trait) sets of inputs which pass through an encoding stage, are fused (by averaging) in the middle of the network, and are then fed into an image decoder.

The image encoder and decoder are identical to the encode and decode portions of the StarGAN generator network, scaled to fewer channels (Choi et al., 2017). More specifically, the network has two downsampling convolutional layers with stride two, four residual blocks, a bottleneck with 16 channels, four more residual blocks, then two upsampling transposed convolutional layers with stride two (Choi et al., 2017). All layers have ReLU activation. We use the first half of this network (including the bottleneck) as the image encoder. We use the remainder of the network as the image decoder. Theoretically, this portion could consist of the encode and decode halves of any image autoencoder; we chose the architecture from StarGAN for the sake of comparability.

The trait encoder takes a 1-dimensional set of traits, feeds these into a single dense layer with Leaky ReLU activation, and reshapes the output to create a vector of the identical shape as the image encoder output. The outputs of the trait and image encoders are then combined into a single latent representation by averaging.

In order to encourage the model to encode the trait information, which is otherwise unnecessary to reproduce the image, 50% dropout is applied to the values from the image encoder. This is then averaged with the trait encoder output to arrive at the combined latent representation. The image decoder projects the representation back into image space, creating the single output image. The architecture is depicted in Figure 2, where "convs" refers to residual convolutional blocks from StarGAN.

Training Procedure

ModifAE is exclusively trained on an autoencoding task. We train ModifAE using the Adam optimizer (Kingma & Ba, 2014) and train for 100 epochs on CelebA images (Liu et al., 2015). The objective is to optimize a single loss function based on two terms. We use the L_1 loss on the image autoencoder. We also optimize the L_1 loss between the trait encoder and image encoder. The total loss is:

$$L = \frac{1}{N}\sum_{p=1}^{N} |x_p - AE(x_p)| + |E(x_p) - E(y_p)| \qquad (1)$$

where x_p is the p^{th} image example, y_p is its trait vector, $E(\cdot)$ is the result of the trait or image encoder, and $AE(\cdot)$ is the output of the full-architecture autoencoder. The second term in this loss function encourages the network to have a similar representation between the trait and the image encodings. The trait encoder obviously does not "know" what the image is, but this constrains the image encoding to include information about the trait.

Why the Model Learns Implicitly to Modify Images

Each image is encoded along with its predicted traits. The image encoder compresses the image down to a bottlenecked latent space, where higher level features about the image are encoded. Simultaneously, the trait encoder projects the given traits to the same latent space, creating an average face representation with those ratings.

Because dropout is applied to the face encoding, the decoder has to use the trait information to "fill in the gaps" in the face representation. Therefore, at training time, faithfully reconstructing the image is reliant on information coming from the trait encoder, and the trait encoder learns to mimic average latent distributions of images with the provided ratings.

At test time, an image can be passed in with any desired traits. The trait encoder estimates the latent space for images with those traits, and the decoder responds by altering the face image towards the encoded trait. Hence, the output image resembles the original but is changed according to the provided traits.

Experiments and Results

In this section, we provide examples of ModifAE's modifications and interpretable transformation maps. We also report an experiment which quantitatively compares the effectiveness of ModifAE and StarGAN with a user study, and we numerically compare the ModifAE architecture with other relevant systems.

Qualitative Evaluation

Multi-Trait Traversals Here, we show that ModifAE is capable of making continuous modifications on multiple traits with a single model (see Figure 3 and Figure 4). This enables ModifAE to modify some traits while holding others traits constant, which can be applied to creating datasets with controlled and isolated modifications for social psychology experiments.

For Figure 3, we trained ModifAE on two traits: "attractive" and "aggressive." The picture in the upper left corner is the original. At the (0,0) point in Figure 3 (unattractive and not aggressive) the man's mouth is fairly neutral, and his features are not very pronounced. As attractiveness and aggressiveness increase, the angles of the face become sharper, there is more definition of features like eyes and eyebrows, and the smile shrinks.

Figure 4 shows interpolations generated by two models. Each was trained on a social trait and a gender category from CelebA. Then, each trait was interpolated while holding the gender bias constant. The resulting figure shows how perception of "aggressiveness" may vary across genders. Likewise,

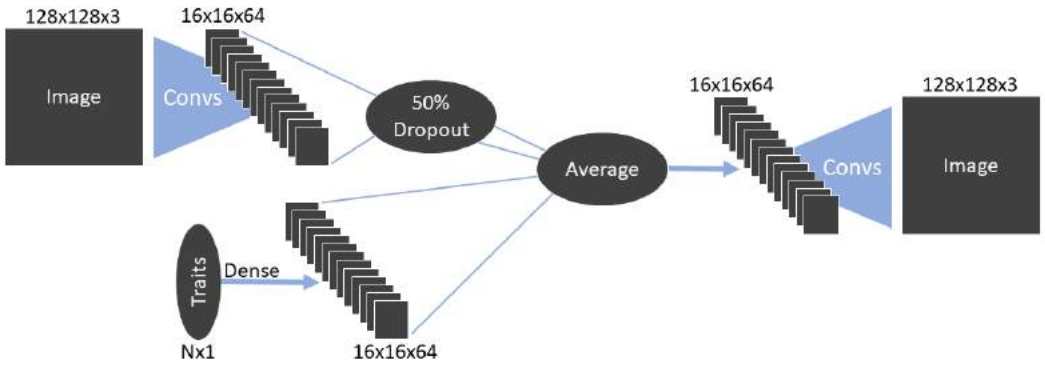

Figure 2: General illustration of ModifAE architecture.

this method can show how other traits may be less correlated with gender perception.

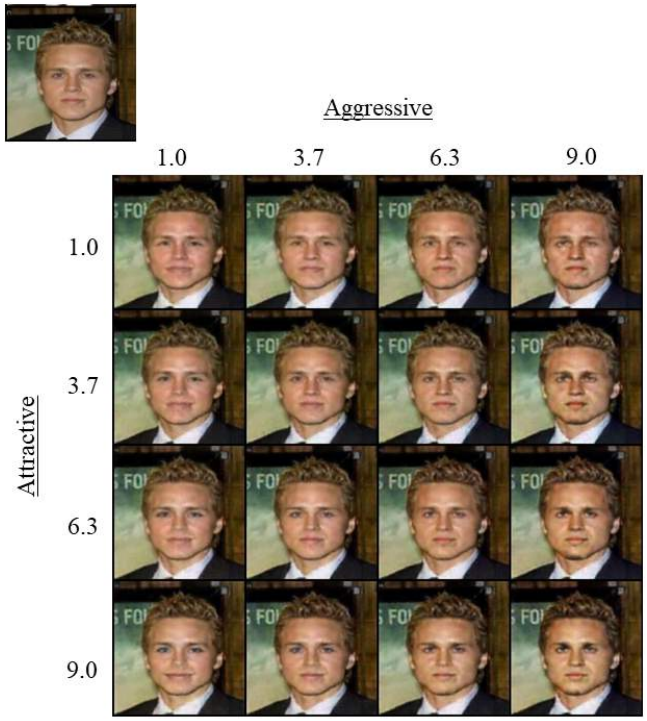

Figure 3: Continuous value, multi-trait image modification by ModifAE.

Qualitative Comparison to StarGAN Comparing our model to StarGAN (Choi et al., 2017), we binarize the continuous traits by doing a median split on the continuous-valued traits and train StarGAN on these two groups (low and high). This is necessary because StarGAN inherently only makes binary changes. The results are shown in Figure 5. While StarGAN produces high-resolution image reconstructions, they occasionally suffer from color distortions or lack of apparent changes. ModifAE makes subtle and reliable modifications to the original images, changing the way

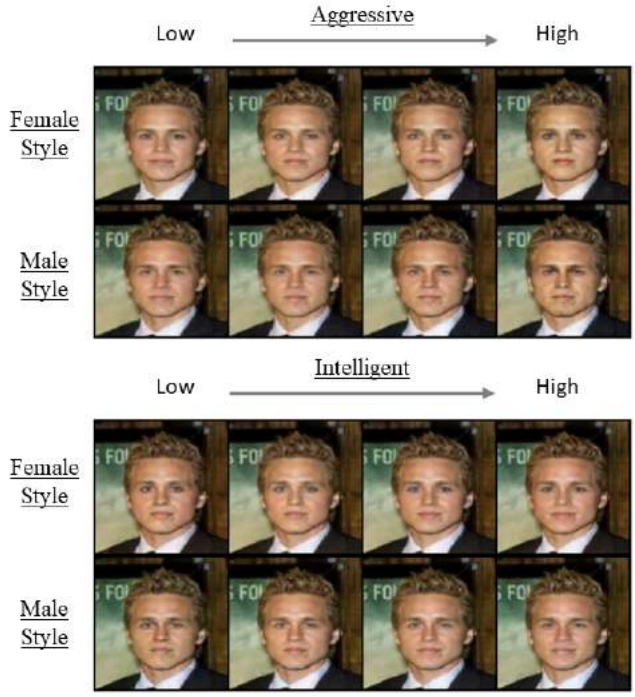

Figure 4: Continuous changes of a face while holding gender bias constant.

the social traits are perceived. In the images produced by ModifAE, more trustworthy faces smile more, and appear to have eyes set farther apart. The ModifAE attractive faces appear to smile more and notably have more well-defined eyes.

Interpretable Transformation Maps As mentioned above, ModifAE addresses the issue of interpretability in generative models. We provide a window into the model's representation of the traits by decoding the representation generated by the trait encoder without giving any actual image input. Figure 6 shows a traversal of the learned "trait faces" or "transformation maps" of attractiveness and intelligence. In this case, we trained the model on a combination

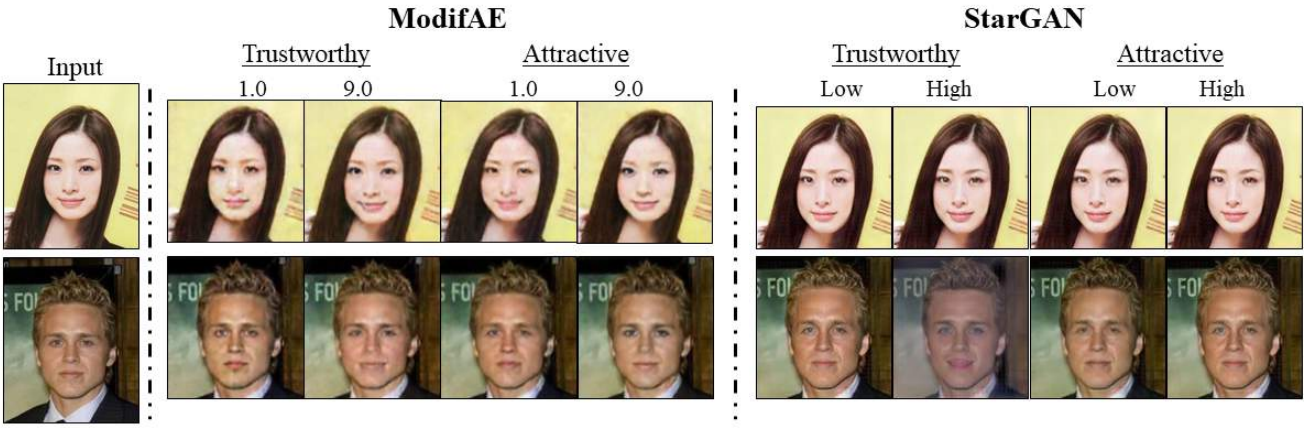

Figure 5: Comparison of ModifAE and StarGAN modifications.

of gender and the given trait, so we show a traversal of the model's representations for male and female faces separately.

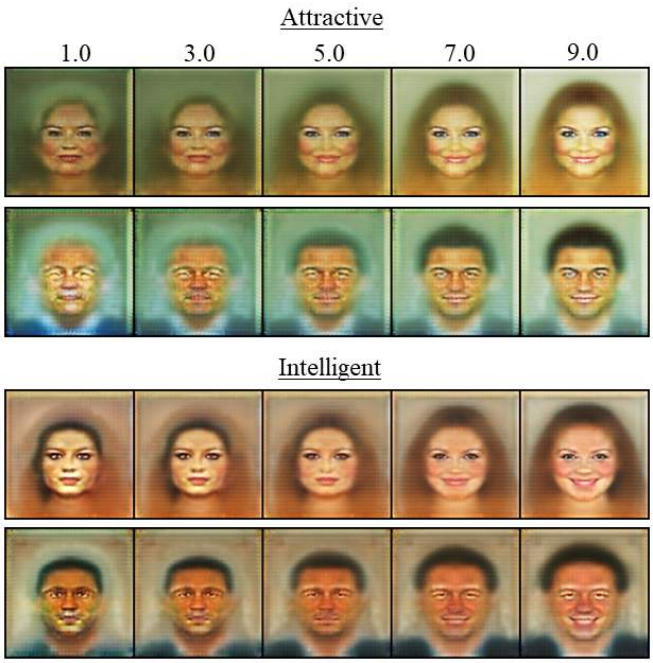

Figure 6: Visualization of model's internal perception of traits. Each is a traversal of a trait (increasing left to right) while gender is held constant.

Quantitative Evaluation

Quantitative Comparison with StarGAN To evaluate the quality of ModifAE's continuous subjective trait modifications, we perform Amazon Mechanical Turk (AMT) experiments on four traits: aggressive, attractive, trustworthy and intelligent. For each trait, we created 90 image pairs, of which 80 are the same identity modified to be at high and low values of each trait. For StarGAN, we used a median split of low and high rated traits to train the model. ModifAE was trained as previously described. For each model, then, faces were modified to be low or high on each trait. Subjects judged which face had more of the particular trait. 10 pairs were repeats in order to judge subject consistency, and 10 pairs were unmodified CelebA faces with high and low ratings. These latter we called "ground truth" pairs to test whether subjects were paying attention. Subjects whose ratings on these pairs were at chance or below were rejected.

Hence, for each trait, we present participants with a sequence of 100 image pairs, and participants are asked to pick which image most exemplifies the trait in each pair.[1] Each pair was evaluated by 15 subjects.

We calculate the fraction of pairs in which subjects chose the image with the higher modified trait across all participants and all pairs. If they choose the face that was modified to be higher in the trait, then they agree with the model's modifications. The results are shown in Table 2. We perform a binomial test to determine whether each trait's accuracy is significantly below or above chance ($^{***}p < 0.001$). Note that the fourth column "Ground Truth" indicates the overall accuracy of the unmodified "ground truth" pairs. Given the variance in human impression judgments, these numbers serve as a reference ceiling for how well the models can perform.

Evaluating ModifAE's Continuity Since ModifAE is able to generate continuous modifications, we evaluated this property by creating two more same-face pairs: Ones modified to have low values and middle values, and ones modified to have middle values and high values. We obtain human agreement (accuracy) over the Low-Mid and Mid-High pairs for each of the four traits. The results are shown in Table 3.

Model Size and Training Time

In contrast with GANs, ModifAE requires fewer parameters and less time to train. StarGAN takes about 24 hours to train on CelebA (Choi et al., 2017); ModifAE takes less than 11

[1] In a pilot experiment, we asked subjects to rate faces with different identities generated in a fine continuum, but found significant variance with no correlation to the intended scores, presumably because the images were not differentiable at that fine a grain.

Table 2: Comparison of ModifAE with StarGAN

Attribute	**ModifAE**	StarGAN	"Ground Truth"
Aggressive	0.68^{***}	0.72^{***}	0.90^{***}
Attractive	0.68^{***}	0.51	0.94^{***}
Trustworthy	0.63^{***}	0.40	0.87^{***}
Intelligent	0.68^{***}	0.58^{***}	0.81^{***}

Table 3: ModifAE Low-Mid-High Level Self-comparison

Attribute	Low-Mid	Mid-High	Low-High
Aggressive	0.60^{***}	0.52	0.68^{***}
Attractive	0.59^{***}	0.52	0.68^{***}
Trustworthy	0.61^{***}	0.53^{*}	0.63^{***}
Intelligent	0.60^{***}	0.50	0.68^{***}

hours. Table 4 shows the number of parameters required by different models trained on the CelebA dataset. The listed values are as reported in the original papers (Perarnau, van de Weijer, Raducanu, & Álvarez, 2016; Zhu et al., 2017) and in the parameter comparisons of Choi et al. (2017).

Note that the majority (over 40M) of StarGAN's parameters are in the discriminator network, and ModifAE uses a smaller version of the StarGAN generator. Also, ModifAE's relatively small trait encoder is the only part of the model which scales with supervising additional traits, so learning more traits with a single model is cheaper with ModifAE. Together, these properties mean that ModifAE takes over fifty times fewer parameters than any of the competing models.

Discussion

Quantitative Experiment Discussion

From Table 2, we can see that for all four traits, ModifAE produces pairs that yield above chance level human agreement. In three out of the four traits, ModifAE significantly outperforms StarGAN; whereas for the aggressive trait, StarGAN performs only slightly better than ModifAE. StarGAN is good at creating discrete changes in facial expressions, which accounts for this advantage.

From Table 3, we find that all the low-mid pairs yield significantly above chance accuracy, yet for mid-high level, only trustworthy pairs have accuracy slightly above chance ($p < 0.05^{*}$). This suggests that human psychological face space is nonlinear and has more differentiation towards the low- to mid-range of social dimensions. Another possibility is that when our model generates faces that are of more extreme scores (e.g. 8 or 9), the model is extrapolating, and produces artifacts that lead to that face being rejected. This speculation requires further analysis to be confirmed.

Interpreting Transformation Maps

The interpretability of the model may be useful in the field of social psychology, giving researchers new suggestions about what features of a face are most important for perceiving a given trait. It can also elegantly summarize the average opinions and biases of a group of raters who have created a dataset, or serve as a visual heuristic for understanding which traits are most similar to each other in human perception.

Table 4: Model size for learning seven traits

Model	CycleGAN	ICGAN	StarGAN	**ModifAE**
Parameters	736M	68M	53M	**1M**

The "intelligent" transformation map appears to show that bigger heads are rated as more intelligent (at least, pictures in which the head appears larger or closer). This suggests a bias that to our knowledge, has not been previously observed. Of course, in this case, it is simply faces that subtend a larger visual angle, rather than real-world head size. In further experiments, the head size should be normalized across images to avoid this potential bias. In addition, experiments could be run where image head size is systematically manipulated with the same face (judged by different subjects), to verify the bias.

The "intelligent" transformation map appears to show that bigger heads are rated as more intelligent (at least, pictures in which the head appears larger or closer). This suggests a bias that to our knowledge, has not been previously observed. Of course, in this case, it is simply faces that subtend a larger visual angle, rather than real-world head size. In further experiments, the head size should be normalized across images to avoid this potential bias. In addition, experiments where humans rate images with systematically manipulated head size could be run to verify the bias.

Conclusion

In this paper, we propose ModifAE: a single network autoencoder, which performs continuous image modification on subjective face traits in an interpretable manner. ModifAE does not require training multiple networks or designing hand-tailored features for image modification. Instead, a single network is trained to autoencode an image and its traits through the same latent space, implicitly learning to make meaningful changes to images based on trait values. Our experiments show that ModifAE requires fewer parameters and takes less training time than existing general methods. It also provides interpretable transformation maps of traits which demonstrably highlight biases in datasets and salient features in human perception of traits. Additionally, in this work, we compute and verify novel continuous subjective trait ratings for CelebA faces. Finally, we demonstrate that ModifAE makes more meaningful continuous image traversals than an equivalent SOTA method (Choi et al., 2017) and examine human agreement with ModifAE modifications in the subjective face trait space.

Abstract

The Simple Recurrent Network (SRN) has a long tradition in cognitive models of language processing. More recently, gated recurrent networks have been proposed that often outperform the SRN on natural language processing tasks. Here, we investigate whether two types of gated networks perform better as cognitive models of sentence reading than SRNs, beyond their advantage as language models. This will reveal whether the filtering mechanism implemented in gated networks corresponds to an aspect of human sentence processing. We train a series of language models differing only in the cell types of their recurrent layers. We then compute word surprisal values for stimuli used in self-paced reading, eye-tracking, and electroencephalography experiments, and quantify the surprisal values' fit to experimental measures that indicate human sentence reading effort. While the gated networks provide better language models, they do not outperform their SRN counterpart as cognitive models when language model quality is equal across network types. Our results suggest that the different architectures are equally valid as models of human sentence processing.

Keywords: Surprisal; Gated Recurrent Neural Networks; Language Modeling; Sentence Processing; Sentence Reading; Self-paced Reading; Eye-tracking; Electroencephalography

Introduction

In psycholinguistics, the Simple Recurrent Network (SRN; Elman, 1990) has been a popular (and reasonably successful) neural architecture for modeling aspects of human sentence processing, and it remains so to this day (Brouwer, Crocker, Venhuizen, & Hoeks, 2017; Frank, Otten, Galli, & Vigliocco, 2015; Rabovsky, Hansen, & McClelland, 2018; Twomey, Chang, & Ambridge, 2014, to name just a few recent examples). However, it has been known since the late 1990s that the SRN struggles to integrate information over many classification steps, due to what is referred to as the vanishing gradient problem (Hochreiter, 1998).

This problem was addressed by neural network models containing recurrent units that have gates with trained weights, such as the Gated Recurrent Unit (GRU; Bahdanau, Cho, & Bengio, 2015) and the Long Short-Term Memory (LSTM; Hochreiter & Schmidhuber, 1997) network. The gating mechanism implemented in GRUs and LSTMs controls the flow of information in the recurrent cell, allowing the cells to memorise information over time, forget it when adequate, and to determine the weighting of old and new input. While the principles of the two architectures are similar, the GRU can be regarded as a more lightweight variation on the LSTM, making use of only two gates and a single hidden state, whereas the LSTM architecture provides three gates and introduces an additional memory state.

Gated networks outperform SRNs on several NLP tasks. For example, LSTMs perform more accurately than SRNs on number agreement (Linzen, Dupoux, & Goldberg, 2016) and conversational speech recognition (Xiong et al., 2017). In the current study, we investigate how well gated networks perform as cognitive models of human sentence processing compared to the traditional SRN. We model human word-level processing effort by using recurrent neural networks as probabilistic language models that estimate the predictability of words in context.

For the language modeling problem, the ability to make effective use of more of the words in the prior sequence can be expected to pose a crucial advantage of a gated recurrent network compared to the SRN. For instance, the processing of long-term dependencies has been proposed as one aspect of natural language processing addressed more adequately by gated networks than by SRNs (Bahdanau et al., 2015). Because gated networks are designed for long-distance encoding, they may also be superior cognitive models: The filtering mechanism implemented by the gates may mirror an aspect of human sentence processing. For example, it is known that humans read the word *or* faster when they processed the word *either* in the prior sequence of words, demonstrating their ability to remember dependencies between words across long spans (Staub & Clifton Jr., 2006). Gated networks may reflect this human behaviour more accurately than SRNs by assigning lower surprisal to the word *or* even when the corresponding *either* is distant.

Although LSTMs and GRUs have already been applied to account for human language performance measures (Futrell et al., 2019; Goodkind & Bicknell, 2018; Gulordava, Bojanowski, Grave, Linzen, & Baroni, 2018; Hahn & Keller, 2016; McCoy, Frank, & Linzen, 2018; Sakaguchi, Duh, Post, & Durme, 2017; Van Schijndel & Linzen, 2018a, 2018b), the question remains whether they form more accurate cognitive processing models than traditional SRNs, beyond what might be expected from their stronger language modeling abilities.

In the current study, we directly compare three recurrent neural network (RNN) language model architectures (SRNs, GRUs, and LSTMs) on their ability to predict human reading data collected in self-paced reading, eye-tracking, and electroencephalography experiments. If the mechanisms imple-

mented in GRUs and LSTMs correspond to cognitive mechanisms applied during sentence comprehension, we would expect predictions by these models to fit human reading data more closely than predictions by SRNs, over and above any advantage that GRUs/LSTMs might have because of their superiority as language models. Conversely, if the cognitive system does not apply anything like a gating mechanism, the SRN may simulate human language processing more closely than GRUs and LSTMs do. In that case, the SRN may predict human processing data more accurately than gated RNNs that are matched for language model quality.

Method[1]

To determine whether or not LSTMs and GRUs outperform SRNs as cognitive models of sentence processing, we train three different kinds of RNN language models, each using one of the three recurrent cell types. We evaluate the models by assessing the predictive power of the surprisal values they assign to stimuli used in three experiments of humans sentence reading.

Human processing data

We assess how well each RNN language model's word surprisal values predict human cognitive processing effort during sentence reading, as measured in self-paced reading (SPR), eye-tracking (ET), and electroencephalography (EEG) experiments. The SPR and ET data come from Frank, Monsalve, Thompson, and Vigliocco (2013) and the EEG data from Frank et al. (2015).

In all three experiments, participants read English sentences sampled from unpublished novels. All sentences are understandable out of their context in the novels. A subset of the sentences were used in the ET and EEG experiments; these were the shortest sentences (maximum length: 15 words) of those from the SPR study. Table 1 displays the numbers of participants and stimuli, along with ranges and means of sentence length for each of the three data sets. Importantly, we make sure that all word types in the stimuli are attested for in the training data, meaning that the language models do not encounter words for the first time when applied to the stimuli.

For this study, we select a single variable from each dataset that is indicative of human processing cost: Reading time (RT) from the SPR data, gaze duration (a.k.a. first-pass reading time) from the ET data, and N400 size from the EEG data set. We follow the insight that reading times reflect the cognitive effort the reader needs to employ during language processing (Levy, 2008). Reflecting this idea, the N400 event-related potential amplitude indicates processing effort on lexico-semantic levels (Kutas, Van Petten, & Kluender, 2006; Kutas & Federmeier, 2011). Earlier research has already demonstrated that these dependent variables, from these particular data sets, indeed correlate with word surprisal values (SPR: Monsalve, Frank, & Vigliocco, 2012; ET: Frank & Thompson, 2012; EEG: Frank et al., 2015).

Network architectures

Our RNN architecture consists of a 400-unit word embedding layer, a 500-unit recurrent layer, a 400-unit feed-forward layer with tanh activation function, and a final layer with log-softmax activation function, which maps to the vocabulary. We do not use pre-trained word embeddings. Rather, the weights of the embedding layer that transforms the vocabulary items to real-valued word vectors are learned during the next-word prediction task, along with the rest of the network weights. The model architectures only differ in that their recurrent layers use either SRN, LSTM, or GRU cells.

Training corpus

As training data for the language models we use section 13 of the English version of the Corpora from the Web (COW, 2014 version; Schäfer, 2015). This corpus consists of randomly ordered sentences collected from web pages. From this section, the 10,000 most frequent word types are selected as our model's vocabulary. One hundred and three word types that appear in the experimental stimuli (see Section on *Human Processing Data*) but are not yet covered in the vocabulary are added, resulting in a final vocabulary size of 10,103 word types. After determining the vocabulary, we select those sentences from the initial COW section that contain only in-vocabulary word types, thus also covering the low-frequency words in the experimental stimuli. We follow this strategy to avoid having to use a (cognitively implausible) UNKNOWN-type. Furthermore, we only keep sentences with a maximum length of 39 words, which corresponds to the longest sentence in the experimental stimuli (not counting punctuation as words). We remove a small number of sentences to arrive at a final selection that contains 6,470,000 training sentences and consists of 94,422,754 tokens in total.

Although this training set and vocabulary size is relatively small by current standards, note that our aim here is not to construct the best possible language model, and not even to provide the most accurate account of human sentence processing effort. Rather, we investigate whether RNN architectures differ in their ability to predict human data.

Network training

We train the networks on one sentence at a time to let model training resemble human language processing and acquisition. Further, we reset the hidden state of the recurrent cells to zero for each new sentence. From the network's log-probability output at each step, the loss function computes the negative log-likelihood. Based on this loss, we optimise the network weights using stochastic gradient descent with momentum (0.9) and an initial learning rate of 0.0025. After each third of the training data, we reduce the learning rate to half of its prior value. As precaution to the exploding gradient problem (Bengio, Simard, & Frasconi, 1994), we clip gradients at 0.25. The error is always back-propagated through the

Table 1: Numbers of participants, number of sentences, range of sentence length, mean sentence length, number of word tokens, and number of data points (after exclusion; see Section *Stage 1: Predicting human data from surprisal*) in the human sentence reading data sets. In the SPR experiment, each participant received a random subset of the 361 possible sentences (see Frank et al., 2013, for details).

Exp.	Part.	Sent.	Range sent. len.	Mean sent. len.	Tokens	Data points
SPR	54	361	5–39	14.1	4957	132,858
ET	35	205	5–15	9.4	1931	28,970
EEG	24	205	5–15	9.4	1931	24,618

entire sentence.

To account for random variation in model performance that is solely due the initial weights and training sentence presentation order, we train each RNN type six times, each time with different random initial weights (uniformly distributed between ± 0.1; with initial biases 0) and a different random order of sentence presentation. However, for each training repetition, the same initial weights (for connections that correspond between architectures) and the same presentation orders are applied across the three recurrent cell architectures. Hence, the *only* difference between the RNN types is in the architectures of their recurrent cells.

Language model evaluation

We evaluate the performance at the nine different training corpus sizes by computing the perplexity on the unseen experimental stimulus sentences. Perplexity is computed as

$$PPL = e^{-|W|^{-1} \sum_{w \in W} \log P(w)},$$

where $|W|$ is the number of word tokens in the experimental sentences. Lower perplexity results from language models that assign higher probabilities to the test data. Perplexity thus expresses the extent to which a language model captures the statistical structures of the data that are useful to predicting the next word, irrespective of the extent to which this is helpful for explaining human sentence processing measures.

Statistical model evaluation

The RNN models' ability to account for the human processing data is evaluated in two stages, as explained in more detail below. First, we compute surprisal for the experimental test items. Surprisal is computed as

$$\text{surprisal}(w_t) = -\log\ P(w_t | w_1, ..., w_{t-1}).$$

and formalises the extent to which occurrence of a word w_t is unexpected, given a sequence of preceding words $w_1, ..., w_{t-1}$ (Hale, 2001; Levy, 2008). The reading-time and N400 measures on each word are regressed on each model's surprisal estimates resulting in a collection of goodness-of-fit measures. Next, we assess the relation between each RNN type's goodness-of-fit and its quality as a language model.

Stage 1: Predicting human data from surprisal Each individual RNN generates surprisal estimates for each word of the 361 stimuli sentences. The surprisal values are obtained after training the network on 1K, 3K, 10K, 30K, 100K, 300K, 1M, 3M, and all 6.47M sentences. This procedure allows to observe how the goodness-of-fit to human data develops as a function of language model quality, which steadily increases with the amount of observed training data. In summary, we have 9 (points during training) $\times$ 6 (training repetitions) $\times$ 3 (RNN types) $=$ 162 sets of surprisal values to compare to the SPR times, gaze durations, and N400 sizes.

The predictive power of each set of surprisal values is assessed by means of linear mixed effects regression, using the `MixedModels` package[2] (v0.18.1) for `Julia` (Bezanson, Edelman, Karpinski, & Shah, 2017). First, a baseline model was fitted to each of the three human data sets. The aim of this baseline is to factor out the effects of the most imporant variables known to affect reading times and N400 sizes and thus be left with an effect of surprisal that is as isolated as possible.

The dependent variables self-paced reading times and gaze durations are log-transformed. In the EEG data, N400 size is analysed as defined by Frank et al. (2015): the average potential on central-parietal electrodes over a 300–500ms window after word onset.

The baseline models include as fixed effects: log-transformed word frequency in the training corpus, word length (number of characters) and word position in the sentence. For the SPR and ET data, we also enter the previous word's frequency and length into the analysis to account for spillover effects that are known to affect reading times (Rayner, 1998). Moreover, we add previous-word RT (log-transformed) to the SPR analysis to address the high correlation between consecutive word RTs that typically occurs in the SPR paradigm; and to the ET analysis we add a binary factor indicating whether the previous word was fixated. For the EEG analysis, we enter baseline activity (i.e., the average electrode potential in the 100ms leading up to word onset) into the regression. All interactions between the fixed effects are also included. Furthermore, there are by-subject and by-item (word token) random intercepts and by-subject random slopes of all fixed-effect predictors.

We exclude data on sentence-initial and -final words, words attached to a comma, and clitics. Furthermore, participants are removed from the analysis if they are not native English

[2] `github.com/dmbates/MixedModels.jl`

speakers or scored less than 80% correct on the yes/no comprehension questions that were presented for approximately half the sentence stimuli. In addition, SPR and ET data points are removed on words directly following a comma or clitic, and when reading times are below 50ms or over 3500ms. For the EEG data, we exclude artefacts as identified by Frank et al. (2015).

The goodness-of-fit of each set of surprisal values for each human data set equals the log-likelihood ratio (decrease in regression model deviance) between the baseline and a regression model that additionally includes surprisal as both a fixed effect and by-subject random slope. For the SPR and ET analyses, the previous word's surprisal is also added (again as fixed and random effects) in order to capture spillover effects. The resulting values are χ^2-statistics, with 2 degrees of freedom for the EEG data and 4 degrees of freedom for the two reading-time data sets. We further add a negative sign to the χ^2-statistics to indicate effects in the negative-going direction, that is, when higher surprisal results in shorter reading times or smaller (less negative) N400 size.

Stage 2: Predicting goodness-of-fit from language model accuracy Networks that form better language models tend to estimate surprisal values that fit human data better (Frank et al., 2015; Goodkind & Bicknell, 2018). In analysis Stage 2, we are interested in ascertaining whether the relation between language model accuracy and goodness-of-fit to human data differs between network architectures.

We quantify language model accuracy as the average log-probability (i.e., negative average surprisal) estimated over the experimental sentences, weighted by the number of times each word token takes part in the analysis described above, that is, for how many participants the data on this word was not excluded. Following this, we fit Generalized Additive Mixed Models (GAMMs), for each of the three RNN types and human data sets separately, to predict the goodness-of-fit measures (from analysis Stage 1) from the language model accuracies, with network training repetition as a random effect. This is done using the `R` package `mgcv` (Wood, 2004).

Results

Language modelling results

Figure 1 reports on the perplexities of the 18 individual language models at 9 different points during training. While the SRNs set in at lower perplexity than the gated networks early in training, the latter ultimately outperform the simple RNNs. Language model performance steadily increases throughout training but a saturation of the language model performance seems only to commence at the final training steps.

Statistial modelling results

Figure 2 displays the goodness-of-fit measures from analysis Stage 1 for each human data set, as well as the fitted curves relating goodness-of-fit to language model accuracy from analysis Stage 2. These plots clearly show that well-trained language models estimate surprisal values that account for reading times and N400 size, and that the goodness-of-fit generally improves as the language models more accurately capture the linguistic patterns. Interestingly, for lower levels of linguistic accuracy, corresponding to models trained on relatively few sentences, the effect of surprisal on gaze duration size is reversed, in that higher surprisal correlates with faster reading. The cause of this reversal remains to be identified.

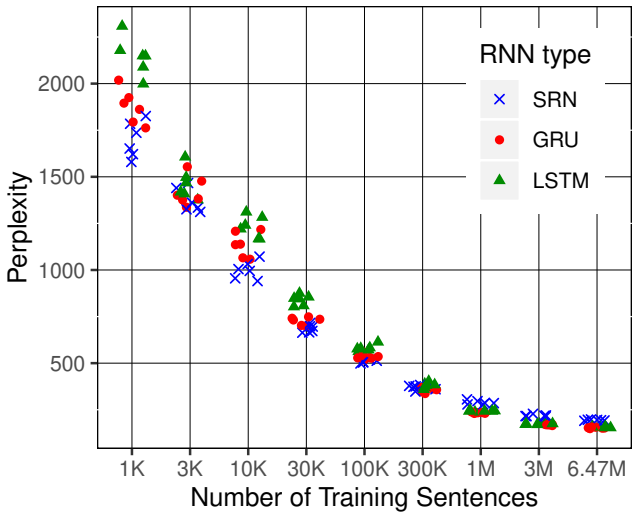

Figure 1: Perplexity on the experimental sentences for each of three RNN types at nine different training corpus sizes. At each training size there are six models of each type with different sentence orderings and initial weights. Data points are subjected to horizontal jitter to improve readability.

The gated RNN models reach higher levels of language model accuracy than the SRNs, which is why they can also outperform SRNs in terms of goodness-of-fit. For similar levels of language model accuracy, however, the three model types account for similar quantities of variance in the human processing data, as is evident from the largely overlapping confidence intervals of the fitted GAMM curves.

This does not imply that different network types make no independent contributions to human data prediction. To test whether the models differ qualitatively in that one RNN explains unique variance over and above the others, we average the surprisal values over the six fully trained versions of each network architecture. Next, we fit linear mixed models including the surprisals from two of the three RNN types and then test whether that regression model fits the data better than a regression with only a single set of surprisal values. That is, for each pair of RNN types we ask whether one explains human data over and above the other.

Table 2 shows model comparisons, testing for the significance of adding the surprisal from the models displayed in rows to the models in columns. The comparisons reveal statistically significant effects of GRU and LSTM surprisal over and above SRN surprisal in all three data sets. For the EEG data, SRN surprisal also explains variance not yet explained

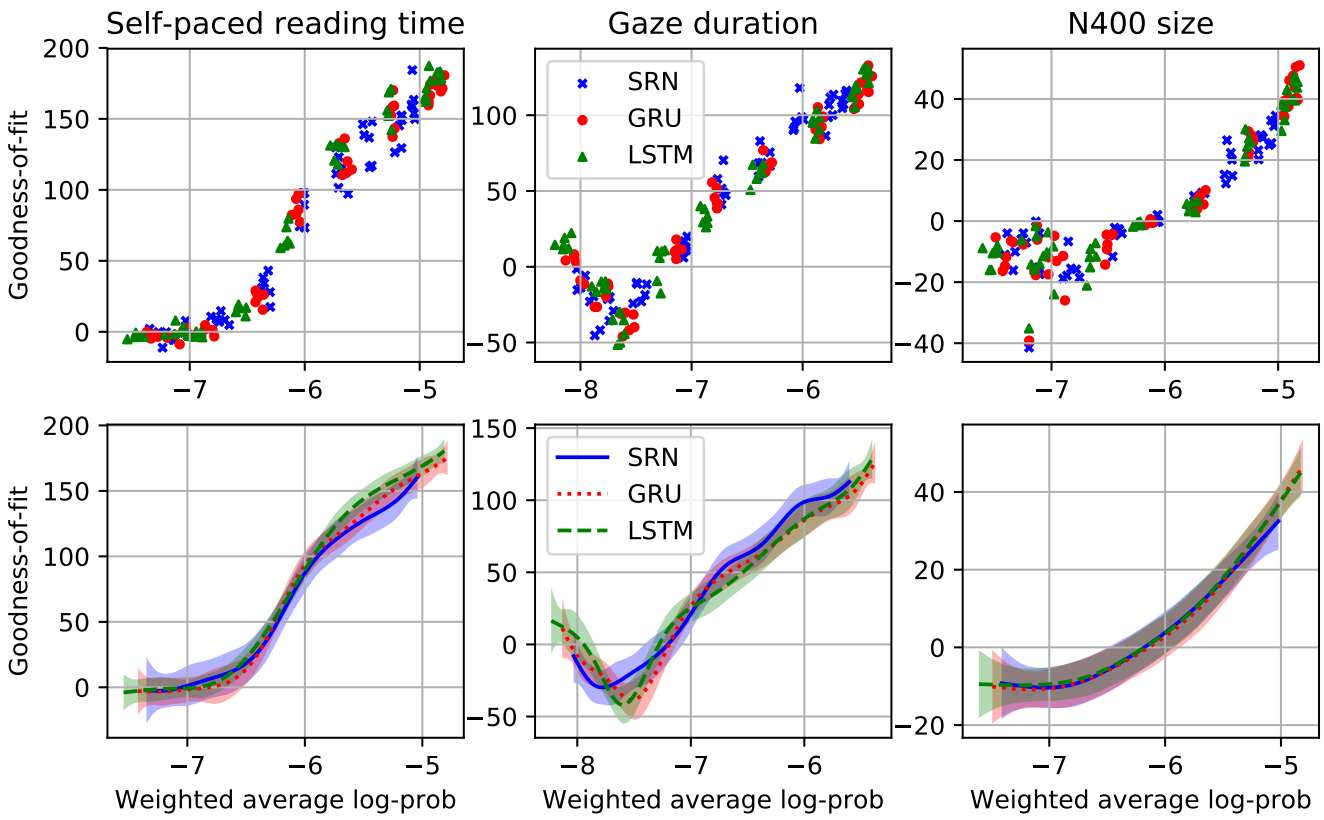

Figure 2: Top row: results from analysis Stage 1. The goodness-of-fit of surprisal to human data is plotted as a function of language model accuracy. Bottom row: results from analysis Stage 2. Plotted are the fitted GAMM curves relating goodness-of-fit to language model accuracy. Shaded areas indicate 95% confidence intervals. Panels on the left, middle, and right side are for SPR, ET, and EEG data, respectively.

by the gated networks.

Discussion

Our comparison of the abilities of SRNs, GRUs, and LSTMs to predict human reading-time and N400 measures (via the networks' word-surprisal estimates) do not reveal any large or reliable difference between the three RNN types, at least, not as long as the different networks' accuracies as language models do not differ. The two gated networks do form better language models than the SRN, resulting in more precise predictions of human data at the highest levels of language model accuracy. However, if the human cognitive system would employ mechanisms akin to the gates in GRU/LSTM recurrent cells, we would expect GRU/LSTM-based surprisal to show better fit than SRN-based surprisal to the human processing data, even without any difference in language model accuracy. Our analyses do not support this conclusion.

The gated RNNs explain variance over and above what is accounted for by the SRNs on SPR, ET, and EEG data. This is an expected effect, given that gated networks form better language models. Their ability to encode relations between word tokens along larger spans is likely giving them a clear advantage in accounting for human data. More surprisingly, on the EEG data the SRNs also explain a portion of variance that is distinct from the one explained by the gated networks. This finding may suggest a potential insensitivity of the N400 ERP component to long-distance dependencies, at least to the extent that N400 size reflects word predictability. Converging evidence for this interpretation is presented by Frank et al. (2015) who demonstrate that an n-gram language model with a context size of three words explains variance over and above an SRN on the same data set.

Conclusion

While gated recurrent neural networks provide better language models than simple recurrent networks, our investigations do not indicate that they have any substantial or reliable advantage as cognitive models of sentence reading, in addition to what is expected from their superior language modeling abilities. Nevertheless, gated networks consistently reached higher linguistic accuracy. This fact alone makes the use of gated RNN advisable not only from a language modeling point of view but also for psycholinguistics (and cognitive science more in general) when as much variance in human data as possible needs to be explained, for example when surprisal is used as a covariate in studies that aim to find a unique

Table 2: Results from regression model comparisons between RNN types. Each χ^2-statistic is the outcome of a log-likelihood ratio test for whether the network type in the table row accounts for variance in the human data over and above the network type in the table column. Asterisks indicate statistical significance level after multiple-comparison correction (Benjamini & Hochberg, 1995): * = $p < .05$; ** = $p < .01$; *** = $p < .001$.

Abstract

Using "A" in noun phrases such as "A father of the victim" is odd, which is commonly explained by the principle *Maximize Presupposition*, requiring speakers to use the alternative with the strongest presupposition (here "The", given its uniqueness presupposition). This results in an anti-uniqueness inference for "A" (clashing with stereotypical expectations here), sometimes labelled as an 'anti-presupposition' (Percus, 2006), as it derives from reasoning over the presuppositions of alternative forms. We compare these inferences to the uniqueness inferences associated with definites, while manipulating uniqueness expectations in a picture manipulation task using visual world eye-tracking. This offers a minimal comparison of uniqueness-based inferences that are lexically encoded vs. pragmatically inferred, and furthermore tests the prediction that the accommodatability of the definite's presupposition plays a role in the derivation of anti-uniqueness inferences (Rouillard & Schwarz, 2017).

Keywords: presuppositions; visual world eye-tracking; definiteness; indefiniteness

Theoretical Background

There is a concurrent claim in the theoretical literature that definite descriptions, and presupposition triggers in general, have to be used if their presupposition (PSP) is fulfilled in the context. Since definite noun phrases come with a presupposition of uniqueness they must be used if this uniqueness presupposition is met in the context, see (1-a). The use of an indefinite noun phrase in (1-b) is infelicitous.

(1) a. The father of the victim came.
b. #A father of the victim came.

There are various theories explaining this effect by assuming that there is lexical competition between the presuppositionally stronger definite and presuppositionally weaker indefinite governed by the principle *Maximize Presupposition* (Heim, 1991; Percus, 2006; Sauerland, 2008; Chemla, 2008). Based on pragmatic reasoning over the stronger alternative – similar to the one used for the derivation of scalar implicatures – the indefinite yields the inference that the presupposition of the definite is false ('anti-uniqueness'). (1-b), for example, has the infelicitous anti-uniqueness inference that there is not exactly one father of the victim. The resulting inferences ('anti-presuppositions') are theoretically set apart from well-studied components of meaning like presuppositions and implicatures based on their weaker epistemic status, and their projection behaviour. Recently, the strength of the epistemic status has been argued to be dependent on accommodatability of the competing presuppositional statement, which is tied to the knowledge state of speaker and hearer (Rouillard & Schwarz, 2017). There is a less prominent alternative view according to which definites and indefinite both come with their own context restrictions, i.e. that the indefinite comes with a novelty condition (Heim, 1983) or its own presupposition of anti-uniqueness (Kratzer, 2005). These make different predictions for the processing profiles associated with anti-uniqueness.

According to the first view (theory A), in which anti-uniqueness is the result of reasoning over presuppositionally stronger alternatives, the consideration of the alternative and its subsequent negation to derive the inference should require extra processing costs, based on the observation that both presuppositions and negation have been independently shown to increase the cognitive load in processing (Schwarz, 2007; Tiemann, 2014; Kirsten et al., 2014; Carpenter, Just, Keller, Eddy, & Thulborn, 1999; Reichle, Carpenter, & Just, 2000; Herbert & Kübler, 2011). As this view works with alternatives it also predicts that drawing the inference might depend on the salience and accommodability of the competitor with "the". In the example in (1) this alternative is very salient and easy to accommodate as it is common knowledge that people have one (biological) father. However, in other examples where this is not the case the inference is not as strong. (2), for example, does not seem to have any implications as to how many pathologically noisy neighbours the speaker has, at least without any further knowledge about the likelihood about it being one or more.

(2) A pathologically noisy neighbour of mine broke into the attic. (Heim, 1991)

According to the second view (theory B), definites and

indefinites should have comparable processing costs, with minimal or no differences in processing patterns as both introduce their own restrictions that are part of their lexically endoed meaning. As a result, the salience of the definite as an alternative should not play a role in deriving any anti-uniqueness inferences.

Albeit the fact that inferences resulting from *Maximize Presupposition* and the principle itself have received a lot of attention in the theoretical literature, there is almost no experimental research on the topic, with few exceptions (Amsili, 2015; Eckardt, 2014; Bade, 2016). There is, however, some experimental research on definiteness versus indefiniteness discussed in the next section.

Previous experimental work

There have been previous experimental investigations of the difference between indefinite and definite determiners. One line of research which is of importance for the present discussion is the study of so called "bridging inferences" (Haviland & Clark, 1974). They describes the inference of unique entities in certain situations where such a referent is stereo-typically unique, e.g. "the bus driver" in a situation where someone is entering the bus. These inferences are associated with different processing costs depending on how easily the referents are accessible (Haviland & Clark, 1974). (Burkhardt, 2006) in an ERP study finds similar effects for both definites and indefinites if they follow contexts that do not explicitly mention the referent.

Many studies on the definite have found additional processing costs if the context does not furnish an appropriate (unique) referent (Tiemann et al., 2011; Kirsten et al., 2014; Tiemann, 2014). Additional processing costs have also been found for the indefinite, which has been attributed to it introducing a new discourse referent (Kirsten et al., 2014; Schumacher, 2009).

A set of studies which is of special interest for our discussion tested the use of definites versus indefinites for stereo-typically unique items in context in which they are typically unique (e.g. stove in a kitchen) or not (e.g. stove in an appliance store) (Clifton, 2013). Clifton found that interactions between contexts and determiner in reading times only emerged if the experiment involved a secondary arithmetic task, which is argued to lead to deeper processing resulting in participants forming a more complete situation model. This model required the accommodation of a unique referent in the mismatching condition of the definite, and the introduction of a new referent in the mismatching condition of the indefinite.

Experiment

The aim of the experiment was to test whether the potential theoretical distinction between (anti-uniqueness-) anti-presuppositions on the one hand, and (uniqueness-) presuppositions on the other hand is supported by processing measures. Additionally, we wanted to test the prediction of theory A that lexical alternatives, as well as the epistemic state of the speaker with regard to the truth of the inference, play a role in the derivation of anti-uniqueness inferences.

Design and Material

For that purpose, we created sentence materials that either contained the definite or indefinite determiner (first factor DETERMINER with two levels, +/-DEF) and combined them with either stereo-typically unique or non-unique nouns (second factor STEREO-TYPICALITY with levels +/-TYPICALLY UNIQUE, see an example in all 4 sentence conditions below.

(3) Someone spilled orange juice on. . .

a. a television +TYPICALLY UNIQUE, -DEF
b. the television +TYPICALLY UNIQUE, +DEF
c. a pillow -TYPICALLY UNIQUE, -DEF
d. the pillow -TYPICALLY UNIQUE, +DEF

. . . in the living room.

A given sentence was paired with two pictures providing settings where the referenced object was either typically unique or not, i.e. the sentences in (3-a) and (3-b) were paired with the two pictures in figures 3 and 4, and the sentences in (3-c) and (3-d) were paired with the two pictures in figures 1 and 2. As part of our task (described in more detail below) participants had to decide which of the two pictures the sentence was about, with the (anti-)uniqueness information conveyed by the respective determiners being key for the picture choice.

Figure 1: -TYPICALLY UNIQUE (*A/The pillow), target for unique Def (pic 1)*

Figure 2: -TYPICALLY UNIQUE (*A/The pillow), target for non-unique Indef (pic 2)*

Figure 3: +TYPICALLY UNIQUE (*A/The TV), target for unique Def (pic 1)*

Figure 4: +TYPICALLY UNIQUE (*A/The TV), target for non-unique Indef (pic 2)*

We created 24 sets of experimental stimuli, for counterbalanced presentation to participants of 6 items per experimental conditions. In addition,there were 24 filler items with the temporal connectives “before” and “after” (e.g. “Peter spilled coffee after doing the dishes") and 12 fillers with the quantifier “several” (e.g. “Peter spilled coffee on several chairs in the dining room").

Norming study

To determine what objects people considered to be stereo-typically unique in a given scenario, our first step was a norming study with 60 native speakers of English. They were asked to rate the typicality of uniqueness by being asked “How typical do you think it is that there is exactly one TV in a standard living room?”. We tested 48 different objects in the norming study. For the 24 critical items used in the study we took the 24 objects with the highest average rating and paired them with objects that received a very low average rating.

Main experimental task

We tested 77 native speakers of American English recruited through the SONA system of the University of Pennsylvania. They received course credit for their participation. Participants engaged in a simple game. In the main comprehension part of the experiment, they heard recordings of descriptions (containing indefinite or definite articles) of spills that happened in different rooms. They then had to try to best match the description they heard by dragging a splash representing a spilled beverage to one of two room settings, which differed in whether they contained one or two of the mentioned type of object (e.g., television or pillow). After going through a practice phase with 4 trials they went on to the 24 experimental trials (plus fillers). See Figure 5 for a screen shot of a sample trial (in a control condition, which sometimes depicted two different types of room settings).

Figure 5: Screen shot of a comprehension trial.

Picture choices, response times and eye-movements were tracked during the comprehension phase. Participants also went through a brief constrained production phase (9 trials), where they had to drag words to construct a sentence of the form above to describe a provided picture. This was intended to engage them with the task more by seeing both sides of the game, and to highlight the alternative choices between determiners in relation to the number of relevant objects in the picture. The determiner choices they were given were “A”, “The” and “Several”. The pictures were created so that each of these determiner would be chosen 3 times (given the theoretical assumptions, e.g. with the definite used for unique items and the indefinite for non-unique ones). There were two practice trials for the production task. A screen shot of a production trial is given in Figure 6 below. Production and comprehension block order was counterbalanced across participants.

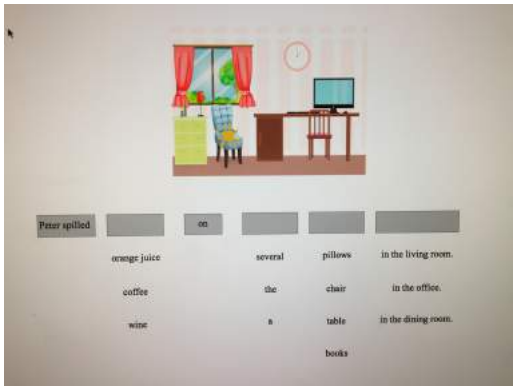

Figure 6: Screen shot of a production trial.

Predictions

Given the theoretical assumptions spelled out above we coded the pictures with two objects matching the description in the relevant noun phrase to be the target picture for the indefinite (pic 2), see again Figure 2 and 4 above. For the definite, we assumed the picture depicting exactly one object of the kind referred to in the sentence to be the target (pic 1), see Figure 1 and 3. Drawing the anti-uniqueness inference which is the basis for the target choice of the indefinite was predicted to be influenced by whether the referenced object is typically unique in the given setting by theory A. This theory predicts target choices to be higher for the indefinite in the non-typically unique condition than in the typically unique condition, whereas the definite should not be affected by this factor. As a result, we expected there to be an interaction between DETERMINER and STEREOTYPICALITY for picture choices. Moreover, based on theory A, anti-uniqueness anti-presuppositions are expected (or at least likely) to show a different pattern in eye-movements than the uniqueness presuppositions evoked by the definite. Again, since drawing the infer-

ence for the indefinite should be facilitated by the object being typically unique, we predict an interaction between DET and STEREO-TYPICALITY for measures reflecting looks to target, as well as a main effect of both factors. No such differences or interactions are predicted by theory B, according to which determiners should be more or less equally affected by stereo-typicality. According to theory A, but not B, the data should also be influenced depending on whether there was exposure to the alternative. Thus order effects of the tasks should be relevant for the processing associated with the indefinite following theory A but not B.

Analysis

Responses were analyzed using logistic mixed effect models as implemented in the glmer function in R (Bates, 2005). Reaction times and fixations on target were log transformed for analysis and analyzed using linear mixed effect models and the lmer function in R (R Core Team, 2017). Participant, condition and item were treated as random factors in both model types, and random effect slopes were included as model convergence allowed.

Results

Responses The anti-uniqueness inference of indefinites is less readily available, and less robust than the uniqueness inference of definites in our data, in line with previous results. This is witnessed by (i) low production 'accuracy' for indefinites when the production block came first, see Figure 7: in the condition where the displayed picture included multiple objects matching the noun phrase description, participants only chose an indefinite about half of the time in their sentences. There is a significant main effect of block order (p<.01) with more target choices for production when it followed the comprehension block and also a significant interaction between DETERMINER and BLOCK ORDER (p<.01) with accuracy of choice being less affected by block order if the target determiner was definite than when it was indefinite.

The weak status of the indefinite is also reflected in (ii) target choice rates in the comprehension task. Overall, there was a main effect of BLOCK ORDER, present at all levels, with overall more target choices when production came first (and comprehension second). Crucially for the present point, there is a bigger susceptibility of the indefinite to plausibility effects biasing against multiple instances of stereo-typically unique objects, especially in the initial comprehension block. This is reflected in an interaction between typical uniqueness and determiner in the 'comprehension first' block (p< .01), driven by more frequent target choices for Def in +typically unique condition (parallel simple effect also present for 'production first'), see Figure 8.

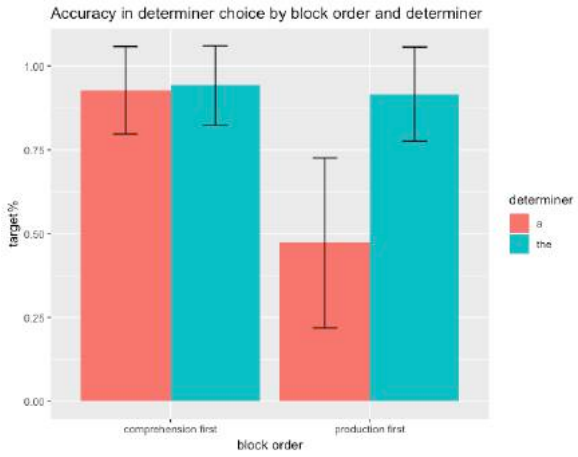

Figure 7: Target determiner choices for production task by block order

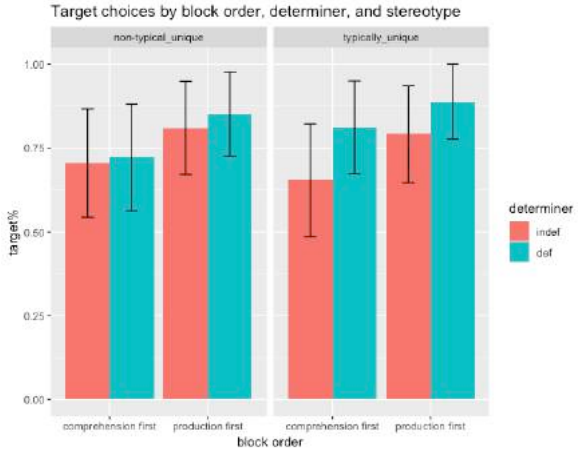

Figure 8: Target selections for comprehension task by block order and stereo-typical uniqueness

Eye movements For the analysis of the eye movements we considered time windows of 200ms between 100ms and 2300ms after noun phrase onset (which is roughly 4 seconds into the trial and the point where, on average, participants picked up the splash to place it on the picture). We looked at the fixations on the respective target for definite (pic 1) and indefinite (pic 2) relative to its competitor. The main dependent measure that we report on below is Target Advantage score, calculated by subtracting the proportion of fixations to the competitor from the proportion of fixations to the target.

In the first time window (100-300ms after noun phrase onset) we find a main effect of definiteness, with a higher target advantage for the indefinite. This effect is likely due to the target for the indefinite (pic 2) being the overall more unusual picture in the typically unique condition (e.g. with 2 TVs). This is also in line with the observa-

tion that in the typically unique cases, there is a significantly higher target advantage for the indefinite ($p<.01$) even before the noun phrase onset, see both graphs in Figure 9 and 10.

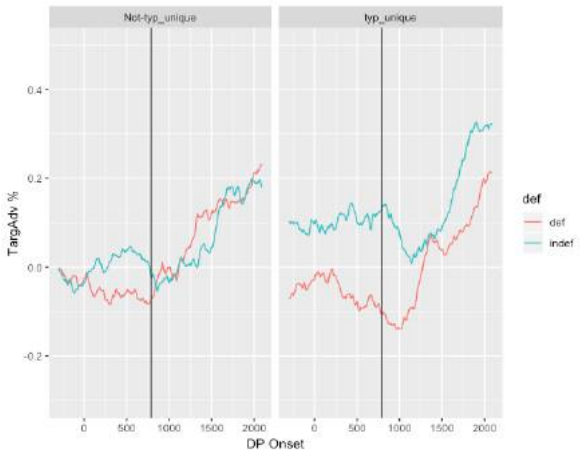

Figure 9: Target advantage by determiner and stereo-typicality for all trials (Black line indicates mean noun phrase-offset/PP-onset.)

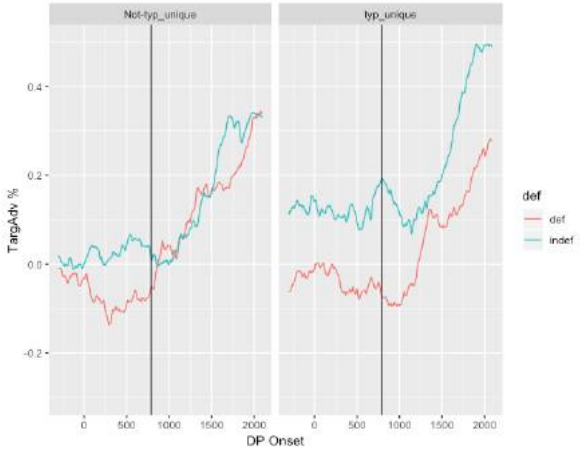

Figure 10: Target advantage by determiner and stereo-typicality for accurate trials (Black line indicates mean noun phrase-offset/PP-onset.)

Given this indication that pic 2, i.e. the target for the indefinite, has an advantage due to inherent properties of the picture, we also looked at the influence of both factors on the looks to pic 1 and pic 2, respectively, see figure 11. We find that in the early time window there is an interaction for looks to pic 1 between both factors: there are more looks to pic 1 for the definite if the item is typically unique and fewer looks to pic 1 for the indefinite if the target is non-typically unique. There are, however no main effects of the two factors. This together suggests that in the first time window the looks to the two pictures are guided by both determiner and stereo-typicality, and not oddness of the pic 2 picture alone.

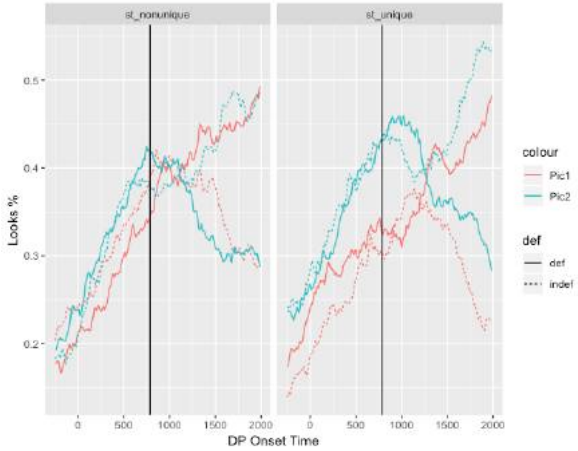

Figure 11: Looks to pic 1 and pic 2 by determiner and stereo-typical uniqueness, all trials)

In the time windows 300-500 and 500-700ms after noun phrase onset, there is a main effect of DEF ($p<.05$), but no interaction with STEREO-TYPICALITY. The effect is significant for the typically unique cases in both time windows ($p<.01$). But it is also marginally significant for the non-typically unique cases in time window 300-500ms ($p<.06$) and significant in the time window 500-700ms ($p<.05$). The interaction between both factors on looks to pic 1 is still marginal significant ($p<.06$), and significant when only looking at data from trials resulting in target choices, see figure 12.

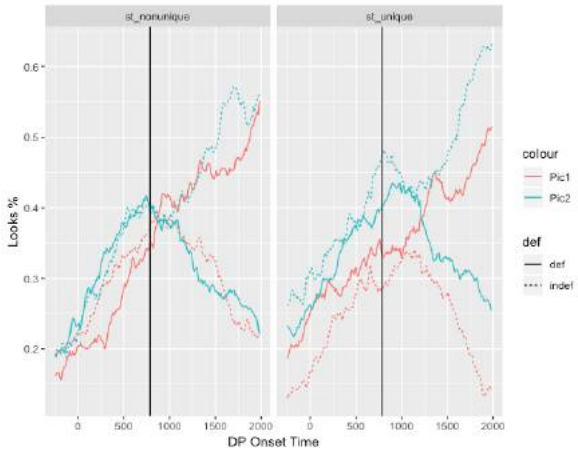

Figure 12: Looks to pic 1 and pic 2 by determiner and stereo-typical uniqueness, accurate trials)

In the time window 700-900 ms after noun phrase onset there is a significant interaction between STEREO-

TYPICALITY and DEFINITENESS in the predicted direction for Target Advantage: stereo-typicality has an effect on indefinites, but not on definites; as shown by the significant simple effect for the former ($p<.01$) and lack thereof for the latter. There is also a significant interaction between both factors in the time window 900-1100ms after noun phrase onset ($p<.01$). Looking at the simple effects shows that the interaction is due to stereo-typicality having a marginal effect on the definite ($p<.07$), but not the indefinite at this point, opposite to our predictions.

To better see potential differences from the properties of the respective target pictures for definites and indefinites, we also investigated looks to pic 1 and pic 2 separately for these time windows. There only are main effects of stereo-typicality for both pictures ($p<.05$ for pic 2, $p<.01$ for pic 1), suggesting that the interactions above are due to the pictures themselves attracting more attention depending on whether the item is typically unique.

No effects show up in time windows between 1100 and 1900 ms for target advantage. However, when considering looks to pic 1 and pic 2 we see a main effect of determiner for both pictures in all time windows between 1100 and 1900 ms after noun phrase onset ($p<.01$) for all of them).

There were no interactions between definite and time windows, and no interactions between block order and definite in all time windows.

Discussion

In combination, these results support the idea that, contrary to a view that sees anti-uniqueness as being based on a lexically encoded presupposition on par with the uniqueness presupposition of definites (theory B), the anti-uniqueness inference for indefinites is pragmatically derived from reasoning over the alternative expression (the definite) and its presupposition (uniqueness) (theory A). This is because, as predicted by theory A, the inference is not present as robustly from the start but is boosted by exposure to the alternatives and how they could matter: when the production follows comprehension, choice of the indefinite in the sentence construction phase increases for pictures with two objects of the relevant sort; and when the comprehension block follows the production block, choices of the picture with two of the relevant items increases for indefinite sentences.

With regards to the eye movement data, we find some effects that are at least in part complicated by the properties of the different target pictures. For the most part, except for very early time windows, the differences between definite and indefinite disappear when looking at only not-stereo-typically unique cases. This becomes especially apparent when looking at trials resulting in target choices, where there is no difference in time course between determiners, at least in the present task. We'd note, though, that the fixation shifts in our data are overall relatively late, which is likely at least partly due to the nature of the task requiring clicking and dragging splash-pictures around. Be this as it may, our data provides no evidence that the additional reasoning involved in deriving the inference by reasoning over the lexical presupposition of the alternative requires extra processing time if the conditions for this contextual reasoning over alternatives are met. This finding will need to be considered in relation to the complex empirical situation in the implicature processing literature, with some studies finding delays for implicature computation, and others not. The present results seem to constitute a case of a different type of a pragmatically derived inference that seemingly does not lead to any delays involved in accessing it. But further work is needed to try to establish this in task variations allowing for an earlier emergence of effects. Finally, a methodological lesson worth noting is that studying anti-uniqueness effects of indefinites experimentally requires careful fine-tuning of the task, as they can be evasive and are highly sensitive to various contextual factors.

Abstract

Creative thinking has long been associated with spreading of activation through concepts within semantic networks. Here we examine one potential influence on spreading activation known as the *fan effect*: increasing concept knowledge leads to increasing interference from related concepts. We tested whether cue association size—an index of semantic richness reflecting the average number of elements associated with a concept—impacts the quantity and quality of responses generated during the alternate uses task (AUT). We hypothesized that low-association AUT cues should benefit quality at the cost of quantity because such cues are embedded within a semantic network with fewer conceptual elements, thus yielding lesser interference from closely-related concepts. This hypothesis was confirmed in Study 1. Study 2 replicated the effect and found an interaction with fluid intelligence, indicating that cognitive control can overcome constraints of semantic knowledge. The findings thus highlight costs and benefits of semantic knowledge for creative cognition.

Keywords: Divergent Thinking; Fan Effect; Fluid Intelligence; Semantic Memory

Introduction

Divergent thinking (DT) is considered a crucial aspect of creative thinking (Runco & Acar, 2012). DT involves generating novel and appropriate responses to open-ended idea generation tasks. However, the basic cognitive processes involved in DT such as memory retrieval are far from understood (Volle, 2018). Recent research highlights both benefits and costs of semantic memory retrieval for creative thought (Beaty, Christensen, Benedek, Silvia, & Schacter, 2017; Hass, 2017a, 2017b; Kenett, 2019). Here, we borrow a classic experimental paradigm from cognitive science research on semantic memory—the fan effect (Anderson, 1974)—to further characterize the impact of semantic memory structure on creative idea generation.

A fan effect is an increase in response time (or error rates) on a recognition test with an increase in the number of associations with a concept in a memory probe (Anderson, 1974). According to Anderson and Reder (1999), the associations among concepts cause interference (i.e., the more association links fanning from a concept node, the greater the interference). Such interference occurs at retrieval (Anderson & Reder, 1999). Thus, during divergent thinking, the fan size of the target cue may relate to interference in retrieving creative responses. This hypothesis fits strongly with the associative theory of creativity.

According to the associative theory of creative thinking, creativity involves the connection of weakly related, remote concepts into novel and applicable concepts (Mednick, 1962). The farther apart the concepts are in semantic space, the more creative the new combination will be. For this new combination to be applicable (i.e., to make sense) a broad body of knowledge is required. While this theory is still debated, the importance of associative abilities in creative processing has been demonstrated (Benedek, Könen, & Neubauer, 2012). Furthermore, recent computational studies have provided further support for how individual differences in creative ability relates to differences in semantic memory structure (Kenett, 2019; Kenett & Faust, 2019).

However, more recent theories have argued that creative thinking is more broadly related to an interaction between semantic memory structure and cognitive control processes that facilitate guided search throughout memory. For example, Beaty and Silvia (2012) examined how fluid intelligence (*Gf*) relates to the serial order effect – the tendency for ideas to become increasingly more original over time during a DT task (Christensen, Guilford, & Wilson, 1957; Hass & Beaty, 2018). The authors found that participants scoring high on *Gf* showed less of a serial-order effect. That is, high *Gf* scores were associated with greater originality earlier in participants' response. Thus, the authors argue for an executive control process operating on semantic memory that facilitates avoidance of high-frequency concepts (i.e., low-originality). Hass (2017b) applied computational approaches to demonstrate that the semantic similarity of participants' DT responses non-linearly decreases as a function of response order. Furthermore, this study found that the semantic similarity of initial DT responses was lower for participants with higher *Gf* scores.

In the current series of studies, we present results from an ongoing project, where we examine for the first time the role of fan size on DT responses. As the fan effect is considered to be related to activation of multiple associations to a

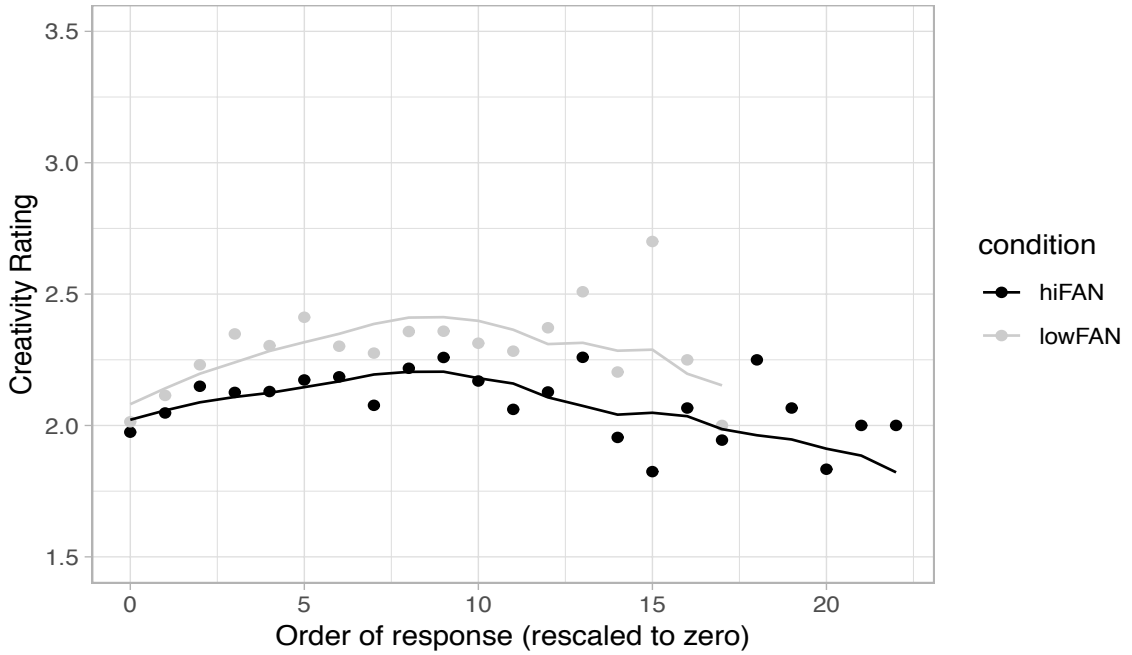

Fig. 1: Average creativity rating as a function of response order. The first response was rescaled to zero for the purpose of growth modeling. Lines represent fitted values for each condition based on the multilevel growth model.

concept that leads to interference, we predict that high-fan cues will lead to a higher number of DT responses but lower overall originality of these responses. Furthermore, we predict that fan size will interact with the serial order effect (Study 1) and with individual differences in *Gf* (Study 2).

Study 1

In Study 1, we sought to test for the existence of a fan effect in the context of performance on the Alternate Uses Task (AUT), a widely used assessment of DT (Runco & Acar, 2012). To this end, we assessed whether the quantity and creative quality of DT responses varied as a function of AUT cue association set size. We selected cue words for the AUT (i.e., common objects) with low- and high-fan size based on free association norms (Nelson, McEvoy, & Schreiber, 2004). Because high-fan cues are presumably embedded within denser semantic networks of highly-related concepts compared to low-fan cues, we hypothesized that participants would generate more AUT responses (i.e., higher fluency) but that this performance benefit would come at the cost of creative quality (i.e., lower originality) due to interference from salient concepts.

Participants

Fifty-five participants were recruited for the study via Amazon Mechanical Turk (AMT; Buhrmester, Kwang, & Gosling, 2011). Participants were offered $4.00 compensation for completion of all 10 tasks. No participants' work was rejected (i.e., all 55 workers were paid), however, a pre-analysis screening procedure identified 14 participants that failed to respond to all 10 cues and 1 participant that provided clearly random responses, and thus did not follow directions. The final sample size for analysis was 40 (30 female) with an average age of 38.1 years (SD = 12.07). A large majority of the sample identified as White/Caucasian (92.5%) with the remaining 7.5% identifying as either African American or "other". This study was approved by Jefferson University institutional review board.

Materials

Stimuli. We constructed low- and high-fan cues to be used in the DT task. Low- and high-fan cues were selected from the University of South Florida free association norms database, that includes norms for 5,000 cue words (Nelson et al., 2004). Importantly, for each of these cue words, the database lists the number and types of different associative responses that were generated to these cue words. The number of associative responses to a cue word was used as a proxy of fan size of the cue word (i.e., cue set size). Out of the 5,000 cue words, cue words of concrete objects that can be used in a DT task were manually selected. Finally, a list of five low-fan (clock, fork, lamp, lens, pen) and five high-fan (soap, rope, stick, marble, balloon) cues were selected. These cue words were matched on key linguistic variables: *frequency* (low-fan $M = 16.4$, $SD = 3.29$; high-fan $M = 21.3$, $SD = 10.97$; $t(8) = 1.00$, $p = .35$) and *concreteness* (low-fan $M = 5.88$, $SD = .67$; high-fan $M = 6.09$, $SD = .23$; $t(8) = .66$, $p = .53$). Critically, the average set size of the high-fan cues ($M = 22$, $SD = 1.22$) was significantly greater than the average set size of the low-fan cues ($M = 6.6$, $SD = 1.51$; $t(8) = 17.67$, $p < .001$).

Divergent thinking task. For each of the ten cue words (low- and high-fan), participants had three minutes to generate as many alternative uses as possible. Two main measures were computed from participants DT performance: originality and

fluency. For each response, *originality* was defined as the average of the originality ratings across independent raters for that response and *fluency* was defined as the sum of responses; we also logged *inter-response time* (the time between the first key strokes of successive responses) and the *order* of entry of each response. Participant-level variables were fluency and composite originality score (i.e., the average of the originality scores per person per prompt).

Procedure

A custom web application was created for administering the experimental tasks (Hass & Beaty, 2018). The interface consisted of an instructions page and a response-collection interface. The instructions page appeared before both blocks of trials (low- and high-fan) and, after reading instructions, participants proceeded to the tasks using a navigation button. The task interface appeared in an 800x600 pixel window and consisted of a text-display, which contained the object prompt for that trial and a text-entry field. The text-entry field allowed participants to edit responses prior to entering them and moving on to the next. Javascript code saved the first key press per response, the time at which the participant entered the response (by pressing ENTER or RETURN), and the text of the response itself. When ENTER was pressed, the text-field was cleared, and participants were not allowed to view previous responses.

First, participants provided consent to participate in the experiment. Following consent, participants were presented with an overall description of their task: that they would be prompted to generate ideas about specific prompts, along with some information about how long it would take, and that they should be ready to type. Participants then completed a practice trial to become acclimated to the typed entry interface which involved typing the names of colors that they knew for 30 seconds. Upon completion of practice, the first set of experimental trials started. They were informed that there would be five trials, each with a different object, and each lasting 3 minutes each. They then pressed a navigation button to continue. The order of trials within blocks and block presentation were randomized, and participants had a short break between blocks. Finally, participants completed a short demographic survey.

Results

Participants' responses were rated for originality on a 5-point scale designed for cognitive studies of DT (Hass, Rivera, & Silvia, 2018) by two research assistants and one AMT worker not involved in the experiment. Inter-rater reliability (ICC(2,3)) ranged from fair to good across the 10 cues (M = .47, SD = .15).

Participants generated a significantly higher number of responses to high-fan prompts (M = 9.17, SD = 3.42) than to low-fan cues (M = 8.1, SD = 3.1), $t(39) = 3.84$, $p < .001$). Furthermore, high-fan responses were rated significantly less original (M = 2.67, SD = 0.26) compared with low-fan responses (M = 3.03, SD = 0.26), $t(39) = 6.47$, $p < .001$. Together, these findings suggest that while high-fan cues afford more associative links (i.e., increased fluency), the effect may interfere with generating original responses (i.e., decreased originality) to them.

To investigate temporal effects of the fan manipulation, two response-level analyses were performed. First, inter-response times (IRTs) were compared across the two conditions with a mixed-effects regression model. In order to conform to model assumptions (namely normally distributed residuals), IRTs were log-transformed and regressed on 1) a fixed-effect of condition (low- vs. high-fan), 2) a random effect of participant, and 3) a random effect of cue. Though mean IRTs were shorter in the high-fan condition (M = 14.50s, SD = 13.99s) compared with the low-fan condition (M = 16.14s, SD = 16.63s), the fixed effect in the log-IRT model was not significant (b = .0004, $p = 0.55$).

Next, the relationship between response order and creativity rating was examined with a mixed-effects model. Prior results have illustrated a curvilinear relationship between serial order and creativity (Hass & Beaty, 2018) so linear and quadratic serial order terms were entered into the model. Interactions between condition (low- vs. high-fan) and both of the serial order terms were also modeled, along with random effects of participant and cue. There were significant linear (b = 0.039, $p < .001$) and quadratic trends (b = -0.016, $p = .02$), but the overall difference between low- and high-fan originality was not preserved in this model (b = 0.062, $p = .61$). Additionally, there was no difference in either the linear (b = 0.025, $p = 0.15$) or quadratic slopes (b = -0.016, $p = .23$) across the fan conditions (Fig. 1).

Discussion

The associative theory of creativity implicates spreading activation across concepts within semantic networks to generate novel ideas (Mednick, 1962). However, little is yet known about the benefits—and potential costs—of semantic memory in creative cognition. Here, we identify such benefits and costs of semantic knowledge to performance on a divergent thinking task. Participants generated more responses during the AUT when using high-fan cues compared to low-fan cues, suggesting that greater semantic content benefits ideational fluency. This benefit, however, came at the cost of originality: participants generated ideas that were rated as less original in the high-fan condition. This finding is consistent with the notion that salient conceptual information (e.g., high-fan associations) can constrain creative thought by acting as a source of interference that must be inhibited to establish more remote conceptual combinations (Beaty et al., 2017; Chrysikou, 2019). In sum, the results of Study 1 suggest that the structure and content of semantic knowledge impacts the quality and quantity of ideas generated during divergent thinking.

Study 2

In Study 2, we sought to replicate and extend the findings from Study 1. Specifically, we employed the same

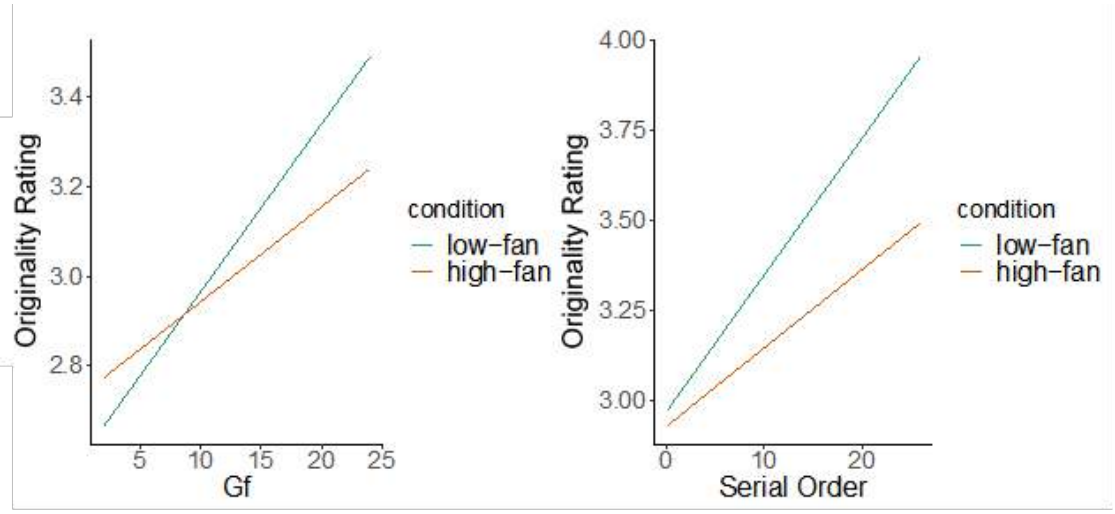

Fig. 2: Interaction effects between serial order and fan effect (left) and Gf and fan effect (right) on participant's originality ratings of their DT responses.

experimental paradigm—varying cue set size across AUT i tems—and further examined potential interactions with fluid intelligence (*Gf*), an individual difference variable with established links to divergent thinking (Beaty & Silvia, 2012). Although *Gf* has been shown to predict the creative quality of DT respons es, the cognitive contribution of *Gf* to creative performance remains largely uncharacterized. One possibility is that *Gf* supports inhibitory control processes, consistent with its strong association with cognitive control (Kane, Hambrick, & Conway, 2005) Thus, *Gf* may be more relevant for high-fan idea generation via the inhibition of salient conceptual knowledge (Beaty & Silvia, 2012). On the other hand, *Gf* may support low-fan idea generation by facilitating spreading activation within a relatively sparse semantic space. In addition to examining the role of *Gf*, we further probed temporal dynamics of the fan effect as a function of cue set size.

Participants

One hundred thirteen participants (50 females) were recruited from AMT. The average age of participants was 37.71 years (SD = 10.49). All participants were fluent in English and the majority (58%) were Caucasian. African Americans comprised 11% of the sample, Asian Americans comprised 5% of the sample, Hispanic Americans comprised 8% of the sample, Native Americans comprised 14% of the sample, while the remainder identified ethnicity as "other". Participants received $5.50 for their participation. Thirty-three participants were excluded from the analysis for failure to successfully complete all tasks or providing nonsensical answers to open-ended questions. The final sample size for the current analysis was $N = 83$. This study was approved by Jefferson University institutional review board.

Materials

Stimuli. The stimuli used in Study 2 were identical to those used in Study 1.

Divergent Thinking. The DT task used in Study 2 was identical to that used in Study 1.

Fluid Intelligence. Based on Kenett et al. (2016), *Gf* was assessed via three separate tasks: 1) The series task from the Culture Fair Intelligence Test (CFIT) which involves choosing an image that correctly completes a series of images (13 items, 3 min); 2) A letter-sets task, which presents a series of four-letter combinations and requires people to determine which set does not follow a rule governing the other four (16 items, 4 min); and 3) A number-series task in which participants complete a sequence of numbers by discovering a guiding rule (15 items, 5 min). To compute a general *Gf* score, we used principal component analysis. This composite *Gf* score was constructed as the sum of the multiplication of each independent *Gf* score by its weight of the first unrotated principal component (Kenett et al., 2016).

Procedure

The DT task was run similarly as in Study 1 and the *Gf* tasks were run via Qualtrics (www.qualtrics.com). Upon providing electronic consent, participants were presented with an overall description of their tasks: that they would be prompted to generate ideas about specific prompts for approximately 30 minutes, and they would then complete some IQ-based tasks for another 20 to 30 minutes. Participants then completed a practice idea-generation trial to become acclimated to the typed entry interface (naming colors). Upon completion of practice, the first set of experimental trials began. The order of trials within blocks and block presentation were randomized, and participants had a short break between blocks. Finally, participants completed a short demographic survey.

Results

Three raters scored responses for originality using the same scale used in Study 1 (Hass et al., 2018). Inter-rater reliability, assessed with interclass coefficients ICC(2,3), was generally high across the 10 cues (M = .68, SD = .12).

Analyzing the fluency and originality of participants responses, our results replicate the findings of Study 1: Participants generated a significantly higher number of responses to high-fan cues (M = 7.56, SD = 3.82) than to low-fan cues (M = 6.33, SD = 3.04), $t(82) = -4.64$, $p < .001$. Furthermore, high-fan responses were rated significantly less original (M = 3.04, SD = .33) compared with low-fan responses (M = 3.12, SD = .44),, $t(82) = 2.14$, $p < .035$. Together, these findings suggest that while high-fan concepts afford more associative links, these links may interfere with establishing more remote conceptual combinations.

Next, the relationship between response order and creativity rating was examined via a mixed-effects model. In our full model, *Gf*, fan, and serial order were assigned as independent measures, and the originality ratings as the dependent measure. Interactions between fan and *Gf*, interaction between fan and serial order, and interaction between *Gf* and serial order terms were also modeled, along with random effects of participant and cue (Table 1). We first compared this model to a model that only included the random effects and found that this model improved the fit to originality ratings, χ^2 (6, N = 83) = 105.52, $p < .001$. Specifically, we find a significant positive relation between each of the three main variables (*Gf*, Fan, and Order) on participant's originality scores. Thus, we replicate and strengthen the results found in Study 1, and replicate previous findings on the effect of *Gf* on DT (Beaty & Silvia, 2012). As for the effect of the interaction terms, we found significant negative relations between both interaction terms (*Gf**Fan and order*fan) on participant's originality scores (Fig. 2). However, due to high collinearity between the serial order variable and the interaction of *Gf* and serial order variable (r = -.71), the interaction effect of serial order and *Gf* was not significantly related to originality scores in this model.

Table 1: Linear mixed effect model of originality

Fixed Effects	*B*	SE	*p*
Intercept	2.28	0.18	< .001
Gf	0.05	0.01	< .001
Fan	0.19	0.10	.05
Order	0.05	0.01	< .001
*Gf**Fan	-0.02	0.00	< .001
Order*Fan	-0.02	0.01	< .001
Random Effects	Name	Variance	SD
Participant	Intercept	0.09	0.30
Cue	Intercept	0.01	0.09
Residual		0.65	0.80

Full model: Originality ~ *Gf* + Fan + Order + *Gf**Fan + Order*Fan + *Gf**Order (1|participant) + (1|cue)

Discussion

Study 2 replicated the findings of Study 1 and extended them by examining individual differences in *Gf* (Beaty & Silvia, 2012). As in Study 1, we found that, compared to low-fan cues, high-fan cues yielded increased fluency but decreased originality. Study 2 further examined temporal dynamics of this fan effect. Specifically, we replicated the serial order effect in divergent thinking—the tendency of idea originality to increase over time (Hass & Beaty, 2018)—and showed how this serial order effect interacted with both fan size and *Gf*. Although the 3-way interaction between serial order, fan size, and *Gf* was not significant, due to exceedingly high collinearity between these independent variables, we found that interaction effects of *Gf**Fan and Order*Fan explained significant variance in creativity ratings.

General Discussion

Divergent thinking tasks are widely used to assess creative thinking, but little is known about the basic cognitive processes underlying their performance. In two studies, we borrowed a classic experimental manipulation from cognitive research on semantic memory known as the fan effect (Anderson, 1974)—the tendency for increasing semantic associations to interfere with memory performance—and show that it similarly (but differentially) impacts the quality and quantity of divergent thinking responses. In Study 1, we found that although participants generated significantly more responses using high-fan cues compared to low-fan cues (i.e., increased fluency), these responses were rated as significantly less original. In Study 2, we replicated these findings and extended them by showing that the fan effect for originality varied as a function of individual differences in *Gf*: as *Gf* increased, so did originality ratings in the low-fan condition compared to the high-fan condition. Taken together, the results extend recent work on the dynamics of memory retrieval and cognitive control during creative idea generation (Benedek & Fink, 2019).

These findings inform a growing literature on the role of cognitive control in divergent thinking. Consistent with past work (Beaty & Silvia, 2012; Benedek, Jauk, Sommer, Arendasy, & Neubauer, 2014), Study 2 found that *Gf* predicted the creative quality of divergent thinking responses. Critically, we found that *Gf* interacted with the fan effect: higher-*Gf* benefited low-fan originality. From a semantic network perspective, the low-fan cues may be embedded in a less densely connected network, potentially blunting spreading activation to remote concepts due to less semantic scaffolding (Mednick, 1962). Thus, one possibility is that *Gf* compensates for such sparse semantic connectivity by driving search processes in a top-down fashion. In other words, when less is known about an object, cognitive control may facilitate strategic and deliberate conceptual combination.

On the other hand, one might predict *Gf* to benefit high-fan originality. Because the high-fan cues may be embedded within a relatively denser network of semantic associations—as reflected by higher ideational fluency in the high-fan

condition across both studies—these associations may have induced interference due to high salience and semantic relatedness. Prior research suggests that salient concepts can disrupt idea generation by priming what is already known and thus not original (Beaty et al., 2017). Thus, cognitive control could benefit high-fan cues via inhibitory mechanisms, i.e., suppressing dominant responses and redirecting search processes (Beaty & Silvia, 2012). Notably, however, Study 2 assessed *Gf*—a proxy measure of general cognitive control which shows strong correlation with executive processes such as inhibitory control (Kane et al., 2005) Future work might resolve this question by examining the contribution of specific executive functions to idea generation under similar semantic constraints.

The present research has potential implications for understanding the role of semantic knowledge in creative cognition (Kenett & Faust, 2019). Across both studies, we found a dissociation between the quantity and quality of ideas as a function of fan size: more ideas are generated when more was "known" about an object—as indexed via semantic associations—but these ideas were deemed to be of less creative quality. An interesting direction for future research would be to explore the extent to which this effect extends beyond "domain-general" creative performance to specific creative domains. Another outstanding question concerns whether the organization of semantic knowledge can be optimized for creativity through learning. We suspect that high creative ability is characterized by extensive domain-relevant knowledge, and superior access to that knowledge, via its hierarchical organization and top-down retrieval.

Abstract

How we mentally represent spatial relations is known to have effects on cognitive processes such as inferences, co-speech gesture, or memorizing. In addition, spatial positions often serve as metaphors that carry valence. For instance, "moving up the social ladder, "getting it right", or being "in front" feels certainly better than "moving down", "having two left feet", or "lagging behind". Spatial position, however, depends on perspective, more concretely on which frame of reference (FoR) one adopts—and hence on cross-linguistically diverging preferences. What is conceptualized as "in front" in one variant of the relative FoR (e.g., *translation*) is "behind" under another variant (*reflection*), and vice versa. Do such diverging conceptualizations of an object's location also lead to diverging evaluations? We tested this with speakers of German, Chinese, and Japanese using an Implicit Association Test (IAT). Data from two studies suggest that across languages the object "in front of" another object is evaluated more positively than the one "behind", and that both location and evaluation depend on the adopted FoR. In other words: linguistically imparted FoR preferences appear to impact on evaluative processes.

Keywords: spatial cognition, frames of reference, valence, IAT, cross-linguistic comparison

Introduction

Space is of fundamental importance, not only for our very existence and survival—and hence for core cognitive activities devoted to them such as orientation and navigation (e.g., Hutchins, 1983; Golledge, 1999)—but also as a source of metaphors for grasping more abstract or elusive concepts such as number or time (Bender & Beller, 2014; Dehaene, 2003; Núñez & Cooperrider, 2013; Walsh, 2003). For instance, preferences for spatial representations seem to provide structure for how we represent temporal relations (Boroditsky, 2000; Boroditsky & Gaby, 2000).

A number of expressions points to the possibility that spatial representations may also provide metaphorical structure for evaluative judgments, especially along the vertical axis and the lateral axis, with *up* and *right* being predominantly linked to positive valence, and *down* or *left* to negative valence in various cultures (Keating, 1995; Lakoff & Johnson, 1999; Meier & Robinson, 2004). Expressions such as "being at the forefront" versus "lagging behind" do hint at corresponding associations along the sagittal axis as well.

The relationship between space and valence, however, is more complex than these examples suggest, and may be mediated by additional factors. For instance, the more positive evaluation of objects to the right than of those to the left is reversed in left-handers (Casasanto, 2009, 2011), and lateralization in terms of handedness even overrides strong cultural conventions (de la Fuente, Casasanto, Román, & Santiago, 2015). Yet, handedness only affects people's embodied experiences of their own right and left; it does not determine whether they mentally represent an object as being located to the right or left. Evaluations of objects are therefore directly dependent on location in space: If an object changes location, its evaluation changes. But what if it is not location in space that changes, but rather the mental representation of this location? Is the valence of objects also affected if relative positions themselves are conceptualized differently depending on a person's preference for referring to these positions? We addressed this question with a focus on the sagittal axis, for which space-valence associations have not been explored. At the same time, it is the only axis along which the conceptualization of location is affected in distinct ways by linguistic and cultural conventions and hence may vary in important ways (Beller, Singmann, Hüther, & Bender, 2015; Majid, Bowerman, Kita, Haun, & Levinson, 2004).

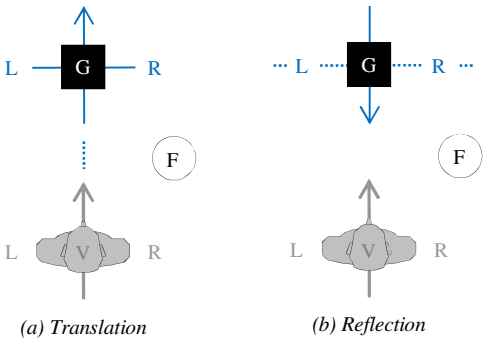

Figure 1:
Two variants of the relative FoR (Levinson, 2003); F: figure; G: ground; V: viewpoint of the observer; L/R: left/right

Indeed, what is assigned as FRONT or BACK along the sagittal axis depends on the frame of reference (FoR) one adopts. While all FoRs are coordinate systems that help to locate one object (the figure) in reference to another object (the ground), they differ with regard to where they are anchored (Levinson, 2003)[1]. The relative FoR relevant for our study is anchored in an observer. Therefore, to locate the figure in reference to the ground, the observer's coordinate system needs to be transferred to the ground. Crucially, this can be done in different ways—by shifting it to the ground (*translation*) or by mirroring it in the ground (*reflection*)—leading to opposing assignments of FRONT and BACK for the very same arrangement (see Figure 1): Whereas translation implies a further-away object to be conceptualized as "in front of" the ground and a nearer object as "behind", reflection implies the nearer object as "in front" and the further-away object as "behind".

Whether these diverging assignments of FRONT and BACK lead to diverging evaluations is the question we sought to answer. We assumed that, regardless of FoR preference, speakers of widely different languages evaluate objects more positively when conceptualizing them as "in front of" another object than those conceptualized as "behind". Since the object conceptualized as "in front" depends on FoR preference, speakers with a preference for *translation* should evaluate the further-away object more positively, whereas speakers with a preference for *reflection* should evaluate the nearer object more positively.

Study 1

In view of the cross-linguistic distribution of the relative FoRs, as obtained from language elicitation tasks (Beller & Bender, 2017; Beller et al., 2015), we recruited native speakers of German in which reflection is prevalent, and of Chinese and Japanese in which translation is more frequent. Introducing a novel approach into this field of research, we use an *Implicit Association Test* (IAT; Greenwald, McGhee, & Schwartz, 1998) to assess the positive versus negative valence of objects that the participants conceptualized as being "in front of" versus "behind" another object, depending on their preferred FoR.

Method

Participants The sample consisted of 43 native speakers of German (28 female; mean age 23 years, range: 18-35), 40 native speakers of Chinese (27 female; mean age 27 years, range: 22-38), and 40 native speakers of Japanese (22 female; mean age 19 years, range: 18-34). The Chinese participants were born in China to monolingual parents, had been living in Germany for 2.8 years on average (SD = 1.9), and reported excellent proficiency in Chinese (M = 5.0, SD = 0.2) compared to moderate levels of German (M = 3.1, SD = 1.3) and English (M = 3.5, SD = 0.9) on 5-point-rating scales. Data collection took place in Germany (for German- and Chinese-speaking participants) and Japan (for Japanese-speaking participants), and was conducted in the participants' mother tongue by native speakers of German, Chinese, or Japanese, respectively, as experimenters. Participation was voluntary, and was rewarded either with course credit or with 2 Euros or 400 Yen, respectively.

Materials In the IATs, participants discriminated stimuli according to either valence or space. For the standard valence discrimination task, six positive nouns (*health, happiness, smile, joy, peace, friend*) and six negative nouns (*agony, suffering, stench, mishap, illness, war*) had to be categorized as positive or negative. For the spatial discrimination task, twelve schematic drawings of two neutral objects were used. The objects were arranged on the front/back axis and were distinguishable by shape and color (blue/green). Counterbalanced across participants, the objects of one color were singled out as those to be categorized as "in front of" or "behind" the objects of the other color. If, for instance, the target color was green,

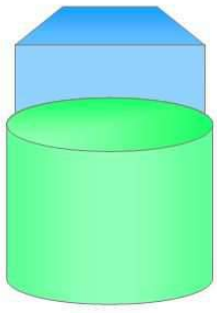

Figure 2:
Example of spatial stimuli used in Study 1

[1] Alternative terminologies are proposed, for instance, by Bohnemeyer and O'Meara (2012) and by Grabowski (1999).

Table 1: Task sequence and example of response key assignment.

			Example of response key assignment	
Block	*N* of trials	Task	D-key	L-key
1	26	Spatial discrimination	behind	in front
2	26	Valence discrimination	negative	positive
3	28	Initial combined task	behind/negative	in front/positive
4	52	Initial combined task	behind/negative	in front/positive
5	26	Reversed spatial discrimination	in front	behind
6	28	Reversed combined task	in front/negative	behind/positive
7	52	Reversed combined task	in front/negative	behind/positive

participants preferring translation (vs. reflection) would categorize the green cylinder in Figure 2 as "behind" (vs. "in front of") the blue cube.

Procedure The IATs were implemented as standard seven-block IATs (for details, see Table 1): Participants first completed two single-task practice blocks (one on spatial and one on valence discrimination). In Blocks 3 and 4, the two tasks were combined by mapping the four categories to two response keys (e.g., *in front*/*positive* on one key and *behind*/*negative* on the other). Block 5 was again a single-task block on spatial discrimination, but with the response key assignment reversed. In Blocks 6 and 7, this task was combined with the valence discrimination task of Block 2, thus mapping *behind*/*positive* on one key and *in front*/*negative* on the other.

The order of combined tasks was counterbalanced across participants (see Nosek, Greenwald, & Banaji, 2007). Stimuli were presented on a vertical computer screen, and responses were given by pressing the D- or L-key on the keyboard[2]. The intertrial interval was 500 ms. All blocks used warm-up trials with additional stimuli (excluded from the analyses), consisting of one trial per category that appeared within each block. Stimuli were presented randomly with the restriction that in the combined-task blocks, spatial and valence stimuli were presented in strictly alternating order.

The IAT effect is defined as the performance difference between the crucial blocks of combined tasks, and is interpreted as revealing the direction and strength of an association (here, between the space and valence categories). Typically, participants respond faster (and more accurately) when two associated categories share a response key than when they do not (Teige-Mocigemba, Klauer, & Sherman, 2010). Accordingly, if *in front* is evaluated more positively than *behind*, then responses should be faster in the *in front*/*positive*—*behind*/*negative* mapping than in the *in front*/*negative*—*behind*/*positive* mapping. If, by contrast, *in front* is perceived more negatively than *behind*, the response pattern should be reversed; and if no such link exists, response speed should not differ between mappings.

For all participants, IAT effects were coded such that positive values corresponded to the expected evaluation of *in front* as more positive than *behind*, independently of whether participants adopted translation or reflection to conceptualize where the target object is located. Assuming that all our participants evaluate objects more positively when conceptualizing them as "in front of" (than "behind") another object, we expected positive IAT effects. These effects may differ in size between samples, as there is no reason to assume that the space/valence associations should be of the exact same strength across cultures. What should differ significantly, subject to FoR preferences, is the object that is evaluated more positively: the further-away object under translation, and the nearer object under reflection.

Which of the two variants of the relative FoR a participant preferred was determined by assessing whether the figure presented in the IAT's practice block of the spatial discrimination task was categorized based on translation or reflection in the majority of trials. This assessment was necessary because adoption of a specific FoR is not determined by language, but based on a combination of (sub-)cultural conventions and individual preferences (Beller et al., 2015; Grabowski & Miller, 2000; Hill, 1982), and should therefore be gleaned from each participant's actual spatial discrimination decision.

Results and discussion

Using Tukey's (1977) criterion, we first examined whether any participant was an extreme outlier in terms of mean response latency in the combined tasks (i.e., with values three times the interquartile range below the first or above the third quartile). This led to the exclusion of two German participants, three Chinese participants, and five Japanese participants. Among the remaining participants, reflection was preferred by all 41 German participants (100%), by 28 Chinese participants (76%), and by 34 Japanese participants (97%), whereas translation was preferred by nine Chinese

[2] Keys were placed on the lateral instead of the sagittal axis to prevent confounding the very data we were interested in, namely on how FRONT and BACK are assigned along the sagittal axis.

Table 2: IAT effects in Study 1 and Study 2.

Study	Sample (*N*)	*M* (*SD*)	95% CI	*t*	*p*	Cohen's d_{D6}
Study 1	German (41)	231 (230)	[158, 303]	7.73	<.001	1.21
	Chinese (37)	146 (284)	[51, 241]	3.07	.004	0.50
	Japanese (35)	167 (207)	[105, 236]	5.48	<.001	0.93
Study 2	German (43)	292 (228)	[222, 362]	11.59	<.001	1.77
	Chinese (48)	153 (309)	[64, 243]	2.54	.015	0.37

participants (24%) and one Japanese participant (3%). Consistency in FoR adoption across the stimuli of the spatial discrimination task was high for all three samples and across FoR preferences, with $M > 94\%$ in each sub-group.

As recommended by Greenwald, Nosek, and Banaji (2003), IAT effects were calculated using the D6 scoring algorithm (used for inferential statistics only; for ease of interpretation, descriptive statistics are based on raw latencies). As expected, IAT effects were significant in all three samples of Study 1, $M \geq 146$ ms, $t \geq 3.07$, $p \leq .004$, indicating considerably faster responses to the *in front*/*positive*—*behind*/*negative* mapping than to the reversed mapping (Table 2).

Importantly, participants' evaluation of *in front* as more positive than *behind* was independent of their preferred variant of the relative FoR. Recall that nine of the 37 Chinese participants adopted translation. IAT effects for these participants were of the same size as those for participants preferring reflection, $t(35) = 1.06$, $p = .298$.

Participants thus evaluated *in front* more positively than *behind*—irrespective of their native language or cultural background. For the quarter of the Chinese participants preferring translation over reflection, the reversal of which object is conceptualized as "in front of" the other involved a corresponding reversal of evaluation of one and the same object: Further-away objects were more positive than nearer objects for participants preferring translation, but more negative for participants preferring reflection.

While the results of Study 1 are basically straightforward, the proportion of translational references among the Chinese- and Japanese-speaking participants was lower than anticipated. One reason could be that the nearer object partly occluded the further-away object, which may have highlighted the former at the cost of the latter (hence privileging reflection; cp. Bennardo, 2000; Grabowski, 1999; Hill, 1982). In addition, partially occluded objects may be devalued *a priori*. Since it was always the further-away object that was partially occluded, devaluation may have contributed to the more negative evaluation of this object by the majority of participants who preferred reflection and hence categorized the partially occluded further-away object as *behind*.

Study 2

To exclude partial occlusion as an alternative account, we repeated Study 1 with new spatial stimuli.

Method

Participants The new samples consisted of 50 native speakers each of German (35 female; mean age 22 years, *range*: 18-34) and Chinese (37 female; mean age 25 years, *range*: 18-33). Chinese participants were born in China to monolingual parents, had been living in Germany for 1.6 years on average ($SD = 1.4$), and reported excellent proficiency in Chinese ($M = 5.0$, $SD = 0.2$) compared to moderate levels of German ($M = 2.5$, $SD = 1.0$) and relatively good command of English ($M = 3.8$, $SD = 0.9$) on 5-point-rating scales. Data collection took place in Germany and was conducted in the participants' mother tongue.

Materials and Procedure For the spatial discrimination task, we now used photographs of real objects that were similar to the objects used in Study 1 both in shape and color, but differed in that no object was occluded (see Figure 3). In addition, an observer with the same looking

Figure 3:
Example of spatial stimuli used in Study 2

direction as that of the participant was inserted to emphasize perspective-taking. Apart from this, material and procedure were the same as in Study 1.

Results and discussion

The same exclusion criteria as in Study 1 led to the exclusion of seven German participants and two Chinese participants. Among the remaining participants, reflection was preferred by all 43 German participants (100%) and by 33 Chinese participants (69%), whereas translation was preferred by 15 Chinese participants (31%). Consistency in FoR adoption across stimuli was again high, with $M > 91\%$ in each sub-group.

IAT effects were computed as in Study 1 and were again significant in the two samples, $M \geq 153$ ms, $t \geq 2.54$, $p \leq .015$, indicating faster responses to the *in front*/*positive*—*behind*/*negative* mapping than to the reversed mapping (for details, see Table 2). Again, participants' evaluation of *in front* as more positive than *behind* was independent of their preferred FoR, as indicated by the non-significant difference between IAT effects for Chinese participants adopting translation versus reflection, $t(46) = 0.29$, $p = .773$.

As in Study 1, participants evaluated *in front* more positively than *behind*—irrespective of their native language or cultural background. And again, the reversal of which object is conceptualized as "in front of" the other involved a corresponding reversal of evaluation. Due to the modified stimuli used in this study, partial occlusion of the further-away object can be excluded as an explanation of its devaluation.

General Discussion

Does the way in which we evaluate objects depend also on how we *conceptualize* their location in space, rather than simply on where they *are* located? The work reported here suggests that this is indeed the case. Findings from two studies across three languages and cultural settings (with native speakers of German in Germany, of Chinese in Germany, and of Japanese in Japan) indicate that participants evaluate objects more positively when they conceptualize them as "in front of" another object than when they conceptualize them as "behind". Importantly, this positive evaluation holds for the further-away object when *translation* is adopted, yet for the nearer object when *reflection* is adopted.

The evidence is in line with the metaphor approach, according to which spatial concepts provide structure not only for more abstract domains, but also for evaluative judgments. While associations between space and valence have been described for the vertical axis (Keating, 1995; Meier & Robinson, 2004) and the lateral axis (Casasanto, 2009, 2011; de la Fuente et al., 2015), the present studies show these associations also for the sagittal axis. More concretely, they reveal that phrases such as "being at the forefront" versus "lagging behind" are not mere metaphorical expressions, but reflect a genuinely more positive evaluation of entities located "in front of" other entities. While the strength of this association differs somewhat across samples, with more pronounced effects for German participants than for the two East Asian groups (likely due to different strength of the association across cultures), its direction is the same in all three groups. This evidence is even more compelling in view of the fact that it was obtained with an *implicit* task specifically designed to tap into more automatic, rather than deliberate, processes.

Crucially, however, our findings also indicate that the association between location and valence is subject to linguistic and cultural conventions that affect how location is conceptualized—namely as *in front* or *behind*. Contingent on the adopted FoR, one and the same object in one and the same location may be evaluated as more positive or more negative: Under translation, the further-away object is regarded as the object *in front* and hence evaluated more positively, whereas under reflection, it is regarded as *behind* and hence evaluated more negatively.

In the current study, the proportion of translational references among the Chinese- (and Japanese-) speaking participants was lower than in previous surveys. While this lower proportion is disadvantageous for statistical power, it is not problematic per se, as such preferences are known to be subject to some variation depending on context (cf., Wilke, Bender, & Beller, 2019). A potentially more critical concern could be raised regarding the IAT itself. As this method assesses the link between relative location and valence by mapping category labels onto response keys, it might be suspected that participants could have used the category labels associated with the keys and their correspondence in polarity as a convenient short-cut (De Houwer, 2001; Proctor & Cho, 2006). However, the cognitive processing of stimuli required for the spatial task involved the computation of ternary relations between figure and ground from one's own viewpoint, which renders it unlikely that the observed effects were brought about by effects of labels or polarity only.

In conclusion, while previous work demonstrated that spatial representations have effects on cognitive processing (e.g., Bender & Beller, 2014; Haun, Rapold, Janzen, & Levinson, 2011; Levinson, Kita, Haun, & Rasch, 2002; Majid et al., 2004), here, we show that how we conceptualize the location of entities may even reverse the evaluation of these very entities. As conceptualizations of location are informed by diverging preferences for spatial FoRs across speech communities, their association with non-spatial conceptualizations and evaluations provides a promising new approach to explore effects of language and culture on cognition, which is a topic of key interest across several sub-disciplines of cognitive science. Opening up new avenues for investigation, implicit approaches like the one presented here could make it to the forefront in this contested field.

Abstract

The associative theory of creativity suggests that creative abilities rely on the organization of semantic associations in memory. Recent research has demonstrated that semantic network methods allow testing this hypothesis. The aim of the current study was to investigate the properties of semantic networks at the individual level, in relation to creative abilities. Semantic judgement ratings were used to estimate individual semantic networks, whose topological properties measured by several graph metrics were correlated with individual creativity scores. We found a correlation between the theoretical semantic distance of our stimuli and the relatedness ratings given by the participants, demonstrating the validity of our approach. Importantly, we found a close relationship between creative abilities assessed by an achievement questionnaire and divergent thinking tasks and individual semantic network metrics, replicating and extending previous similar findings.

Keywords: creativity; semantic networks; network science; associative thinking

Introduction

The associative theory of creativity hypothesizes that creative abilities are related to individual differences in the organization of semantic associations in memory (Mednick, 1962). In support of this theory, several findings showed that more creative individuals had less common word associations or a less constrained organization of semantic associations (Beaty et al., 2014; Bendetowicz et al., 2017; Benedek et al., 2012; 2017; Kenett et al., 2014; Rossmann & Fink, 2010; Volle, 2018) and that in brain-damaged patients, rigid semantic associations were associated with poor creative abilities (Bendetowicz et al., 2018; Ovando-Tellez et al., 2019). Thus, the properties of semantic associations play a critical role in the cognitive processes that bring forth original ideas. Recently, computational methods exploring semantic memory structure in creativity are paving the way to uniquely study its role in creativity. One such computational approach is based on network science methodologies (Kenett, 2018; Kenett & Faust, 2019).

Network science is based on mathematical graph theory, providing quantitative methods to investigate complex systems, such as semantic memory, as networks (Siew et al., in press). In semantic networks, concepts or words are represented as nodes that are connected to each other by edges (denoting semantic similarity between concepts). The few studies that have applied semantic networks in the field of creative thinking indicate that studying the properties of semantic networks is a promising approach to explore creativity (Kenett, 2018; Kenett & Faust, 2019). For example, Kenett et al. (2014) investigated the semantic networks of low and high creative participants, based on free associations generated by both groups to a list of cue words. The authors showed that the semantic networks of low creative participants were less connected and more spread out compared to high creative participants.

However, aggregating over participants into groups may obscure individual differences related to creativity. To address this issue, Benedek et al. (2017) developed a new method to estimate individual semantic networks, based on semantic judgment ratings. Participants rated the relations between all possible pairs of 28 cue words, chosen to represent seven different categories. These relatedness ratings served as a proxy to the organization of these cue words in an individual's semantic memory. The authors showed how individual-based semantic network metrics correlated with individual-based creativity scores (Benedek et al., 2017) for specific types of filtered networks. However, in their study, the authors subjectively selected such cue words, and also applied a specific task, the Alternative Uses Task (AUT), to measure creative ability.

The general aim of the current study was to replicate and extend the relationships between the properties of individual semantic networks and creative abilities found by Benedek et al. (2017). Individual semantic networks were estimated using a modified version of Benedek et al. (2017) in which we controlled for the selection of the cue words based on a computational method. Participant's creativity was more extensively assessed via a creativity battery, including the

AUT used in the original study, a problem-solving task, and a creative achievement questionnaire. Specific network metrics of the individual semantic networks were computed and were correlated with the obtained creative scores.

Materials and Methods

Participants

Twenty-three healthy individuals aged between 22 and 37 years (26.96 ± 4.25) were included in the study. Participants were French-native speakers, right-handed with no neuropsychiatric disease. Two participants were excluded from the graph analysis because they rated >70% of word pairs as unrelated. This study was approved by the French ethical committee Sud Mediterrannée IV. Participants gave written consent and were paid for their participation.

General Overview

The study was composed of two parts. In the first part, the associative judgment task (AJT) was devised to estimate individual's semantic networks. The AJT was adapted from Benedek et al. (2017) by constructing new verbal material controlled for linguistic and semantic properties. In the AJT task, participants are asked to rate the semantic relatedness of pairs of words. In the second part, participants performed the AJT and a set of creativity tasks. AJT ratings were used to estimate the individual AJT-based semantic networks and network metrics were correlated with creative scores.

Part 1: The Associative Judgment Task (AJT)

We first used computational methods in order to develop and select a new set of cue words to be used in the AJT, accounting and controlling for semantic and linguistic properties. This was achieved by 1) estimating a large French semantic network, based on a large database of semantic association norms in French, and 2) by selecting a set of cue words, based on the properties of this network.

Creation of a French Semantic Network. To construct the French version of the AJT, we estimated a French semantic network of 1,081 words, based on French verbal association norms (Debrenne, 2011; http://dictaverf.nsu.ru/dictlist). This dataset was collected by asking French native speakers to provide the first word that came to mind after receiving a cue word. We selected words for which at least 400 participants provided a response. The final data contains 1,081 cue words and 26,268 responses from the participants.

The French semantic network was estimated using a network approach developed to analyze free association data (Kenett et al., 2014). According to this approach, each node represents a cue word and edges between nodes represent the association between these nodes. These associations represent the similarity profiles across any pair of cue words, i.e., the overlap of associative responses generated by the sample to each of the cue words.

The network was estimated in the following way: First the associative responses were preprocessed to standardize responses (correction of typos, elimination of non-words and articles, and spelling homogenization). Second, a data matrix was constructed such that each column is a cue word, and each row is a unique associative response. Thus, each cell denotes how many participants generated response *i* to cue word *j*. Third, the correlation between any pair of cue words was calculated using Pearson's correlation. This resulted in a 1,081 by 1,081 matrix where each cell denotes the semantic correlation between node *i* and node *j*. To minimize noise and possible spurious associations, we finally applied the planar maximally filtered graph filter (Kenett et al., 2014). To examine the structure of the networks, the edges were binarized so that all edges were converted to a uniform weight (i.e., 1). This allowed us to compute the shortest path between nodes in the network, serving as the theoretical semantic distance between them (Kenett et al., 2017).

Selection of AJT Stimuli. To select the verbal material to be used in the AJT, we developed a new computational method that allowed us to objectively select words with specific associative and linguistic properties from the French semantic network.

From the French semantic network, hierarchical tree structures were created recursively, using each node as a seed and searching for its neighbors. For each iteration, the neighbors of the neighbor's nodes were searched. In total we performed 4 iterations, considering that Kenett et al. (2017) demonstrated that most participants judged as unrelated the words separated by more than 4 steps in a force choice task. However, this tree procedure generated nodes that were separated by more than 4 steps when they belong to distinct branches, which allowed us to also generate word pairs that will be likely judged as unrelated. To avoid having one central node related to all the others by 4 steps or less, the initial seed node was removed.

The computation returned several solution trees among which one was selected for the AJT task based on the following criteria. First, for experimental reasons, the total number of nodes in the tree was limited to 35, i.e., 595 possible pair combinations between all words that had to be rated by the participants during the experiment. Second, we computed the *theoretical semantic distance* for all possible word pairs in term of the number of steps separating them in all of the trees. We selected the tree that optimized the proportion of pair words separated by 1, 2, 3, 4, or 5 or more steps. The selected tree contained a set of 35 words involving 595 possible word pairs with semantic distances distributed as follow: 10% of 1 step, 18% of 2 steps, 28% of 3 steps, 26% of 4 steps, 15% of 5 steps and 3% of 6 steps.

Part 2: AJT-based networks and creativity

Procedure of the AJT. Participants were presented successively with all the 595 combinations of pairs of the 35 selected words and were asked to rate their semantic relatedness, using a visual scale ranging from 0 (unrelated) to 100 (strongly related). Each trial started with the display of the word pair and a visual scale presented at the center of the

screen. After 2 seconds, the slider appeared in the middle of the scale. Participants could then freely move the cursor on the scale using a mouse and validated their response by a left click. They had to respond within 2 seconds. The final position of the slider in the scale after validation was considered as the semantic relatedness rating (Fig. 1).

In total, participants performed 6 different runs of 100 trials each (except the last run with 95 trials). Each run was composed of 4 blocks of 25 trials and separated by 20 seconds rest periods with a fixation cross. The trials were pseudo-randomly ordered within blocks with the constraint that each block contained a similar proportion of word pairs of each theoretical step. This order was fixed across participants. Before starting the task, participants performed a short practice. In addition, we checked that all participants were familiar with the 35 AJT words.

Relatedness ratings were coded for each participant and values were averaged separately for each theoretical distance and overall (see Fig. 2).

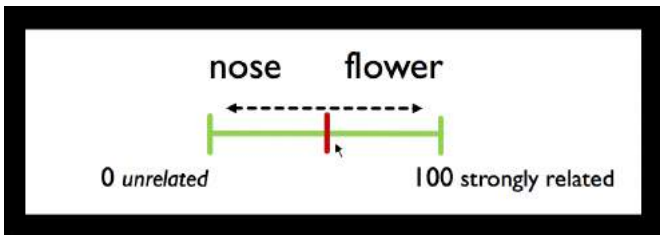

Fig. 1: Schematic representation of an AJT trial.

Estimating AJT-based individual semantic networks. Participant ratings of the word pairs during the AJT task served as a proxy of the organization of these words in their individual semantic network. We created a *n* by *n* matrix in which *n* represented the words used in the AJT task and each matching cell represented the semantic relatedness judgement given by the participant for these two words.

We employed two network filtering methods, one that had revealed significant relationships to creative abilities in previous work (Benedek et al., 2017) and a more conservative method that keeps more information in the network. In the first filtering method, we applied a fixed minimum relatedness threshold to the data and only edges with a weight of at least 50 were maintained. Since the value of 50 is the middle of the AJT scale, only edges corresponding to moderate to high semantic relatedness were kept and set to 1 whereas all the others were removed, resulting in an unweighted undirected network (UUN). In the second filtering method, all the edges were kept with their weight, so it preserved the variability in semantic judgments and resulted in a weighted undirected network (WUN). In this graph, each edge was weighted by the relatedness judgement given by the participant. For both networks, when the participant judged two words as unrelated (rating = 0), the two corresponding nodes had no edges linking them.

Based on the metrics previously related to creative abilities (Benedek et al., 2017; Kenett et al., 2014), we computed the following network metrics to characterize the structure of an individuals' semantic networks: the clustering coefficient (*CC*), the average shortest path length (*ASPL*), the diameter of the graph (*D*), smallworldness (*S*), betweenness centrality (*BC*), and modularity (*Q*). *CC* measures the degree to which nodes in a graph tend to cluster together. *ASPL* measures the average shortest number of steps that separate any pair of nodes, and *D* represents the longest path in the network. S is computed as a ratio between *CC* and *ASPL*. *BC* corresponds to the fraction of all shortest paths in the network that contain a given node. *Q* refers to the percentage of the network that is integrated into small-community structures. Analyses were performed with the Brain Connectivity Toolbox in Matlab (Rubinov & Sporns, 2010).

Creative Assessment. Creativity was assessed using the Combined Associates Task (CAT), the Alternative Uses Task (AUT) and the Inventory of Creative Activities and Achievements (ICAA).

The CAT is an adaptation of the Remote Associates Task (Mednick, 1962) developed by Bendetowicz et al. (2017; 2018) and assesses the ability to form new combinations between remotely associated words. In this task, participants are asked to find a word linked to three cue words with no apparent associations in a maximum of 30 seconds. CAT defines close and distant trials depending on the semantic distance between the cue words and the solution. 40 trials with an equal number of close and distant trials were administered. To quantify the data, four scores were analyzed. *CAT_Solving* is the sum of correct responses. *CAT_Close* and *CAT_Distant* correspond to the sum of correct responses in close and distant trials respectively, and *CAT_Index* corresponds to the difference in performance between distant and close trials, corrected by the averaged performance and was shown to reflect creative processes (Bendetowicz et al., 2017).

During ***the AUT*****,** participants were asked to generate original uses for a common object in three minutes. At the end of the three minutes, the participants selected their two most creative responses, as top-two scoring has been observed to be an effective approach to assess creativity (Benedek et al., 2013; Silvia et al., 2008). This procedure was repeated for three objects: tire, bottle and knife. The corresponding nouns naming the objects were presented on the screen during the 3 minutes. Scores for fluency and originality were assessed for each object. *AUT_Fluency* refers to the total number of ideas generated by the participant and *AUT_Originality* counts the number of infrequent ideas (given by less than 5% of the participants) among the top-two ideas of the participant.

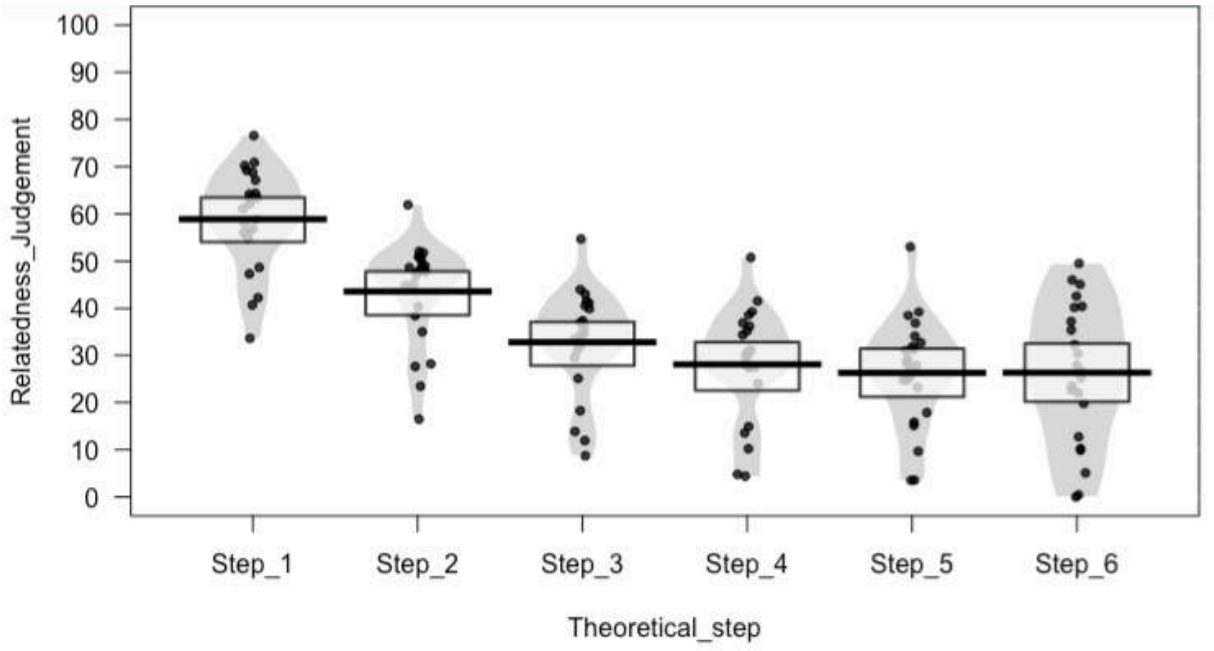

Fig. 2: AJT Task validation. Relatedness ratings of the participants are plotted against theoretical distance. X-axis - Theoretical distance according to the French semantic graph. Y-axis - Relatedness ratings given by the participants. Dots symbolize individual mean response ratings; bars show the mean across participants; white bands correspond to the inference representing the 95% of a Bayesian highest density interval; and the grey area displays the smooth density distribution.

The ***ICAA*** questionnaire was used to quantify everyday creative activities and achievements (Diedrich et al., 2018). This questionnaire contains two parts. In the first part, participants answered questions focused on 8 different specific domains. For each domain, the quantification considered aspects related to how many times the participant had carried out a certain activity over the last 10 years, the level of achievement they have attained in the domain and how many years they have engaged in the specific domain. In the second part, participants described the five most creative achievements in their life. The scores *ICAA_1* (creative activities) and *ICAA_2* (creative achievements) were obtained as the total score for part one and part two respectively.

Results

Relatedness Judgments and Theoretical Semantic Distance

Relatedness ratings within each participant ranged from 0 to 100 indicating that participants used the full scale to rate relationships. Overall mean relatedness ratings across participants ranged from 13.49 to 54.02, with a mean of 33.22 (± 8.66) and median of 34.08. For each participant, we found a significant negative correlation between the relatedness ratings and the theoretical distance ($p < .001$) with a correlation coefficient from -.2 to -.3 (Fig. 2).

AJT-based Network Metrics and Creativity

The network metrics were correlated to the creativity measures using Kendall Tau-b. These correlations were done separately for the WUN and UUN metrics. Fig. 3 shows an illustration of two WUN networks, from a high creative and a low creative participant, chosen among participants with respectively the highest vs poorest scores in both *AUT_Originality* and *ICAA_1*.

Significant correlations were found between several metrics from the WUN networks and creativity scores. *ICAA_1* negatively correlated with *D* ($\tau = -.32$, $p < .05$) and *ASPL* ($\tau = -.34$, $p < .05$) and positively with *S* ($\tau = .32$, $p < .05$). *AUT_Originality* negatively correlated with *D* ($\tau = -.45$, $p < .01$), *ASPL* ($\tau = -.41$, $p < .05$) and *BC* ($\tau = -.39$, $p < .05$) and positively correlated with *CC* ($\tau = .35$, $p < .05$). Similar correlations were found between several metrics from the UUN networks and creativity scores. *ICAA_1* correlated negatively with S ($\tau = -.41$, $p < .05$). *AUT_Originality* negatively correlated with *D* ($\tau = -.51$, $p < .01$), *ASPL* ($\tau = -.44$, $p < .05$), *BC* ($\tau = -.46$, $p < .01$), *S* ($\tau = -.49$, $p < .01$) and *Q* ($\tau = -.38$, $p < .05$). All *p*-values reported above are uncorrected and did not survive an FDR correction.

AJT behavior and Creativity Scores

To test whether creativity also relates more directly to AJT behavioral measures (Rossman & Fink, 2010), Pearson correlations were computed between the creativity scores and AJT relatedness ratings, overall and separately for each

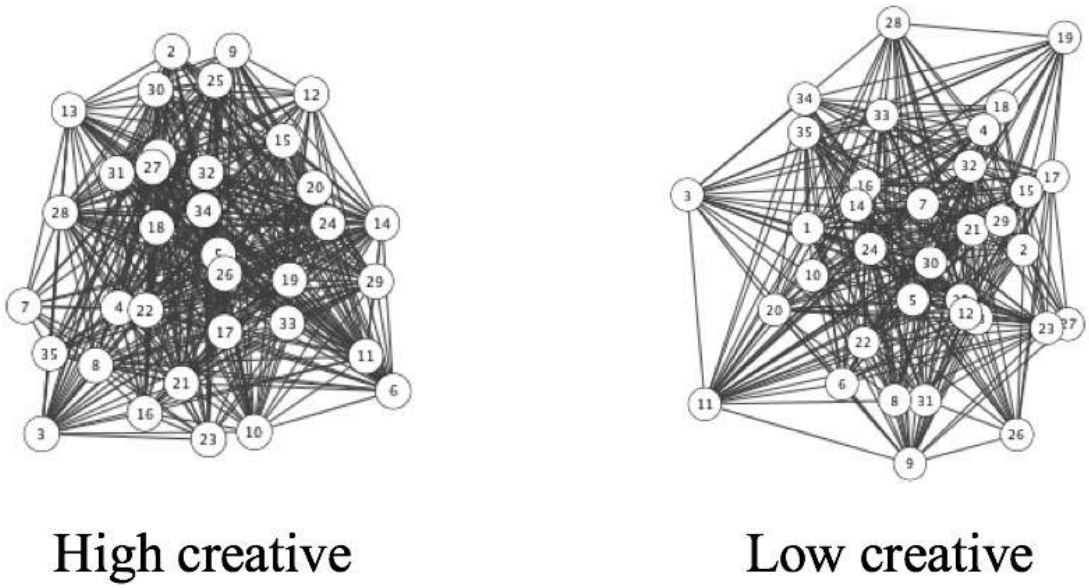

Fig. 3: Example individual semantic networks of a low and high creative participant (weighted undirected networks). Circles represent nodes (single words, labelled as numbers), grey lines represent the edges connecting the nodes, with higher weighted edges having a shorter length representing higher semantic relatedness. The high and low creative participants were chosen among participants with the highest and lowest scores in creativity assessments, respectively (*AUT_Originality* and *ICAA 1*).

theoretical step from 1 to 6. The mean AJT relatedness ratings correlated positively with *AUT_Originality*, $\rho(19) = .54$, $p < .05$: Participants judging word pairs as more related overall produced more original ideas at the AUT task. Correlations with the other creativity scores were not significant.

When analyzed separately for each theoretical distance, AJT relatedness judgement correlated with *AUT_Originality* for word pairs separated by 6 steps, $\rho(19) = .55$, $p < .01$, 5 steps, $\rho(19) = .46$, $p < .05$, 4 steps, $\rho(19) = .46$, $p < .05$, 3 steps, $\rho(19) = .49$, $p < .05$ and 2 steps, $\rho(19) = .56$, $p < .01$. Participants judging theoretically distant word pairs (step >= 2) as more related produced more original ideas at the AUT task. AJT relatedness ratings for close word pairs (1 step apart) correlated positively with *CAT_Solving*, $\rho(19) = .50$, $p < .05$, and *CAT_Close*, $\rho(19) = .55$, $p < .001$: Participants judging theoretically close word pairs (1 step apart) as more related were better at combining word associates and solved more CAT trials. No statistical results survive FDR correction for multiple comparisons.

Discussion

This study aimed to investigate the link between individual differences in the organization of semantic associations and creativity using computational methods based on graph theory. Individual semantic networks were estimated using an adapted version of the method from Benedek et al. (2017) by controlling the selection of the words based on computational methods. To this purpose, we first estimated a unique and large-scale semantic network in French. Next, we developed a method allowing to select a set of words in French while controlling for their semantic distance. Then, the selected words were used in a semantic relatedness judgement task and these relatedness ratings were used to estimate individual semantic networks. Several metrics characterizing the structure of these networks were computed and related to creative assessment scores.

Our results showed that the theoretical semantic distance correlated with the relatedness judgments of the participants, thus converging with the results of Kenett et al. (2017). Theoretical distance relies on the properties of a semantic network estimated from a free verbal association task submitted to a large number of independent volunteers and from the similarity between the generated associates of all cue words. This semantic network allows to measure a theoretical distance as the number of steps separating two nodes in the network. That this measure was strongly related to the subjective similarity judgement of our participants between these cue words validate the use of path length computed on such semantic network as a measure of semantic distance (also converging with results from Kenett et al., 2017). However, it is important to note that while the correlations were highly significant, the Kendall τ coefficients were of moderate size (mean of $\pm$ .22). One possibility would be that the relationship between the theoretical distance and rated distance between selected stimuli may not be linear across the full range of steps. In addition, other factors could impact these subjective relatedness ratings. For instance, subjective ratings showed a high inter-individual variability that could in part be explained by creative abilities, as indicated in the second part of our study.

The next step of the current study consisted of a behavioral experiment aiming to examine the relationships between the organization of semantic memory and creative abilities. The findings showed that some network metrics for both WUN and UUN networks were related to creativity measures including the originality of ideas generated during the AUT (*AUT_Originality*) and the creative activities in life assessed with ICAA (*ICAA_1*). However, those network metrics were not significantly correlated to the number of ideas generated in the AUT (*AUT_Fluency*) and creative achievements (*ICAA_2*) measured with the same tasks, nor to CAT scores.

Indeed, the results showed that participants with more original ideas in the AUT and/or more creative activities in their real life (*ICAA_1*), exhibit WUN networks that are less spread out (shorter *D* and *ASPL*), were more clustered (higher *CC*), showed greater small-world connective properties (higher *S*) and the nodes tended to have a more homogeneous connective role in the network (lower *BC*). Similarly, AJT-based UUN networks were also less spread out with shorter path length, less modular (lower *Q*) and with uniform nodes (lower *BC*) but with reduced small-world properties (*S*) in more creative participants.

Importantly, these findings replicate and expand the results from Benedek et al. (2017) who used UUN networks and showed similar correlations between *CC* and *ASPL* metrics and AUT; we additionally observed correlations between the AUT and other metrics (*BC*, *Q*, *D*). In WUN networks additional correlations were shown between network metrics (*D* and *ASPL*) and *ICAA_1*. These correlations indicate that the organization of semantic memory measured by network metrics is also a relevant factor in real life creativity.

Overall, the current findings suggest that more creative participants exhibit a more clustered and densely connected semantic network whereas less creative participants have a more spread out and fragmented network. These results are in line with the few previous studies that examined semantic memory and creativity (Benedek et al., 2017; Kenett et al., 2014; 2018; Kenett & Faust, 2019). Together these studies strengthen the view that exploring the organization of semantic associations using individual networks is both relevant and valuable for the neuroscience of creativity and support the associative theory of creativity.

Additionally, our method allows us to explore the relationships between AJT ratings and creativity measures. The AJT ratings averaged across all theoretical distances and separately for each theoretical distance greater than 1 was positively correlated with originality in AUT. This finding indicates that participants who produced more original ideas also identified word pairs as more related, especially for pairs of words being theoretically more distant. This result is consistent with Rossmann and Fink (2010) that showed a positive relationship between originality and the evaluated associative distance between unrelated word pairs. These findings suggest that creative people are able to perceive connections between concepts that others may not see. Conversely, the mean AJT rating for theoretically close word pairs (1 step apart) positively correlated with the total number of correct responses in CAT when considering all trials (*CAT_Solving*) or close trials only (*CAT_Close*). Participants who found close links in the CAT also judged theoretically close pairs as highly related. However, contrary to what was expected, the correlations with AJT ratings failed to reach significance when considering distant trials only (*CAT_Distant*) or the difference in performance between distant and close trials (*CAT_Index*). It is possible that distant trials involve additional processes that are less dependent on semantic associations (Bendetowicz et al., 2018). We cannot rule out that the small number of CAT trials used in this experiment may have influenced this result.

Finally, our results indicate that network metrics provide insight why people rate concepts as more or less related and that they are relevant quantitative measures to study creativity. However, statistical analyses revealed that no correlation with creativity scores survived the corrections for multiple comparisons. The small sample size may explain the lack of power, and more participants will be included in this study to address this issue. Nevertheless, the trends in the results and their consistency with previous studies are encouraging. Overall, the findings suggest that exploring individual semantic networks based on a controlled verbal material is a promising approach to study creativity.

Conclusions and Perspectives

To conclude, our data indicate a close relationship between the organization of semantic associations represented by semantic networks and creative abilities. Although the results will need to be confirmed in a larger sample, which is an ongoing project, the current study is consistent with previous studies performed in this field and offers improvements in semantic network methods. Our results are notably in agreement with previous studies that showed a link between creative abilities and the ability to make semantic connections between unrelated concepts. Developing new methods to measure the ability to make new semantic connections is an important challenge to better understand the mechanisms of creative cognition (Benedek & Fink, 2019). The analysis of individual semantic networks is one of the most promising approaches to achieve this goal.

The results of this study also offer interesting hypotheses to test regarding the brain substrates that underlie creative abilities. For instance, the same paradigm can be combined with functional MRI to explore how brain network activity and connectivity covary with the ability to connect distant concepts as measured by semantic network metrics. Moreover, graph theory can be used to study how brain network connectivity relates to the organization of semantic networks in the context of creativity.

Finally, the current study provides valuable insight regarding the fruitfulness of the newly created French semantic network. This network could be especially useful for measuring the semantic distance of words produced by participants in cognitive tasks or building new French task material in which semantic distance needs to be controlled.

Abstract

Peak End Rule (Kahneman, 1993; 2011) suggests that the average of the peak and end moments of an event disproportionately affect memory and thus perception of the experience. We investigate PER's application to the experience of reading fiction. Gillian Flynn's *Gone Girl* (2012) is an ideal case study because it is commercially popular but, unlike most popular novels, has a distinctly amoral ending. We hypothesize that humans expect moral payoffs at the end of narrative fiction, and that when these expectations are not met (i.e., pain at the end of the experience), as in the case of *Gone Girl*, readers' perceptions of the story will be influenced by this pain and manifest as disappointment and dislike. We reference existing models in evolutionary psychology, which seek to explain human altruism, and models in cognitive science, which seek to explain patterns in memory and assessment. To quantify disappointment and dislike, we conduct a programmatic corpus linguistic analysis of 40,000 web-scraped Amazon product reviews of *Gone Girl,* comparing them to reviews of eight other similarly popular novels from the same year. Results show that reader sentiments about *Gone Girl*, both the overall review ratings and analysis on a sentence-by-sentence basis, are more positive than for the comparison novels. When only reviews mentioning "end" are analyzed, however, the effect reverses, with a similar finding at the more granular level of sentences mentioning "end." These findings support our hypothesis that moral endings, or lack thereof, significantly shape reader perceptions of a novel.

Keywords: peak end rule; narrative endings; sentiment analysis; corpus linguistics; web scraping; Amazon product reviews; morality in narrative; evolutionarily stable systems; social cooperation; *Gone Girl*

Introduction

The principle of Peak End Rule (PER) suggests that a memory of an experience is influenced disproportionately by two key moments: the most intense moment of pain in the episode and the level of pain felt at the end of the episode (Kahneman et al., 1993). Multiple experiments have supported the notion of PER, utilizing a variety of methodologies (Fredrickson & Kahneman, 1993; Kahneman, 2011; Redelmeir & Kahneman, 1996). While Kahneman (2011) studied how subjects evaluate fictional stories of people's lives (ending happily or sadly) in a Peak End Rule framework, it remains to be explored how PER applies to readers' perceptions of literary fiction. In the present study, we explore such perceptions as expressed through reader book reviews. Here, the event to which PER applies is the reading of a novel. Since we assume that such review assessments are highly correlated to perceptions formed during the reading event, perception and memory here are then intertwined.

Literary critics working within an evolutionary framework believe fiction to be inherently moral (Gardner, 1978; Gottschall, 2012). Regardless of how much readers delight in highly problematic narratives, they nevertheless expect a moral payoff by way of closure (Carroll, 2011; Flesch, 2009; Gardner, 1978). Moreover, it has been shown that authors and filmmakers are acutely aware of this expectation and use cognitive biases in the construction of narratives to manipulate the effect on readers (Smith, 2015).

This expectation for moral endings may be rooted in the evolutionary advantages of altruism. Altruistic action is necessary in group systems because it ultimately promulgates group stability (Flesch, 2009). In Evolutionarily Stable Systems, people are cooperators, defectors, or punishers (Flesch, 2009). Cooperators constantly track the behavior of others in their group using gossip, honest signaling, and other social tools to ensure that no one is defecting (Dunbar, 2004; Flesch, 2009; Harari, 2015; Zahavi & Zahavi, 1997). If cooperators catch defectors, they seek to punish the latter by exposing their free-riding behavior to the rest of the group. This same human propensity for altruistic punishment has been demonstrated through the game theory constructs of the Ultimatum Game and the Prisoner's Dilemma (Fehr & Fischbacher, 2003; Güth et al., 1982; Tucker, 1983).

William Flesch argues that the moment the author allows moral characters to expose and punish immoral characters is the "pleasure of fiction" (Flesch, 2009). In fact, it is not just the authors' ability, but their social responsibility to provide this payoff (Carroll, 2011). Reader expectations for this payoff are also influenced by genre: when viewers watch more fictional television, they develop stronger Just World Beliefs, as opposed to when they watch news/infotainment

television (Appel, 2009). This could be because fictional narratives "tend to stimulate moral evaluation," whereas nonfictional television is saturated with immoral behaviors not necessarily followed by moral consequences (Appel, 2009). In this way, genre affects readers' expectations.

A case study: *Gone Girl*

Using the novel *Gone Girl* by Gillian Flynn (2012), we present an emblematic case study for moral endings in fictional narratives. *Gone Girl* is a useful case in that it is commercially popular, topping *New York Times* (NYT) bestseller lists and garnering over 40,000 product reviews on Amazon, but its ending is highly disturbing because of its lack of morality (Amazon Customer Reviews, 2016; New York Times Bestsellers, 2012, 2013).

For readers to engage with a book, they inherently need to trust the narrator (Carroll, 2011). Flynn expertly manipulates this trust to deliver a spectacularly amoral ending, thus experienced by the readers as particularly painful. With two unreliable narrators, Flynn's readers perceive their highly manipulated empathy for the two protagonists, Nick and Amy, as wasted. In exchange for this deception, readers expect Flynn to craft an even stronger, satisfying ending.

However, the novel's ending is both abrupt and lacking in a moral payoff. The book has no altruistic punishers. The defector, Amy, is not punished sufficiently; she succeeds in all of her free-riding efforts. As one reader comments: "I was disappointed in the ending. I was hoping for either justice on Nick's side or the demise of Amy. Ending just wasn't what I had hoped it would be." Given the principle of Peak End Rule, we would expect readers' perceptions and global assessments of the novel to be most influenced by the painful and unsatisfying ending (Kahneman, 2011).

To assess this and other related claims about moral closure in novels, this paper linguistically analyzes Amazon product reviews of *Gone Girl* (Amazon Customer Reviews, 2016). This methodology is derived from an increasing usage of online corpora to assess opinions of a product or work (Allington, 2016; Boot, 2013).

Hypotheses

Readers expect moral endings out of *New York Times* bestselling narrative fiction, and when these expectations are not met, as is the case in *Gone Girl*, readers will feel dissatisfied and disappointed because their unspoken contract with the author has been broken. Specifically, we may expect to observe the following:

(1) Readers of *Gone Girl* will more frequently discuss the ending, as compared to other best-selling literary novels.

(2) While *Gone Girl* is similarly popular (i.e., best-selling), with comparable overall Amazon review numerical ratings (scale: 1-5 "stars"), reviews discussing the "end" will garner significantly lower ratings for *Gone Girl*. Discussing "end" is not expected to similarly affect the comparison corpus.

(3) At the sentential level within *Gone Girl* reviews, mentioning "end" will be associated with significantly more negative surrounding sentiment, as judged by a machine-learning classifier. No similar effect is expected for the comparison corpus.

(4) Descriptively, adjectival collocates of "end" are expected to be substantially more negative within the *Gone Girl* corpus.

Methods

Two corpora were created and analyzed using a combination of web-scraping tools, custom scripting software, part-of-speech tagging, deep-learning sentiment classification, and the R statistics platform (version 3.5.1, R Core Team, 2018). Throughout this work, we consider references to the ending of a novel to be any of "end," "ends," "ended," or "ending," referring to this set collectively as simply "end."

Materials

Star-rated consumer reviews of novels were extracted from the Amazon website and organized into two corpora: one for the novel *Gone Girl* (Flynn, 2012) and one for a group of comparison works.

***Gone Girl* corpus** A total of 39,436 product reviews of the novel *Gone Girl* by Gillian Flynn were extracted in December 2016 using ParseHub web-scraping software. Data collected were: title of review, content of review, date published, and star rating. After a pilot study of the full corpus, final analysis was limited to the first 2,000 reviews chronologically following the book's release, all within 2012, in order to avoid any influence of the movie *Gone Girl* (Fincher, 2014), announced in 2013 and released in 2014.

Comparison corpus The comparison group of novels comprises all works that, like *Gone Girl,* appeared on the NYT bestselling fiction list for two or more consecutive weeks in 2012 or 2013. Our collected corpus contains product reviews for: *11/22/63* by Stephen King, *Fifty Shades of Grey* by E.L. James, *Reflected in You* by Sylvia Day, *The Racketeer* by John Grisham, *A Memory of Light* by Robert Jordan and Brandon Sanderson, *Until the End of Time* by Danielle Steel, *Inferno* by Dan Brown, and *The Cuckoo's Calling* by Robert Galbraith. Amazon reviews were extracted, collecting title of book, plus as before: title of review, content of review, date published, star rating.

Here, the number of reviews extracted for each novel was limited to either the first 2,000 chronologically or all reviews appearing within the first two years of release, whichever was less. As with *Gone Girl*, this was done to limit any potential influence from television or cinematic releases based on the books. Within these parameters, a total of 14,460 reviews were extracted, *11/22/63* and *Until the End of Time* via ParseHub, with the remainder collected using the webscraper.io utility (Balodis, 2018).

All tokens of the phrase "until the end of time," without regard to case, were excluded from analysis, as this is not only a somewhat fixed multi-word expression (MWE) in English, but here it is also specifically the title of one of our comparison novels. We assume the use of "end" in this expression does not actually refer to the ending of the narrative. A second fixed MWE, "loose ends," was similarly excluded.

Results

Use of *end*

Per hypothesis 1, reviewers of *Gone Girl* discuss the ending more. In the comparison corpus, 25.7% of the reviews mention "end," 3.7% of the review titles, and "end" compromises 0.21% of all words. The corresponding figures for *Gone Girl* are 52.4%, 8.4%, and 0.63%, more than double in each case (Figure 1).

Differences by "star" rating

Hypothesis 2 predicts that mentioning "end" will lower Amazon review numerical ratings for *Gone Girl* more so than for the comparison set. Figure 2 appears to bear this out.

To explore this further, we fit a linear mixed-effects regression model to predict review star rating from fixed effects for source corpus, length of review (in words, log-reduced to limit outlier effects), and whether or not each review included mention of "end" in its title or body text, with a random effect for individual book title.[1] We trialed all

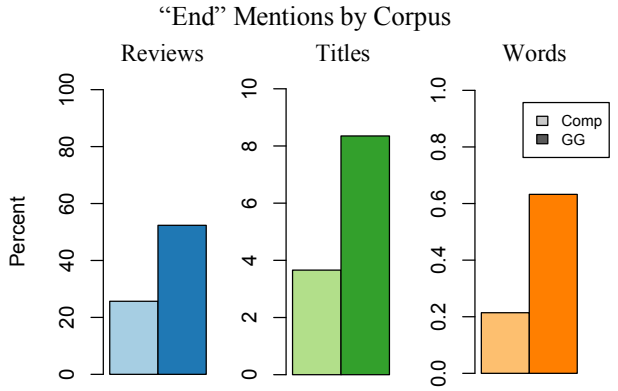

Figure 1: Percentages of "end" mentions for comparison corpus ("Comp", lighter bars) vs. *Gone Girl* corpus ("GG", darker bars).

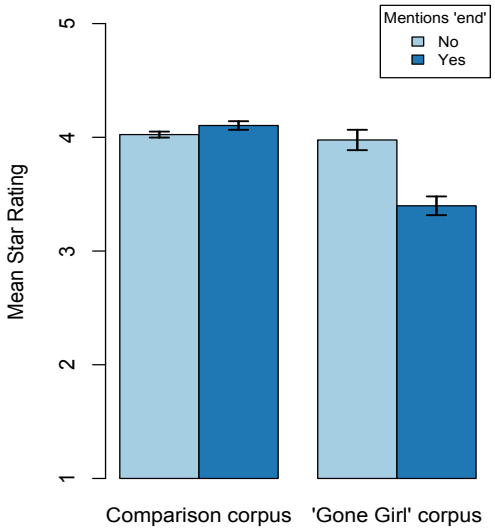

Figure 2: Effects of mentioning "end" on overall reviewer rating. (Comparison corpus *N*=14.5K, *Gone Girl N*=2K.)

possible two-way interactions among the fixed effects, as well as a maximal random effects structure (Barr et al., 2013). Stepwise model optimization preserves the random intercept for book title, the associated random slope for review length, and interactions of source corpus with both review length and "end" mentions (Table 1).[2]

As a baseline, there was no significant difference in overall star rating among these popular works when "end" was not mentioned (main effect of source corpus, $\hat{\beta} = 0.019$, $t = 0.078$, $p = 0.9403$), and longer reviews correlated with somewhat lower ratings overall ($\hat{\beta} = -0.283$, $t = -7.182$, $p = 0.0002$).[3] When "end" is mentioned, mean ratings

Table 1: Fixed effects and interactions from linear regression, with baseline *y*-intercept of about 4 out of 5 stars.

	Coef. $\hat{\beta}$	SE($\hat{\beta}$)	*t*	*Pr*(>|*t*|)
Intercept	3.964	0.081	49.181	< 0.0001
Corpus: *Gone Girl*	0.019	0.242	0.078	0.9403
Review length	-0.283	0.039	-7.182	0.0002
Mentions "end"	0.260	0.026	10.145	< 0.0001
Gone Girl × length	0.353	0.118	3.006	0.0197
Gone Girl × "end"	-0.870	0.064	-13.606	< 0.0001

[1] We do not also include a random effect for "participant" (i.e., reviewer) since, with rare exception, there is just one review per reviewer available within our pair of corpora—that is, there is no clustering to model.

[2] The model exhibits negligible collinearity, with condition number $\kappa = 1.41$ (where Cheney and Kincaid 2007 suggests 10+ is problematic) and largest variance inflation factor (VIF) for any single predictor = 1.31 (10+ again being high, per Hair et al. 1998).

[3] Inclusion of length in this analysis was motivated by an anonymous commenter's concern that lower ratings for *Gone Girl* reviews mentioning "end" might arise if these reviews tended to be longer, where longer reviews might in turn correlate with lower ratings. As reported above, the main effect of review length does turn out to be correlated with lower scores overall, but we find that greater length specifically among the *Gone Girl* reviews actually positively influences star rating (interaction of source corpus and length, $\hat{\beta} = 0.353$, $t = 3.006$, $p = 0.0197$). Further, *Gone Girl* reviews overall are not significantly longer than the comparison group ($\bar{x} = 101.5$ words *GG* vs. 100.6 *comp*, $t = 0.322$, $p = 0.7473$), and *Gone Girl* reviews mentioning "end" are actually significantly shorter on average than reviews mentioning "end" within the comparison corpus ($\bar{x} = 123.0$ vs. 160.4, $t = -7.027$, $p < 0.0001$).

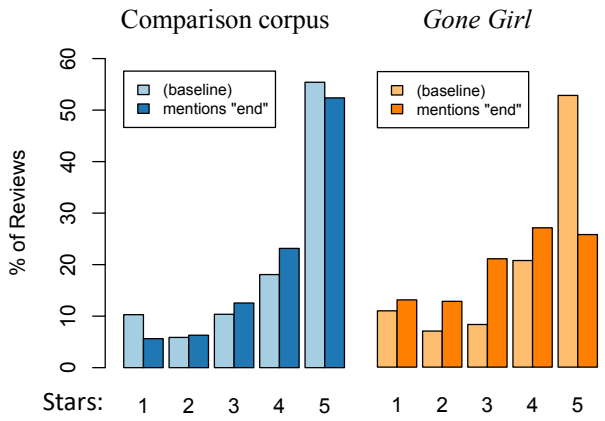

Figure 3: Star ratings by source, with and without "end."

actually increase overall ($\hat{\beta} = 0.260$, $t = 10.145$, $p < 0.0001$), but looking at the interaction terms, among *Gone Girl* reviews that mention "end," scores significantly decline ($\hat{\beta} = -0.870$, $t = -13.606$, $p < 0.0001$) as predicted.

Figure 3 further illustrates the distribution of star ratings with and without "end" mentions.

Sentiment analysis

The analyses detailed above offer a view of how mentioning "end" is reflected in an extrinsic measure of overall reviewer satisfaction—the star ratings. But a question remains with regard to what reviewers express more directly about the ending of the story.

To explore such an intrinsic measure, we began by splitting review text at punctuation points, a proxy for clause boundaries, yielding 136K such segments, including 12,277 for *Gone Girl*, of which 1,066 mention "end." We applied deep-learning sentiment annotation via the Stanford CoreNLP toolkit (Socher et al., 2013; Manning et al. 2014) to rate the emotional content of each segment of text ("clause") as "Very negative," "Negative," "Neutral," "Positive," or "Very positive."

Recasting these ratings as a continuous scale (-2 to +2), we once again fit a linear mixed-effects regression model, now predicting sentiment score from fixed effects for source corpus, clause length, and whether or not each such individual segment of text included mention of "end." To these, we added random effects, now both for book title and for individual review.[4] As before, we also model all possible two-way interactions of the fixed effects and the maximal random-effects structure supported by the data. Stepwise optimization this time preserved all main effects and their interactions (Table 2), as well as both of the random intercepts and a random slope for the separate effect of "end"-mention within each given review.[5]

Table 2: Fixed effects and interactions from regression, with baseline *y*-intercept = 0.02 (i.e., overall "Neutral" sentiment).

	Coef. $\hat{\beta}$	SE($\hat{\beta}$)	*t*	*Pr*(>|*t*|)
Intercept	0.020	0.038	0.515	0.6223
Corpus: *Gone Girl*	0.068	0.114	0.593	0.5720
Clausal length	-0.181	0.003	-61.121	< 0.0001
Mentions "end"	0.052	0.021	2.462	0.0139
Gone Girl × "end"	-0.351	0.041	-8.575	< 0.0001
Gone Girl × Length	0.025	0.010	2.406	0.0161
"End" × Length	-0.048	0.022	-2.149	0.0317

At this clausal level, there was again no significant main effect of source corpus, meaning segments of *Gone Girl* reviews overall were neither more positive nor more negative than those in the comparison corpus ($\hat{\beta} = 0.068$, $t = 0.593$, $p = 0.5720$). We also find that longer clauses are more likely to bear negative sentiment (main effect of length, $\hat{\beta} = -0.181$, $t = -61.121$, $p < 0.0001$), much as our previous analysis found that longer complete reviews received lower star ratings. This effect was, however, weakened within *Gone Girl* review prose (interaction term, $\hat{\beta} = 0.025$, $t = 2.406$, $p = 0.0161$). Among all clauses mentioning "end," mean sentiment increases overall ($\hat{\beta} = 0.052$, $t = 2.462$, $p = 0.0139$), much as did full-review star ratings. Critically, though, *Gone Girl* "end"-mentions are significantly more negative (interaction $\hat{\beta} = -0.351$, $t = -8.575$, $p < 0.0001$), just as we saw with lower star ratings for full reviews, again as predicted by Hypothesis 3.

Most common descriptive terminology

Finally, we examined adjectival collocates of "end" to see how reviewers specifically describe the respective endings. Here, we began by applying part-of-speech (POS) labels to all text, once again using Stanford CoreNLP (Toutanova et al., 2003; Manning et al., 2014), then analyzed adjectives appearing within a three-word window of "end," left or right, without crossing clausal or sentential boundaries. Negated contexts (e.g., "not good," "never disappointing") were excluded from this portion of the analysis (Pang et al., 2002).

The most frequent adjective used to describe "end" in the *Gone Girl* corpus was "disappointing," which in combination with the related form "disappointed" was almost twice as frequent as the next most used word to describe the ending of the story, "worst" (Table 3).

Examples from the *Gone Girl* reviews of the use of "disappointing" or "disappointed" in relation to "end" include: "the ending was disappointing to the point of making me wish I had not spent my time reading this," "it was a good book, but the ending was a disappointment," and "the big disappointment was the ending…this book ended horribly."

[4] Whereas our previous analysis—star ratings applied to the full reviews—did not include a per-review (i.e., "participant") effect.

[5] As with our earlier model, we find negligible collinearity, with $\kappa = 1.15$ and largest VIF for any single predictor = 1.77.

Table 3: Most common adjectives used in descriptions of "end" in the *Gone Girl* corpus. Coding for sentiment as rated by the Stanford CoreNLP toolkit (Socher et al., 2013; Manning et al. 2014): red/– = negative; green/+ = positive; gray/~ = neutral.

Adjective	Frequency (%)
– disappointing	5.08
– worst	3.81
+ good	3.60
– horrible	2.97
– unsatisfying	2.97
~ little	2.75
– awful	2.54
+ happy	2.54
– terrible	2.33
– bad	2.12
– disappointed	1.91

The adjective most frequently used to describe the ending in the comparison corpus was "great" (Table 4). Excerpts from reviews including use of "great" to describe "end" in the comparison corpus include: "great story...with a literally killer climax and great ending," "what a great ending to a terrific trilogy," "the ending was great and totally unexpected," and "awesome book, great ending to an epic saga."

While these respective sets of most frequent adjectives appear largely disjoint, we find a few terms in common among those frequently applied in both corpora, e.g., "good" and "little." To then further explore which terms most distinctively apply to "end" in one corpus as compared to the other, we examined relative frequency across the two data sets. We log-reduced values and *Z*-score normalized for comparison, then found the ratio of "end"-description frequency for *Gone Girl* over the comparison set. The largest ratios (Table 5) represent terms most frequently applied to "end" for *Gone Girl* vs. the comparison group.

Table 4: Most common adjectives used in descriptions of the endings of comparison novels. (Sentiment coding as in Table 3.)

Adjective	Frequency (%)
+ great	12.36
+ good	5.53
+ happy	3.76
+ perfect	2.69
+ wonderful	2.23
~ little	2.07
+ amazing	2.00
+ satisfying	2.00
+ fantastic	1.69
~ first	1.69
+ excellent	1.53

Table 5: Adjectives most distinctively applied to "end" in *Gone Girl* vs. comparison novels, as measured by relative frequency across the two. (Sentiment coding as in Table 3.)

Adjective	GG/Comp ratio
– awful	24.54
– worst	18.40
– anticlimactic	15.34
– flat	12.27
– bizarre	9.20
– disappointed	9.20
– unsatisfying	8.18
– ridiculous	7.67
– atrocious	6.13
– terrible	6.13
– horrible	6.13

Gone Girl corpus examples of "awful"—24.54 times more likely to be used to describe "end" for *Gone Girl* than for the comparison set—include: "slow pace and awful ending—don't waste your money," "great book, awful ending," "it could've been a perfect novel, but that God awful ending!" and "awful ending…makes you feel dirty for wasting so much time on a sick, twisted book."

Finally, we further visualized this notion of relative frequency ratio, focusing on the 20 adjectives with greatest average "end"-collocation frequency across the two corpora. Figure 4 graphs their respective (log-reduced, normalized) frequencies for the two data sets, with sentiment labeling once again as above in Table 3. Terms below the dividing line were more frequently "end" collocates for *Gone Girl,* none expressing positive sentiment. Those above the diagonal, none of which express negative sentiment, were more frequently applied to "end" for comparison works.

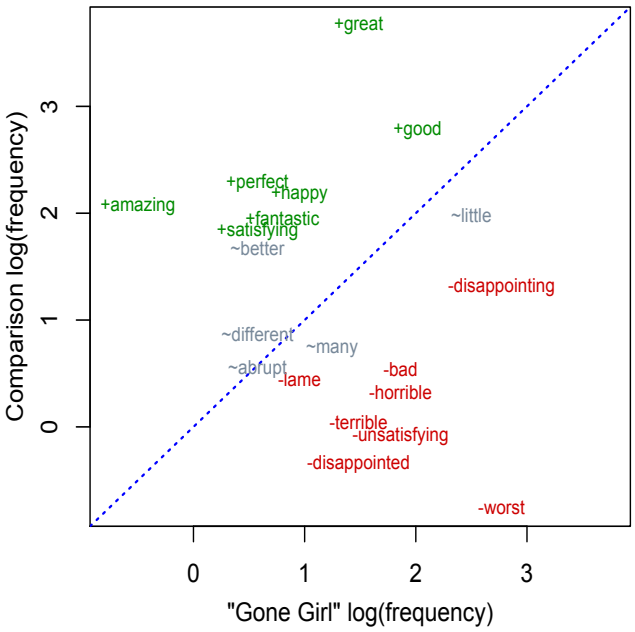

Figure 4: Relative frequency of collocates across corpora.

Discussion

Moral payoffs are closely related to the pleasure of fiction. Readers make an unspoken contract with the author before reading a book: I will read your book, expecting that the morally problematic content will be cleaned up by the end. When this baseline assumption is violated, as is the case in *Gone Girl*, the ending becomes a salient discussion topic. Our findings confirm this: mentions of "end" were twice as common in *Gone Girl* reviews than comparison novel reviews.

And readers do not merely discuss the ending: they vividly express their disappointment. In fact, "disappointed" was used almost 10 times more often in relation to the ending of *Gone Girl* than for the comparison novels. This adjective in particular is revealing in the context of the reader/author contract, because it signifies readers' expectations and their lack of fulfilment.

In contrast, the adjectives most frequently used to describe "end" in our comparison group of novels were generally positive, suggesting satisfaction with the ending and, therefore, fulfillment of the unspoken contract with the author.

Gone Girl is an important case study in the expectation for moral payoffs in novels because it lacks a moral ending, yet it is commercially popular. In fact, in terms of overall review scores, *Gone Girl* is just as highly rated as comparison best-selling novels. What stands out, however, is that when reviews are separated into those that mention "end" and those that do not, *Gone Girl* reviews significantly differ from comparison reviews. Crucially, we found that while including a mention of "end" in the comparison corpus does not significantly affect star rating, mentioning "end" in the *Gone Girl* corpus significantly lowers ratings. This suggests that *Gone Girl*'s amoral ending is a salient cause for overall dissatisfaction with the novel.

While this conclusion is made on the basis of reviewers' overall star ratings, an extrinsic measure, we found similar evidence in programmatic sentiment analysis of review prose. Here, the effect of mentioning "end" was even more pronounced: *Gone Girl* commentary about matters other than "end" was significantly more positive than in reviews of comparison works, while discussions of "end" were significantly more negative.

The fact that discussions of "end" were extremely negative in the *Gone Girl* corpus suggests that reviewers act as altruistic punishers in the framework of Evolutionary Stable Systems. Because Flynn controls the narration that explains the world of *Gone Girl*, readers expect her to act as the primary altruistic punisher in the novel's social ecosystem. If there is a defector within the novel, it is Flynn's job to guide the narration such that the defector is exposed and consequently punished. In the case of *Gone Girl*, there is more than one defector, and Flynn fails to craft the narration to punish any of them appropriately. Readers experience and react to Flynn's lack of punishment and become second-order altruistic punishers themselves; they go to Amazon and write product reviews for the novel, explaining their opinions of the ending and exposing Flynn herself as a defector for her failure to include a moral ending.

Therefore, we see that the evolutionary advantages of altruistic behavior not only guide immediate social groups, but literary communities as well. The principle of Peak End Rule further compounds this: when psychologically amoral, painful moments occur at the end of experiences or narratives, the impact is amplified. This heightening of moral discomfort is what drives readers to write over 40,000 product reviews for a novel, over half of which include a discussion of the "end," with "disappointing" as a key descriptor.

Future Directions

Given the wealth of data available via Amazon, further investigation using more novels and more reviews is an important next step. We would also like to consider reviews from other Internet sources, such as GoodReads.

Another possibility would be to examine responses to the movie *Gone Girl*, looking at how these compare with reactions to the novel. Although Flynn wrote the screenplay for the movie, its narration style inherently changes with the shift in medium, meaning that reactions to the ending could shift as well.

Conclusion

The Peak End Rule principle suggests that endings of experiences or narratives significantly affect a person's overall memory, or perception, of that event. Though first explored through cognitive research on human memory, the principle also applies to readers' perceptions of literary novels, and in particular, their endings. That is, moral endings, or lack thereof, as in the case of *Gone Girl*, have a strong effect on readers' perceptions of novels.

In light of the human propensity for cooperation, *Gone Girl*'s lack of a moral ending dramatically affects reader response, in comparison with other popular contemporary novels. This investigation demonstrates the profound effect endings have in shaping conception of stories, as well as our expectation for a moral payoff in literary novels—even disturbing ones.

Abstract

Pragmatic inferences are an integral part of language learning and comprehension. To recover the intended meaning of an utterance, listeners need to balance and integrate different sources of contextual information. In a series of experiments, we studied how listeners integrate general expectations about speakers with expectations specific to their interactional history with a particular speaker. We used a Bayesian pragmatics model to formalize the integration process. In Experiments 1 and 2, we replicated previous findings showing that listeners make inferences based on speaker-general and speaker-specific expectations. We then used the empirical measurements from these experiments to generate model predictions about how the two kinds of expectations should be integrated, which we tested in Experiment 3. Experiment 4 replicated and extended Experiment 3 to a broader set of conditions. In both experiments, listeners based their inferences on both types of expectations. We found that model performance was also consistent with this finding; with better fit for a model which incorporated both general and specific information compared to baselines incorporating only one type. Listeners flexibly integrate different forms of social expectations across a range of contexts, a process which can be described using Bayesian models of pragmatic reasoning.

Keywords: Pragmatics; Word learning; Common ground; Bayesian models

Introduction

One of the most astonishing features of natural language is that it allows us to communicate precise meanings despite the fact that most utterances are inherently ambiguous. While the conventional mapping between sounds (words) and objects constrain what a speaker may mean by an utterance, the intended meaning of the utterance is not reducible to the words that are contained in it. It takes additional pragmatic inference to recover the intended meaning (Levinson, 2000).

Pragmatic inferences rest on a set of expectations that interlocutors bring to the table when entering a communicative interaction. On the one hand, speakers and listeners have the general expectation that their partner communicates in an informative and relevant way (Sperber & Wilson, 2001). Grice (1991) summarised this expectation via the *Cooperative Principle*: "Make your contribution such as is required, at the stage at which it occurs, by the accepted purpose or direction of the talk exchange in which you are engaged." Importantly, the second half of the Cooperative Principle describes a second type of expectation: interlocutors expect each other to produce and interpret utterances *in light of the shared common ground between them* (H. H. Clark, 1996). Common ground refers to bits of information that are assumed to be shared, either because they were mentioned over the course of the conversation or grounded through some form of joint experience (Bohn & Koymen, 2018). Note that by its very nature, common ground may vary with the individuals involved in a particular conversation.

These same general and specific expectations can support children's word learning (E. V. Clark, 2009; Tomasello, 2009). On the one hand, children have been found to learn novel words by assuming speakers are generally informative (Frank & Goodman, 2014). That is, in the absence of any prior interaction with the speaker, children interpreted a novel word as referring to the most informative referent. On the other hand, children use conversation-specific common ground expectations to decide which object a specific speaker is referring to when they use a novel word (Akhtar, Carpenter, & Tomasello, 1996). For example, when a speaker expressed preference for a particular object, children expect a novel word from the same speaker to refer to the previously preferred object (Saylor, Sabbagh, Fortuna, & Troseth, 2009).

But how do listeners integrate general and common ground-related expectations during word learning? Are pragmatic inferences strengthened additively when both support a particular interpretation? How are they weighed when they are in conflict? The Rational Speech Act (RSA) framework (Frank & Goodman, 2012; Goodman & Frank, 2016) offers a formal framework for addressing this information integration problem. RSA models are characterized by a recursive structure in which a pragmatic listener tries to uncover a speaker's intended meaning by assuming the speaker chose their utterance in order to get a naive listener to recover their intended meaning. RSA models have made accurate quantitative predictions about various forms of pragmatic language use and word learning (Goodman & Frank, 2016). However, a comprehensive treatment of how general and common ground expectations are integrated is still missing.

Within RSA models, each agent in the recursion is modeled as a Bayesian reasoner; thus, information integration is treated as a process of probabilistic inference. The speaker-general informativeness expectation is already encoded in the structure of the model: Speakers produce utterances to aid the listener in disambiguating referents. We operationalize speaker-specific, common ground information as the shared prior probability of referents in the context of the utterance.

Thus, a natural locus for information integration within these models is the trade off between the prior probability of a particular referent and the likelihood of that referent given the current utterance.

Here we evaluate this rational, pragmatic account of information integration. We isolate speaker-specific and common-ground information experimentally, then test how adult listeners combine them in a word learning setting. In Experiments 1 and 2, we replicate findings showing that listeners expect speakers to a) produce informative utterances (Experiment 1) and b) communicate about things that are relevant to common ground (Experiment 2). Based on these results, we generate model predictions using the RSA framework about how these two components should be integrated. In Experiment 3, we test how listeners integrate their expectations and compare model predictions to empirical data. Experiment 4 replicates and extends Experiment 3 by varying the strength of common ground assumptions. For all experiments, we pre-registered the sample size, experimental design and the statistical analysis. For Experiment 3 and 4, we also registered the model structure and predictions (see [masked for peer review])

Method

General Design

Experiments were conducted online using Amazon's Mechanical Turk. Fig. 1 provides a schematic overview of the setup and experimental procedures. The instructions informed participants that they would see a number of animal characters asking for novel toys. Participants were asked to identify the toy being requested by a particular animal. The basic layout involved two tables with toys on them, located left and right of a little hill, on which the animal was standing. For each animal, we recorded a set of utterances (one speaker per animal) that were used throughout the experiments to provide information and make requests. At test, toys were requested using the following utterance: "Oh cool, there is a [non-word] on the table, how neat, can you give me the [non-word]?". Participants responded by clicking on one of the toys. Each experiment started with two training trials in which animals requested familiar objects (car and ball).

Experiment 1

Participants, Design and Procedure

All participants were recruited from Amazon Mechanical Turk and had US IP addresses. Sample size in each experiment was planned to be 120 data points per cell. Experiment 1 had 40 participants. In the test condition, one table contained one object of type A and the other table contained one object of type A and one of type B (see Fig. 1, left). On each trial, the animal introduced themselves (e.g. "Hi, I'm Dog"), turned towards the table with the two objects and made a request. If listeners expect speakers to produce informative utterances, they should select object B. This choice follows from the counterfactual inference that if the (informative) speaker would have wanted to request A, they would have turned to the table that only contained A. On the other hand, since B is only located on the table together with A, there was no alternative way to request B in a less ambiguous way. In the control condition, both tables contained two objects, one of which was randomly determined as the correct one. No inference was therefore licensed. Each participant received three trials in each condition for a total of six trials, presented in a randomized order.

Results and Discussion

Participants selected the less frequent object above chance in the test condition ($t(39) = 5.51$, $p < .001$, see Fig. 2) and did so more often compared to the control condition (generalized linear mixed model (GLMM[1]):$\beta = 1.28$, se = 0.29 $p < .001$). This result replicates earlier work (Frank & Goodman, 2014) and is consistent with the hypothesis that listeners expect speakers to communicate in an informative way.

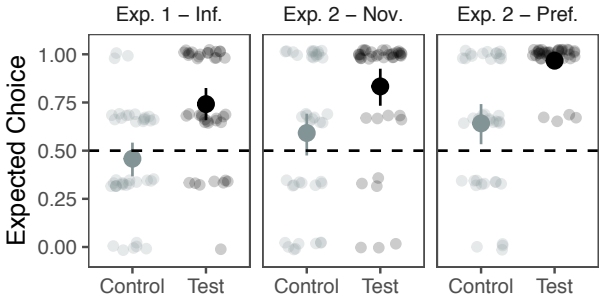

Figure 2: Results from Experiment 1 and 2. For preference and novelty, control refers to a different speaker (see Fig. 1). Transparent dots show data from individual participants, solid dots represent condition means, error bars are 95% CIs. Dashed line indicates performance expected by chance.

Experiment 2

We manipulated common ground expectations based on procedures that have successfully been used in developmental studies (e.g. Akhtar et al., 1996; Saylor et al., 2009). Speakers either expressed preference for one object or one object was new to the speaker.

Participants, Design and Procedure

We collected data from 80 participants, with 40 in each condition. In the preference condition, each table had a different object. In the beginning, the animal appeared on the hill and introduced themselves. Next, they turned to one of the tables and expressed either that they liked ("Oh wow, I really like that one") or disliked ("Oh bleh, I really don't like that one") the object before turning to the other side and expressing the respective other attitude. Then, the animal disappeared. After a short period of time, either the same or a different animal appeared and requested an object while facing straight ahead

[1]All models had maximal random effects structure conditional on model convergence.

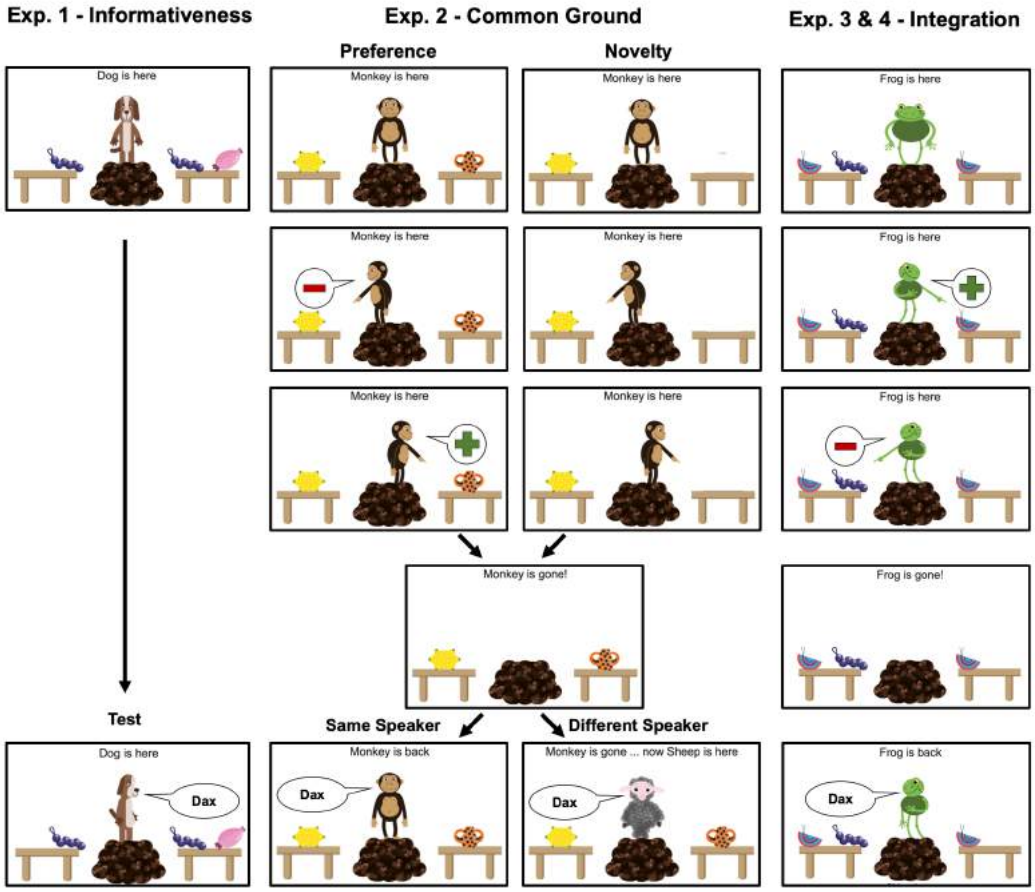

Figure 1: Schematic experimental procedure. In all conditions, at test (bottom), the speaker ambiguously requested an object using a non-word (e.g. dax). Participants clicked on the object they thought the speaker referred to. Informativeness (Experiment 1, left) translated to making one object less frequent in context. Common ground (Experiment 2, middle) was manipulated by making one object prefered by or new to the speaker. Green plus signs represent utterances that expressed preference and red minus of dispreference (see main text for details). Experiment 3 (right) combined manipulations. When expressing e.g. preference for an object on a table with two objects (panel 3 from top), the respective object was temporarily enlarged. Condition for Experiment 3 shown here: preference - same speaker - incongruent.

(see Fig. 1, middle). If participants took into account the information they gained about the speaker, they should select the previously preferred object if the returning animal was the same. If a different animal returned, they should choose randomly between objects.

In the novelty condition, one table was initially empty while there was an object on the other table (see Fig. 1). The animal turned to one of the sides and commented either on the presence ("Aha, look at that") or the absence of an object ("Hm, nothing there"). Next, the animal disappeared. The same animal re-appeared and the sequence above was repeated. When the animal disappeared for the second time, a second object appeared on the empty table while the animal was away. Like in the preference condition, we now manipulated if the same animal or a different one returned. In case of the same animal returning, listeners could infer the referent of the subsequent request by considering that one object was new to the speaker and therefore more likely to be of interest to them. However, no such inference was licensed when a different animal returned because both objects were novel.

Results and Discussion

Participants selected the preferred object above chance when the same animal returned ($t(39) = 29.14$, $p < .001$, see Fig. 2) and did so more often compared to trials in which a different animal returned (GLMM: $\beta = 2.92$, se = 0.56, $p < .001$). Thus, listeners inferred the referent of the utterance by considering previous interactions with the speaker. Interestingly, participants transferred preference to some extent from one animal to the other and selected the preferred object above chance when a different animal returned ($t(39) = 2.7$, $p = .01$). In sum, this study shows that adults make comparable infer-

ences to children (Saylor et al., 2009).

The novel object was selected above chance when the same animal returned (t(39) = 6.77, $p < .001$) but not when a different one appeared (t(39) = 1.49, $p = .144$, see Fig. 2). Furthermore, the two conditions differed in the expected direction (β = 6.27, se = 1.96, $p = .001$). Thus, like children (Akhtar et al., 1996), adults used their prior information about the speaker to resolve ambiguity in the utterance.

Experiment 3

In Experiment 3, we combined the expectations studied in Experiment 1 and 2 to see how listeners integrate them.

Participants, Design and Procedure

A total of 121 individuals participated in the experiment. The test situation was the same as in the test condition in Experiment 1 (see Fig. 1, right): One table with object of type A and the other with an object of type A and B. Again, the animal always turned to the table with two objects and ambiguously requested an object. In Experiment 1, the listener had no prior information about each object. In Experiment 3, however, we manipulated common ground expectations in the same way as in Experiment 2. For example, the animal would turn to the table with one object and express that they don't like object A, then turn to the other table and express that they like object B. Next, after quickly disappearing, they would reappear, turn to the table with two objects and make a request.

For each common ground condition, there were 4 conditions in Experiment 3 resulting from the cross of congruent/incongruent informativeness with same/different speaker. If the preferred/novel object was the less frequent one (object B), the two expectations were congruent. If the preferred/novel object was the more frequent one (object A), expectations were incongruent. For each type of expectation alignment, we varied if the same or a different animal returned. Participants either completed the preference or novelty version with two test trials in each of the four conditions. Before discussing the empirical results, we briefly discuss the model we used to predict expectation integration.

Model Predictions

To derive predictions, we used a probabilistic RSA model that simulates a pragmatic listener reasoning about a cooperative speaker who is trying to refer to an object (Frank & Goodman, 2012). The speaker chooses how to refer to the object by reasoning about a naive listener who does not know the labels for the object (Frank & Goodman, 2014). The conditional probability that the listener chooses a referent given an utterance is defined as follows:

$$P_L(r_s|u) \propto P_S(u|r_s)P_S(r_s)$$

Here, $P_S(u|r_s)$ is the likelihood that the speaker will use an utterance u to refer to a specific referent r. It is defined in terms of a utility function $U_S(u;s)$ consisting of the surprisal of u for a naive listener L_0, who interprets u according its literal semantics:

$$P_S(u|r_s) \propto exp(\alpha U_S(u;s))$$

The numerical strength of the expression above depends on a scalar value, α, which can be interpreted as an indicator of how rational the speaker is in choosing utterances (i.e. as α increases, the speaker is more likely to choose the most informative utterance).

The term $P_S(r_s)$ denotes the prior probability that a speaker will refer to a given referent. This probability represents the listeners expectations about the speaker depending on the manipulation (preference or novelty) and the identity of the speaker (same or different speaker).

We used the results from Experiment 1 and 2 to specify α as well as $P_S(r_s)$ in our model. We set α so that a model with uniform priors would predict the average proportion measured in Experiment 1. The prior probability for each object was set to be the proportion with which this object was chosen in Experiment 2[2]. Based on these parameter settings, we predicted the proportion with which listeners will choose the more informative object in each of eight unique conditions mentioned above (see also Fig. 3). We compared the fit of this pragmatic model to two alternative models using Bayes Factors (BF). The first alternative model ignored the speaker specific expectations (uniform prior model) while the second ignored the informativeness inference (prior only model). All models included a noise parameter, reflecting that participants may respond randomly instead of in line with the intended manipulation on a given trial. Noise parameters were estimated based on the data. They range between 0 and 1 and reflect the proportion of responses that are estimated to be random instead of following the pattern predicted by the model.

Results and Discussion

Results are discussed in the form of the proportion with which listeners chose the more informative object (i.e., the object that would be the more informative referent when only considering speaker general expectations). For a comparison to chance within each unique condition see Fig. 3. Combinations of alignment and speaker identity differed in how they influenced participants' responses (GLMM model term: `alignment*speaker`; β = -2.64, se = 0.48, $p < .001$). Fig. 4A shows the mean response in each unique condition compared to the pragmatics model. Model predictions and data were highly correlated (r = 0.96, $p < .001$). Model fit was much better in the model taking into account both types of expectations compared to the uniform prior (BF = 2e+79) or prior only model (BF = 1.8e+34). The inferred noise level in the pragmatics model was 0.27 (95% HDI: 0.21 - 0.34).

[2]Proportions were measured when participants chose between two objects. However, in Experiment 3, three objects were involved. For each object we used the proportion measured in Experiment 2 as the prior probability.This approached spread out the absolute probability mass for each object but conserved the relative relation between objects.

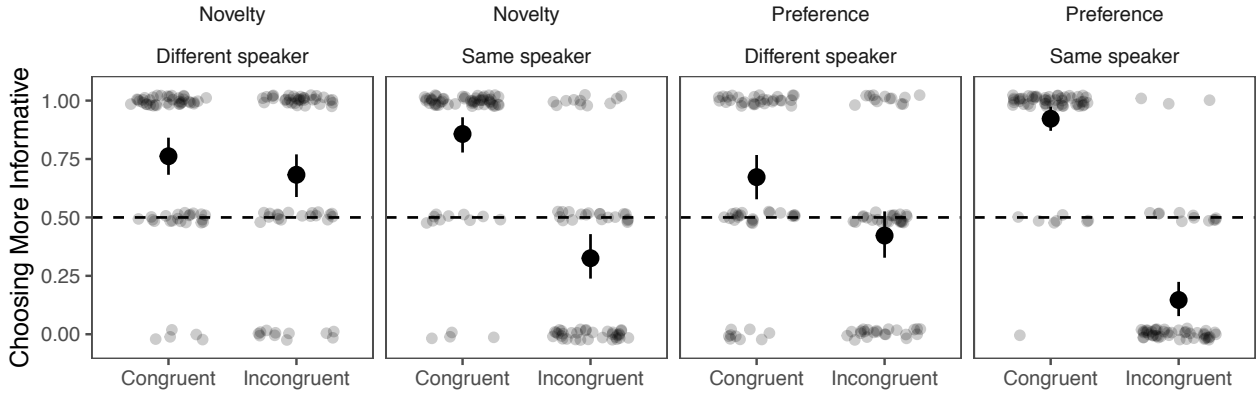

Figure 3: Results from Experiment 3. Dashed line indicates performance expected by chance. Plotting conventions are the same as in Fig. 2. All conditions in which CIs do not overlap with chance line are also statistically different from chance based on two-tailed Wilcoxon tests.

Interestingly, as in Experiment 2, there was a transfer of preference in the case of speaker change. Participants were at chance in the preference - different speaker - incongruent condition (see Fig. 3). If preference would have been specific to a particular individual, participants should have selected the less frequent object above chance (as they did in the corresponding condition with the novelty manipulation). Because it takes into account the measurement from the earlier experiment, our model predicts these results; future work might explicitly model generalization across speakers.

Experiment 4

Here we replicated and extended Experiment 3 by manipulating the strength of the common ground expectations.

Participants, Design and Procedure

This experiment had 453 participants. The structure of the experiment was the same as in Experiment 3. For each common ground expectation (preference and novelty), we intended to have a strong, a medium and a weak condition. The strength of each condition was determined by the proportion with which participants chose the preferred/novel object given the manipulation. We succeeded in generating quantitative variability for novelty. For preference we piloted a number of additional manipulations but did no find one that yielded a weaker preference compared to a medium condition.

The strong manipulations were identical to Experiment 3 and the results are therefore a direct replication (see Fig. 4C). For novelty, in the medium condition, the animal turned to each table only once before the test. In the weak condition, the animal only turned to the table with an object before the test (instead of turning to and commenting on both). In the medium condition for preference, the animal only expressed liking and did so in a more subtle way (saying only: "Oh, wow" while pointing to the object). Participants were assigned to one level of common ground expectation and completed two test trials in each of the four conditions (alignment x speaker change).

Model predictions were obtained in the same way as in Experiment 3; with α inferred from the data and $P_S(r_s)$ measured empirically (in a set of corresponding experiments parallel to Experiment 2).

Results and Discussion

As noted above, the strong prior condition was a direct replication of Experiment 3. Results from the two rounds of data collection were highly correlated (r = 0.97, $p < .001$, see Fig. 4C). Across levels of prior manipulation, the data from Experiment 4 were highly correlated to the corresponding model predictions (r = 0.91, $p < .001$, see Fig. 4B). Again, the pragmatics model provided a much better fit compared to the flat prior (BF = 4.4e+74) or prior only model (BF = 1.8e+84). The inferred noise level in the pragmatics model was 0.28 (95% HDI: 0.24 - 0.32).

Discussion

Language use and learning requires balancing different types of expectations about one's interlocutor - expectations about how speakers behave in general and expectations about how a particular speaker might behave in a particular context. Here we used a Bayesian pragmatics model to predict this integration process. Experiment 1 and 2 replicated previous studies showing that adult listeners expect speakers to produce utterances informatively and also with respect to common ground. We then combined the procedures from the first two experiments to study how listeners would integrate expectations. We used the results from Experiment 1 and 2 to specify model parameters that represented the two types of expectations, generating predictions about new behavior. Experiments 3 and 4 showed that both types of expectations influenced listeners inferences. Overall, listener behavior was accurately described by our model, suggesting that listeners trade-off flexibly between speaker specific and general pragmatic expectations.

Notably, Experiment 3 also included situations in which the two expectations were in conflict. For example, in some

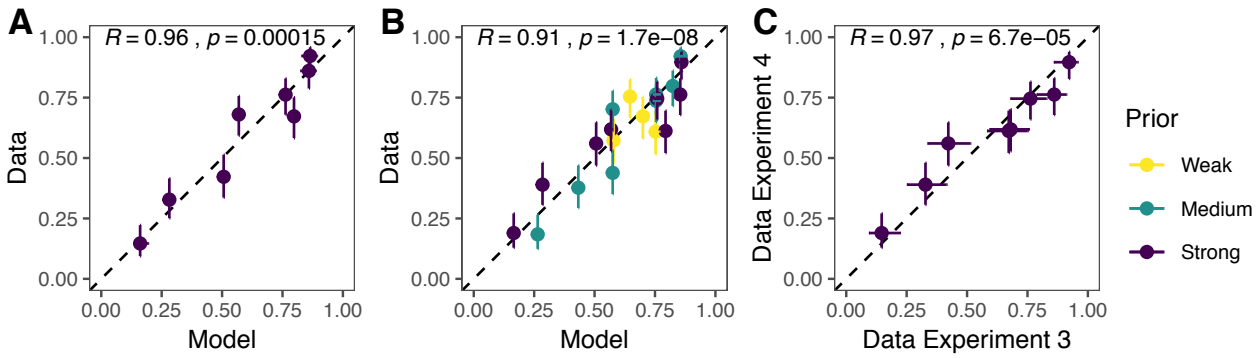

Figure 4: (A) Model predictions compared to data for Experiment 3 and (B) Experiment 4. (C) Data for strong prior manipulation in Experiment 3 and 4, providing a noise ceiling for the reliability of measurements. Error bars = 95% HDIs.

trials the speaker expressed preference for object A, which was also the more frequent (less informative) object. In these situations, a majority of participants chose the preferred object as the referent (see also Fig. 3 preference–same speaker–incongruent). A simple explanation for this pattern might be that common ground manipulations were simply "stronger", corroborated by the fact they produced higher rates of expected choice than the informativeness expectation when the two were presented in isolation (see Fig. 2). In Experiment 4, however, the medium manipulation for novelty yielded numerically weaker results compared to the informativeness expectation in Experiment 1, and yet participants still selected the novel object above chance when the expectations were in conflict. Why is this? Because common ground is represented in our model as the listener's prior distribution, speakers can reason about it in choosing their utterance. That is, in the mind of the listener, the speaker computes the effect of each utterance on a naive listener with shared common ground. Therefore, when prior interactions implicate one object as the more likely referent, the speaker reasons that this object will be the inferred referent of any semantically plausible utterance, even when the same utterance would point to a different object in the absence of prior information.

A range of probabilistic models have been used to model word learning (e.g. Fazly, Alishahi, & Stevenson, 2010; Frank, Goodman, & Tenenbaum, 2009; Xu & Tenenbaum, 2007). RSA models differ from these approaches in that they treat word learning as the outcome of a social reasoning process. In contrast to models for cross-situational word learning (Fazly et al., 2010; Frank et al., 2009), RSA models show how learning might occur in a one shot scenario based on pragmatic reasoning alone. While the ad-hoc informativeness inference characteristic for RSA would be predicted by the model of Xu and Tenenbaum (2007), in their work it follows from the "size principle" of generalization (Tenenbaum & Griffiths, 2001) and not from social reasoning. In contrast to RSA, this approach does not offer a straightforward way to incorporate other types of social information such as expectations following from common ground.

We treated common ground expectations as equivalent to more basic manipulations of contextual salience (e.g. in Frank & Goodman, 2012) and did not explicitly model the social-cognitive processes that give rise to these expectations. The interaction around the object prior to the test event simply increased the probability that this particular speaker will refer to the object subsequently. The same change could be brought about if one of the objects would be made perceptually more salient, for example by making it flash. In future work, it would be interesting to explore ways to model common ground expectations explicitly as well as to contrast perceptual and interactional salience.

Our work integrates different perspectives on the study of pragmatic inference. Previous work focused either on general or speaker specific expectations. The methodological approach taken here illustrates how computational and experimental approaches can be used in conjunction to explicate theories of language use and learning.

Conversation Transition Times: Working Memory & Conversational Alignment

Julie E Boland
University of Michigan

Abstract

Fluent conversation is a marvel of multi-tasking within the language domain: listeners must simultaneously comprehend the speaker, predict a turn transition point, and plan a response. Experiment 1 used spontaneous conversation to investigate the apparent demands of conversation on working memory by manipulating the difficulty of a secondary task. The experiment found support for Load Theory's (e.g., Lavie et al. 2004) prediction that both conversational fluency and performance on a secondary task would decrease as working memory load increased. However, there was also some support for Pickering and Garrod's (2004, 2013) proposal that dialogue is facilitated by a collection of automatic cognitive operations when interlocutors are well-aligned (i.e., using the same words, phrases, and structures to discuss the same topics). Experiment 2 tested two claims motivated by this account: alignment is necessary for fluent turn transitions, and lexical repetition between speakers is an essential component of the alignment advantage. We found support for the former claim, but not the latter.

Keywords: Conversation, Dialogue, Working Memory

Introduction

When a conversation is fluent, the shift from one speaker to the next proceeds rapidly, usually with little or no overlap. In fact, the silent pauses between speakers (i.e., turn transitions) average less than 500ms across cultures, and around 200ms for English speakers in two-party conversations (e.g. Sacks, Schegloff, & Jefferson, 1974, Wilson & Wilson, 2005; Stivers et al, 2009). Levinson and Torreira note that it takes about 600ms to name a picture using a single word, and 425ms of that time is estimated to be necessary for the lexical retrieval and phonological encoding processes for a single word (Indefrey & Levelt, 2004). Thus, it is clear that the signal to begin preparing one's response cannot be the end of the current speaker's utterance, because turn transition times would be on the order of seconds, not milliseconds.

Current theories of conversation explain short transition times by positing multiple processing streams that allow the listener to prepare her response while simultaneously comprehending the current speaker and anticipating a turn transition point (Garrod & Pickering, 2015; Levinson & Torreira, 2015). This multi-tasking burden would seem to induce a heavy working memory load.

Many studies have reported a relationship between working memory and language processing (e.g., Danenman & Carpenter, 1980; DeDe, Caplan, Kemtes, & Waters, 2004; Lewis, Vasishth, & Van Dyke, 2007; Martin & Slevc, 2014). For example, Fedorenko, Gibson, and Rohde (2006) found that participants had difficulty comprehending complex sentences when they had to simultaneously remember three words that were semantically related to the words in the sentence, presumably because comprehending the sentence and remembering the words competed for the same working memory resources. In contrast, conversational participants manage to simultaneously comprehend the current speaker, predict when he will end his turn, and plan a response. All three tasks presumably use the same language system with no apparent interference and surprising efficiency. Thus, conversational fluency presents an interesting puzzle in light of established theories for how working memory supports language comprehension and language production.

If conversation places high demands on working memory, it should be difficult to converse while simultaneously doing another task. For example, Load Theory (Lavie, Hirst, de Fockert & Viding, 2004) predicts a decrease in processing fluency as working memory load is increased. The predictions of Load Theory, as applied to conversation, were supported by Boiteau, Malone, Peters, and Almor (2014), who found that conversation interfered with a simultaneous mouse-tracking task. In turn, the mouse-tracking task modulated speaking rate slightly, but did not increase the rate of disfluencies. Boiteau et al. did not examine fluency variables, such as turn transition time and turn length, nor did they manipulate the difficulty of the secondary task. Several other papers examined the relationship between language production and a secondary task, and also found trade-offs between the language and non-language tasks (Becic et al., 2010, Kemper, Herman, & Nartowicz, 2005; Sjerps & Meyer, 2015).

The literature supports the view that conversation carries a substantial working memory load, but in practice, people often converse while doing something else. In fact, Pickering and Garrod's (2004, 2013) Alignment account suggested that conversational fluency is attained via many automatic mechanisms, at least when interlocutors are well-aligned (i.e., using the same words, phrases, and structures to discuss the same topics). We test three claims from this account:

(i) Well-aligned conversation makes minimal demands on central resources

(ii) Topic alignment enhances conversational fluency
(iii) Lexical repetition enhances conversational fluency

Experiment 1 investigated (i) by manipulating the difficulty of a secondary task. Experiment 2 investigated claims (ii) and (iii) using a picture-description paradigm. The primary focus is on transition time, but speech rate, utterance length, turn type, and the occurrence of disfluencies were measured and analyzed as well, because there may be tradeoffs among these fluency measures.

Experiment 1

If the multi-tasking required for fluent conversation strains the working memory system, adding a secondary task should decrease conversational fluency. To test this, we had participants perform a letter version of the n-back task (Smith & Jonides, 1997) while carrying on a casual conversation with an experimenter. For the n-back task, participants saw a sequence of letters on a computer screen. Both lower-case and upper-case forms of a letter counted as the same letter, to encourage verbal encoding of the stimuli. In the 1-back condition, participants pressed a key if the current letter matched the previous letter. In the 2-back condition, participants pressed a key if the current letter matched the one two letters back. The Load Theory predicts a greater impact on conversational fluency in the 2-back condition, compared with the 1-back condition, and compared with conversation alone.

Method

Participants Forty undergraduates (9 male) received course credit for participation. All were native English speakers.

Procedure The experiment consisted of five experimental blocks: Conversation-Only, 1-back alone, 2-back alone, Conversation with 1-back, and Conversation with 2-back. Stimuli in the n-back consisted of upper and lower case tokens of 8 letters: A, F, J, K, L, O, S, U. The order of the blocks was rotated across five groups, so that each block occurred equally often in each serial position.

Participants were greeted by one of four native English speakers (two male, two female), who conducted the experiment and served as the other interlocutor in conversation blocks. Each experimenter ran two participants on each of the five block orders. The experimenter and the participant were separated by a cubicle barrier for all blocks. Before beginning the experiment, participants were first trained on the 1-back and 2-back tasks. After training, participants completed the experimental blocks. The conversation topics were always in the same order, regardless of block order: 1. life in a college town, 2. pop culture, 3. personal background. Each of the three conversation blocks was 8 minutes long.

The conversation blocks were audio-recorded. The middle 5 minutes were transcribed, with the onset and offset of each turn marked. These transcription records were used to code turn type and disfluencies, and to compute turn transition time, turn length, and speech rate. Alignment was (very roughly) estimated using Latent Semantic Similarity (LSS, Landauer and Dumais, 1997, online pairwise comparisons tool http://lsa.colorado.edu, settings: document to document, general reading up to 1st year college, maximum dimensions).

Results

Small differences in the participants' transition times were found as a result of the secondary tasks (see Figure 1). Interestingly, the longest transition times were observed for the experimenter, who had no secondary task other than to keep the conversation going.

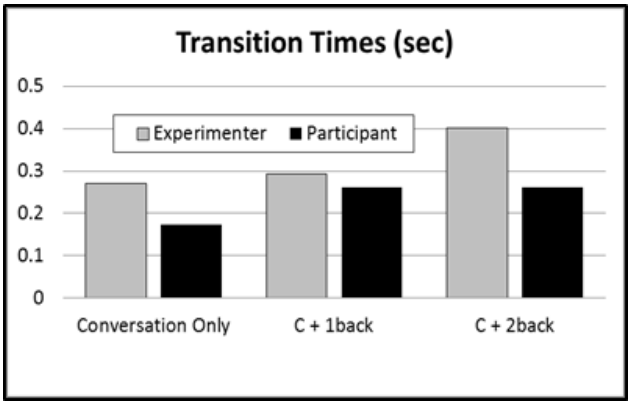

Figure 1: Transition time (in seconds) by task condition, for both participant and experimenter.

Table 1 summarizes the results of a linear mixed effects model on the participants' turn transition times: lmer(trans_time ~ Experimenter + Order + Turntype + Block + LSS + (1 + Block |subj)). The four experimenters, five block orders, and four most common turn types were used as control variables. To save space, only significant effects for control variables are included in Table 1.

Table 1. Analysis of Participant's Transition Time

	Estimate	t	p
Block C vs C1	.06	1.61	.11
Block C vs C2	.08	2.14	.04
Exp1 vs Exp4	-.23	-4.83	.00
Ord1 vs Ord3	.19	3.49	.00
Agree vs Answer	.23	6.92	.00
Agree vs Quest	.23	4.13	.00

There was no effect of the secondary task on participants' speech rate, but the task manipulation did impact both

utterance length and the probability of a turn-initial filled pause. As predicted by Load Theory, participants took longer turns and made fewer turn-initial filled pauses in the Conversation-Only block compared with blocks that combined conversation with the n-back task.[1]

Across all four dependent measures, the strongest predictor of the participant's conversational fluency was turn type, overshadowing the secondary task manipulation. The four most common turn types (agreement, answering a question, asking a question, or making a comment) made up 98% of the participant turns. As shown in Figure 2, type of utterance was a strong predictor of both transition time and utterance length.

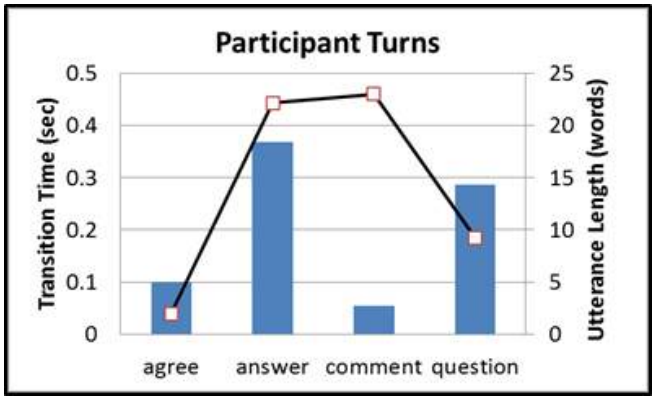

Figure 2: Participant's transition time (bars) and utterance length (line) by turn type.

As predicted by Load Theory, performance on the n-back task was worse in the blocks that required simultaneous conversation, especially in the 2-back condition (see Table 2). Participant means were submitted to a 2 (n-back level) by 2 (alone or w/conversation) by 5 (order) repeated measures ANOVA, with the third factor as a between-participants variable. Robust effects of n-back level [$F(1,35) = 139.23$, $p < .01$], conversation [$F(1,35) = 280.02$, $p < .01$], and their interaction [$F(1,35) = 98.54$, $p < .01$] were observed. No effect of order or interactions with order approached significance [all F's less than 1.9].

Table 2: Percent Correct (w/standard error) on n-back.

	alone	w/conversation
1-back	99 (.2)	91 (.8)
2-back	97 (1.5)	79 (1.1)

One-minute clips from the conversations were presented to 108 naive listeners, who judged whether the participant (always the first speaker in the clip) had been under no load, low load, or high load from a secondary task. As shown in Table 3 with correct responses highlighted, listeners were highly inaccurate. Their bias was to guess "none" or "low." This suggests that participants in the primary experiment were largely successful at maintaining fluency, despite the extra load from the secondary task.

Table 3. Percent load judgments by audio clip condition.

	C only	C+1-back	C+2-back
None	50	47	41
Low	40	37	42
High	10	16	17

Consistent with the Alignment hypothesis, there was some evidence that participants were more fluent when the alignment between speakers was highest, as illustrated in Figure 3: The higher the Latent Semantic Similarity (LSS) between speakers, the faster the participant's speech rate. The LSS was also a marginal predictor of transition time. To be sure, all of the conversations were at the high end of the LSS scale, which ranges from -1 to 1. Thus, there may have been insufficient variance to find a stronger correlation.

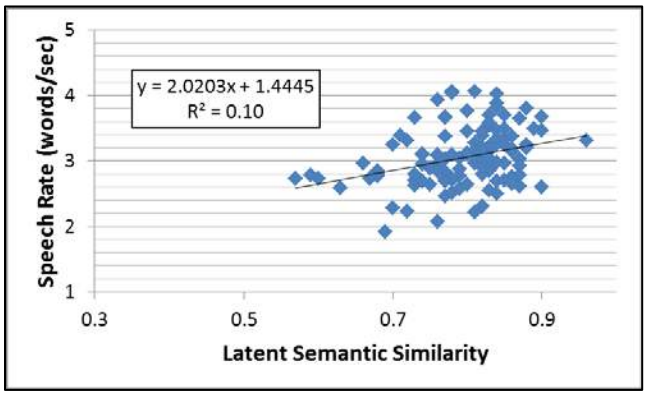

Figure 3: The relationship between participant speech rate and Latent Semantic Similarity.

Discussion

Load Theory was supported by the decrease in accuracy on the n-back task when it was paired with conversation, and by the increase in transition times with n-back load, While transition times remained within the normal range of around 200ms cited by Stivers et al. (2009) and others, participants seemed to use compensatory measures, such as shortening their turns and beginning their turns with a filled pause, in order to maintain short transition times when faced with a challenging secondary task.

While the experiment was not a clear test of Pickering and Garrod's (2004, 2013) Alignment account, the apparent robustness of conversational fluency to a secondary task (albeit with some modulations) is consistent with their account. Furthermore, the modest correlation between LSS and speech rate is suggestive. Unfortunately, there are no established, objective measures of conversational alignment,

[1] See Appendix for statistical support.

making it difficult to rigorously test Pickering and Garrod's predictions. Nonetheless, the strong effect of turn type (see Figure 2) seems problematic for their account. Turn type determines how quickly participants can begin planning their responses and how much planning is required. The robust turn-type effects suggest that the cognitive operations supporting utterance planning are less automatic than maintained by strong versions of the Alignment account (e.g., Pickering & Garrod, 2013).

Experiment 2

Because alignment can't be manipulated in spontaneous conversation, Experiment 2 used a picture description paradigm to test the effects of two aspects of alignment (shared topic and shared vocabulary). Topic was manipulated within-participants, such that each of the participant's picture descriptions was preceded by a pre-recorded sentence that was either a description of the same picture or a description of a different picture. Shared vocabulary was measured by counting the number of content words from the pre-recorded sentence that were repeated in the participant's picture description.

While it may seem odd to treat pre-recorded stimuli as a speaker in a conversation, this approach was successful in a recent experiment. Corps, Crossley, Gambi, and Pickering (2018) found that participants answered pre-recorded yes/no questions faster when the final word was predictable, with transition times averaging around 400ms. Participants were encouraged to respond quickly, answering "as soon as you expect the speaker to finish the question" (p. 83). While these transition times are slower than typical transition times in dyadic English conversations and the responses were very simple, the finding demonstrates that participants were actively predicting the content of the pre-recorded stimuli and using those predictions to prepare their own response during the other speaker's turn, analogous to conversation.

We encouraged participants to time their utterances to coincide with the offset of the pre-recorded stimuli through a scaffolded training procedure. However, this study did not use question/answer pairs, making the link to conversation somewhat more tenuous.

Method

Participants Twenty-nine undergraduates participated for course credit and were randomly assigned to one of two lists. All were native English speakers

Procedure On each of 36 trials during the experiment, participants looked at a line drawing of a complex scene while listening to an auditory sentence. Participants were instructed to describe the scene as soon as the auditory sentence ended. The participant was instructed to refer to the entity indicated by the arrow in their description of the picture (see Figure 4). In the Match condition, the auditory sentence was about the current image; in the Mismatch condition, an auditory sentence for a different image was substituted. Across the two lists, every picture occurred in both the Match and Mismatch conditions, and each participant received half of each type. After the participant finished their utterance, the next screen presented a printed word and participants judged whether it had been in the auditory sentence of the current trial (50% had been). This recognition probe encouraged attention to the auditory sentence. For the image in Figure 4, the matching sentence was “William was very pleased with himself for surprising his wife with an anniversary gift”, and the probe word was "pleased".

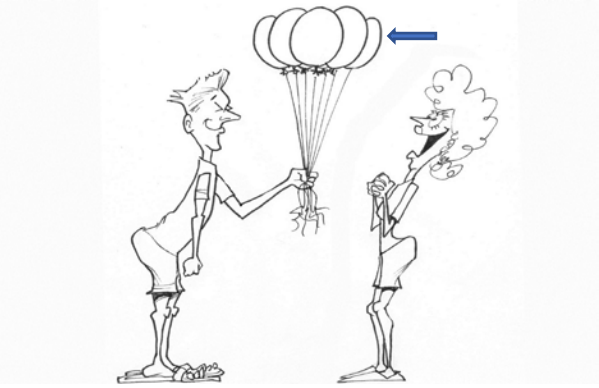

Figure 4: Example line drawing.

Prior to beginning the experiment, participants practiced each component of the task: describing the pictures while referring to the entity indicated by the arrow, timing their response to commence as closely as possible to the end of the auditory sentence, and answering yes/no to the recognition probe word.

Both the pre-recorded auditory stimuli and the participant’s picture descriptions were audio-recorded and transcribed as in Experiment 1, with the participant and the pre-recorded stimuli treated as different speakers.

Results

The participants' utterances were coded for transition time, speech rate, utterance length, the presence of disfluencies, and the number of content words repeated from the pre-recorded stimulus (see Table 4).

As predicted by the Alignment account, fluency was higher in the Match condition. There were shorter transition times and more succinct descriptions when the auditory stimulus sentence described the same image as the participant's sentence. The effect on transition time was confirmed in linear mixed effect model, summarized in Table 5: lmer(trans_time ~ Condition +RepeatWords.C +Accuracy + Utt_words.C + (1 + Condition|subj) + (1 + Condition|trial)). Accuracy on the recognition probe and the number of words in the participant's utterance were included

as control variables[2].

Table 4. Means (standard error) for Experiment 2

	Matched	Mismatched
Transition Time	515 ms (22)	575 ms (25)
No. of Words	10.01 (.17)	9.56 (.16)
Speech Rate	3.23 w/s (.04)	3.15 w/s (.04)
Disfluent %	33 (2)	33 (2)
No. Repeated Words	1.42 (.05)	0.12 (.02)
Probe Accuracy %	87 (1)	77 (2)

Table 5. Transition Time Analysis for Experiment 2

	Estimate	t	p
Intercept	.51	7.83	.00
Condition	**.08**	**2.55**	**.01***
RepeatWords.C	.03	1.25	.21
Accuracy	-.02	-.87	.38
Utt_words.C	**.14**	**4.51**	**.00***

Participants were more accurate overall on the recognition probe in the Match condition than in the Mismatch condition [2-tailed paired t-test: $t(29) = 4.54$, $p < .001$]. This could be because greater alignment eased overall processing load. Alternatively, higher accuracy on Match trials could reflect participants having produced the probe word themselves when describing the picture. This occurred on 9% of Match trials with a "yes" probe word and less than 1% of the time on Mismatch trials with a "yes" probe word. Not surprisingly, participants never used the probe word themselves on "no" trials, in which the probe word was not in the pre-recorded sentence. When analyzing only the "no" probe trials, the effect of Match remained robust [95% Match, 84% Mismatch condition, $t(28) = 4.15$, $p < .001$], consistent with the hypothesis that greater alignment eased overall processing load.

Contrary to the Alignment prediction, repetition of words did not increase fluency. Instead, the numerical trends went in the opposite direction (see Figure 5): the more content words the participant repeated from the auditory stimulus sentence, the longer the transition time and the more wordy the image description. This surprising pattern might arise if participants used a lot of pronouns in the Match condition, rather than repeating referring expressions from the auditory stimulus. This pattern was not found. Although, there was a slight numerical difference in pronoun usage (.66 pronouns per utterance in the Match condition, .60 in the Mismatch condition), it was not significant in a 2-tailed, paired t-test ($t(29) = 1.41$, $p > .10$), nor was there an effect of pronouns or an interaction between pronouns and Match/Mismatch, when pronoun usage was added to the statistical model used for Table 5.

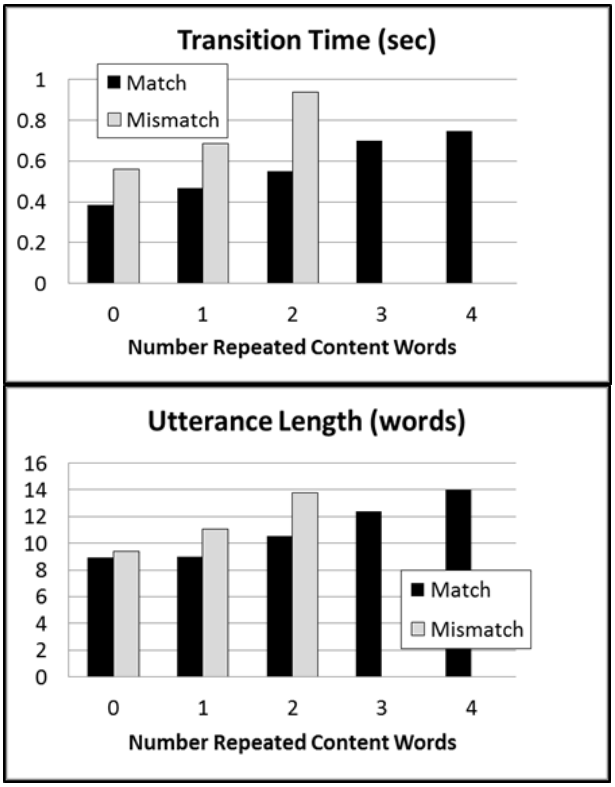

Figure 5: Transition times (upper bar graph) and utterance length (lower) in the Matched and Mismatched condition, when controlling for number of repeated words.

Discussion

Despite the artificiality of the paradigm, a shared topic decreased transition time, as predicted. This effect suggests that participants planned their utterance during the auditory stimulus, analogous to spontaneous conversation.[3] Furthermore, it provides some direct support for the Alignment account. However, the topic alignment advantage did not come from the most obvious source--lexical repetition of words in the auditory stimulus. Rather, the Match advantage in this paradigm must be due to other phenomena, such as more accurate prediction of the end of the auditory stimulus and semantic priming. It remains possible that lexical repetition plays a more important role in natural conversation than it did in this paradigm, but the

[2] To verify that the results remained the same when including only trials on which participants attended to the recorded sentence, an additional statistical model was run, including only trials on which participants responded accurately to the probe word. It was identical to the original model, except that accuracy was excluded. As expected, the same pattern of effects reported in Table 5 was obtained.

[3] In an earlier version of the experiment that did not include the pre-experiment training, mean transition time was well over a second, with no effect of match. Thus, participants may not multi-task in this paradigm (i.e., plan their utterance during the auditory stimulus while predicting its endpoint) unless explicitly encouraged to do so.

current experiment found no support for the lexical repetition prediction, motivated by the Alignment account.

General Discussion

Prior research indicated that conversation competes for central resources when paired with a secondary task from another domain, such mouse-tracking, walking with groceries, or driving (Becic et al., 2010; Boiteau et al., 2014, Kemper et al., 2005; Sjerps & Meyer, 2015). However, except for Boiteau et al., this research did not use natural, spontaneous conversation and examined relatively few measures of conversational fluency. Experiment 1 used spontaneous conversation to extend this finding to a secondary task (mixed-case letter n-back) that uses resources within the language domain. Consistent with prior research and with Load Theory, we found interference effects for both conversation fluency and the secondary task. We also found that turn type was a strong predictor of multiple conversational fluency variables, reflecting the differential processing demands of agreeing, questioning, answering, and commenting.

In addition, we explored some predictions of the Alignment theory using a picture description paradigm with pre-recorded stimuli instead of a live interlocutor. To increase the similarity with natural conversation, we trained participants to time their utterances to coincide with the offset of the auditory stimulus, while obeying other task-specific constraints. In this paradigm, participants initiated their own utterance closer to the offset of the auditory stimulus when both utterances shared the same topic (a co-present image). This finding is consistent with the Alignment account. However, the number of content words shared between the auditory stimulus and the participant's picture description was not related to conversational fluency in the direction predicted by the Alignment account.

In sum, we found considerable support for theories in which conversation consumes processing resources, such as working memory and attention. At the same time, we were surprised that participants were able to maintain typical transition times as working memory load increased. Our results from the two experiments suggest that this feat was possible because of shared topics across adjacent turns and due to compensatory mechanisms, such as making turns shorter or beginning turns with a filled pause.

Acknowledgments

This research was made possible by a team of undergraduates who helped create the experiments, collect the data, and participate in the conversations for Experiment 1. They and additional students transcribed coded the data: Kelly Kendro, Jocelyn Brickman, Meher Sabri, Madylin Eberstein, Yaozong Huang, Olivia Shulman, Maxwell Recknagel, Thinh Nguyen, Lindsey Harris, Katherine Hall, Hussam Hashem, Luciana Rosania, and Natalie Jackson.

The probability of a sentence-initial filled pause not analyzed using the above statistical model due to the large number of 0's (no filled pause) across trials. Instead, the probability of a sentence initial filled pause for each participant, in each condition, was analyzed using repeated measures ANOVA. There was a main effect of block [$F(2, 76) = 6.79$, $p < .01$], with a probability of .09 in the Conversation-Only condition, .14 in the Conversation with 1-back condition, and .15 in the Conversation with 2-back condition.

An Insight into Language: Investigating Lexical and Morphological Effects in Compound Remote Associate Problem Solving

Abstract

Understanding the processes leading to insight has remained one of psychology's greatest challenges. In this study, we examined how different lexical properties affect cognitive processes involved in a popular class of insight problems: Compound Remote Associates (CRAs). These properties were familiarity, lexeme meaning dominance, and semantic transparency. We found that a higher proportion of problems were solved when they were presented beginning with the most familiar cues, but not when they began with right-headed dominant or the most semantically transparent cues. Further, we found that participants focused their efforts disproportionately on first and last cues, that subjective ratings of insight decreased as trial times elapsed, and that the magnitude of reported insight increased with the number of cues successfully solved. This suggests that participants can monitor their progress in such problems. These results contest longstanding assumptions of requisite periods of impasse and the absence of incremental progress in insightful problem solving.

Keywords: compound remote associates; insight; language and thought; problem solving

Introduction

Insight has sparked some of history's greatest accomplishments – from Einstein's special theory of relativity to Newton's universal law of gravitation. These sudden "aha!" moments also permeate our everyday lives – from practical household problems to puzzles in video games. However, our understanding of the processes underlying insight have remained subject to empirical gaps and theoretical debate (Batchelder & Alexander, 2012). Indeed, a prevailing assumption of the literature has been that insight occurs by merit of one solving an "insight problem" (Topolinski & Reber, 2010). To make meaningful progress toward understanding insight, we must first explore the cognitive mechanisms involved in problems in which it is reported.

One such class of problems are Compound Remote Associates (CRAs) (Bowden & Jung-Beeman, 2003). The CRA task was developed as a modified version of the Remote Associates Test (RAT) (Mednick, 1962), which has been correlated with performance in insight problems. The difference between the original RAT and CRAs is that the latter only uses structural associates based on syntax (Worthen & Clark, 1971). In CRAs, people are presented three cue words and must produce a solution word that is common to all three, forming compound words and phrases. For example, the solution to the triad "COTTAGE, SWISS, CAKE" is CHEESE (forming "COTTAGE CHEESE," "SWISS CHEESE," and "CHEESECAKE," respectively). The task is designed such that a solver must break free of high-frequency associations to access globally satisfactory solutions.

CRAs have many advantages over classic insight problems: 1) they have large, normed databases, 2) many can be completed in single, short experimental sessions, 3) they can be solved with and without insight, 4) people have reliably demonstrated that they can make subjective judgments of insight regarding them, 5) they can be used in neuroimaging studies to identify the neural correlates of insight, and 6) they can be supplemented with time-based measures of solution latencies. As a result, they have been widely used to explore various cognitive domains, such as intuition (Topolinski & Strack, 2008), sleep (Cai et al., 2009),

and computational/deep learning (Olteteanu, Gautam, & Famomir, 2015).

Much of the past research on the RAT and CRAs has defaulted to a correlational account that simply assumes insight and ignores the underlying processes that may drive it. This problem was highlighted by Topolinski and Reber (2010), who pointed out that many researchers neglect to explain the *phenomenology* of insight yet rely on it as a sufficient condition.

Recent studies have attempted to mend this by modelling CRA performance. Gupta, Jang, Mednick, and Huber (2013) were among the first to provide a formalized account of individual differences in CRA search behavior. They employed a norm-based model that defined the best guess at solutions based on the average of cues in the Word Association Space (WAS) (Steyvers, Shiffrin, & Nelson, 2005). This was contrasted with a frequency-biased model that assumes people's search is biased by word fluency, based on Griffiths, Steyvers, and Firl's (2007) work with PageRank and associative frequency. As predicted, they found that the probability of a given response is biased toward high-frequency words. Thus, people perform poorly if they're biased in favor of high-frequency incorrect words, precluding access to low-frequency correct responses.

This work was extended by Olteteanu and Falomir (2015), who developed the comRAT-C; a computational model that solves compound RAT queries, based on a cognitive theoretical framework for creative problem solving (CreaCogs) (Olteteanu, 2016). The knowledge base (KB) comprising the CRAs themselves used language data (2-grams pruned for relevance) from the Corpus of Contemporary English (COCA). They found that the comRAT-C used a convergence process similar to that of human solvers, and that the frequency of cues in the KB influences responses. The comRAT-C was able to correctly solve 64 of the 144 items in Bowden and Jung-Beeman's (2003) list of normed CRAs, in addition to suggesting unlisted, yet plausible solutions in more than 20 cases – suggesting its own form of creativity. Overall, their study laid a solid computational framework for formalizing the processes in CRA problem solving.

A promising experimental approach was taken by Smith, Huber, and Vul (2013), who used Latent Semantic Analysis (LSA) to evaluate the similarity between people's guesses, word cues, and answers. They accomplished this by having participants enter every word considered while searching for the answer, regardless of their correctness. By doing this, they focused on the search processes used when generating candidate answers through a probabilistic sampling framework. They found sequential dependencies between responses in a problem, with subjects generating semantically similar chains of responses. Additionally, people seemed to focus primarily on one cue at a time. However, their procedure assumes that guesses accurately reflect the implicit nature of the search, even though the very act of conscious report may alter the search process.

The main body of work on CRAs has focused on associative aspects - not the requisite that responses be syntactic *compounds* (with the notable exception of Olteteanu and Falomir (2015)). Indeed, research has largely ignored the morphological properties of the compounds themselves and how they affect performance and the likelihood of reported insight. We have thus failed to adequately address a critical aspect of their character. This approach has potentially restricted us from discovering how people attain insight in these problems. A look at the nature of compounds and their lexical elements is necessary to better understand the underlying cognitive processes involved in these problems.

Compound Word Research

Early work on compound words used a lexical decision paradigm (Taft & Forster, 1975), which measures peoples' response times (RT) in classifying words and nonwords. One such study found that only the lexical status of the first constituent word in a compound affects processing, with longer RT for word-word and word-nonword pairs (e.g., DUSTWORTH, FOOTMILGE) than nonword-word and nonword-nonword pairs (e.g., TROWBREAK, MOWDFLISK) (Taft & Forster, 1975). Thus, it appears that morphological decomposition takes place when processing compound words, instead of the words being stored and retrieved as a whole.

There has been considerable work on visual word recognition in recent years facilitated by databases containing lexical characteristics and behavioral data, such as latencies of word naming and lexical decisions for large sets of words (e.g., Balota et al., 2007) and investigations of word length (New, Ferrand, Pallier, & Brysbaert, 2006). Though initially focused on monosyllabic and monomorphemic words, this work has been extended to address processing in multisyllabic words (Yap & Balota, 2009) and English compound words.

Research suggests that English compounds are processed differently from length and frequency-matched monomorphemic words. For instance, both semantically-transparent compounds (e.g., ROSEBUD) and opaque compounds (e.g., HOGWASH) are processed more quickly than their monomorphemic counterparts (e.g., GIRAFFE) (Ji, Gagné, & Spalding, 2011). This sense of morphological complexity has ignited debate in the psycholinguistic literature, with competing perspectives on compound representation and processing (see Fiorentino & Poeppel, 2007).

The current study investigates the roles of three lexical properties involved in compound processing and, by extension, CRAs: word familiarity, semantic transparency, and lexeme meaning dominance. Thus, we investigated if and how they differentially affected CRA performance and the likelihood of insight. To do this, we used Juhasz, Lai, and Woodcock's (2015) database of 629 compound words to construct 21 novel CRA problems. This database, which adapted items from the English Lexicon Project (ELP: Balota

et al., 2007), compiled subjective ratings for six properties believed to affect morphological processing. The questionnaires used by these authors are available in their Supplementary Materials. We will now briefly explore each of these selected properties and justify their inclusion in the study.

Familiarity Whole word frequencies may be interpreted as analogous to whole word access and have thus been studied in compound word recognition (Juhasz, Lai, & Woodcock, 2015). However, English compound frequencies tend to be low relative to other languages, resulting in experimental challenges and a consequential gap compared to Dutch (Kuperman, Schreuder, Bertram, & Baayen, 2009) and Finnish (Kuperman, Bertram, & Baayen, 2008) counterparts. Rated familiarity can be regarded as a measure of subjective frequency and has been demonstrated to affect word recognition in English monomorphemic words. In particular, familiarity has been shown to influence eye fixation durations, along with word frequency (Juhasz & Rayner, 2003). This was further demonstrated in an experiment by Juhasz, White, Liversedge, and Rayner (2008), which found that familiarity affected gaze duration for both long (ten or more letters) and short (seven or fewer letters) English compound words.

We thus contend that ratings of familiarity can be used as a subjective proxy for word frequency and have a role in affecting morphological processing and CRA performance.

Semantic Transparency Semantic transparency also plays an important role in how compounds are processed and represented (Libben, 1998). A fully transparent compound is one in which both constituents contribute to the meaning of the compound word (e.g., SUNLIGHT), while a fully opaque compound is one in which neither constituent contributes to its meaning (e.g., FLAPJACK). There are also partially-opaque compounds, in which only one constituent contributes to the compound's meaning (e.g., JAYWALK, CHEAPSKATE) (Juhasz et al., 2015).

Libben (1998) proposed a model in which semantic transparency is represented in two distinct ways: the semantic relationship between the meaning of a constituent morpheme within a compound, and the meaning of the morpheme independent of it. For example, the opacity of the compound SHOEHORN results from HORN not being transparently related to the compound as a whole, whereas SHOE is fully transparent. Thus, it is classified as a T-O compound (wherein T = transparent, O = opaque). Compounds require some level of semantic transparency to be tied to semantic representations of their lexemes. Using a lexical decision task, Libben, Gibson, Yoon, and Sandra (2003) found that fully opaque and T-O compounds were responded to more slowly than other compound types, though there was a significant priming effect on all four compound types relative to neutral primes.

Research has demonstrated that semantically transparent compounds are especially susceptible to morphological decomposition, and that semantic priming only seems to occur when there is at least one transparent lexeme. Using Dutch compounds, Sandra (1990) used semantic associates of constituents as primes for transparent (e.g., BIRTHDAY primed by DEATH), opaque (e.g., SUNDAY primed by MOON), and pseudo-compounds (e.g., BOYCOTT primed by GIRL). Facilitatory priming effects were only observed for constituents in transparent compounds.

Lexeme Meaning Dominance Compared to other languages, English compound words tend to be right-headed (i.e., the second constituent word – or lexeme - is the semantic head of the compound). This lexemic dominance primarily defines the meaning of the compound. In a study by Inhoff, Starr, Solomon, and Placke (2008), location and word frequencies of lexemes were manipulated in lexical decision, naming, and sentence reading tasks. They found an effect for larger word frequency for the dominant lexeme in each task. Lexeme dominance also affected first fixations on compound words. These results suggest the headedness of a compound affects how it is recognized and subsequently processed.

Since all the word cues presented in the CRAs in this experiment are the second lexemes, their contribution to the overall meaning of the compound should affect the speed of access when solving each problem.

The Current Study

In accordance with the evidence above, we predicted that CRA problems beginning with word cues that 1) are the most familiar, 2) are the most semantically transparent, and 3) have right-headed lexeme dominance would result in the highest levels of performance and reporting of insight.

To test this, we staggered the presentation of word cues on-screen, with cues either increasing or decreasing in ratings for the relevant lexical domain. Thus, we actively constrained and manipulated the search processes used by solvers. As CRA triads are commonly presented at once, this presents an experimental departure that, we hypothesize, differentially affects performance and captures some of the latent features of this process. To our knowledge, this is one of the first studies to actively manipulate cue presentation in CRAs in such a way with precise behavioral predictions.

Another departure is in how problems are scored. CRAs are typically scored according to whether a submission 1) conforms to all three cue words and 2) conforms to the suggested response of the researchers, precluding other "incorrect", yet plausible responses. This does not allow for investigation of partially correct problems, in which fewer than three cues are satisfied by the solution candidate. We address this issue using a lexicon to test whether submitted responses form valid compounds against each individual cue presented, either as a prefix or suffix. This allows for a more comprehensive picture of the processes and strategies employed in such problems.

Together, this study contributes to the CRA literature in three major ways: 1) it uses a staggered presentation of word cues, facilitating semantic activation and lexical search

behavior, 2) it investigates the morphological properties of the compounds themselves, and 3) it uses partial scoring for each word cue. The goal of the study is to determine how the aforementioned lexical properties affect solution retrieval and if they influence performance and the probability of reported insight.

Methods

Participants

Each experimental condition was composed of two counterbalanced groups, comprising six groups total. All participants (n = 128) were University of California, Irvine undergraduate students, who were awarded course credit through the SONA system for their role in the study. The age distribution was 18-21 (n = 110), 22-25 (n = 11), 26-30 (n = 5), and 31-40 (n = 2). Everyone identified as a native English speaker, with 53 participants identifying as multilingual (though additional languages spoken were not specified).

In the *Familiarity* condition, Group 1 consisted of 23 participants (n = 21 females), and Group 2 consisted of 22 participants (n = 14 females).

In the *Lexeme Meaning Dominance* condition, Group 3 consisted of 21 participants (n = 14 females), and Group 4 consisted of 21 participants (n = 19 females).

Lastly, in the *Semantic Transparency* condition, Group 5 consisted of 21 participants (n = 16 females), and Group 6 consisted of 20 participants (n = 18 females).

Fourteen participants were excluded from the final analysis, as they did not meet the criteria of answering at least two of the three practice problems correctly.

Materials

We constructed 21 novel CRA problems from compounds that had at least three common stems (thus forming three cues with a common solution). For example, there are 10 compound words in Juhasz et al.'s (2015) database with the shared prefixed stem FOOT. The mean ratings for whatever variable was in question (on a 1-to-7 scale for familiarity and transparency and on a 1-to-10 scale for lexeme meaning dominance) were then sorted in descending order and the words with the highest and lowest values were selected. The mean of these two values was then calculated and the compound word with that value or its closest approximate was selected as the middle term. Using the same example of FOOT for the variable of familiarity: FOOTPRINT has the highest value at 7, FOOTPATH has the closest approximate to the mean with a value of 5.85, and FOOTHILL has the lowest value at 4.71. This forms the CRA problem "PRINT, PATH, HILL," with the solution FOOT. All compounds in this database begin with a prefixed solution stem. Thus, unlike other studies, the solution is always the first lexeme in the compound.

In the event of a tie between two compound word values, the compound with the closest letter length to the other two words was selected. If the competing compound had the same length, the tie was broken by identifying which one more closely matched the mean age of acquisition value of the other two compounds.

Due to the limited number of candidate items, some words were repeated in both problem and solution terms. For example, PORT occurs in the problems "PORT, BASE, SICK" and "FOOD, PORT, BOARD." There was also an instance of a having the same phonetic representation (WASTE and WAIST). Participants were told that words may occur more than once both as cues and as solutions.

Each condition was counterbalanced so that problems were presented in both ascending and descending order across two groups. This was done to control for potential order effects.

Procedure

Participants were given instructions and a working definition of "insight" (*Insight occurs when the answer suddenly pops into your head, accompanied by a strong burst of positive emotion ("aha!").*). They were then given an example CRA problem ("CREAM, SKATE, WATER," solution = ICE) and were asked to complete three practice problems with feedback. All four of these problems were pulled from the Bowden and Jung-Beeman's (2003) set of CRA norms and were the four easiest problems with uniformly prefixed solution stems.

The experiment was conducted using a MATLAB interface. Word cues were presented sequentially with 5-second delays between each cue. The first word cue appeared in the left-center of the screen, the second appeared in the center, and the third in the right-center. Cues remained on-screen after their presentation for the remainder of the trial. Figure 1 demonstrates the display of a typical problem trial.

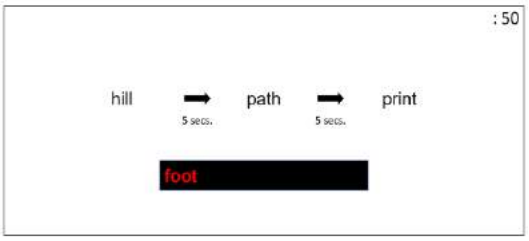

Figure 1: Example of problem trial.

Each trial lasted for one minute. A countdown timer appeared on the top right-hand corner of the screen when 50 seconds remained and turned red when 10 seconds remained. Participants typed their responses in a black box below the cues. They were encouraged to answer as quickly and as accurately as possible. They could submit their response at any time following the presentation of the third cue. Participants were forced to proceed after the minute had expired and whatever was typed into the solution box was accepted as the submitted response.

Following each problem trial, participants were asked to report the level of insight they experienced on a scale of 1 ("no insight") to 7 ("complete insight"). They were also

reminded of its operational definition on the bottom of the screen.

At the end of the experiment, participants were asked to provide a brief (150-word max.) description of what strategies they used to solve these problems. We also asked them to describe the difference they felt between solving problems with and without the feeling of insight. This was done to determine individual differences in reporting criteria and as a check for cross-validity with our definition. This data will also be evaluated to inform future, related experiments.

Participants were scored based on how quickly and accurately they responded to each problem.

Results and Discussion

First, we tested the hypothesis that presentation order of cues according to ratings in each lexical condition would affect performance. These results are shown in Figure 2. Note: "Direction" denotes whether the cue presentation sequentially increased or decreased for the lexical property in question (that is, "Down" indicates that the first cue had the highest rating for the property, while "Up" started with the lowest rating). It appears that the only observed difference was in familiarity, with a higher proportion of problems successfully solved when they began with the most familiar word cue (M = 0.383, SD = 0.126), rather than the least familiar cue (M = 0.301, SD = 0.161, $t(226) = 4.304$, $p < .001$, $d = 0.570$). The estimated Bayes factor suggested that the data were .001:1 in favor of the alternative hypothesis, suggesting decisive evidence for a presentation order effect (Jeffreys, 1961). While this finding was not shared by the other properties (lexeme meaning dominance and semantic transparency), there are several other important findings – some of which challenge widely-accepted assumptions regarding the "special process" view (Bowden, Jung-Beeman, Fleck, & Kounios, 2005) of the insight phenomenon.

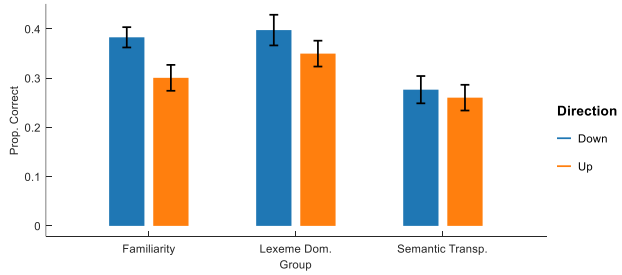

Figure 2: Differences in performance for each lexical property.

For further analysis, we used English compounds derived from the Touchstone Applies Science Associates (TASA) corpus and derived a lexicon of over 122,000 words, including hyphenated compounds. We used this lexicon to test whether a submitted response forms a valid compound against each individual cue presented, either as a prefix or suffix. The results of individual cue matches are shown in Figure 3, which demonstrates that the proportion correct for suffixes is smaller than that of prefixes. Further, submitted responses had a smaller likelihood of being valid prefixes for middle cues (M = 0.351, SD = 0.162) than for first cues (M = 0.411, SD = 0.182) and last cues (M = 0.402, SD = 0.174, $F(2,228) = 8.049$, $p < .001$). The estimated Bayes factor suggested that the data were .032:1 in favor of the alternative hypothesis, or rather, 31.25 times more likely to occur under the model including an effect for cue position than the model without it, providing strong evidence for its effect. This suggests that participants were alternating between cues when attempting to generate a solution, rather than using parallel processing. One possible explanation is that since cue presentation was staggered – and thus their search was guided – there may be primacy and recency effects whereby they were able to test and generate more candidate solutions following the first word cue, then worked backwards once all cues were presented using the third cue.

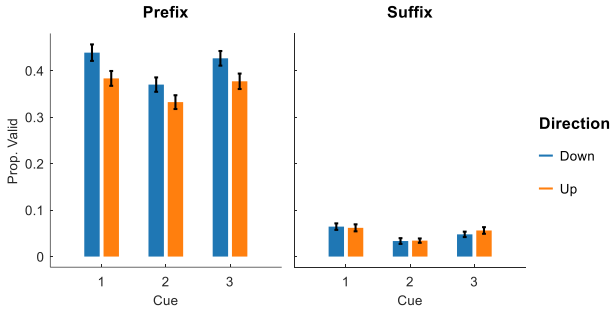

Figure 3: Proportion of valid prefixed (left) and suffixed (right) responses for each word cue position, according to lexicon.

Another interesting finding was that ratings of insight decreased as time elapsed throughout trials, as demonstrated in Figure 4. This finding holds for both correct and incorrect trials. This seemingly challenges the popular assertion that there must be a period of impasse, or mental block, preceding the experience of insight (Ohlsson, 1992). To the contrary, there were higher ratings of insight in the immediate time following the presentation of all three cues (i.e., 10-20 seconds) than in the time before the end of each trial (50-60 seconds). It is possible that participants simply rated solutions that they perceived to be correct as insightful *de facto* (hence, being submitted quickly), and correctly rejected the occurrence of insight for incorrect solutions proffered as a final guess before trials ended.

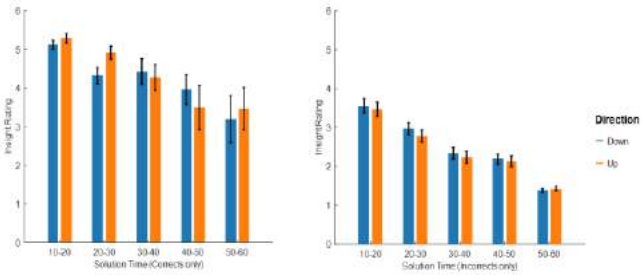

Figure 4: Insight ratings as a function of solution time (in secs.) for correct solutions (left) and incorrect solutions (right).

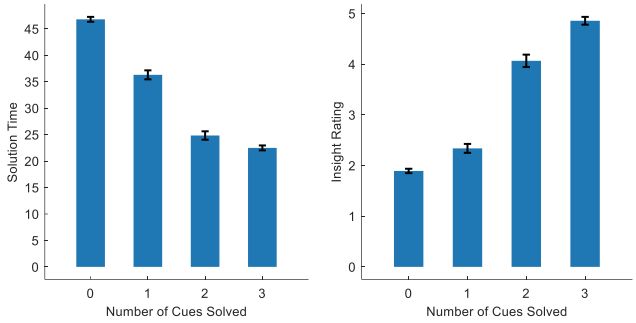

Figure 5: Solution time (in secs.) as a function of cues solved (left); Insight ratings as a function of cues solved (right).

Finally, there is the reporting of insight, itself. As demonstrated in Figure 5, fewer cues were likely to be solved as more time elapses in trials. The magnitude of reported insight also increased along with the number of cues correctly solved. Rather than an all-or-none experience – the "sudden, certain burst" frequently reported and used as a necessary criterion (Chronicle, MacGregor, & Ormerod, 2004) - it appears that participants used ratings of insight to indicate confidence in their answers. Indeed, these ratings increased as a function of the number of cues their proposed solution fit. There is not the presence of absolute insight for totally correct trials (in which all three cues are satisfied by the proposed solution), nor the absence of insight if this is not achieved. Rather, it exists on a continuum. This suggests more of an analytic approach, in which participants reliably monitor their progress in each problem and the likelihood of success using insight as a proxy for said progress. This contrasts previous research which states that incremental feelings of "warmth" do not precede moments of insight and are instead relegated to analytic or non-insightful problem solving strategies (Metcalfe & Wiebe, 1987). It should be noted again that a property of CRAs is that they can be solved with *or* without insight. What we argue here is the usefulness of insight ratings in CRAs to indicate perceived progress.

One limitation to the current work is that it used novel CRAs instead of those with established norms for difficulty and magnitude/frequency of reported insight (such as Bowden & Jung-Beeman, 2003). Applying lexical ratings to such a database for the dimensions present in Juhasz, Lai, and Woodock (2015) would be informative for future studies. Future research could also have subjects generate their own list of compounds given a set of word stems. Through doing this, researchers could collect latency data for how long people take to produce words, indicating their availability in memory. Researchers could also use LSA to analyze these participant-generated sequences of compounds to describe search behavior. These data could be applied across participants to establish cross-reliability and a more naturalistic set of items with norms.

All problems in the current study have suggested solutions that are the first lexeme in the compound. Since stem placement seems to matter in the processing of compounds (Taft & Forster, 1975), it may be beneficial to compile and use compounds with common prefixes and suffixes in future studies.

The self-identified magnitude of insight in our study was still based on subjective report. While this study focuses on the cognitive processes underlying these problems, rather than attempting to formalize insight in a significant manner, similar studies attempting to so may wish to include neural and/or physiological covariates to identify correlates of insight (e.g., EEG, fMRI, skin conductance, eye-tracking) (see Bowden et al., 2005 for suggested neurocognitive approaches). Future studies should also explore participants' differences in reporting thresholds, as one person may be more willing to identify the occurrence of insight than another. These individual differences could be applied to a signal detection theory model.

This study offers modest progress into understanding the linguistic contributors to CRA processing. There are other factors that should be investigated, such as if compounds with noun-noun links and adjective-noun links differentially affect performance. Other variables to investigate are word length effect (New et al., 2006), imageability, age of acquisition, sensory experience, or a combination of the above.

There may also be a reading direction effect present, as cue presentation always proceeded from left-to-right on the screen. To circumvent potential perceptual biases, future studies using a similar design may benefit from counterbalancing the order of reading direction, as well.

Lastly, it is important to be remain cognizant that not all insight problems are the same, and the phenomenology in CRAs may differ from that of other insight problems. It would be premature to make any sweeping statements about modeling insight from discoveries made in one class of problems.

Conclusion

If we are to solve the problem of insight, we must better understand the cognitive processes underlying the methods

we use to study it. Since we've largely neglected to explore these commonly-used procedures, we've defaulted to assumptions that they are "insight problems" simply because they elicit feelings of insight (based on the many and inconsistent criteria of researchers). While there have been both promising empirical and theoretical attempts to address this problem in recent years, much work remains. Better understanding the driving mechanisms, including lexical properties, within CRA problem solving will further inform us about how creativity is exercised and, perhaps, how insight is attained.

Efficiency and Flexibility of Individual Multitasking Strategies - Influence of Between-Task Resource Competition

Jovita Bruening

Abstract

Evidence exists that individuals prefer distinguishable strategies for self-organized task scheduling in multitasking. They either prefer to work for long sequences on one task before switching to another (i.e., blocking), to switch repeatedly after short sequences (i.e., switching), or to process the current stimuli of two tasks before responding almost simultaneously (i.e., response grouping). We tested whether the strategies efficiency differs depending on the resource competition between tasks in a free concurrent dual-tasking paradigm and whether individuals adapt their strategies accordingly. Our results show that switcher and response grouper are more efficient than blocker during low than high resource competition between tasks. Comparably, more switchers shifted to a response grouping strategy than blockers towards a switching strategy. Overall, especially those individuals benefited from a lower resource competition, who already preferred a more flexible approach in dealing with the multitasking demand during high resource competition.

How Real is Moral Contagion in Online Social Networks?

Abstract

People increasingly turn to online social networks for information and debate. This means that the structures and properties of these networks, and the information they propagate, play crucial roles in the development of social beliefs, attitudes, and morals. Recently, research has shown that the presence of specific language drives the diffusion of moral messages, regardless of the informational quality, in a phenomenon dubbed *moral contagion* (Brady et al., 2017). Due to the widespread attention and implications of such findings for science and society, we investigate the presence of moral contagion across six sets of data that capture the communications of naturally-occurring networks on Twitter. Across a large corpus of diverse tweets (n = 525,229), we find moral contagion to be an inconsistent and often absent phenomenon that does not effectively predict message diffusion. The implications and reasons for this finding are discussed.

Keywords: moral contagion; social networks; social influence; computational social science; Twitter

Introduction

The advent of internet-based communications has permitted global connections at previously unfathomable speeds and volumes. While these connections present immense opportunities via global knowledge sharing and peer-to-peer collaboration, the magnitude of our interconnectedness also presents new liabilities, such as new forms of political persuasion.

The spread of psychological and behavioral phenomena is often likened to that of a pathogen moving from node to node, individual to individual, as a result of repeated exposure. Whereas concepts of "peer effects" and interpersonal influence have existed in psychology and sociology domains for quite some time (e.g., Allport, 1920; Redl, 1949), the formalization of *social contagion theory* has done well to shed light on the impacts that social networks have on everyday life. In a series of seminal studies, Christakis and Fowler (2007, 2008; Fowler & Christakis, 2009, 2010) utilized mass longitudinal datasets and network statistics to show that everything from obesity and smoking to happiness and cooperative behavior can cascade and cluster across social networks. From these findings, the development of collective behaviors, norms, and ideologies is understood to be a product of not only the aggregation of individuals, but also the topology of how individuals are arranged. For example, the proximity and volume of interpersonal ties of groups in social spaces, be it digital or not, increases the probability of both social information and behavior being transmitted amongst them. Simultaneously, this reinforcement of social homogeneity makes it difficult for intergroup connections to be made (i.e., echo chambers). As such, social contagion theory provides a lens through which the diffusion of information and the creation of collective intelligence can be examined.

Moral Contagion

In an interesting application of social contagion theory, Brady, Wills, Jost, Tucker, and Van Bavel (2017) present their conceptualization of *moral contagion*, which directly applies the process of social transmission to information diffusion. Extant literature suggests that morality is a powerful force in human reasoning and rationalization, with studies showing that one's moral beliefs are the foundation for one's ideology and political views (Graham, Haidt, & Nosek, 2009; Haidt, 2001). But how does an issue become moralized in the first place? Adopting the social intuitionist approach, Brady et al. (2017) explain that moral beliefs are less a product of private, individual reasoning and more the result of interpersonal processes and cultural norms (Haidt, 2001). What's more, they elaborate that the communication of moral ideas is tied to the use of emotion in social transmission. In other words, emotions, which serve as demonstrated contagions in social networks (e.g., Coviello et al., 2014; Ferrara & Yang, 2015; Kramer, Guillory, & Hancock, 2014), are highly associated with moral judgements and may serve as a segue to moralizing debates that would be otherwise nonmoral (Brady et al., 2017). In their analysis of a large corpus of Twitter communications, they find that not only does emotion drive the diffusion of moral content through social networks, but that the mere presence of moral-emotional words in a tweet increases its transmission by approximately 20% (Brady et al., 2017). Within the contemporary context of ideological polarization, the finding that moral-emotional language diffuses at such a high rate is concerning. As people increasingly rely on their online networks as news sources, blending spaces of socialization with information, the tendency of moral-emotional language to diffuse across networks means that feelings of outrage or disgust might be weaponized as tools of persuasion. Of course, there is a time and place for moralization, but the claims of Brady et al. (2017) suggest that their emotionally-driven moral contagion is highly impactful across domains, going so far

as to say that "it seems likely that politicians, community leaders, and organizers of social movements express moral emotions…in an effort to increase message exposure and to influence perceived norms within social networks" (p. 7316).

Because of the implications for society's ability to effectively reason and debate with contentious issues, the present study seeks to explore the prevalence of moral contagion across diverse, naturally-occurring social networks. More specifically, we aim to put the conclusions drawn by Brady et al. (2017) to the test by recreating their methodology and assessing whether moral-emotional language does in fact predict the diffusion of moral information regardless of quality or "truthiness."

Method

To investigate the presence of moral and emotional contagion in online social networks, an adaptation of Brady et al.'s (2017) methodology was employed. Specifically, we use the R programming language to recreate the main analysis strategy from Brady et al. (2017), reproduce their findings with their cleaned aggregated data, and then apply the analyses to five unique Twitter datasets that capture naturally-occurring social networks. Datasets and R scripts are made available at https://osf.io/943zm/.

Datasets

A total of six datasets were analyzed in this study. Four pre-existing datasets were obtained via the Open Science Framework (OSF) and Google's dataset search engine, which hosts links to a wide range of open data repositories. One dataset (*#MuellerReport*) was self-collected by connecting to the Twitter REST API with the `rtweet` package in R. While no specific dataset or topic was initially targeted, certain criteria were employed. To be considered for this study, datasets had to contain Twitter data (i.e., tweet messages and retweet counts), contain a significant number of messages written in English, and relate to a polarizing or morally-charged real-world issue, event, or social movement. Datasets were further narrowed by collapsing repeated messages into a single observation (to generate a composite diffusion count that combined the raw retweet count with the number of times the message appeared in the dataset) and removing non-English messages. Since the found datasets did not include language identifying metadata, the `textcat` package in R was employed to extract English tweets in these instances.

Brady et al. (2017) First and foremost, the present study drew directly from the recent study of moral contagion in social networks by Brady et al. (2017). Their data, which is generously shared on a public OSF project page, was thus crucial to the present study for both inspiration and corroboration. The data collected by Brady et al. (2017) focused on topical political issues in the United States: gun control, same-sex marriage, and climate change. Using the Twitter API and sets of topic-related filter words (e.g., *guns*, *gun control*, and *NRA* for the gun control topic), tweets and metadata were extracted between 30 October and 15 December 2015.

***#MeToo* Tweets** A second dataset comprised of Twitter messages containing the *#metoo* hashtag was obtained from the data.world repository. The raw dataset (n = 393,135) was extracted with the Twitter API between 29 November and 25 December 2017, little more than a month after the *#metoo* hashtag first appeared online in coordination with the "Me Too movement" (Turner, 2018). The "Me Too movement" is a movement against sexual harassment and assault. It was ignited by Hollywood sexual abuse allegations and has since become an international phenomenon garnering widespread media attention, support, and critique.

***#WomensMarch* Tweets** A third dataset with tweets containing the *#womensmarch* hashtag was also obtained from the data.world repository. Using the Twitter API, 15,000 messages were collected that referenced the pro-women's rights, and effectively anti-Trump, protest that took place in the wake of the presidential inauguration on 21 January 2017 (Adhokshaja, 2017). The Women's March has since become a worldwide movement with annual marches in late January to non-violently protest for women's reproductive rights, LGBTQ rights, immigration and healthcare reform, as well as racial, gender, and religious equality.

Post-Brexit Tweets A fourth dataset containing unfiltered tweets and metadata from the morning that Brexit was announced was obtained from the Mendeley Data repository. This unfiltered dataset (n = 17,998) was collected with NCapture from QSR, and employed a tight temporal parameter so as to capture the global public's reaction to the political event (Parker, 2017). Brexit refers to the result of the 2016 EU Referendum in the United Kingdom, and this dataset includes Twitter responses from across the globe.

Viral 2016 US Election Tweets A fifth dataset (n = 9,001) containing viral tweets (those with 1,000+ retweets) from the 2016 US Presidential Election was obtained from the Zenodo repository. The set of tweets was collected with the Twitter API and extracted messages that contained specific hashtags (*#MyVote2016*, *#ElectionDay*, and *#electionnight*) and/or user handles (*@realDonaldTrump* and *@HillaryClinton*) (Amador, Oehmichen, & Molina-Solana, 2017). This dataset was of special interest as it contained many "fake news" messages as coded by the curators, which one would might expect to use especially morally- and emotionally-charged language to garner extra attention.

***#MuellerReport* Tweets** A sixth dataset (n = 229,046) was collected by using the *#muellerreport* hashtag to retrieve

tweets from the Twitter API created between 23 and 25 March 2019 — the weekend during which US Attorney General William Barr released his summary of Special Counsel Robert Mueller's investigation into Donald Trump's 2016 presidential campaign. This corpus was of special interest because the Mueller Report has been (and at the time of writing, *still is*) a major source of controversy. While originally a non-polarized issue, the public opinion has divided overtime (Thomson-DeVeaux, 2019), meaning that moral-emotion might have played a part in moralizing conversations on Twitter.

Procedure and Analysis

All datasets were wrangled with R. Tweets were preprocessed with the `tm` and `dplyr` packages, and then a simple dictionary-based approach was employed to quantify the use of specific rhetoric in each message. To do so, the same three dictionaries used and validated by Brady et al. (2017) were used. One dictionary contains distinctly moral words and stems (n = 316; e.g., *fair*, *racism*, *family*), one contains distinctly emotional words and stems (n = 819; e.g., *panic*, *fear*, *heartwarming*), and one contains moral-emotional words and stems (n = 72; e.g., *shame*, *victimize*, *disgust*) that appeared in both of the original moral and emotional dictionaries (i.e., a subset of the moral and emotional dictionaries that was extracted to form the third unique dictionary). Through this categorization, "moral emotions" are considered distinct from "nonmoral emotions" because they are linked to triggers and functions specific to moral contexts, making them especially relevant to political debate (Haidt, 2003; Brady et al., 2017). For instance, outrage and disgust are often considered prototypical moral emotions because their expression can be elicited by perceiving a moral transgression, the breaking of some social axiom that threatens the collective order (e.g., infringement of human rights). In contrast, sadness is a nonmoral emotion because it can be triggered by nonmoral cues (e.g., the death of a loved one). The presence of these categorized words (moral, emotional, and moral-emotional) in each tweet was counted, so that each observation was coded with a discrete word count for each dictionary.

To accurately assess the degree to which each tweet in a given dataset diffused across the social media platform, the present study utilized a collapse-and-count scheme similar to that of Brady et al. (2017). Essentially, there are two measures of diffusion that can be calculated in an observational Twitter dataset: the retweet count displayed in collected metadata and the number of times a message appears in the dataset itself. Thus, the present study quantified diffusion by counting the presence of identical messages in each dataset, adding this count to the message's actual retweet count recorded in the metadata, and then collapsing repeated messages into a single observation.

To measure contagion effects, a negative binomial regression model was used. This model accounts for the overdispersion of data and effectively models count variables (i.e., discrete word counts and diffusion counts). In an effort to maintain consistency with Brady et al. (2017), incidence rate ratios (IRRs) were used as the ultimate indicator of the existence and magnitude of contagion effects. The `MASS` and `lmtest` packages were used for the main analysis.

Results

For the main analysis, negative binomial regression models with maximum likelihood estimation were fit onto each dataset to follow in line with the methodology of Brady et al. (2017), and to allow for a consistent measurement of moral, emotional, and moral-emotional contagion. The presence of contagion was determined by exponentiating the regression coefficients to generate incidence rate ratios (IRR) for each language dictionary, which were then used to plot diffusion prediction lines (Figure 1).

Brady et al. (2017) Across the corpus of 313,002 tweets, there was an average of 0.23 moral-emotional, 0.36 moral, and 0.69 emotional words per tweet. The main analysis indicated that moral contagion did indeed exist in the data collected by Brady et al. (2017). For distinctly moral language, there was a slight main effect (IRR = 1.02, $p <$ 0.05, 95% CI = 1.01, 1.04), and the same went for distinctly emotional language (IRR = 1.03, $p < 0.001$, 95% CI = 1.01, 1.04). Crucially, the presence of moral-emotional language appeared to have a strong effect on message diffusion (IRR = 1.21, $p < 0.001$, 95% CI = 1.19, 1.24). This result corroborates the statistics reported in Brady et al. (2017) to show that the use of moral-emotional language in tweets increases the likelihood of getting retweeted or otherwise shared among individuals in the social network platform by up to 21%. We also performed likelihood ratio tests to assess the statistical model's goodness of fit against nested univariate models that used *only* moral, emotional, *or* moral-emotional language as a predictor of diffusion (Table 1). These tests confirmed that the multivariate negative binomial regression model was effective for predicting message diffusion in the dataset.

***#MeToo* Tweets** After preprocessing the dataset, 151,572 unique tweets remained for analysis with an average of 0.21 moral-emotional, 0.30 moral, and 1.03 emotional words per tweet. The negative binomial regression model displayed a small but significant effect of distinctly moral language (IRR = 1.05, $p < 0.001$, 95% CI = 1.02, 1.09), as well as a significant effect of emotional contagion (IRR = 1.13, $p <$ 0.001, 95% CI = 1.11, 1.15) such that emotional language increased a message's diffusion by 13%. Curiously, while both moral and emotional language had a significant relationship with increased diffusion, moral-emotional language was significantly associated with message diffusion in a negative direction (IRR = 0.89, $p < 0.001$, 95% CI = 0.79, 0.85). Likelihood ratio tests confirmed that the multivariate model was the best fit for the dataset (Table 1).

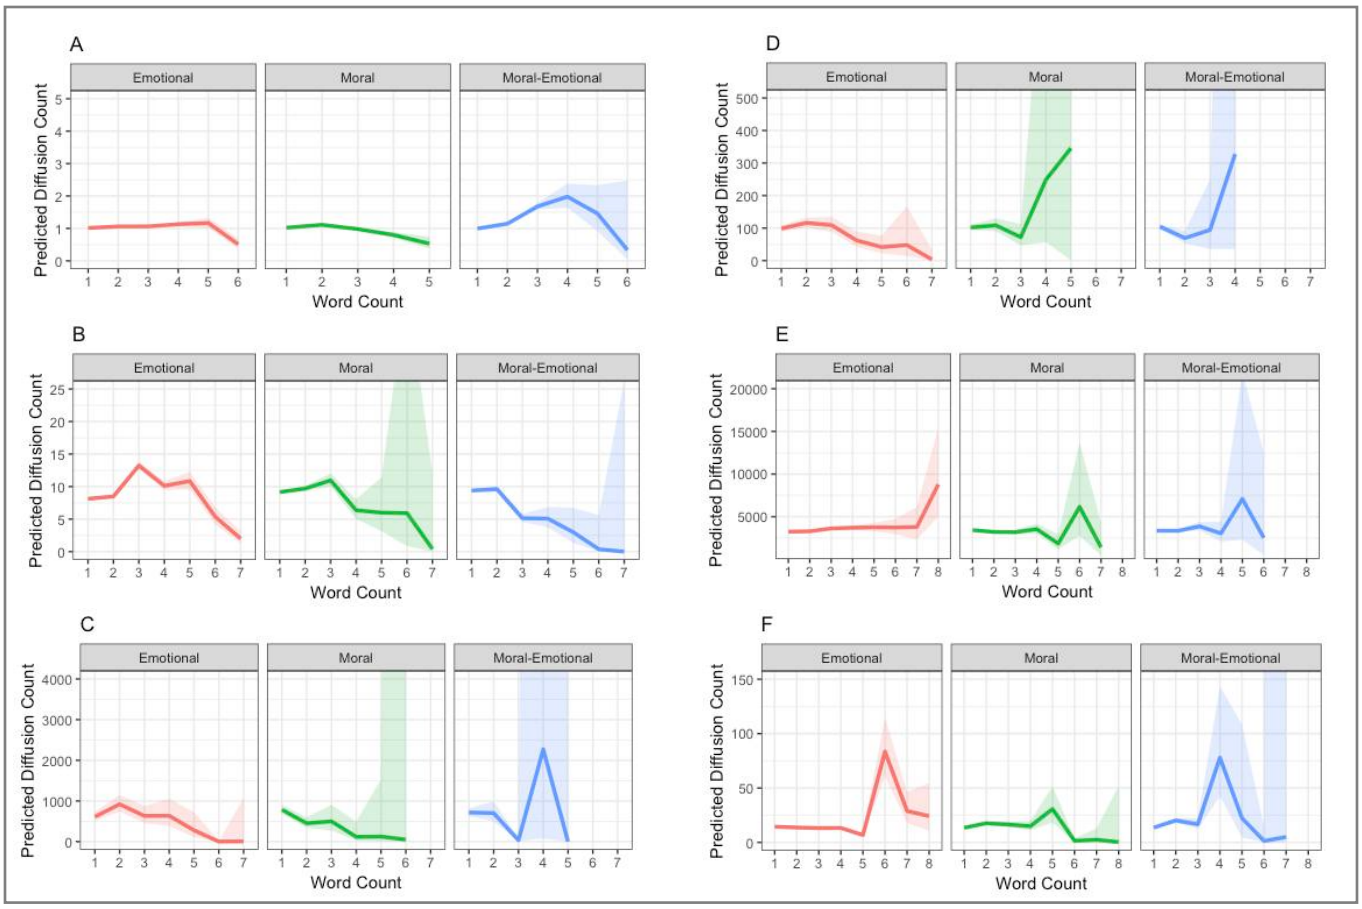

Figure 1: Predicted message diffusion trends as determined by multivariate negative binomial regression models. A = Brady et al. (2017) aggregate dataset; B = *#MeToo* dataset; C = *#WomensMarch* dataset; D = Post-Brexit dataset; E = Viral 2016 US election dataset; F = *#MuellerReport* dataset. 95% CIs are represented with the shaded areas. Note that scales vary widely as a result of the range of diffusion counts present in each dataset.

Post-Brexit Tweets Of the 7,124 analyzable tweets from the morning of the Brexit announcement, there was an average of 0.08 moral-emotional, 0.20 moral, and 0.69 emotional words per tweet. The regression model showed that there was no significant effect of moral language (IRR = 1.05, *n.s.*, 95% CI = 0.91, 1.22), emotional language IRR = 0.95, *n.s.,* 95% CI = 0.88, 0.1.04), or moral-emotional language (IRR = 0.86, *n.s.*, 95% CI = 0.71, 1.07) on message diffusion. While this goes against the claims of Brady et al. (2017), the large confidence intervals and low levels of moral, emotional, and moral-emotional language present in the dataset make the findings here generally inconclusive. In fact, a likelihood ratio test demonstrated that the main multivariate model was not suited to this corpus of tweets. Univariate models, where an isolated word dictionary alone is used to predict diffusion rates instead of the combined three, were slightly better at explaining the data (Table 1).

***#WomensMarch* Tweets** The 3,783 analyzable tweets, messages pertaining to the Women's March movement had an average of 0.17 moral-emotional, 0.31 moral, and 0.86 emotional words per tweet. Upon fitting the negative binomial regression model to the data, it was found that there was no effect of distinctly emotional (IRR = 0.98, *n.s.*, 95% CI = 0.86, 1.13) or moral-emotional language on diffusion (IRR = 0.95, *n.s.*, 95% CI = 0.72, 1.28). However, there was a significant negative effect of distinctly moral language on diffusion (IRR = 0.67, $p < 0.001$, 95% CI = 0.55, 0.82). This finding also contradicts that of Brady et al. (2017) and suggests that both emotional and moral contagion effects are domain specific. Likelihood ratio tests also indicated that a univariate model with *only* moral language was a better predictor of diffusion within the dataset (Table 1).

Viral 2016 US Election Tweets The 8,243 analyzable viral tweets from the 2016 US Presidential Election were found to have an average of 0.17 moral-emotional, 0.35 moral, and 0.98 emotional words per tweet. Analysis showed that there was indeed a small effect of emotional contagion (IRR = 1.05, $p < 0.001$, 95% CI = 1.03, 1.07), whereas the association with distinctly moral language decreased message diffusion (IRR = 0.96, $p < 0.01$, 95% CI = 0.93, 0.99). These findings set up what would have been an ideal

case for emotion to drive the diffusion of moral content, however the regression model showed that there was no significant relationship between moral-emotional language and message diffusion (IRR = 1.02, *n.s.*, 95% CI = 0.98, 1.06), despite hinting at an association in the expected positive direction. Nevertheless, likelihood ratio tests indicated that the multivariate model was the most appropriate predictor of the dataset, having outperformed each of the possible nested univariate models (Table 1).

***#MuellerReport* Tweets** In 41,505 unique analyzable tweets from the *#MuellerReport* corpus, an average of 0.18 moral-emotional, 0.47 moral, and 1.25 emotional words per message was found—the highest level of distinctly moral and distinctly emotional language of all datasets. Interestingly, a textbook moral contagion effect as per Brady et al. (2017) was found here. The negative binomial regression model showed that there was a significant effect of emotional contagion (IRR = 1.07, $p < 0.001$, 95% CI = 1.04, 1.09), and that the association between distinctly moral language and message diffusion was not statistically significant (IRR = 1.05, *n.s.*, 95% CI = 1.00, 1.11). And most importantly, there was a significant relationship between moral-emotional language and diffusion (IRR = 1.33, $p < 0.001$, 95% CI = 1.23, 1.46). This effect is even stronger than that of Brady et al. (2017), suggesting that the presence of moral-emotional language can increase a message's diffusion by 33%. Likelihood ratio tests supported the main multivariate model as the best explanation of the dataset (Table 1).

Aggregated Data Finally, we sought to rule out that the observed differences to Brady et al. (2017) were due to non-content differences in the samples, such as sample size. On top of analyzing each individual dataset, an aggregate dataset was compiled from the *#MeToo*, *#WomensMarch*, Post-Brexit, Viral 2016 US Election, and *#MuellerReport* datasets. This was done in an effort to present an analysis of a novel corpus that is similar in size to that addressed by Brady et al. (2017). However, it should be noted that statistics are skewed toward the *#MeToo* dataset as it is significantly larger than the others, comprising 71% of the aggregated data. Like the Brady et al. (2017) dataset, which captured discourse around multiple topics, this compilation of Twitter data also reaches a diverse range of contentious topics, as well as, in theory, a diverse range of individual Twitter users. This aggregation of five datasets into a single corpus (n = 212,227) displayed and average of 0.20 moral-emotional, 0.33 moral, and 1.05 emotional words per tweet. Analysis here showed that neither moral-emotional language (IRR = 0.90, $p < 0.001$, 95% CI = 0.87, 0.94), nor moral language (IRR = 1.00, *n.s.,* 95% CI = 0.97, 1.03), nor emotional language (IRR = 0.99, *n.s.,* 95% CI = 0.97, 1.00) predicted an *increase* in message diffusion. However, moral-emotional language was the only key variable that displayed a significant association with diffusion. This finding is reiterated by likelihood ratio tests, which showed that the multivariate model was slightly outperformed by a nested univariate model that used moral-emotional language only (Table 1). Further analysis with larger datasets, and examinations of specific moral-emotions (e.g., positive vs. negative affect; high- versus low-arousal) is planned for future studies in order to explore possible explanations.

Table 3: Likelihood ratio test statistics of deviance for goodness of fit. Significance indicates that the multivariate model (composed of moral-emotional language, distinctly moral language, *and* distinctly emotional language predicting diffusion) is the better fit for the dataset than the respective univariate model (composed of moral-emotional language, distinctly moral language, *or* distinctly emotional language predicting diffusion). The "Aggregate" column refers to the combined data from the *#MeToo*, *#WomensMarch*, Post-Brexit, Viral 2016 US Election, and *#MuellerReport* datasets. Significance codes: '***' < 0.001 '**' < 0.01 '*' < 0.05.

Univariate model	Dataset						
	Brady et al. (2017)	#MeToo	#Womens March	Post-Brexit	Viral US 2016 Election	#Mueller Report	Aggregate
Moral-emotional language only	30.07***	191.50***	13.06**	1.50	43.70***	27.73***	2.56
Distinctly moral language only	446.74***	212.59***	0.20	3.52	38.92***	86.72***	30.63***
Distinctly emotional language only	432.70***	43.62***	14.07**	2.12	9.62**	62.47***	26.85***

Discussion

Our results suggest that moral contagion driven by moral-emotional language is not as general a phenomenon as Brady et al. (2017) propose. In fact, the statistical models displayed no noteworthy effects of moral contagion in four of the six observational datasets analyzed. While the significant results of the likelihood ratio tests (Table 1) effectively link the use of moral, emotional, and moral-emotional language with information diffusion in most cases, the domain specificity of certain contagion effects in our results spurs a series of conceptual and methodological considerations.

Invoking morality in reasoning is known to harden existing belief structures, delegitimize authority, and, in extreme cases, dehumanize opposing perspectives (Ben-Nun Bloom & Levitan, 2011; Crockett, 2017). While morality can of course be a force for good—providing shared identities and guiding ethical behavior—the introduction of *unnecessary* morality and its emotional underpinnings can jeopardize rational debate. It is for this reason that moral justifications carry weight in some domains but not others. For example, loading an argument with moral-emotional language might be an effective strategy in discourse pertaining to human rights, yet that same strategy is likely to be penalized in an argument over mathematics. Sentiments about where morality is appropriate may be changing, and this may very well be a factor driving ideological polarization. But it seems unlikely a priori that moral language will be viewed the same in all domains. Our results are in keeping with such considerations.

There are also a number of methodological issues that potentially restrict the generality of studies such as this. Perhaps most conspicuous is the inability to parse true *causal* contagion from network homophily. The observational data used here and in Brady et al. (2017) fails to distinguish actual contagion (where exposure to a "contagious" condition has a causal effect on an individual's shift from state A to state B) from manifested homogeneity (where individuals with similar characteristics act in similar ways, irrespective of conditional exposure). It could be argued that the act of retweeting or sharing a message is a behavioral metric because it requires some motivated action. However, Brady et al. (2017) note that where moral contagion has been documented, it has been "bounded by [ideological] group membership" (Brady et al., 2017, p. 7313). This makes it important for future research to heed the substantial body of literature concerning the homophily-contagion problem (e.g., Aral, Muchnik, & Sundararajan, 2009; Shalizi & Thomas, 2011). Plus, Dehghani et al. (2016) specifically show that expressions of moral purity can predict the distance between users on Twitter, which further suggests that moral contagion may simply be an inadvertent measure of moral homophily. Along similar lines, the measurement of diffusion is also an imperfect operationalization of social influence. While collapsing repeated messages into a single observation ensures the language of a single repeated message does not skew analysis, it effectively penalizes unconventional retweeting (e.g., paraphrasing a message's content rather than clicking "retweet"), and is prone to overlook retweet chains (e.g., retweets of retweets) that might indicate true virality of a message (Brady et al., 2017). Crucially though, this imperfection applies to every dataset in the present study such that it cannot explain the discrepancies between datasets.

Needless to say, the use of social media analytics for investigations of the broader human condition has limitations with respect to external validity and representativeness (Tufekci, 2014). It is entirely possible that findings from studies conducted solely in the Twitterverse are in fact unique to the Twitterverse. Plus, the nature of Twitter metadata and correlational analyses like regression modelling mean that network agent variables (those pertaining to qualities of individual nodes/people) and structural variables like network topology are easily conflated. It may still be that human beings are susceptible to moral-emotionally-framed messages (Brady et al., 2017), but that unseen confounds, especially differences in network topology, can undermine contagion effects. Though the reverse is also possible, namely that contingent effects of topology may masquerade as a preference for moral-emotional language. Either way, the findings presented here demonstrate the need for a close partnership between descriptive accounts of "big data" analytics and controlled experimentation in order to draw confident conclusions about social rationality in the digitalized age.

Conclusion

Human reasoning is rarely, if ever, fully autonomous. We depend on our social environments for information and corroboration, and as these environments undergo digitalization, understanding how their evolution translates into new modes of influence is imperative for safeguarding spaces of rational debate. With high-profile papers (e.g., Brady et al., 2017) already pointing out concerning dynamics like moral contagion in real-world social networks, the present paper adds to this line of inquiry by illustrating the inconsistencies of such findings and offering theoretical and methodological explanations. Importantly, the results here indicate that given the diversity of naturally-occurring social networks, predicting the diffusion of information requires investigations of not only properties of the information itself, but also the domain specific topology of the networks through which it travels. Despite the limitations of current computational social science research, it is safe to say that exploring digital discourse can provide valuable insight into the state of human reasoning and argumentation in a time that has been labelled "post-truth."

Politically Motivated Causal Evaluations of Economic Performance

Zachary A. Caddick (zacharycaddick@pitt.edu)

Abstract

The current study seeks to extend research on motivated reasoning by examining how prior beliefs influence the interpretation of objective graphs displaying quantitative information. The day before the 2018 midterm election, conservatives and liberals made judgments about four economic indicators displaying real-world data of the US economy. Half of the participants were placed in an 'alien cover story' condition where prior beliefs were reduced under the guise of evaluating a fictional society. The other half of participants in the 'authentic condition' were aware they were being shown real-world data. Despite being shown identical data, participants in the Authentic condition differed in their judgments of the graphs along party lines. The participants in the Alien condition interpreted the data similarly, regardless of politics. There was no evidence of a 'backfire' effect, and there was some evidence of belief updating when shown objective data.

Keywords: motivated reasoning; politics; biases; reasoning; decision-making

Introduction

Previous research has shown that individuals often reason differently about information depending on whether it is congruent with their prior beliefs. Individuals tend to more easily accept information that is congruent with prior beliefs and desires and discount information that is incongruent with prior beliefs and desires. This process is known as motivated reasoning. In the current research, we studied the influence of political attitudes on how people interpret time series graphs of the economy. This research is at the intersection of two fields: causal reasoning about time series data, and motivated reasoning.

Motivated Reasoning and Causal Reasoning: Similarities and Differences

The fields of motivated reasoning and causal reasoning have long been intimately connected in certain ways, yet also distant in other ways. The current research aims to advance both of these fields, and to advance research on the intersection of the two.

In one aspect, these two fields have studied similar questions about the role of prior beliefs and desires on the acceptance or rejection of new information. On the causal reasoning side, there has been considerable research into how people incorporate new information with prior causal beliefs (e.g., Alloy & Tabachnik, 1984). Furthermore, many of the particular topics that have been studied in the field of motivated reasoning have had to do with causal or at least predictive relations. For example, in a seminal work on motivated reasoning, Kunda (1987) found that people tend to believe that other people who have attributes similar to themselves are less likely to get divorced than people with dissimilar attributes. Note how in this study, the attribute is as a potential cause or predictor of the effect (divorce). Other research on motivated reasoning that is less directly related to causation still often studies acceptance of causal-scientific explanations, for example, about global warming (Campbell & Kay, 2014).

On the other hand, there are also important differences between these fields. First, causal learning has traditionally been focused on the rational (Bayesian) updating of beliefs given new information, whereas motivated reasoning has focused on affective reasons for failing to update beliefs.

A second difference, more relevant to the current research, is that most research on causal reasoning has focused on the inferential process - how a learner infers a cause-effect relationship from a set of data. In contrast, research on motivated reasoning does not involve inference. Instead, participants are typically presented with a fact or a set of facts, and the question is whether participants accept or reject the facts (e.g., Ranney & Clark, 2016).

One recent study on motivated reasoning has investigated inference from data, similar to causal reasoning research. Kahan, Peters, Dawson, and Slovic (2017) presented participants with quantitative information in 2x2 contingency tables about the number of cities that did or did not ban handguns in public and whether there was an increase or decrease in crime, and participants were asked to infer the relation between gun bans and crime. Despite being presented with quantitative data, participants were more likely to make correct inferences when the data supported their prior attitudes about guns. The current research is in a similar vein–it investigates the role of political attitudes on inferences about economic trends.

Motivated Reasoning about Economics

The political arena is an especially ripe medium for motivated reasoning to occur, and has been one of the most studied types of motivated reasoning. Politically-relevant stimuli also provides a unique opportunity to study the intersection of motivated and causal reasoning about objective quantitative data that has high ecological validity.

Politicians often make competing statements about the credit or blame for the same economic outcomes. For example, in a speech to democratic supporters, former President Obama said: "…when you hear how great the economy's doing right now, let's just remember when this recovery started" (USA Today, 2018). In contrast, Kevin Hassett, the Chairman of The White House Council of

Economic Advisers, has stated "I can promise you that economic historians will 100 percent accept the fact that there was an inflection at the election of Donald Trump and a whole bunch of data items started heading north" (Horsley, 2018). Similarly, citizens also interpret the same economic outcomes based on political lenses. For example, Republicans interpret the 2017 tax bill as having more personal benefit than Democrats (Bump, 2018).

The current experiment is a controlled study to understand how people view the exact same economic data in different ways based on political orientation. There is little research into the cognitive processes engaged in motivated reasoning about objective economic data. In this study, we assessed politically-motivated reasoning before and after participants viewed economic time-series graphs, and after making judgments about the impact of each president.

Backfire Effects

One concern with the possibility of presenting participants with objective data is that it might actually produce a "backfire" effect in which the participant doubles-down and strengthen their prior belief. For example, Nyhan and Reifler (2015) found that participants who had previously held high levels of concern about potential side effects of flu vaccinations became less likely to get flu vaccinations after exposure to corrective information. However, evidence for the backfire is mixed. A more thorough investigation by Wood and Porter (2018) found no evidence of backfire effects. These two studies on backfire effects used text-based presentation of facts. In the current study we assess whether participants exhibit backfire effects when presented with economic time series data that require them to make an inference. Whether participants exhibit a backfire effect could help reveal whether such information might be useful for changing voters' opinions.

Current Study

In the current study, participants were shown time series graphs of economic variables, and the graphs denote the times when Democratic vs. Republican presidents held office. Participants were asked questions about whether Democrats or Republicans were better for the economy. This study allowed us to ask a number of questions that provide insight into motivated causal reasoning.

First, will people learn from the time series graphs and change their beliefs about which party is better, or will they exhibit a 'backfire' effect? This question is especially relevant for political campaigns wondering how objective economic data changes voters' opinions. One reason that a backfire effect could happen is because quantitative graphs always ignore some contextual information, and people may latch onto such factors to reinforce their prior beliefs. For example, in the current study, presidents only have limited control of the economy and there are other external factors (e.g., Congress, the Federal Reserve, international politics).

Second, to what extent do people engage in motivated reasoning even about highly objective, quantitative data? Participants were asked questions at multiple levels of granularity, from fairly general about Democratic vs. Republican presidents in general, to the influence of particular presidents, which could potentially show different degrees of motivated reasoning.

Third, the current research also provides a unique opportunity for research on causal reasoning. Recently there has been more research on causal reasoning about time series data (Rottman, 2016; Soo & Rottman, 2018). One of the challenges involved in making causal inferences in general, and from time series data in particular, is that the data are often ambiguous and can be interpreted in multiple ways. The current study extends prior research in two ways. First, it provides new methods for studying how people reason about real-world time-series data (as opposed to researcher-generated data). Second, it is the first causal reasoning study we know of that explicitly studies the role of motivated reasoning in causal attribution.

Methods

Participants

On November 5th, the day before the 2018 United States midterm election, 403 participants were recruited via Amazon's Mechanical Turk. They were paid $4 for participating in this study. Mechanical Turk premium qualifications were used to sample 200 individuals who had previously identified as liberals, and 200 who identified as conservatives. Three participants completed the study without accepting the HIT, resulting in 403 participants.

Stimuli and Design

Participants reasoned about time series graphs of four economic variables (Figure 1), within-subjects. Each graph depicted the period from 1977 through the most recent economic data when the study was conducted. We had to choose a year to begin the graphs. We wanted to include Reagan because of his important role in current political-economic debates, but we figured that the current electorate would probably have less partisan views about Carter and earlier presidents. Carter was included because one of the questions about Reagan requires having a trend line before Reagan took office. The graphs were accompanied with hyperlinks to the data sources to increase transparency. Unlike Figure 1, the colors of the two parties were red and blue for the Republican and Democratic parties. A brief explanation of each economic variable was included.

We desired to be able to compare participants' motivated reasoning against a more objective condition in which motivated reasoning is eliminated. To do this, half of the participants were presented with 'authentic' graphs like those in Figure 1. The other half saw graphs just like Figure 1, except the origin of the data was disguised; participants were told that the data came from a fictional alien society. Made-up alien names were used for the political parties and

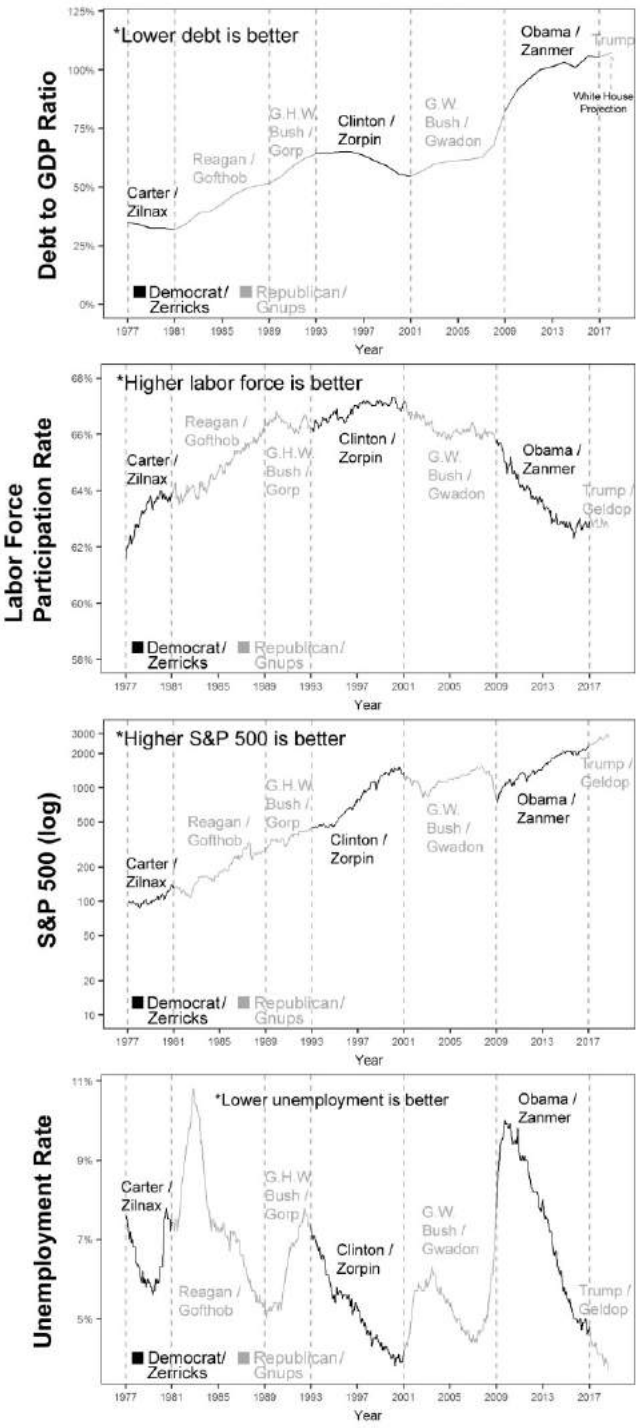

Figure 1: Stimuli for Authentic and Alien conditions combined together. The text "White House Projection" on Debt to GDP Ratio graph was only present for the Authentic condition. Alien graphs had a range of 3061-3621 years.

presidents. The alien graphs did not include the hyperlinks, and the colors of the two parties were green and orange (not red and blue) to reduce suspicion.

Procedure

Figure 2 provides a summary of the procedural flow of the

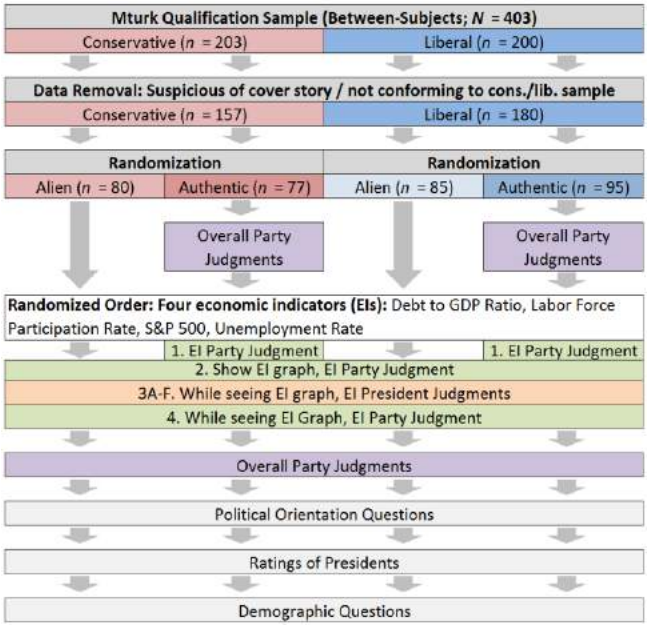

Figure 2: Study procedure flow. "EI" = economic indicator.

study. First, participants from both the liberal and conservative samples were randomized to either 'Authentic' or 'Alien cover story' conditions. Participants in the Alien condition were told to "*Please imagine that in roughly 1,000 years, there is an alien society on another planet. The government of this society has two political parties, Zerricks, and Gnups. Your goal for this study is to figure out whether the Zerricks or Gnups parties generally do a better job of handling the society's economy…*" Participants in the Authentic condition were not provided with an introduction, as we presumed that participants were acquainted with the major US political parties.

Next, participants in the Authentic condition completed an "Overall Party Judgment" (*"Which political party do you believe is better for the economy overall*?": 1 = strongly believe Rep., 4 = neutral, no opinion, 7 = strongly believe Dem.). Alien condition participants did not make this judgment as they had no prior beliefs about the fictional aliens.

Next, participants completed blocks of judgments about each of the four economic indicators in a random order. In Step 1, participants in the Authentic but not Alien condition made the Economic Indicator Party Judgment ("*Which political party do you believe is better for [econ. indicator]*?": 1 = strongly believe Rep., 4 = neutral, no opinion, 7 = strongly believe Dem.). Then, in Step 2, participants were shown an economic indicator graph like in Figure 1. With the graph still visible, they made another Economic Indicator Party Judgment.

In Step 3 (sub-steps: A-F), with the graph still visible, participants made judgments about the influence of each president (from Reagan to Trump; Figure 3). This 14-option question allowed participants to make precise judgments about the nature of the change in the trend line. If participants' judgments are still influenced by their political

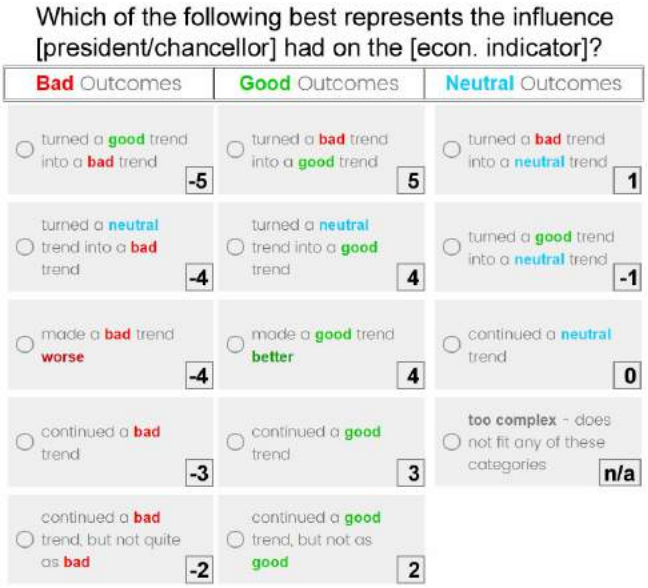

Figure 3: Economic Indicator President Judgments. The numerical coding scale was hidden during the study.

orientation, it would mean that motivated reasoning has an influence on even very low-level causal reasoning. Because prior research (Soo & Rottman, 2018) has found that people focus on changes in trends more than absolute levels, this question asked how trend in the variable changed during the president's time in office compared to before. To analyze these judgments, we turned the 14-option scale into a -5 to +5 scale, where +5/-5 means that the president had a very good/ bad influence on the trend. The numbers in Figure 3 display this scale mapping.

In Step 4, participants made the Economic Indicator Party Judgment one last time with the graph still present. The reason for asking this question three times was to see if participants' judgments become less biased with more exposure to the data and thinking about the data.

After completing the questions about the four economic indicators, participants made a final Overall Party Judgment without any graphs presented alongside this question.

Participants went on to complete four questions on political orientation. We used one of these questions (1 = extremely liberal, 4 = moderate/middle of the road, 7 = extremely conservative) to ensure that the participants' current political orientation matched the MTurk Qualification. Afterwards, participants rated how much they "liked" each of the presidents and completed demographics.

Results

Participants

Participants in the Alien condition were asked about degree of suspicion for the cover story after completing the study. Fifteen participants were dropped from analyses due to selecting that they "strongly suspected that the data reflected the United States." The remaining participants were included in analysis. Fifty-seven participants selected "I was a bit suspicious, but I didn't think much of it." The majority (n = 108) selected "No, I did not suspect that the data reflected the United States."

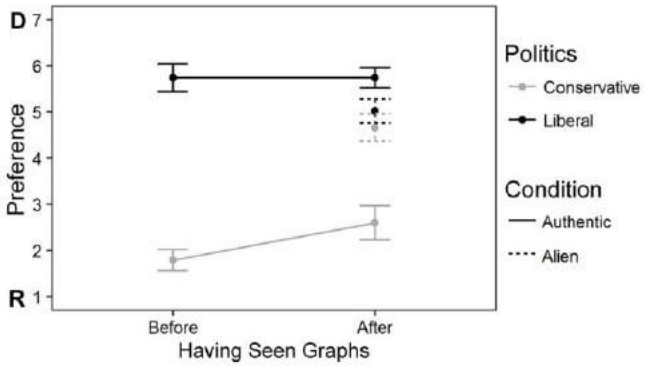

Figure 4: Overall party judgments before and after seeing time series graphs. Error bars are 95% confidence interval. D/R denote Dem./Rep. leaning judgments.

Another 53 participants were dropped because their responses to a question about whether they identified as conservative or liberal did not conform to how they previously identified according to the qualification. Thus, 337 participants were included in the analyses.

Conservative (M = 43; SD = 12) and liberal (M = 38; SD = 11) participants had similar ages. Conservative and liberal samples were predominately white (91% & 83%, respectively). Liberals were a bit more educated. The education breakdown was as follows for conservatives and liberals, respectively: high school or lower (19% vs. 9%), some college but no degree (23% vs. 27%), associate's or bachelor's (47% vs. 54%), and master's or higher (11% vs. 9%).

Statistics

For all the following analyses that used mixed-effect models, we used the R packages 'lme4', 'lmerTest' for p-values, and 'r2glmm' for R^2_{NSJ} effect sizes (Jaeger, 2017). Effects coding was also used for all mixed-effect models.

Overall Party Judgments

Figure 4 presents the overall party judgments. The overall impressions of the graph are as follows. First, there do not appear to be differences in the Alien condition by politics. We note that participants' ratings in the Alien condition are more favorable to Democrats (the means of the Alien condition are above the midpoint of the scale).[1] This suggests that we should expect to see more changes in beliefs for conservatives rather than liberals. Second, in the Authentic condition, there are large differences between

[1] The fact that participants in the Alien condition tended to believe that the Democrats (disguised as aliens) were better for the economy than Republicans (disguised as aliens) is intended merely as a summary of the stimuli used in this experiment, not as a political statement. There are many other economic indicators aside from these four, and there are historical events not depicted on the graphs that could affect their interpretation.

conservatives and liberals, though the difference appears to become somewhat smaller suggesting that participants are learning rather than having a backfire effect. Third, even after seeing the graphs, there still appear to be large differences by political orientation in the Authentic condition. We now assess these questions statistically.

First, overall party judgments between liberal and conservative participants were not significantly different after seeing the graphs for the Alien condition, $t(159.05) = 1.80$, $p = .074$, $d = .28$. The remaining analyses focus on the Authentic condition.

Second, we tested whether the judgments changed over time by doing a regression with time (before vs. after seeing the graphs), political orientation, and the interaction, and a by-subject random intercept. There was a main effect of politics ($\beta = 3.54$, $SE = .18$, $t = 19.71$, $p < .001$, $R^2_{NSJ} = .635$) implying strong politically-motivated reasoning. There was a significant effect of time ($\beta = .40$, $SE = .10$, $t = 4.08$, $p < .001$, $R^2_{NSJ} = .022$). Most importantly, there was a significant interaction between politics and time ($\beta = -.81$, $SE = .20$, $t = 4.08$, $p < .001$, $R^2_{NSJ} = .022$), implying that the two groups moved *closer together* after seeing the graphs. Third, even after seeing the graphs, overall party judgments between liberal and conservative participants were still significantly different, $t(125.66) = 14.33$, $p < .001$, $d = 2.13$.

Economic Indicator Party Judgments

Figure 5 shows graphs of the judgments of which party is better at controlling each of the four economic indicators. These judgments were made at three timepoints in the Authentic condition, and at two timepoints in the Alien condition. The overall impressions of the graphs are as follows. First, for the most part, the differences in the Alien condition by politics are small, if present at all.[2] Second, there appear to be some changes in beliefs after seeing the graph (Step 1 to Step 2), but there are few changes after making the president judgments (Step 2 to Step 4). For this reason, we just focus our analyses below on Steps 1 and 2. Third, even after seeing the graphs, there are still substantial differences between liberals and conservatives. We now test these impressions statistically.

First, at Step 2, we tested whether there are any differences based on political orientation within the Alien condition. We conducted a linear regression with a by-subject random intercept and a by-economic-indicator random intercept. There was no significant effect of politics ($\beta = .29$, $SE = .23$, $t = 1.28$, $p = .278$, $R^2_{NSJ} = .01$).

We then tested for motivated reasoning within the Authentic condition in Steps 1 and 2. We tested for the main effects and interaction of Time and Politics. We used a linear regression with by-subject random intercepts and

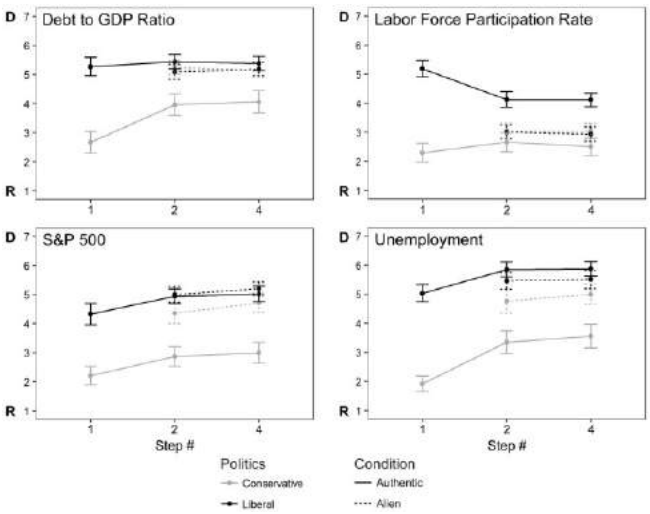

Figure 5: Mean economic indicator party judgments and 95% CIs. D/R denote Dem./Rep. leaning judgments.

slopes for time. The model also had by-economic-indicator random intercepts with random slopes for time and politics, and the interaction. We found significant differences in economic indicator party judgments based on participants' political orientation ($\beta = 2.28$, $SE = .22$, $t = 10.23$, $p < .001$, $R^2_{NSJ} = .344$), implying politically-motivated reasoning. There was not an effect of Time from Step 1 to Step 2 ($\beta = .54$, $SE = .32$, $t = 1.69$, $p = .188$, $R^2_{NSJ} = .028$). There was a marginal interaction between politics and Time ($\beta = -.80$, $SE = .32$, $t = 2.48$, $p = .082$, $R^2_{NSJ} = .016$). Perhaps there was a trend that conservatives and liberals' beliefs moved closer together after seeing the graphs, though this was only evident for some of the economic indicators (Figure 5).

Lastly, we tested for differences in economic indicator party judgments for the Authentic condition at Step 2 (after seeing graphs). This model included a by-subject random intercept and a by-economic-indicator random intercept and slope for politics. There was still a significant effect of politics on economic indicator party judgments ($\beta = 1.88$, $SE = .28$, $t = 6.71$, $p = .001$, $R^2_{NSJ} = .260$).

In sum, participants' judgments were biased by politics, and there was a trend of becoming less biased after seeing the graphs.

Economic Indicator President Judgments

Participants judged how each president influenced each EI. Because these judgments were very specific, they should be less open to interpretation than the other judgments. We wanted to test whether participants' political motivations would still affect these judgments. To test this, we reverse coded the judgments about Republican presidents. This means that judgments that are higher on the -5 to +5 scale are more positive towards Democrats, and judgments that are lower are more positive towards Republicans.

Participants made 24 judgments (6 presidents x 4 EIs). There were large differences across these 24 items because certain indicators performed very well or very poorly during

[2] Three of these economic indicators were more favorable for Democrats (the judgments in the Alien condition are higher than the midpoint of the scale for all but the Labor Force Participation Rate). This means that we would expect more changes in beliefs for Republicans than for Democrats in all but the Labor Force Participation Rate judgments.

certain presidencies. We used mixed effects models with by-item random intercepts and slopes for politics to account for the 24 items and by-subject random intercepts.

There was a significant effect of political orientation in the Authentic condition (β = .97, *SE* = .17, *t* = 5.87, *p* < .001, R^2_{NSJ} = .016). However, there was also a significant effect of political orientation in the Alien condition (β = .38, *SE* = .13, *t* = 2.96, *p* = .004, R^2_{NSJ} = .002). It is possible that some participants in the Alien condition realized that the alien chancellors were actually American presidents but did not report being highly suspicious.

To test whether there was more political bias in the Authentic condition than the Alien condition, we ran a model that also included condition and politics and their interaction as a by-item random slopes. There was no significant effect of condition (β = .17, *SE* = .11, *t* = 1.50, *p* = .138, R^2_{NSJ} = .001). We found a significant effect of politics; the judgments in the Liberal sample were a bit more favorable to Democrats (β = .68, *SE* = .12, *t* = 5.63, *p* < .001, R^2_{NSJ} = .008). Most importantly, there was a significant interaction between condition and politics, (β = .59, *SE* = .19, *t* = 3.14, *p* = .002, R^2_{NSJ} = .001). This suggests that economic indicator president judgments of conservatives and liberals were farther apart for the Authentic condition, and that there still is an effect of motivated reasoning even for judgments about specific presidents and specific economic indicators.

Discussion

Previous research has shown that individuals tend to preferentially view evidence congruent with prior beliefs and de-emphasize incongruent evidence. Our findings support that perceptions of quantitative information are influenced by the presence of prior beliefs. When prior beliefs were absent in the Alien condition, participants' judgments were largely in agreement with one another. However, when making judgments about US political parties, our participants' judgments were strongly influenced by their political beliefs.

The Economic Indicator President Judgments may offer the most supportive evidence of motivated reasoning as participants engaged in belief maintenance even when making very specific judgments (e.g., President X "changed a neutral trend into a bad trend"), implying that prior beliefs can influence even low-level perceptual judgments. However, the bias for these very specific judgments were not as strong as for the overall party judgments and economic indicator party judgments.

Despite the evidence of motivated reasoning, our participants did change their initial beliefs after viewing an objective graph, at least for the overall judgments. This suggests that presenting people with objective time series graphs of the economy might be a useful strategy for changing voters' minds. Perhaps another more radical strategy to change opinions is to show voters time series graphs with the political parties disguised, like in the Alien condition, to help them make judgments in a bias-free context, before revealing the political parties. In future research we plan to test whether this strategy is effective.

It is important to note that even though we have been calling the effects in the paper "politically motivated," the current results cannot distinguish between rational use of prior beliefs versus self-protective motivational forces. One view is that the liberal versus conservative participants have different prior knowledge (e.g., about other relevant economic factors that could have been causes of changes in the graphs), and interpret the graphs differently based on their different knowledge (Jern, Chang, & Kemp, 2014). The other view, which is traditionally called 'motivated reasoning' is that they interpreted the graphs differently simply to support self-serving desirable outcomes (i.e., protecting their political self-identity).

However, we believe the current results are still useful in that they show how disparate of views people can have making judgments from quantitative data (as opposed to prior research that used text-based stimuli). Another novel feature of this study is that it involved making inferences or generalizations, whereas prior research has focused simply on subjects acceptance of a textual argument.

More generally, given the current time of heightened polarization and misinformation, more research is needed to understand biased reasoning and find interventions to reduce biased reasoning about quantitative information.

Speech Processing does not Involve Acoustic Maintenance

Spencer Caplan

John Trueswell
University of Pennsylvania, Philadelphia, Pennsylvania, United States

Abstract

What happens to the acoustic signal after it enters the mind of a listener during real-time speech processing? Since processing involves extracting linguistic evidence from multiple, temporally distinct sources of information, successful communication relies on a listeners ability to combine these potentially disparate signals. Previous work has shown that listeners are able to maintain, and rationally update, some type of intermediate representations over time. However, exactly what type of information is being maintainedbe it acoustic-phonetic or rather a probability distribution over phonemeshas been underspecified. In this paper we present a perception experiment aimed at identifying the internal contents of intermediate representations in speech processing. Using an accent-adaptation paradigm, we find that listeners adapt to modulated acoustic signal when the corresponding orthography is provided before the audio, but not when audio follows the orthography. This supports the position that intermediate representations are uncertainty-distributions over discrete units (e.g. phonemes) and that, by default, speech processing involves no maintenance of the acoustic-phonetic signal.

The emergence of monotone quantifiers via iterated learning

Abstract

Natural languages exhibit many *semantic universals*: properties of meaning shared across all languages. In this paper, we develop an explanation of one very prominent semantic universal: that all simple determiners denote monotone quantifiers. While existing work has shown that monotone quantifiers are easier to learn, we provide a complete explanation by considering the emergence of quantifiers from the perspective of cultural evolution. In particular, in an iterated learning paradigm, with neural networks as agents, monotone quantifiers regularly evolve.

Keywords: semantic universals; generalized quantifiers; monotonicity; iterated learning; neural networks

Introduction

While natural languages show great variability, there are features that they all appear to share. Linguists call these features linguistic *universals*. Universals have been found at all levels of linguistic structure: phonological, syntactic, and semantic.[1] Some universals might follow from constraints on what humans are physically capable of doing. For instance, there is no language whose prosody requires the production of ultrasounds. The reasons for other universals are harder to understand, leading to multiple proposed explanations.

One well-supported claim is that at least some universals are to be explained in terms of *learnability*.[2] More precisely, it is easier to learn a language that satisfies the universal than it is to learn a language that does not satisfy the universal, and this difference in the complexity of acquisition causes languages that satisfy universals to spread. In the case of universals of lexical semantics such as the one we focus on below, the learnability explanation says that lexical entries whose meaning satisfies the universal are easier to learn, and therefore more likely to be lexicalized. Complicated meanings can be obtained through complex grammatical constructions and compositional interpretation thereof.

The learnability explanation is an empirical, causal claim about the origins of linguistic universals. One way to support the learnability explanation for a specific universal is to provide a model of learning that is cognitively realistic and on which expressions that satisfy the universal are indeed easier to learn.

Finding an appropriate model of learning can however only partially explain a linguistic universal. Learnability is a fact about individual cognition, while a universal is a feature of a whole language. A second challenge consists in connecting these two levels, showing the effects of learnability on emerging language structure. This is the so-called problem of *linkage*.[3]

Iterated learning (IL) is a method that addresses the problem of linkage. In IL, parents teach children their language, who teach the next generation their language, and so on and so forth. The crucial insight of IL is that learning is not an inert process in cultural evolution, since the languages of a cultural child and its cultural parent are generally slightly different. The changes caused by learning are not random, but rather tend to be guided by the learner's cognitive biases. As a consequence, over time languages adapt better and better to the agents' cognitive biases. Learnability can then affect the frequency of different traits.[4]

Previous work has addressed the learnability challenge by showing that quantifiers, responsive predicates, and color terms that satisfy certain semantic universals are easier to learn for neural networks.[5] In this paper, we address the problem of linkage by building an iterated learning model of the evolution of the semantic structure of quantifiers. In particular, we will use neural networks as our agents and standard gradient descent as the learning method inside the context of iterated learning. The next section briefly reviews the theory of generalized quantification and the universal of *monotonicity*. After that, the following section presents the model of cognition and the iterated learning model, as well as an information-theoretic measure of the *degree of monotonicity* of a quantifier. Experiments with this model and their results are presented in the following section. Results are discussed in the final section, along with possible future directions.

Quantifiers and monotonicity

Determiners are expressions that take a common noun as an argument and return a Noun Phrase. Determiners can be grammatically simple—e.g. *some*, *few*, *most*—or complex—e.g. *fewer than three* or *at most five*.[6] Determiners express generalized quantifiers.[7] (Monadic) Generalized quantifiers are properties of sets of subsets of a domain of discourse. The generalized quantifiers expressed by natural language determiners are of type $\langle 1,1\rangle$, i.e. properties of exactly two sets. Equivalently, a quantifier of type $\langle 1,1\rangle$ takes (the characteristic function of) a set A and returns a function from (the characteristic function of) a set B to truth values. A is the *left argument* and B the *right argument* of the quantifier. For instance, the sentence "most As are B" is true if and only if the number of As that are B (cardinality of the intersection of A and B, i.e., $|A \cap B|$) is greater than the number of As that are not Bs (i.e., $|A - B|$), i.e.:

$$[\![most]\!] = \{(A,B) : |A \cap B| > |A \setminus B|\}$$

Various universals have been proposed about which generalized quantifiers are expressed by simple determiners. In the following, we focus on the *monotonicity* universal proposed by Barwise and Cooper (1981). This says that all simple determiners across all languages express monotone quantifiers. A quantifier is monotone iff it is *upward* monotone or *downward* monotone. A quantifier Q is upward monotone [downward monotone] iff for any three sets A, B and B', if $Q(A)(B)$ and $B \subseteq B'$ [$B' \subseteq B$] then $Q(A)(B')$. As an example, consider the upward monotone quantifier $[\![most]\!]$. Assume that the sentence "Most cats sleep" is true and that everything that sleeps is alive, i.e. $[\![sleep]\!] \subseteq [\![alive]\!]$. The monotonicity of $[\![most]\!]$ ensures then that "Most cats are alive" is true.

Monotonicity is an interesting universal because it is easy to imagine non-monotone quantifiers. Examples of non-monotone quantifiers abound among the meanings of complex determiners: "an even/odd number of" or "exactly 2", etc. The commonness of non-monotonicity among complex quantifiers makes the lack of simple non-monotone quantifiers especially puzzling and in need of an explanation. Previous work proposed to explain the universal of monotonicity in terms of the greater learnability of monotone quantifiers.

Steinert-Threlkeld and Szymanik (in press) propose to use neural networks in this context. A neural network is a computational device that can learn to approximate functions by observing tuples of inputs and relevant outputs, and progressively minimizing a suitably defined distance between the true output and the network's own prediction. In the case of a quantifier, the input is a structure where the relevant sets are specified and the output is 1 iff the structure verifies the quantifier and 0 otherwise. In practice, given a structure the neural network outputs a probability that can be interpreted as confidence that the structure verifies the quantifier.

[6] Exactly how to draw the distinction between simple and complex and whether, for instance, *most* is simple or complex, do not matter for present purposes.

[7] For more information on generalized quantifier theory from linguistic, computational, and cognitive perspectives, see also Peters and Westerståhl (2006) and Szymanik (2016).

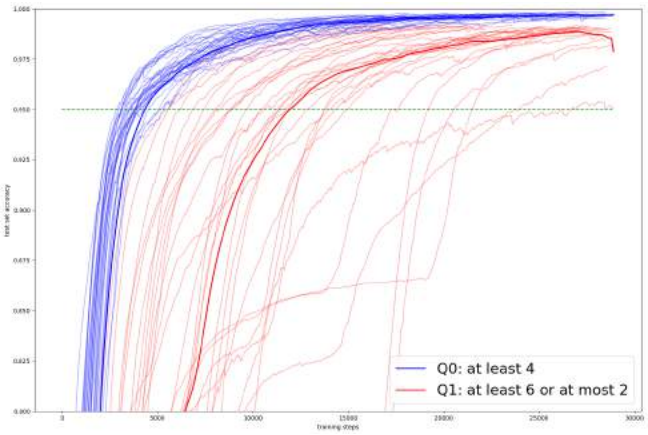

Figure 1: Learning curves on a neural network for the monotone *at least 4* (blue) versus *at least 6 or at most 2* (red). The x-axis is number of training steps; the y-axis is accuracy (percentage correct) on a test set of examples the network has not yet seen. This was Figure 4 in Steinert-Threlkeld and Szymanik (in press).

Data about how fast neural networks learn different kinds of quantifiers was produced with the following algorithms. First, two quantifiers are picked such that one satisfies the universal and the other does not. Then, the two quantifiers are taught to a neural network until it has accurately learned them. The crucial information is how long on average it takes neural networks to accurately learn quantifiers that satisfy the universal compared to ones that do not. Various universals were tested in this way. In the case of monotonicity, the data was produced both for a downward monotone and for an upward monotone quantifier. The neural networks were strikingly faster at learning monotone compared to non-monotone quantifiers. Figure 1 shows an example.

As discussed above, knowing that meanings with certain features can be learned more easily only goes some of the way in explaining the features' universality across various languages. A full explanation also needs to show that the structure can and eventually will be reached by processes of cultural evolution. In the rest of this paper, we develop an iterated learning model of the cultural evolution of quantifiers that embeds the learning model of neural networks, and show that monotonicity reliably emerges.

Methods

Iterated learning

IL models start with two groups of randomly initialized agents, the first and second generations. Each agent in the first generation—the *cultural parent*—is associated with one agent in the second generation—the *cultural child*. A set of

linguistic production data is generated for each cultural parent and used as input for the cultural child. The cultural child tries to approximate its cultural parent's language. In the following step, the process is repeated with agents in the second generation as cultural parents and the new agents in a third generation as cultural children. The cultural transmission process is iterated for some number of generations. Each cultural family line is called a *chain* of IL.

Crucially, the agents do not learn their parent's language perfectly. There can be various reasons for this. First, there can be a bottleneck in learning. This happens when the learner does not observe everything that is needed to perfectly reconstruct the language, and therefore has to guess some aspects of it. The number of data points given to the learners is fixed for all generations and agents and is called the *bottleneck size*. A second reason is that the agent might not have perfect memory or perfect reasoning abilities, and might therefore learn a language that does not perfectly conform to the given data. In this case, the more rational the agent, the closer the learned language will be to the teacher's language. A third reason is that the cultural parents might produce language in a way that is stochastic rather than deterministic. This can make the language harder to approximate and impossible to learn perfectly. For instance, a cultural parent might pick among the signals compatible with a certain observation according to a categorical distribution. The cultural child would need to infer the parameters of the distribution, a task which cannot in general be accomplished perfectly with a finite number of observations.

The changes introduced by each learner accumulate over generations. Since these changes are not completely random, but rather tend to be consistent across agents, the languages tend to change in the same way over time in different chains. In sum, IL is a way to study how the cognitive system of the learners determine which languages one should expect to see spoken in a population of such agents. The crucial individual level components of an IL model are the set of possible languages, and the way the agents learn them. We now explain these two components in turn.

Model of models, quantifiers, and language

Since the focus is on the evolution of monotonicity, we simplify the language model by assuming that the quantifiers are conservative and extensional.[8] This amounts to saying that the truth value of each quantifier only depends on the elements in A and $A \cap B$, and not on $\overline{A \cup B}$ or $B \setminus A$. Therefore, the truth of any quantifier depends only on which of the elements of A are also elements of B, and which are not. Assuming conservativity and extensionality both reduces the number of possible quantifiers that agents can speak and simplifies the model of each quantifier, since only A and $A \cap B$ need to be encoded. Moreover, we assume that the left argument of the quantifiers is fixed to some set A with cardinality n.

Assuming conservativity/extensionality and a fixed set A, we can represent the part of the world—called a *model*—that is relevant to determining the truth value of a quantifier as a bit vector of a fixed length n. Each element of the model represents an object in A. Each element has value 1 iff the object corresponding to that bit is also an element of B, and 0 otherwise. For instance, the vector $[0,1,1]$ would model a situation where $A = \{o_1, o_2, o_3\}$ and o_2, $o_3 \in B$. The set of models is the set of all binary strings of length n, i.e. the set of possible relations between a fixed A and any possible B. We call M' a *submodel* of a model M iff M' is 0 everywhere where M is 0. For instance, $[0,1,1,0,0]$ is a submodel of $[0,1,1,1,1]$. Note that each model is a submodel of itself.

We represent a *quantifier* as a function from models to single bits. An example of a quantifier is $Q(x) = 1$ if $\sum_{i=1}^{n} x_i > 2$ otherwise 0, meaning "more than two". Since for A of size n there are 2^n different models, each quantifier is a 2^n-sized bit vector. Each element of the quantifier vector corresponds to a model and has value 1 iff the model verifies the quantifier and 0 otherwise.

To see how this works in practice, consider a set A of size 3. There are 8 possible ways in which any other set B can overlap with A. Each of these is modelled as a bit vector of size 3. For instance, $[0,1,1]$ says that the second and third object of A are also elements of B, but the first is not. The English expression "all As are B" is modelled by a bit vector of size 8 that has value 1 at the index corresponding to the model $[1,1,1]$ and 0 otherwise. If the models are ordered lexicographically[9] and the last model is therefore $[1,1,1]$, then the quantifier corresponds to the vector $[0,0,0,0,0,0,0,1]$. We call a quantifier *degenerate* if and only if it corresponds to a vector of identical elements, 0s or 1s. A degenerate quantifier corresponds intuitively to a quantifier that is true or false of every model.

Each agent encodes a single quantifier. Agents do not encode the quantifiers directly. Rather, given a model they produce a truth value by using a neural network. The next two sections clarify the connection between the neural networks and the agent's behaviour.

Neural Networks

Because of the aforementioned learnability results of Steinert-Threlkeld and Szymanik (in press), the agents that make up the generations in our iterated learning setup are *neural networks*. Each network has n input neurons (one for each bit of a vector corresponding to a model) and one output neuron (how probable it thinks that the true output is a 1), with two hidden layers of 16 neurons each. We made this

[8] These, next to monotonicity, are two prominent semantic universals distinguishing natural language quantifiers from all logically possible quantifiers. Extensionality means that extending or shrinking the universe of discourse has no effect on the truth-value of the quantifier sentence as long as the left and right arguments are unchanged. Conservativity means that only the part of B that is common to A matters for the truth-value of the sentences. In other words, the elements in $B \setminus A$ can be safely ignored when determining the truth-value. See Peters and Westerståhl (2006) for definitions.

[9] In that case, lexicographic order is the dictionary order over sequences of letters from the alphabet $\{0,1)$ with 0 preceding 1 in the order.

choice so that the networks had enough expressive power to represent many quantifiers, including complex ones. Future work will analyze the effect of architecture choices on the results presented below. The networks and learning, which will be described in the next section, were implemented in PyTorch.[10]

Such a network learns from input/output pairs using a fancier version of gradient descent called Adam (Kingma & Ba, 2015). The network receives a number of true input/output pairs, which it iterates over in small batches. For each batch, it guesses the correct outputs for the inputs, and then updates its parameters (weights and biases connecting the neurons) in such a way that its future outputs are guaranteed to be closer to the truth.[11] Because this style of learning is fairly gradual, we introduce one more parameter to our simulations, namely *number of epochs*: this is how many times the network processes its training set in each generation. In other words, the network sees a portion of its parent's language, as determined by *bottleneck size*, but gets to learn from that portion number-of-epochs times.[12]

Model of the agents

Each agent plays two roles in an IL simulation. The first role is to learn a language given data from the previous generation. The second role is to produce data used to teach to the following generation. To produce this data, the agent is prompted with randomly chosen models.

In the learning phase, each agent receives learning data consisting of a set of tuples ⟨model, judgment⟩. The judgment is a single bit expressing whether the quantifier used by the agent is compatible or not with the model. This data is used to train the agent's neural network as described in the previous subsection.

Production works as follows. The agent feeds an observed model to its neural network. The neural network returns a number in the $[0,1]$ interval. Then, the agent rounds the number and returns it. The returned number expresses whether the agent's quantifier is compatible or not with the model that the agent observed. The production behaviour is deterministic, since an agent always produces the same bit given the same model.

Prompted with a string of 1s and 0s, agents produce a 1 or 0. The former models a state of the world, the latter models the compatibility of the agent's quantifier with the world state. However, nothing in the simulation implies that neural networks are interpreting 1 and 0 as True and False respectively in their input and output. Therefore, the output of an agent under-determines which quantifier the agent speaks, even when the output for all models is known. For instance, an agent that returns 1 for input $[0,0,1,1]$ can be interpreted as accepting the model where $B = \{o_3, o_4\}$ (if 1 is interpreted as True in the model and in the quantifier), as rejecting the model where $B = \{o_3, o_4\}$ (if 1 is interpreted as False in the quantifier and True in the models), as accepting the model where $B = \{o_1, o_2\}$ (if 1 is interpreted as True in the quantifier and False in the models), or as rejecting the model where $B = \{o_1, o_2\}$ (if 1 is interpreted as False in the quantifier and the models). Crucially, the interpretation of the bits has to be consistent across the models and across the quantifier judgments. Therefore, each agent can be interpreted as speaking four quantifiers, depending on whether 1 and 0 are interpreted as meaning true or false in the models and in the agent's output. We discuss below how we deal with underdeterminacy when it might make a difference to the interpretation of the results.

Measures of monotonicity

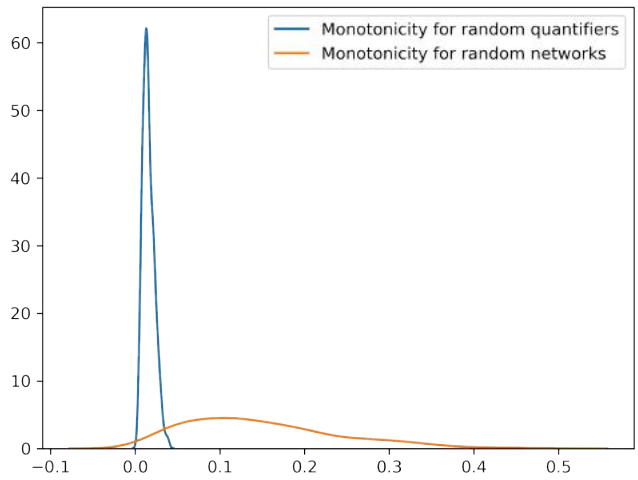

Figure 2: Kernel Density Estimation of the distribution of degrees of monotonicity from a sample of 300 completely random quantifiers and 300 random neural network agents. The x-axis is the measure of monotonicity we describe in the main text.

According to the standard definition, monotonicity is a binary property. A possible way of analyzing the results would be to find the proportion of monotone languages in every generation. However, some quantifiers are intuitively more monotone than other quantifiers. For instance, consider the three quantifiers "some", "between 3 and 5" and "an even number of". While "some" is monotone and the other two quantifiers are not, intuitively "an even number of" is the least monotone of the three. To track finer changes in monotonicity level over time, we define a graded measure of monotonicity.

We measure monotonicity in information-theoretic terms as the proportion of uncertainty in the output of a quantifier that is removed after knowing that there is a submodel where the quantifier is true (i.e. a 1). For a perfectly (upward) monotone quantifier Q, if a model M has a submodel to which the quantifier assigns 1 then Q will assign 1 to M. Therefore, for

[10] `http://pytorch.org`

[11] For general introductions, see Nielsen (2015); Goodfellow, Bengio, and Courville (2016).

[12] In some experimental literature — for example, Carr, Smith, Culbertson, and Kirby (2019) — this is also referred to as *exposures*.

a monotone quantifier all the uncertainty is removed and the measure has value 1.

More formally, first define the random variables $\mathbb{1}_Q$ and $\mathbb{1}_Q^{\prec}$ on the space of possible models as follows. $\mathbb{1}_Q$ is the value that Q assigns to the model M. $\mathbb{1}_Q^{\prec}$ is whether a model has a submodel that the quantifier considers true (assigns 1 to). The entropy of $\mathbb{1}_Q$, $H(\mathbb{1}_Q)$, quantifies the uncertainty about what truth value Q will assign to a model. The conditional entropy $H(\mathbb{1}_Q \mid \mathbb{1}_Q^{\prec})$ quantifies the uncertainty about what Q will assign to a model, given that one knows whether the model has a submodel that Q considers true (assigns 1 to). $H(\mathbb{1}_Q \mid \mathbb{1}_Q^{\prec})$ is minimized (attains value 0) for a perfectly monotone quantifier: if you know that a model has a true submodel, and the quantifier is upward monotone, you know the truth value of that model. The difference between the entropy and the conditional entropy between these variables is known as the mutual information:

$$I(\mathbb{1}_Q;\mathbb{1}_Q^{\prec}) := H(\mathbb{1}_Q) - H(\mathbb{1}_Q|\mathbb{1}_Q^{\prec})$$

This measures how much information $\mathbb{1}_Q^{\prec}$ provides about $\mathbb{1}_Q$. For a perfectly monotone quantifier, $H(\mathbb{1}_Q|\mathbb{1}_Q^{\prec}) = 0$, and so $I(\mathbb{1}_Q;\mathbb{1}_Q^{\prec}) = H(\mathbb{1}_Q)$. In other words: for a monotone quantifier, knowing which models have a true sub-model provides as much information as knowing the entire quantifier.

While this roughly captures what we want from a measure of monotonicity, it needs to be normalized to form a degree that applies across quantifiers, since $0 \leq I(\mathbb{1}_Q;\mathbb{1}_Q^{\prec}) \leq H(\mathbb{1}_Q)$. We do this by dividing by $H(\mathbb{1}_Q)$, moving the upper bound to 1. In total then, we measure monotonicity as

$$\begin{aligned}\mathsf{mon}(Q) &:= \frac{I(\mathbb{1}_Q;\mathbb{1}_Q^{\prec})}{H(\mathbb{1}_Q)} \\ &= \frac{H(\mathbb{1}_Q) - H(\mathbb{1}_Q|\mathbb{1}_Q^{\prec})}{H(\mathbb{1}_Q)} \\ &= 1 - \frac{H(\mathbb{1}_Q \mid \mathbb{1}_Q^{\prec})}{H(\mathbb{1}_Q)}\end{aligned}$$

To see how this measure tracks intuitions, consider the previous mentioned quantifiers "some", "between 3 and 5" and "an even number of". "Some" gets monotonicity 1.0, because knowing whether a model has a submodel that verifies "some" eliminates all uncertainty about the truth of the model. Recall that each agent can be interpreted as instantiating any of four quantifiers, which can be monotone to different degrees. This raises the question of which of the four degrees of monotonicity should be considered in the analysis of the results. The monotonicity of an agent's language is the highest among the degrees of the quantifiers compatible with the agent's language. For instance, an agent whose quantifier is "between 3 and 5" has degree 0.7517 and one with "an even number of" has degree 0.001.

We compare the results of the simulation to the distribution of the measure in randomly generated quantifiers. There are two different random distributions of quantifiers. On the one hand, there are the quantifiers instantiated by randomly initialized agents. On the other hand, there are the quantifiers sampled uniformly from the space of possible quantifiers. These two distributions are depicted in Figure 2. While the completely random quantifiers have a narrower distribution, both types of random distribution are very skewed towards low degree of monotonicity. This makes sense: monotonicity is a relatively rare property, and so should not be expected to appear randomly. We now turn to the results, showing that higher degrees do emerge via iterated learning.

Materials

For our experiments, we used a fixed model size of 10 (which, recall, is also the size of the input to the agents), with 10 agents in each generation, and varied the bottleneck size (200, 512, 715, 1024) and number of epochs (4 and 8). For each setting of those two parameters, we ran 20 trials.

The code, data, and instructions for running experiments may be found at `https://github.com/thelogicalgrammar/NeuralNetIteratedQuantifiers`.

Results

The first result is that monotone quantifiers evolve consistently and rapidly for some values of the simulation parameters. More specifically, the evolution of monotonicity depends on the bottleneck size and the number of epochs, i.e. how much of the parent's language is observed by the cultural child. See Figure 3 for the results. If the networks get too much input, they learn the quantifier accurately and change is very slow. If the networks get too little input, the learning has little effect and no pattern emerges. If languages are somewhat stable across generations, but enough variation is allowed by not over-training the cultural children, monotonicity evolves.

A second result is that the monotone quantifiers that emerge are in large part non degenerate. In Bayesian models that include a prior for simplicity, degenerate languages become widespread under pure IL (Kirby, Tamariz, Cornish, & Smith, 2015). Here, however, degenerate quantifiers are a small minority (about 0.005% of all quantifiers).

The third result is that most non-degenerate monotone quantifiers fall in one of a few types. About 79% of the perfectly monotone quantifiers show the following pattern: there is some index i such that the quantifier—call it Q_i—assigns 1 to a model iff the model is 1 at i (or an equivalent pattern obtained by switching 0 and 1 uniformly in the models and/or in the quantifier). Q_i is true iff o_i, the object represented by index i, belongs to the set B.[13]. Therefore $Q_i(A)$ functions like a proper noun for o_i. Just like "Anna is human" is true iff Anna belongs to the set of humans, "$Q_i(A)$ is B" is true iff o_i belongs to the set B.

[13] In set-theoretic terms, Q_i is a *principal ultrafilter* If U is a finite non-empty set, a set F is a principal ultrafilter on U if there is an $a \in U$ such that $F = \{B \in \mathcal{P}(U) | a \in B\}$. In the present model, Q_i is (the characteristic function of) a principal ultrafilter on B because it it contains every subset of B that contains i.

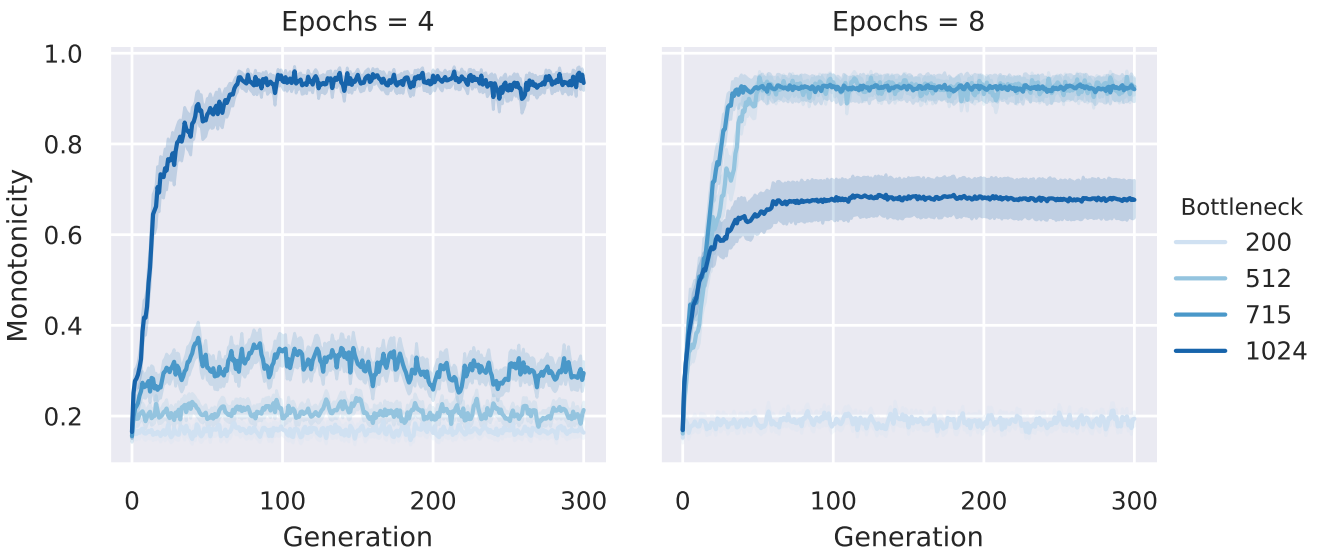

Figure 3: The simulation was ran 20 times for each combination of bottleneck size and number of epochs in a population of 10 agents and a maximum model size of 10. The plot shows how the average monotonicity level across all languages changes over 300 generations. Convergence to monotonicity depends on how much the learners' neural networks are trained, which itself depends on the number of epochs and the bottleneck size. With small bottleneck and few epochs, monotonicity does not evolve. With a bigger bottleneck size and more training epochs, monotone languages become widespread. However, increasing the training data further tends to impede the development of monotone languages.

For other monotone quantifiers $Q_{\{j,k\}}$, there are two indices j,k (with $j \neq k$) such that $Q_{\{j,k\}}$ assigns 1 to a model iff the model has value 1 at both j and k (or, again, an equivalent patterns obtained by switching 0 and 1 in the models and/or in the quantifier). $Q_{\{j,k\}}$ is true iff B contains two specific elements of A, and false otherwise.[14] It can be interpreted as the conjunction of two proper nouns. Like "Anna and Rob are human" is true iff Anna is human and Rob is human, "$Q_{\{j,k\}}(A)$ is B" is true iff o_j is B and o_k is B.

Discussion

The results we presented support the learnability account of the origins of semantic universals of quantification. While previous work compared quantifiers satisfying semantic universals to quantifiers that do not, we have presented a model where the former are selected out of all of the possible quantifiers by a process of cultural evolution. Moreover, the preference for monotone quantifiers is not a consequence of an explicitly coded bias for simplicity, but rather of an independently motivated, biologically plausible model of learning. The results therefore suggest that not only are monotone quantifiers easier to learn, but they are also widespread in language *because* of their learnability.

This model can be straightforwardly extended in various ways. The agents judged their quantifier compatible with a given model simply by rounding the output of their neural network. An alternative to this is for the agents to accept a model with a probability proportional to the network's output. Such so-called sample agents do not straightforwardly instantiate a quantifier, since they can produce inconsistent output when repeatedly prompted with the same model. However, preliminary results have shown that neural networks are capable of doing *statistical learning*: given enough data, they approximate not just whether their parents tend to reject or accept a model, but also the probability of acceptance.

While the quantifiers that emerge from our experiment are monotone, they are unnatural in certain respects. For instance, the proper-name-like quantifiers that emerge are not *quantitative*, i.e. their truth value depends not simply on the number of 1s and 0s, but on the identity of particular elements.[15]

To try and explain the emergence of quantifiers which are both monotone and quantitative, it might be necessary to make it more difficult for the networks to rely on the identity of particular objects by, for instance, shuffling the order of models in the parent and the teacher's inputs. Another pressure that might contribute to shape the meaning of quantifiers comes from communication (Kirby et al., 2015). While

[14] These are called in set-theoretic terms *principal filters*. They are not principal ultrafilters because their truth depends on more than one element.

[15] See Steinert-Threlkeld and Szymanik (in press) for the definition of and motivation for quantity, which generalizes the isomorphism/permutation constraint in generalized quantifier theory as discussed, for instance, in Peters and Westerståhl (2006).

some semantic universals of quantification might have an advantage in cultural evolution because they conform well with learning biases, other universals might evolve because they lead to more successful communication. Therefore, combining iterated learning with a pressure for accurate communication might help more natural quantifiers emerge. We leave all of these exciting possibilities to future work.

"Natural concepts" revisited in the spatial-topological domain: Universal tendencies in focal spatial relations

Abstract

It has long been noted that the best examples, or foci, of color categories tend to align across diverse languages (Berlin & Kay, 1969)—but there is limited documentation of such universal foci in other semantic domains. Here, we explore whether spatial topological categories, such as "in" and "on" in English, have focal members comparable to those in color. We document names and best examples of topological spatial relations in Dutch, English, French, Japanese, Korean, Mandarin Chinese, and Spanish, and find substantial consensus, both within and across languages, on the best examples of such spatial categories. Our results provide empirical evidence for focal best examples in the spatial domain and contribute further support for a theory of "natural concepts" in this domain.

Keywords: Language and thought; spatial cognition; categories; semantic universals.

The central role of foci

For decades, discussions of natural language categories such as "dog" or "blue" have emphasized prototypes, family resemblance, and fuzzy sets—all notions specifying relations between central cases and boundaries, and recognizing gradation in category membership. An especially well-studied and debated case is that of focal colors, or best examples of color categories (e.g. Berlin & Kay, 1969; Heider, 1972; Kay & McDaniel, 1978; Roberson et al., 2000; Regier et al., 2005; Abbott et al., 2016). Despite the ongoing debate, there is broad consensus that such best examples of color categories often (but not always) align across languages, and that languages sometimes have composite categories apparently organized around multiple foci—for example a composite green-blue or "grue" category.

Despite the attention given to focal colors, studies of categorization and semantic typology in many other semantic domains have not emphasized category best examples as prominently, but have instead tended to characterize categories as sets, such that an exemplar may simply be a member of the category or not. Within the domain of spatial topological relations, previous work has drawn on extensional patterns in naming as evidence for central exemplars and core meanings of categories like "in" and "on" (e.g., Levinson et al., 2003; Johannes, Wang, Papafragou, & Landau, 2015; Johannes, Wilson, & Landau, 2016; Landau, Johannes, Skordos, & Papafragou, 2017), but without directly querying speakers about best examples per se. Here, we employ empirical best example data to provide a long-overdue response to a call by Feist (2000: 236) to determine whether spatial relational categories, like colors, have focal members.

In what follows, we review key findings on focal colors and their relationship to color category semantics. We then describe parallels to color in the domain of spatial topological relations, and summarize an account (Levinson et al., 2003) of focal spatial relations that was developed and evaluated on the basis of spatial naming data, but without grounding in empirical best examples. We then present our study, which reexamines the hypotheses of this previous account using empirical best example data from seven languages. We explore three related questions about focal category members in the spatial domain:

1. Is there consensus within languages on focal spatial relations?
2. Is there consensus across languages on focal spatial relations?
3. Do spatial categories exhibit composite structure, with more than one focus per category?

To preview our results, we find initial evidence for universal tendencies in focal spatial relations, both within and across languages, based on naming and best example data from seven languages. We also find evidence for at least three composite spatial categories, where a single lexical category includes multiple foci. We conclude that focal spatial relations share some of the distinctive features of foci in the color domain.

Focal colors

Berlin and Kay (1969) proposed two key features of focal colors that we consider in the spatial domain: (1) a set of universal focal colors (red, green, yellow, blue, white, and black), and (2) an evolutionary sequence of color categories, by which languages follow a common hierarchy to successively partition color space, progressively subdividing the focal colors into categories. Kay and McDaniel (1978) elaborated this proposal, specifying multi-foci *composite categories* as shown in Figure 1.[1] By this model, the initial two-term category system represented as the first split in the diagram will group WHITE, RED, ORANGE, and YELLOW into a single "warm" category. Kay and McDaniel argued that

[1]Kay and McDaniel's (1978) proposal included two closely-related hierarchies, only one of which is shown here for illustration.

large categories like this in the early stages of the hierarchy are composite, and may be focused at any of their constituent foci. Accordingly, this "warm" category could be focused at WHITE, YELLOW, or RED but not ORANGE, as it is not one of the proposed universal color foci. Similarly, "grue" terms composed of GREEN and BLUE (the latter inclusive of PURPLE) could be focused at either of the two constituent foci, GREEN or BLUE.

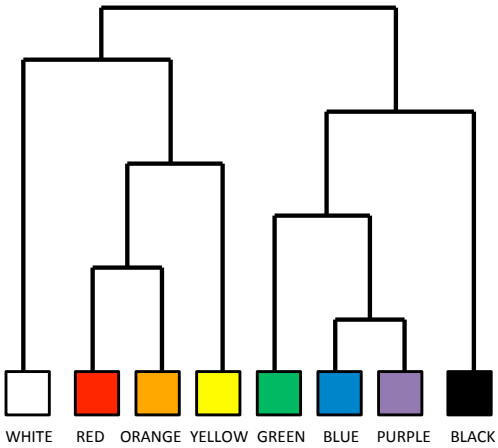

Figure 1: Kay and McDaniel's (1978) proposed evolutionary hierarchy of color terms.

Focal spatial relations?

In our analysis of spatial category best examples, we explore analogs to two distinctive focal color phenomena: cross-language agreement on specific focal colors, and the composite nature of categories spanning multiple foci. To do so, we draw on a proposal for spatial topological concepts by Levinson and colleagues (2003) that parallels much of Kay and McDaniel's (1978) characterization of color. Levinson et al. (2003) proposed an implicational hierarchy of spatial "natural concepts" (or notional clusters of related meanings) modeled on Kay and McDaniel's (1978) color hierarchy and based on a study of spatial semantics in a set of nine diverse languages. In their proposal, Levinson et al. suggest that spatial topological categories, as in color, tend to undergo successive subdivisions in which distinct focal senses of composite categories "split into primary (single-focus) categories over time" (Levinson et al., 2003: 512), as shown in Figure 2.[2]

The present study

To our knowledge, ours is the first study to document empirical best examples in the spatial topological domain. We ask whether speakers of seven languages (1) agree on best examples for common spatial terms in their language, (2) agree on

[2]We interpret Levinson et al.'s (2003) proposal to include two related hierarchies, one of which is shown here for illustration, and both of which are specified in Carstensen and Regier (2013).

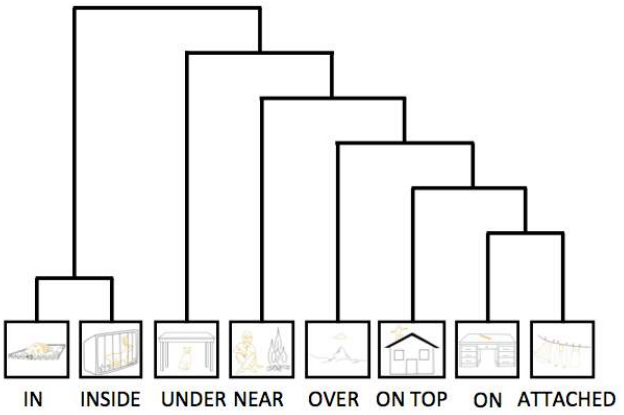

Figure 2: Levinson et al.'s (2003) proposed evolutionary hierarchy of topological spatial concepts, specifying a predicted order in which spatial categories in language will tend to subdivide distinct spatial notions as new terms emerge in the lexicon.

focal best examples *across* languages, and (3) demonstrate composite categories subject to successive differentiation of focal notions in keeping with Levinson et al.'s hypothesized spatial category hierarchy. If so, this finding would provide empirical evidence for focal best examples in the spatial domain that share key aspects with color foci, and contribute further support for Levinson et al.'s suggested "natural concepts."

Methods

In order to investigate whether spatial relations have focal members within and across languages, native speakers of seven languages (a convenience sample: English, Dutch, Spanish, French, Mandarin Chinese, Japanese, and Korean) were asked to name the spatial relation depicted in each of a set of cards, and then asked to select the best example, good examples, and all possible examples of the spatial terms they provided.

Participants The study included native speakers of 7 languages: 24 English, 29 Spanish, 18 French, 19 Japanese, 13 Dutch, 18 Korean, and 18 Mandarin Chinese speakers. All participants were native speakers of their respective language, and tasks were administered in that language by experimenters who were also native speakers.

Stimuli Stimuli were the 71 spatial scenes of the Topological Relations Picture Series (TRPS) by Bowerman and Pederson (1992). Scenes are line drawings showing an orange figure object located relative to a black ground object (e.g., a cup on a table; see Figure 2).

Procedure

Instructions and object labels for each of the TRPS scenes (e.g. cup, table) were translated from English to the study language and then backtranslated to ensure accuracy.

1. Scene naming. Participants were shown each of the spatial scenes in one of two fixed random orders, and asked to name the spatial relation in each. Each scene was shown above a fill-in-the-blank in the participant's native language with labels specifying the figure and ground objects, and the participant filled in the blank to complete a normal, everyday sentence answering the question "Where is the [figure]?" For example, the participant may see "The cup ____ the table," and respond "The cup is on the table."[3] The topological relation markers (prepositions or short phrases) supplied by each participant were sanitized by the experimenter, collapsing over responses that differed solely in components without spatial meaning (e.g., variation in verb tense).

2. Category mapping task. After the naming data was sanitized to produce a list of unique labels given by the participant, the experimenter provided an array (from Levinson et al. (2003) Figure 5) with all stimuli organized for contiguity in the spatial relations depicted. Participants were then asked, for each unique spatial category they had named, to first identify the TRPS scene that is the best example (BE) of that category by placing a large coin on the scene in the array, then to identify all good examples (GEs) of that category (with smaller coins, e.g. nickels), and finally to identify all exemplars (AEs) of that category (by placing small coins on each exemplar in the array to visually "map" the category).

Naming data. In total, participants used 55 unique spatial labels in English, 146 in Spanish, 22 in French, 29 in Japanese, 56 in Dutch, 149 in Korean, and 100 in Mandarin. We selected a subset of these responses for analysis by taking the label most frequently applied to each of the 71 TRPS scenes by speakers of each language (with ties broken randomly). This produced a total of 85 *modal categories* for further analysis (11 for English, 9 for Japanese, 9 for French, 9 for Spanish, 8 for Mandarin, 19 for Korean, and 20 for Dutch; see listing in Appendix, Table 1[4]).

Analysis and results

1) Is there consensus on focal spatial relations?

To determine whether speakers within each language share foci for common spatial categories in their language, we measure how well the speakers' choices of best examples align with each other. For each of the 85 spatial categories c, we created a 71-dimensional vector b_c representing the TRPS stimuli in which we tally the number of times speakers of that language chose each stimulus as a best example for category c. To measure how well speakers align with each other on the best examples for each category c, we use entropy (H), a measure of the uncertainty of a distribution:

$$H(b_c) = -\sum_{i=1}^{n} p(b_{c,i}) \cdot \log_2(p(b_{c,i})) \quad (1)$$

where $p(b_{c,i}) = b_{c,i}/\sum_j b_{c,j}$, that is, the proportion of a language's speakers that chose stimulus i as the best example of category c. Entropy is minimal (0) if all speakers choose the same best example (i.e., a Dirac distribution), and maximal ($\log_2(n)$, here $\log_2(71) = 6.15$) if the distribution of best examples is uniform across all stimuli. Thus, entropy is a measure of how flat or un-peaked a distribution is. The average entropy of these empirical best example distributions is $M_{emp} = 0.99$ ($SD = 0.70$), much lower than the entropy of a uniform distribution—but high enough to indicate variation in best example choices.

To determine if the amount of alignment within each category is greater than might be expected by chance, we modeled chance agreement as a scenario in which each participant randomly chose a best example from the set of scenes they had selected in the category mapping task as good or best examples of the category. Following this approach, we would expect to see peaks in each simulated best example distribution resulting from coincidences in random selection, but also as a result of varying categorization across participants: often one participant's good examples of "on" represent a subset of another participant's good "on" selections, creating peaked best example distributions in this simulation even when all members of a category have an equal probability of being selected as the best example. To model chance entropy values for each category, we used Monte Carlo simulations to create pseudo-random distributions of best examples for each of the 85 categories, and compared the empirical entropy of each category's best examples (BEs) to the entropy values of the simulated distributions. To create the simulated BE distribution for each category, we simulated each speaker choosing at random one of their best or good examples for that category. Thus, each simulated best example distribution $b_{c,sim}$ was comparable to the original in having the same number of votes as the empirical distribution, but chosen at random from each speaker's best *and* good examples.[5] For each of the 85 categories, 2,000 simulated best example distributions were created, and the entropy of each was calculated. We then measured where in this distribution of simulated entropies the empirical category's entropy fell. If speakers of each language agree *substantively* with each other (within languages) on the best examples for each category, then the entropy of the empirical best example distribution should be smaller than the entropies of more than 95% of the resampled distributions. Indeed, this was true for 76 of the 85 categories.[6]

Across all 85 categories, the entropy of the empirical best examples ($M_{emp} = 0.99$) is significantly lower than the mean entropy of 2000 example vectors randomly-sampled from participants' naming data for each category ($M_{sim} = 1.81$; paired $t(83) = 13.78$, $p < .001$). That is, empirical best examples of each category are significantly more peaked than they would be if chosen at random from all good and best

[3] Mandarin speakers filled in two separate blanks at the typical positions for verbs and prepositions, respectively.

[4] We render Korean in Hangul to avoid ambiguity across differing romanization schemes.

[5] This procedure was also performed using speakers' naming data instead, with very similar results.

[6] The 9 exceptions: SP 'cuelga,' FR 'dessus,' JP 'ni,' KO '나,' and '달려,' NL 'om,' 'hangen aan,' 'zitten om,' and 'zitten aan.'

examples selected by speakers as part of that category. Figure 3 shows the entropy of the empirical best example distribution for each of the 85 modal categories plotted against the mean of the 2,000 resampled entropies for each. Overall, the empirical best examples were more aligned than expected by chance in a majority of the categories, showing that speakers of a given language largely agree on focal spatial relations. We now turn to whether this alignment on spatial foci is also seen cross-linguistically.

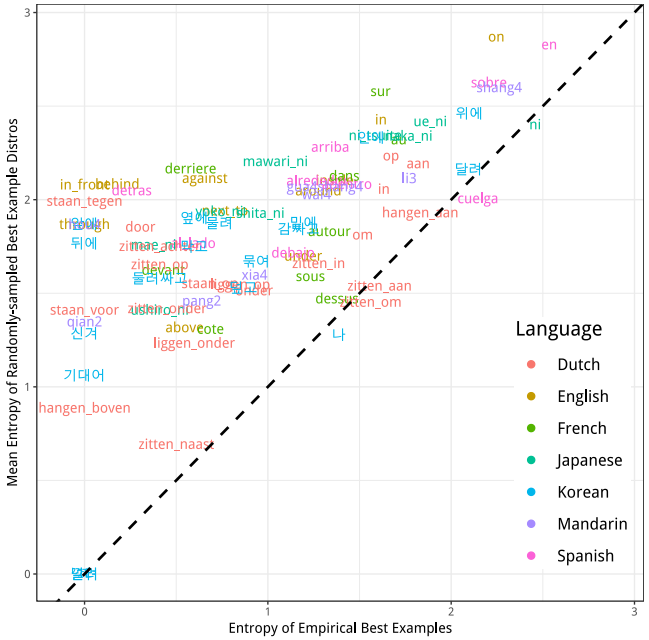

Figure 3: Consistency of best example choices across speakers for each category. Empirical entropy of the best example distributions of 85 spatial categories in 7 languages vs. the mean entropies of 2,000 randomly-chosen best example distributions created from each participant's chosen good and best examples of a category. The empirical best example distributions showed more alignment (lower entropy) than the resampled distributions for 80 of the 85 categories.

2) Does this consensus on focal spatial relations extend across languages?

We now investigate if there is consistency in the stimuli that get selected as best examples by speakers of different languages. In other words, we ask whether different languages align their best example choices on the same stimuli. To do so, we first tallied each language's best example distribution for the modal categories over all 71 TRPS stimuli, adding the b_c vectors for each language L into a single summed BE count vector per language, b_L. These summed BE counts, b_L, were then normalized $p(b_{L,i}) = b_{L,i}/\sum_j b_{L,j}$, meaning cell $p(b_{L,i})$ is the probability that stimulus i was selected as a best example for any of the modal categories of language L. The language-specific best example distributions $p(b_L)$ were then averaged together (with equal weight to each language) to obtain a cross-language BE distribution.

Figure 4 shows normalized best example distributions per language, as well as the cross-linguistic average ("all languages"). To determine how aligned the best examples are across languages, we compare the entropy of the cross-language distribution (3.70) to the distribution of entropies from a Monte Carlo simulation. For each language's summed BE distribution $p(b_L)$, the probabilities across stimuli were randomly permuted (swapping cells to preserve the overall structure of the distribution), and then the resulting normalized cross-language distribution was calculated (as above) on the permuted summed distributions for each language. The entropy of this pseudo-random cross-language BE distribution was found, and this procedure was repeated 10,000 times to generate a set of permuted entropies. The resulting distribution is shown in Figure 5. The empirical distribution's entropy (3.7, shown in red) was lower than all 10,000 entropies of the permuted distributions, which had a mean of ($M = 3.81$).

An additional, possibly more conservative, Monte Carlo simulation was also carried out. As before, the counts across stimuli for each language were randomly permuted, but this time only shuffling between stimuli that were selected by at least one speaker of the relevant language as a best example. Only permuting non-zero slots may increase the likelihood of chance alignment, depending on the number of such slots and their pre-existing cross-linguistic alignment. However, the empirical distribution's entropy was again lower than all 10,000 entropies of the randomly-permuted non-zero distributions, which had a mean of 3.82. These results confirm quantitatively that speakers of these seven languages share some consensus on foci for spatial relations, as is suggested qualitatively by inspection of Figure 4, where we have highlighted nine spatial scenes that were selected as best examples by a large proportion of participants across languages.

3) Do spatial categories exhibit composite structure, with more than one focus per category?

Finally, we consider three cases of composite spatial categories, analogous to "grue" in color, in which a single lexical category includes multiple foci. For this, we examine OVER/ON categories, at the third stage of the hierarchy in Figure 2. Levinson et al. (2003) propose that categories inclusive of OVER and ON senses are composites of four spatial foci: OVER, ON, ON-TOP ("location above eye-level"), and ATTACHMENT. In keeping with parallel work on color, Levinson et al. suggest that composite categories may or may not be focused at all of their constituent foci, so clustering of best example choices at OVER, ON, ON-TOP, ATTACHMENT, or any combination of these senses is consistent with this view. Alternatively, many classic models of central tendencies (e.g., mean, mode, prototype) would predict a single central focus. To the extent that the OVER, ON, ON-TOP, and ATTACHMENT senses are distinct from each other, a single-focus view suggests that a lexical category would be focused at only one of these four senses.

We will examine the best example distributions for three

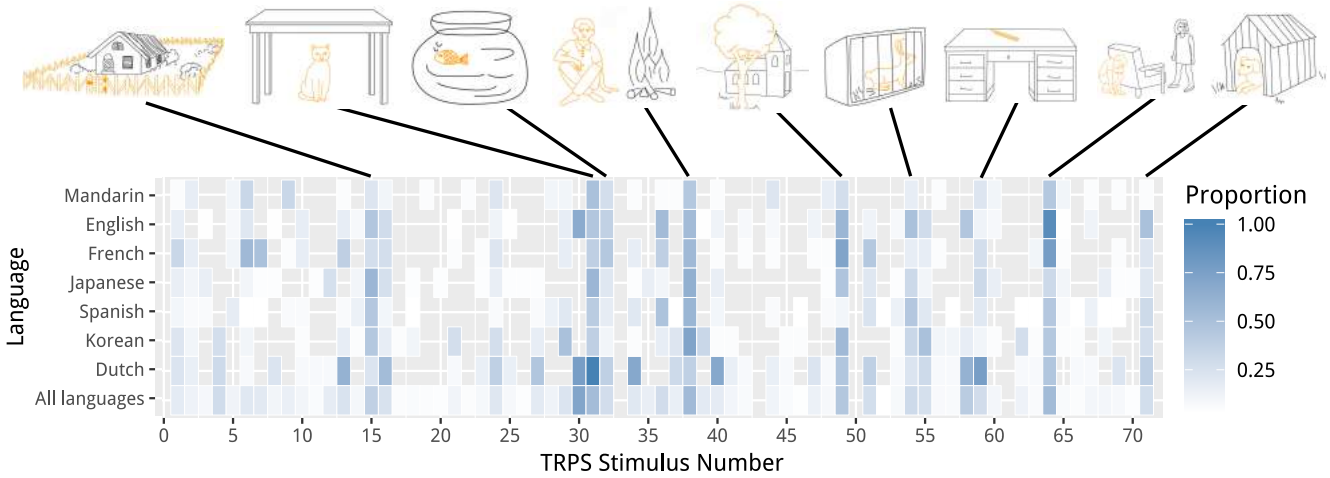

Figure 4: Focal spatial relations. Heatmap of the proportion of participants choosing each TRPS stimulus as a best example for the modal spatial categories in each language. The nine stimuli at the top are those that were selected as best examples in all seven languages, and selected by a large proportion of participants in all languages (best example frequency was greater than 1SD above the median for best examples in the "all language" average).

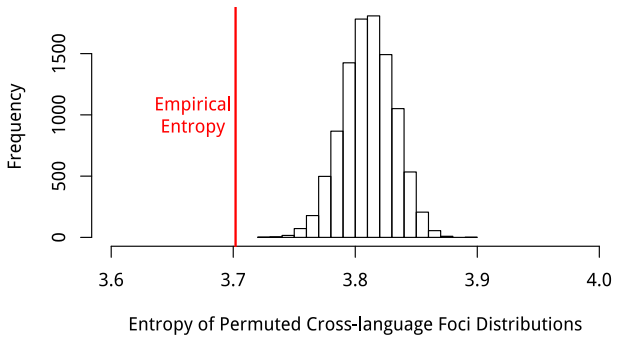

Figure 5: The entropy of the empirical cross-linguistic BE distribution was less than the entropy of all 10,000 randomly-permuted (by language) BE distributions ($p(b_L)$), whether all cells of $p(b_L)$ are permuted (shown) or only non-zero cells.

composite categories spanning these four predicted foci for evidence of composite (bi- or multi-modal) foci. To do so, we compare the best examples of OVER/ON composite categories in Mandarin, Korean, and Japanese to two smaller categories that represent the next stage of subdivision in Levinson et al.'s spatial hierarchy—OVER and ON (the latter inclusive of ON-TOP and ATTACHMENT)—using the closest corresponding modal categories in English, Spanish, French, and Dutch. If the composite categories in Mandarin, Korean, and Japanese have composite *foci*, we would expect their focus distributions to resemble combinations of the focus distributions for ON and OVER in languages that distinguish these senses (i.e., English, Spanish, French, and Dutch).

In this analysis, we measure the similarity of normalized BE distributions of individual spatial categories ($p(b_c)$) from different languages. Following the color literature, the similarity of two distributions will be measured using Jensen-Shannon Divergence (JSD), a finite-valued, symmetric measure of the difference between two probability distributions. JSD is minimal, 0, when the two distributions are identical and has a maximum of 1 in our comparisons.

The three composite categories we consider are Mandarin "shang4," Korean "위에," and Japanese "ue ni." Shown in Figure 6, the foci of these three categories closely correspond to each other (M-K JSD=.23; M-J JSD=.30; K-J JSD=.27). Mandarin's "shang4" corresponds well to the combined (averaged) category foci of two categories in the four other languages: English "above" and "on" (JSD=.35), Spanish "arriba" and "sobre" (JSD=.21), French "dessus" and "sur" (JSD=.21), and Dutch "hangen boven" and "op" (JSD=.46). Like "shang4", Korean "위에" corresponds similarly well to the same combined foci: English "above" and "on" (JSD=.21), Spanish "arriba" and "sobre" (JSD=.15), French "dessus" and "sur" (JSD=.11), and Dutch "hangen boven" and "op" (JSD=.35). Similarly, Japanese "ue ni" matches the averaged BE distribution of English "above" and "on" (JSD=.41), Spanish "arriba" and "sobre" (JSD=.32), French "dessus" and "sur" (JSD=.29), and Dutch "hangen boven" and "op" (JSD=.44) Importantly, these OVER-ON category pairs all have foci distributions that are more distant from each other: above-on JSD=1.0, arriba-sobre JSD=.50, dessus-sur JSD=.92, hangen boven-op JSD=1.0.[7] As shown in Figure 6, this suggests the existence of composite spatial categories with multiple distinct foci, analogous to "grue" cases in the color domain.

[7]The mean JSD of any category's foci to the average of any two other categories' foci is .91 (median=1), and the mean JSD of any two single categories' foci is 0.97 (median=1).

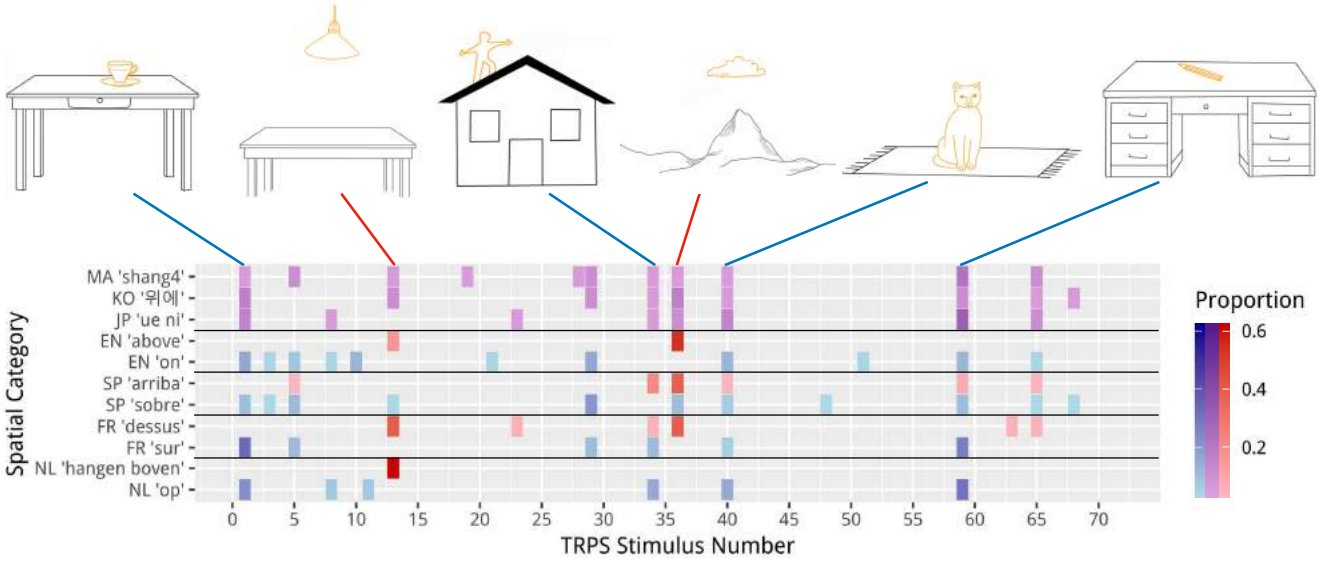

Figure 6: Cross-linguistic comparison of three expected composite categories: the best examples of Mandarin (MA) "shang4," Korean (KO) "위에," and Japanese (JP) "ue ni" span the best examples of separate OVER and ON categories in other languages (e.g., English (EN) "above" and "on"). The six scenes depict foci speakers align on, with red lines indicating OVER foci and blue lines indicating ON-TOP (man on house) and ON foci. Purple heatmap color coding indicates terms with composite extensions, red indicates OVER terms, and blue indicates ON terms.

Discussion

This study used empirical best example data from seven languages to explore whether spatial topological categories have focal members comparable to those in color. We documented names and best examples of topological spatial relations in Dutch, English, French, Japanese, Korean, Mandarin Chinese, and Spanish. To our knowledge, this is the first study to directly acquire and analyze best examples of spatial relations—although others e.g., Landau, Johannes, Skordos, and Papafragou (2017) have investigated related notions such as "core" spatial concepts.

In the first analysis, we considered whether there was consensus within languages on the best examples of spatial relations. Indeed, for the majority of categories speakers were significantly more aligned in their choice of best example than would be expected by chance (i.e., if they had drawn best examples merely from their chosen good or best examples). This demonstrates that within each of these seven languages, speakers tend to agree on focal spatial relations.

Our second analysis examined whether this consensus on focal spatial relations extended across languages. We found that the empirical cross-language distribution of best examples was significantly more aligned than would be expected by chance, confirming that speakers of these languages share some consensus on foci for spatial relations.

Finally, we investigated whether spatial categories reflect composite structure, with focal distributions organized around multiple distinct senses. For this, we examined the best examples of Mandarin "shang4," Korean "위에," and Japanese "ue ni," broad categories that encompass multiple predicted foci. We found evidence suggesting that these categories are indeed semantic composites, focused at multiple senses: the best examples of these large categories resembled combinations of best examples from distinct (and uncorrelated) categories, such as English "above" and "on." This finding supports a previous account of spatial topological semantics and may provide evidence for composite categories in the spatial domain comparable to "grue" in color.

However, there are grounds for caution in the interpretation of these findings. The classic composite category within the color domain, "grue," is evidenced by a focal distribution with both blue and green best examples, but where intermediate colors are not selected as best examples, making for two distinct peaks in the focal distribution. While the "above" and "on" foci selected as best examples of Mandarin "shang4," Korean "위에," and Japanese "ue ni," correspond to distinct attractors or "notional clusters" in Levinson et al.'s (2003) proposal, it is possible that "intermediate" spatial notions would also be selected as focal, making for a single focal peak that is inclusive of both "above" and "on" senses. Future work should examine possible composite categories with clear intermediate cases between the predicted foci to determine whether these senses are indeed distinct, exhibiting the double-peak structure seen in some "grue" cases.

This study offers empirical evidence for universal tendencies in spatial relations based on naming and best example data. Our findings provide evidence for focal best examples in the spatial domain and contribute further support for a theory of "natural concepts" in this domain.

The shape of language experience in two traditional communities

Marisa Casillas
Max Planck Institute for Psycholinguistics, Nijmegen, Netherlands

Abstract

This study sketches the language environments of children ages 0;03;0 growing up in two traditional, indigenous communities: one Tseltal (Mayan) and the other Yl (Papuan). Past ethnographic work has suggested that caregivers' ideas about talking to young children differ greatly between these two communities. However, the present daylong recording analyses suggest that, in fact, children are rarely directly addressed in both places, with no age-related increase and with most child-directed speech coming from adults. Children's manual activities also suggest that child-carrying practices and cultural context moderate the extent to which children might use co-occurrence between held objects and ambient language to learn words.

The Role of Basal Ganglia Reinforcement Learning in Lexical Priming and Automatic Semantic Ambiguity Resolution

Abstract

The current study aimed to elucidate the contributions of the subcortical basal ganglia to human language by adopting the view that these structures engage in a basic neurocomputation that may account for its involvement across a wide range of linguistic phenomena. Specifically, we tested the hypothesis that basal ganglia reinforcement learning mechanisms may account for variability in semantic selection processes necessary for ambiguity resolution. To test this, we used a biased homograph lexical ambiguity priming task that allowed us to measure automatic processes for resolving ambiguity towards high frequency word meanings. Individual differences in task performance were then related to indices of basal ganglia functioning and reinforcement learning, which were used to group subjects by learning style: primarily from choosing positive feedback (Choosers), primarily from avoiding negative feedback (Avoiders), and balanced participants who learned equally well from both (Balanced). The pattern of results suggests that balanced individuals, whom learn from both positive and negative reward equally well, had significantly lower access to the subordinate homograph word meaning. Choosers and Avoiders, on the other hand, had higher access to the subordinate word meaning even after a long delay between prime and target. Experimental findings were then tested using an ACT-R computational model of reinforcement learning that learns from both positive and negative feedback. Results from the computational model confirm and extend the pattern of behavioral findings, and provide a reinforcement learning account of lexical priming processes in human linguistic abilities, where a dual-path reinforcement learning system is necessary for precisely mapping out word co-occurrence probabilities.

Introduction

The field of the neurobiology of language has traditionally focused on the contributions of cortical structures to linguistic processes (Tremblay & Dick, 2016). However, research from different sub-fields suggests that the subcortical basal ganglia are an essential part of the neurobiological bases of human linguistic abilities (Crosson, 1985; Booth, Wood, Lu, Houk, & Bitan, 2007; Seo, Stocco, & Prat, 2018). To date, no existing account of the neurobiology of language is able to systematically explain what the role of these subcortical structures is across the many levels of linguistic processing. Thus, in its current stage, the field suffers from a limited understanding of the neural processes that give rise to language. A detailed whole-brain understanding of this human ability is key to inform robust models of language neurobiology and also to advance our understanding of language disabilities for translational purposes. In an effort to contribute to a whole-brain model of language functioning, this work focuses on understanding the role of the basal ganglia in language.

Given that the basal ganglia are some of the most neurobiologically ancient structures (Lieberman, 2001), it is reasonable to assume that their role in human linguistic abilities is analogous to the more general motor or cognitive functions observed in other species. Indeed, many prominent theories and models of basal ganglia functioning stem from observations of motor control (Mink, 1996) and extend these functions to non-motor and abstract cognitive processes spanning from cognitive control (Graybiel, 1995; Stocco, Lebiere, & Anderson, 2010) to working memory capacity (Hazy, Frank, & O'Reilly, 2007). Thus, the current research aims to understand basal ganglia contributions to language in the context of the already well-understood and well-established theories of selection and reinforcement learning (RL). To test the hypothesis space of basal ganglia selection processes in language, we turned to semantic processing as a model system for competition between multiple viable alternatives. Specifically, this work is grounded on models of models of semantic activation spreading (Collins & Loftus, 1975).

Semantic ambiguity (also referred to as lexical ambiguity) occurs when a word refers to multiple different concepts (Vitello & Rodd, 2015). For example, the word "hot" can refer either to temperature or to food spiciness. Cases of semantic ambiguity may arise in conversational settings, and are also more commonly encountered in written form such as news headlines, puns, poetry, and novels. The ability to properly disambiguate an input into the contextually appropriate represented meaning is key for listening and reading comprehension. More importantly, this process provides details on a fundamental neurocognitive mechanisms, such as the contextual integration of information, statistical learning, inhibition, and selection processes used to manage simultaneous and competing neural representations that are at odds with the task goal of accurate transfer of information in communicative settings.

Semantic ambiguity can arise in a variety of different ways. The first class of ambiguity arises from words that have different unrelated meanings. For example, "bark" can refer to the sound a dog makes, or the outermost layer of a tree. In this case, both meanings of "bark" constitute a true homonym,

but are also homographs and homophones (same spelling, and same sound, respectively). Furthermore, words can be encountered in contexts where only the written form is ambiguous (e.g., the homographs for "lead"), or only the spoken form is ambiguous (e.g., the homophones for "be/bee" or "seam/seem").

The cognitive mechanisms supporting the resolution of semantic ambiguities are best understood by exploring theories on the dynamics of semantic information and its representation. When a listener or reader first encounters a word with multiple meanings, all meanings are quickly activated and available in parallel. This refers to the automatic component in semantic processing. Furthermore, if encountered in isolation or in a highly ambiguous context, an ambiguous word will be automatically disambiguated towards the highest frequency meaning, reflecting another series of automatic selection processes. However, if an ambiguous word is encountered following a strong biasing context towards one specific meaning, only the contextually-relevant word meaning is available. This suggests that when ambiguous words are encountered, all meanings are initially activated, but this activation is modulated by multiple factors such as sentence context and meaning frequency.

While most research focused on understanding the neural mechanisms supporting lexico-semantic processing and ambiguity resolution has focused on cortical structures such as the left inferior frontal gyrus (for a review, see Vitello & Rodd, 2015), there is evidence suggesting a key involvement of subcortical structures in this process (e.g., Ketteler, Kastrau, Vohn, & Huber, 2008; Mason & Just, 2007). For example, a lexical priming investigation found that monolingual individuals experience abnormalities in the neurocognitive dynamics that shape lexical priming (Copland, Chenery, & Murdoch, 2001). Specifically, healthy participants show no traces of subordinate word activation following a long delay between prime and target, and thus reflect automatic semantic ambiguity resolution towards the dominant or highest frequency meaning. Parkinson's Disease (PD) patients, whom have decreased dopaminergic functioning resulting in a general hyperactivity of the basal ganglia indirect pathway, on the other hand, exhibit a longer-term activation of the multiple competing representations.

Although findings such as these have been traditionally framed under a selection and inhibition framework, we explore the hypothesis that the signature role of basal ganglia in RL may more accurately explain its role in semantic processing. In other words, the basal ganglia may be involved in statistical learning and predictive processing during language comprehension. Critical for the current investigation, the activity of the basal ganglia is often modeled as reflecting Temporal Difference (TD) learning. As it happens, TD-learning does not accurately reflect the computations of the basal ganglia, which are the result of the opposite contributions of two conflicting pathways. Their contribution have been modeled as the sum of competing RL systems (Frank, Seeberger, & O'reilly, 2004; Stocco, 2018). Individuals vary in the learning rates of the two pathways as a function of biological parameters (such as density of dopamine receptors: Frank, Moustafa, Haughey, Curran, & Hutchison, 2007) and external factors (administration of dopamine: Frank et al., 2004), and individual differences in the preponderance of each pathway can be indirectly measured through the PSS task (Frank et al., 2004; Stocco et al., 2017). Thus, the current investigation tests the hypothesis that individual differences in PSS task behavioral indices of basal ganglia pathways will be related to performance in a lexical prime style task. Furthermore, we make the prediction that a balance in functioning across both pathways is critical for optimal semantic processing and ambiguity resolution.

Methods

Participants

Informed consent was obtained from participants prior to the experiment, as outlined by the University of Washington Institutional Review Board. Participants were recruited using the Psychology Departments Participant Research Pool and all participants were compensated with course credit for their participation. Data were collected from 140 healthy monolingual participants (66 females, mean age = 19.4 years). Seven subjects were excluded from analyses due to low accuracy ($\leq$0.50) in the primary experimental task, the Word-Pair Task (WPT).

Tasks

All participants completed the following tasks in four pseudo-randomized orders to control for possible fatigue effects induced by the WPT and PSS task length.

Word-Pair Task Measures of lexical priming were collected using the WPT. This task was designed to measure the availability of dominant and subordinate word meanings following the presentation of primes with multiple meanings. The primes used shared both phonetic and orthographic forms across both word meanings, making them true homographs (e.g., "Bat"). The prime and target words were presented in the center of the screen, one at a time, separated by an inter-stimulus interval (ISI) of either 150 ms (short) or 850 ms (long). Prior to starting the task, participants were asked to place their right index finger on the "P" key of the keyboard, and their left index finger on the "Q" key of the keyboard. Participants were then asked to respond with a button press if the target word was related or unrelated to the prime. Key mappings for related and unrelated were counterbalanced.

There were two conditions of interest (1 and 2) and two control conditions (3 and 4): (1) homograph prime / dominant target, (2) homograph prime / subordinate target, (3) prime / related target, and (4) prime / unrelated target. These four conditions will be referred to as dominant, subordinate, related, and unrelated (respectively) form here on for simplicity purposes. Participants completed 100 total prime-target

pair trials, where 20 belonged to condition 1, 20 to condition 2, 30 to condition 3, and 30 to condition 4. Word frequency meanings were obtained from (Twilley, Dixon, Taylor, & Clark, 1994), and subordinate words were defined as having a relatedness frequency of less than 0.3 in a 0-1 scale, while dominant words had a relatedness frequency of greater than 0.7. Since each homograph prime is associated with two meanings, but each prime was presented once for each participant, two WPT versions were created. In one version, the dominant meaning of a homograph was used (e.g., version A contained "Bank" / "Money") while the other version used the subordinate meaning (e.g., version B contained "Bank" / "River"). The two lists were counter-balanced for word frequency, word length, and syllable length.

Probabilistic Stimulus Selection Task The PSS task is an iterative, two-alternative, forced-choice decision-making paradigm first introduced by Frank et al. (2007). In this task, participants are repeatedly asked to select one of two stimuli presented on the screen. Participants are also told that some of their choices would result in success, and some of them would result in failure, depending on which stimulus they choose. Feedback on the outcome of their decision is presented immediately after participants select a stimulus. To encourage participants to avoid explicit strategies (such as rote memorization of each stimulus history of successes), stimuli are implemented as complex shapes that are difficult to verbalize, typically Hiragana characters presented to non-Japanese speaking participants. Unbeknownst to participants, each stimulus has a predefined "success" probability. Six stimuli in total are used in the experiment, with success probabilities varying linearly from 80% to 20%. In the first phase, the stimuli are divided into fixed pairs, with the highest probability stimulus always paired with lowest probability one, then second higher stimulus paired with the second lowest one, and the third highest probability stimulus paired with the third lowest one.

Two values are calculated from the test phase of the PSS task: *Choose* accuracy, which represents the accuracy in choosing the most rewarding stimulus over others; and *Avoid* accuracy, that is, the proportion of times in which participants avoid the least rewarding stimulus. If we indicate the six stimuli with the letters $A, B \ldots F$, with A being the most rewarding stimulus and B the least rewarding one, then Choose and Avoid accuracies are calculated as the probability of choosing A when paired against C, D, E, and F, and the probability of choosing C, D, E, or F when they are paired with B, respectively.

Previous patients and genetic studies have demonstrated a functional connection between these two measures and the basal ganglia pathways. For example, Parkinson's patients, whose indirect pathway dominates over the direct one due to a loss of dopaminergic inputs from the substantia nigra pars compacta (SNc), have higher Avoid accuracy than Choose accuracy. Furthermore, this pattern is reversed when drugs are administered that overcompensate the direct pathway activity. Additionally, individuals with genetic alleles that cause a greater production of dopamine receptors in the direct pathway tend to be Choosers rather than Avoiders; conversely, individuals whose alleles cause greater number of dopamine receptors in the indirect pathway tend to be Avoiders (Frank et al., 2007; Frank & Hutchison, 2009).

Analyses

Behavioral Data Cleaning Target words in the WPT were cleaned on a by-participant basis for RT outliers, defined as trial RTs greater than or lower than three standard deviations from the mean.

Participant Groups Participant groups were created using PSS Choose and Avoid scores. Since one of the guiding assumptions of this investigation was that one's ability to learn from *both* positive and negative feedback, groups were created using a relative score where Avoid was subtracted from Choose, which resulted in scores between 100 and -100. Third-group splits were then used to separate individuals into participant groups. Thus, high values (approximately 33 to 100) reflected participants who learned primarily from positive feedback (Choosers), low values (approximately -100 to -33) reflected participants who learned primarily from negative feedback (Avoiders), and values around zero (-33 to 33) reflected individuals who learned equally as well from positive and negative feedback (Balanced). This resulted in 44 Choosers, 38 Avoiders, and 52 Balanced participants.

Analysis with Linear Mixed Effects Models The data were analyzed using linear mixed effects (LME) models, as this method has been previously shown to outperform the traditional procedures such as ANOVA (Kristensen & Hansen, 2004), and can adequately handle imbalances in group sizes. However, for validation purposes, the same results were reproduced using ANOVA (although not reported herein). LME models were specified using the R lme4 package (Bates, Mächler, Bolker, & Walker, 2015). The model was specified using the following formula:

$$\text{Target Accuracy} \sim \text{ISI} \times \text{Condition} \times \text{PSS Group} + (1 + \text{Condition} \mid \text{Participant})$$

where the dependent variable is Target Word accuracy, the fixed-effects term is the factors for ISI (short or long) $\times$ Condition (dominant or subordinate) $\times$ PSS Group (Choosers, Balanced, or Avoiders), and the random effects term allows for each participant to have a different slope (or effect) for Condition, while intercepts and slopes for each participant by Condition are allowed to be correlated (e.g., higher intercepts may also have steeper slopes). Finally, a type III ANOVA with Satterthwaite's method was used to test for significance between the factors of interest in the LME model.

Computational Model

A theoretical model was implemented to examine predictions on the relationship between reward learning and lexical re-

trieval[1]. The model was developed in the ACT-R cognitive architecture (Anderson, Fincham, Qin, & Stocco, 2008; Anderson et al., 2004), a general theory of cognition that enables the development of complete models capable of end-to-end simulations of a complete task while maintaining a high degree of psychological plausibility. The model described herein is based on a previously published model of the role of the basal ganglia in the PSS task (Stocco, 2018). According to this model, the conflict between the two pathways can be simulated in ACT-R as a conflict between the selection of opposite and symmetric *productions*, that is, state-action pairs that implement minimal cognitive steps. Productions representing the direct pathway implements "Go" actions, while those representing the indirect pathway represent opposite "No Go" actions. For example, the choice between two options in the PSS task, *A* and *B*, can be represented as the competition between two alternative pairs of productions, "Choose A" and "Avoid A" and "Choose B" and "Avoid A". In ACT-R, the competition between productions is resolved through a softmax algorithm that preferentially selects the actions with the highest estimated *utility*, a scalar quantity that depends on the history of previous successful uses of the production and is learned through a reinforcement-learning algorithm. Importantly, Stocco, 2018 noticed that both individual differences due to differential expressions of dopamine genes (Frank et al., 2007) and the effects of basal ganglia pathologies (Frank et al., 2004) can be successfully captured by differentially altering the learning rates of "Choose" and "Avoid" productions. The different learning rates will be indicated as α_C and α_A, respectively.

An ambiguity resolution experiment can also be understood as as a two-alternative forced choice (2AFC) task in the context of lexical retrieval. In essence, two homographs are competing for access to semantic retrieval. Consequently, for each choice, two competing selections are performed. Thus, if the two homographs are a dominant and a subordinate interpretation of the same written word, each of them will have two production rules associated with them, "Choose Dominant" and "Avoid Dominant", and "Choose Subordinate" and "Avoid Subordinate".

Contrary to traditional 2AFCs, in lexical access the two options are not equivalent in terms of response times. Selection of the dominant meaning is usually associated with much shorter retrieval times than selection of the non-dominant meaning. In our model, this was captured by forcing those production rules that select the subordinate meaning ("Avoid Dominant" and "Choose Subordinate") to have a longer execution time. As a consequence, under short ISI, the subordinate meaning is never successfully selected. Under longer ISIs, however, participants *do* have a chance to select these meanings, so that the eventual firing of productions that select the subordinate interpretation could result in the successful retrieval of the least common meaning of the homograph.

[1]Code for the model is available on our laboratory's GitHub repository: *http://github.com/UWCCDL/BAGELS_ACTR*

Finally, to derive predictions from the model, we conducted an extensive set of simulations of the utility values associated to production rules under different reward conditions, corresponding to different situations in which the selection of the dominant or subordinate meaning are correct. Specifically, we examined a hypothetical situation in which the dominant meaning is contextually correct 80% of the time and the subordinate 20% of the time. To simulate the large amount of experience with the occurrence statistics of different lexical items that is associated with adult native speakers, the model was let to learn the corresponding utility values until they reached asymptotic values.

Importantly, these simulations of language experience were conducted under different learning rate parameters. The parameter values were chosen to reflect the values that were found to best capture genetic variance of dopamine receptors in healthy adults in Stocco (2018). Specifically, we simulated three groups of individuals, exhibiting a preference to learn from positive feedback ($\alpha_C = 1.5, \alpha_A = 1.0$), a preference to learn from negative feedback ($\alpha_C = 1.0, \alpha_A = 1.5$), or no preference between the two ($\alpha_C = 1.5, \alpha_A = 1.5$). These parameters are associated with different performance profiles in the PSS task, corresponding to a preference for "Choose A", for "Avoid B", or for a balance between the two (Stocco, 2018).

Results

General Word-Pair Task Results

Mean accuracy for dominant trials (M = 0.90, SD = 0.14) was significantly higher than for subordinate trials (M = 0.55, SD = 0.15, t(138) = 22.17, $p < 0.0001$). Differences in mean RTs were also observed, faster for dominant trials (M = 832.04, SD = 194.71) than subordinate trials (M = 996.25, SD = 238.26, t(138) = -13.77, $p < 0.0001$).

General Probabilistic Stimulus Selection Task Results

Subjects performed similarly across Choose (M = 69.78, SD = 22.24) and Avoid (M = 67.99, SD = 22.22) trials. Furthermore, as in previous studies using the PSS Task (Stocco et al., 2017; Frank et al., 2007; Frank & Hutchison, 2009), Choose and Avoid trials were not correlated (r(138) = -0.12, p = 0.14).

Linear Mixed Effects Model Results: Relating WPT Performance and PSS Groups

The LME model predicting Target accuracy had a total explanatory power (conditional R^2) of 90.62%, in which the fixed effects explained 68.43% of the variance (marginal R^2). The model revealed a significant main effect of Condition ($F(1, 131) = 1096.33$, $p < 0.0001$). A significant two way interaction between Condition $\times$ ISI was also observed ($F(1, 262) = 6.47$, $p = 0.012$), alongside a significant three-way interaction between Condition $\times$ ISI $\times$ PSS Group ($F(2, 262) = 3.86$, $p = 0.022$). Marginal two-way interactions were observed for Condition $\times$ PSS Group ($F(2, 131) = 2.45$, p =

0.087) and also ISI × PSS Group (F(2, 262) = 3.00, p = 0.051). For details, see Figure 1.

A follow-up analysis using the orthogonal contrasts extracted from the LME model suggest that the three-way interaction between Condition × ISI × PSS Group is explained by higher accuracy to Target Words during the Subordinate condition observed in PSS Choosers (difference = 0.083, t(166.85) = 2.41, p = 0.028) and Avoiders (difference = 0.086, t(166.95) = 2.60, p = 0.017), relative to the Balanced group, during the long ISI.

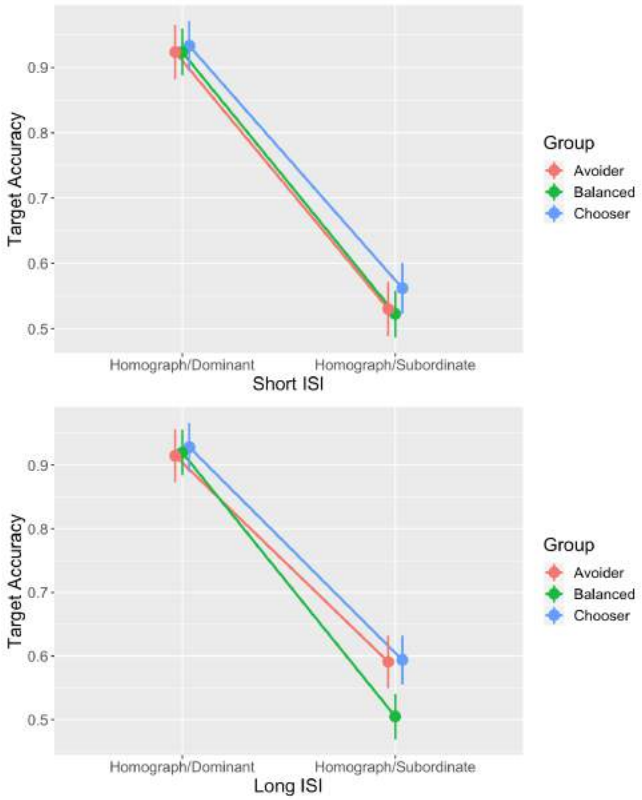

Figure 1: Top: Accuracy Dominant and Subordinate conditions for the short ISI. Bottom: Accuracy for Dominant and Subordinate conditions for the long ISI.

PSS Groups & Reading Experience Control Measure

The Author Recognition Test (Stanovich & West, 1989) score differences computed in order to ensure that differences in sensitivity to the subordinate word meaning observed was not driven by reading experience. There were no differences between Choosers and Balanced participants (t(94) = -0.44, p = 0.66), nor between Avoiders and Balanced (t(88) = -0.06, p = 0.95) that could account for the effect observed in the LME model results reported previously.

Computational Model Results

To generate predictions, the model was run for 1,000 times under the different values of α_C and α_A associated with Choosers, Avoiders, or Balanced individuals. The model predicts that, under short ISI, all three groups should perform at chance for the subordinate meaning, with no difference in performance. Under long ISI, however, the model predicts that Avoiders and Choosers should have greater than chance performance for the subordinate condition (62% and 63%, respectively), while Balanced individuals should still perform essentially at chance (55% accuracy). Note that these predictions are parameter-free, and come remarkably close to the actual results of our experiment. In the model, this asymmetry in behavior is due to the fact that different initial learning rates α_C and α_A result in biased estimates of success when selecting dominant and subordinate meanings, respectively. In particular, the model predicts that Choosers would tend to overestimate the probability of the subordinate meaning, while Avoiders would tend to underestimate the probability of the dominant meaning, with both cases resulting in a tendency to favor the selection of the subordinate meaning. Under balanced learning rates, instead, the model correctly estimates the rarity of the subordinate meaning and tends to select it significantly less often.

Discussion

The current project explored the hypothesis that human linguistic ability, and specifically semantic processing, is dependent on core basal ganglia RL mechanisms. The results provide evidence for the proposed hypothesis, and more specifically, suggest that individual differences in learning from positive or negative feedback are predictive of automatic semantic ambiguity resolution in context-free lexical ambiguity priming paradigm. Specifically, task performance was in line with behavioral predictions by the computational cognitive model, which predicted that action-selection in the basal ganglia for dominant and subordinate meanings would happen in line with an individual's estimate of success for choosing either meaning. To illustrate this, when a Balanced participant reads the word "bank" they co-activate the associated "money" and "river" meanings. Selection happens in line with their learned estimate that"river" rarely occurs following "bank," and this subordinate meaning is unavailable for the semantic relatedness judgment, resulting in poor task performance (for this condition, only). Thus, the signal generated by the basal ganglia during semantic selection can be seen as reflecting an individual's estimate of that word-meaning co-occurrence, or in other words, the individual's representation of relative frequency of a meaning associated with a lexical form.

Furthermore, findings from this investigation are compatible with the widely accepted view that prefrontal cortex (PFC) regions and specifically the left inferior frontal gyrus (LIFG), are involved in semantic selection processes (Vitello & Rodd, 2015). While the LIFG may very well be the primary driver of semantic selection, it is known to make use of biasing signals to rule out multiple competing representations (Schnur et al., 2009). This biasing signal is posited

to stem from the basal ganglia, as research on the functional and anatomical properties of the PFC-basal ganglia network has shown that two of the five main cortico-striatal-thalamo-cortical loops project directly to lateral prefrontal regions, including dorsolateral PFC and lateral orbitofrontal cortex (Alexander, Crutcher, & DeLong, 1991). Thus, the basal ganglia posses the functional, anatomical, and computational properties necessary to provide biasing signals to LIFG during semantic ambiguity resolution.

Interestingly, these results reproduce and extend, by artificially segmenting a continuum of basal ganglia-mediated Choose and Avoid learning in a healthy population, findings observed in clinical groups. As mentioned previously herein, PD patients show abnormal lexical priming effects, with disrupted automatic semantic ambiguity resolution and sustained multiple competing representations. Additionally, literature focusing on the cognitive effects of Huntingtons Disease (HD) a basal ganglia dysfunction characterized by hyper-dopaminergic signaling and thus a hyper-active direct pathway, reveals that HD patients also have an increased susceptibility to semantic priming (Randolph, 1991). Taken together, these findings highlight the importance of a competitive dual-path RL system that gives rise to learning from both positive and negative feedback.

Possible alternative explanations exist for the current set of experimental results. Many theoretical and computational models of basal ganglia functioning focus on its role as "gates" that modulate prefrontal cortex functioning through selection (or Choose) and inhibition (or Avoid) mechanisms. Thus, under this framework, we would anticipate to find that Choosers would manage conflict in multiple competing representations by selecting the relevant or dominant word meaning, while Avoiders would inhibit the subordinate meaning. This is, however, not what is observed in the behavioral results, where both Choosers and Avoiders show identical performance in the subordinate condition after the long delay. This pattern of results is most compatible with a RL explanation of statistical learning, where a one-path mechanism (akin to traditional TD-learning) would over-estimate the utility of the lower frequency meaning. In other words, it is possible that Choosers are overly sensitive to low frequency reward probabilities, while Avoiders are less sensitive to high frequency reward probabilities. This results in a misrepresentation of the relative frequency effect observed between the dominant and subordinate word meanings.

This proposed role of the basal ganglia in RL through statistical mapping of the rich and dynamic linguistic environment, and engaging in live predictive processing may ultimately account for its involvement across multiple language processing modalities. In fact, a great deal of work exists that discusses evidence of basal ganglia involvement in language through the lens of a pacemaker-like, live, temporal processing machine that synchronizes internal states with external inputs (Kotz, Schwartze, & Schmidt-Kassow, 2009). While this research has focused mostly on morphosyntactic processing, its framework is both compatible with the one proposed herein and can be extended to multiple processing domains, including those beyond linguistic processing (e.g., non-linguistic cognitive functioning and motor processing). We consider these exciting areas for future research.

Abstract

How infants determine correct word-referent pairings within complex environments is not yet fully understood. The combination of multiple cues, including gestures, may guide learning as part of a communicative exchange between parent and child. Gesture use and word learning are interlinked, with early child gesture predicting later vocabulary size, and parental gesture predicting child gesture. However, the extent to which parents alter gesture cues during word learning according to referential uncertainty is not known. In this study, we manipulated the number of potential referents across conditions during a word learning task with 18–24-month-olds, and explored how changes in parental gesture use translated into infant word learning. We demonstrate that parents alter their gesture use according to the presence, but not the degree, of referential uncertainty. We further demonstrate that a degree of variability in the number of potential referents appears to benefit word learning.

Keywords: word learning; gesture; vocabulary development; parent-infant interaction

Introduction

Between 18–24 months of age, children's expressive vocabulary rapidly increases from approximately 90 to 320 words (Fenson et al., 1994). Children learn language in busy and variable environments containing multiple possible referents, but how they determine what the intended referent for a given word is remains under-investigated. Finding the correct word-referent pairing is a problem of substantial difficulty, as described by the well-known 'gavagai' problem (Markman, 1989; Quine, 1960), where a second language learner cannot know whether an unknown utterance – 'gavagai' – refers to a rabbit present in the scene, the rabbit bouncing, the rabbit's colour, or a range of other potential meanings. Infants face the same problem as the second language learner, with a further disadvantage – the lack of a first language to base their learning upon.

Recent attention has turned towards examining the multiple potential cues present in language learning environments that might help children to delineate referents of unfamiliar words (Monaghan, 2017). One of the earliest sources of information to support word-referent mappings is provided before children are able to speak: gestures in parent-child interactions. Within these interactions, gesture appears to be facilitative of word learning. For example, spontaneous pointing by the infant during a gaze-following task at 10–11 months predicted vocabulary growth at 24 months (Brooks & Meltzoff, 2008), and Fenson et al. (1994) found an increase in infants' gesture use between 8–16 months correlated with word comprehension. Parent and infant gesture use also appears to be reciprocal in nature. Rowe, Özçalışkan and Goldin-Meadow (2008) observed gesture use in parent-child dyads at four-month intervals between the ages of 14–34 months, then administered a vocabulary test at 42 months. They found that child gesture use at 14 months predicted vocabulary size at 42 months, and that parent gesture use predicted child gesture use at 14 months. Between 22–34 months, they found that child gesture use (number of gestures with or without speech) mirrored parent gesture use. Infant gesture therefore appears to predict language development and appears to be related to parental gesture use.

The nature of this relationship seems rooted in the informative role of gestures in word learning during active communication between parent and child, with gesture adding significant value to information exchange. The use of gesture as a response in perspective-taking tasks has demonstrated that infants use and adjust their gestures according to parent knowledge states. In a similar way to how older children (from 3.5-years) adjust their speech responses to actively incorporate a communicative partner's perspective (Nadig & Sevidy, 2002; Nilsen & Graham, 2009), when parents do not have the same information as infants, infants are more likely to gesture to support mutual understanding (O'Neill, 1996). Gesture thus may play a vital role in aiding effective communication when verbal ability is still being established. Infant gesture may also serve an interrogative function by acting as a signal to gain critical information from parents about a specific object (Iverson & Goldin-Meadow, 2005; Southgate, van Maanen & Csibra, 2007). Given that gestures are a vital means through which infants interact with and learn about their surrounding context, how might this assist children in navigating the complex environment surrounding word learning?

On the other side of this communicative partnership, gesture use by caregivers may provide valuable information about intended referents during rapid vocabulary development. In particular, parental gestures such as pointing serve as a useful tool for identifying a referent when learning word-referent pairs. Iverson et al. (1999) reported parental pointing during 15% of exchanges related to word learning. Furthermore, the quality of parental gesture appears to have

an effect on word learning. Cartmill et al. (2013) assessed parental input quality during parent-child interactions at 14–18 months by asking adult participants to guess words from muted observational videos. This provided a measure of input quality by indicating how informative non-verbal and gestural communication was in determining word meaning. When correlated with child vocabulary at 53 months, children whose parents produced higher quality input had higher receptive vocabulary.

Thus, both the frequency and quality of parental gesture are related to infant word learning and provide valuable cues that enable the child to predict the referents for their growing vocabulary. However, it is not yet known how adaptive parental gesture is to the information present in the environment, or what kind of gestures are most helpful to infants under conditions of differing referential uncertainty.

In verbal communication, we know that speakers adjust their phonology, prosody, word selection, and syntax in accordance with the context of communication and the listener's perspective (Bannard, Rosner, & Mathews, 2017; Brown-Schmidt & Duff, 2016; Gorman et al., 2013). We also know that children can adapt their gesture and speech to accommodate the perspective of adults (Bahtiyar & Küntay, 2009). Parents also adapt their spoken labelling behaviour according to infant familiarity with objects (Cleave & Kay-Raining Bird, 2006; Masur, 1997) and how conventional the label is (where conventionality refers to there being a culturally agreed referent for a specific word; Luce & Callanan, 2010). However, we do not know the extent to which parents adjust their gesture use contingently based on referential uncertainty during infant word learning.

In this study, we address this issue, testing whether parents would offer a higher number of gestural cues when a target item was amongst more, rather than fewer, distractor objects. Furthermore, we measured whether the type of gestures that occur, and their correspondence with speech, affected children's learning of novel words. Greater referential uncertainty, as determined by a higher number of potential referents for a novel label, has led to less reliable and slower word learning in previous studies (Smith, Smith, & Blythe, 2011; Trueswell et al., 2013). Consequently, we would expect parental gesture to play a stronger role in delineating referents when there is a higher degree of referential uncertainty. In a word learning task, we manipulated the number of potential referents for a novel word between one, two, and six referents. We hypothesised that parental gestural cues would increase with the frequency of potential referents from the one- to the six-referent condition, particularly for deictic cues (gestures directing attention to a specific object). We predicted the same pattern for the co-occurrence of speech with gesture, in particular for speech that used the target label. We then examined whether these cues translated into infant word learning accuracy by testing infants on their knowledge of the novel label. We hypothesised that infants of parents who offered more gestural cues would show higher word learning accuracy.

Method

Participants

Fifty-three monolingual English infants aged between 18–24 months-old (M = 20.9 months, SD = 1.7, 25 female) were recruited from a database of families who had registered interest in study participation at Lancaster University Babylab. Infants were from middle-class families (determined via parental education level). During training, six parent-infant dyads were excluded due to infant fussiness. Twenty-seven infants (M = 20.8 months, SD = 1.6, 14 female) also completed the testing phase, with the remaining sample excluded due to infant fussiness (n = 4) or incomplete trials (n = 16; less than 5 of 6 test trials).

Materials

Nine novel objects were used as referents for the novel words. Each novel object was a different colour and shape. Three novel words, selected from the NOUN database (Horst & Hout, 2016), were used as labels (*noop*, *darg*, and *terb*). Three objects were chosen as targets randomly for each participant, with all other objects serving as foils, and each novel label was randomly paired with each target per participant. Stimuli position, target, and condition order during training and testing were counterbalanced across participants using a Latin square. Parents also completed the UK-CDI (Alcock, Meints, & Rowland, 2017), a measure of receptive, expressive, and gesture (communicative and symbolic) vocabulary. Communicative gestures are declarative (deictic and imperative gestures) and symbolic gestures form a larger subset of actions with objects, games, and pretend play (representative gestures).

Procedure

Infants were seated on their parent's lap and viewed stimuli from 70 cm away. Each group of stimuli was presented for 30 seconds, with a moveable opaque screen shielding objects from view in-between trials. Parents were asked to imagine they were teaching real words for real objects. Familiarisation with the objects took place outside of the experimental room with the parent only. The labels and a three-word object description were visible to the parent throughout training to eliminate the need for parents to remember the novel label and paired target.

Participants began with one warm-up trial, where the experimenter placed a ball as a familiar object on a tray and instructed the parent to teach the infant the word as if it were novel. The aim was to familiarise parents with the procedure without increasing task demands. Parents then proceeded to the training phase, where they taught infants novel label-referent pairs with unfamiliar objects as stimuli. In the one-referent condition, only the target was presented; in the two-referent condition, one target and one foil were presented; and in the six-referent condition, one target and five foils were presented (see Figure 1). Each participant received each of the three conditions once.

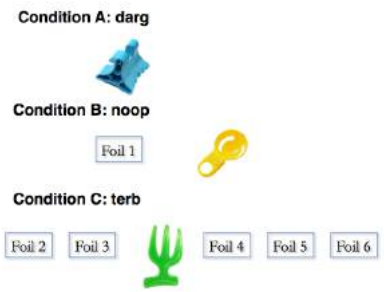

Figure 1: Training trials example.

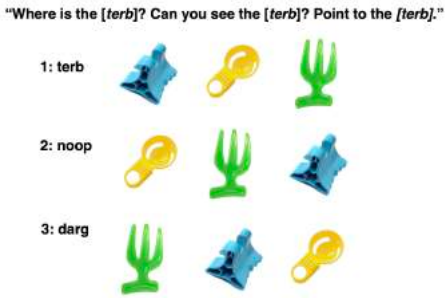

Figure 2: Testing trials example.

After completing all three training conditions, participants were then administered six testing trials, with each target word tested twice (see Figure 2). At the start of each trial, the infant was asked by the experimenter "Where is the [*target*]? Can you see the [*target*]? Point to the [*target*]." The trial ended when the infant made a response or the prompt had been repeated twice without a response.

Coding

All sessions were video-recorded and then coded for gestures and speech with gesture per utterance according to Rowe et al.'s (2008) coding scheme. A second coder coded 20% of the videos with an overall inter-rater reliability $\kappa = 0.78$ for gesture ($N = 284$) and $\kappa = 0.86$ for speech with gesture ($N = 160$).

Gesture types were split into three main groups (Rowe et al., 2008): *representational* gestures, indicating properties of the target referent such as size, shape, or function; *deictic* gestures, singling out the target referent by pointing with the arm and index finger extended or with the arm extended and the palm exposed and *other* gestures, which included all gestures not aimed towards the referent (those aimed at foils and related to caregiving interactions such as hugging).

The co-occurrence of speech that indicated properties of the target referent (e.g. size, shape, or function) with gesture was coded as *supplementary*. The co-occurrence of speech that singled out the target referent with gesture was coded as *complementary*. The frequency of referent label use was also recorded.

Results

A series of linear mixed effects models (lmer; lme4 in R, v3.4.1, 2017) were used to predict parents' use of gestures during training (gesture subtypes and co-occurring speech with gesture subtypes were dependent variables). These models were built up progressively with the addition of fixed effects of condition and child vocabulary (scores of communicative gesture, symbolic gesture and expressive subscales of CDI), comparing each model to a null model or previous best-fitting model using log-likelihood comparison after the addition of each new term (Barr et al., 2013). Random effects of subject and infant age were included in each analysis.

Environmental uncertainty effects on parental gesture use

The linear mixed effects models demonstrated a significant effect of condition on overall gesture count ($\chi^2(2) = 11.73$, $p = .003$). Consistent with our hypothesis, parents gave more gestural cues when they were faced with a higher number of potential referents (see Figure 3), with a significant difference between one- and two-referent conditions ($t(94) = 2.12$, $p = .037$), and one- and six-referent conditions ($t(94)=3.51$, $p = .001$), but not two- and six-referent conditions ($t(94) = 1.39$, $p = .167$). The addition of child vocabulary measures did not improve model fit (communicative gesture: $\chi^2(1) = 0.38$, $p = .539$; symbolic gesture: $\chi^2(1) = 0.28$, $p = .598$; expressive: $\chi^2(1) = 0.34$, $p = .560$). No significant interactions between fixed effects were found.

The relation between gestural cues and number of referents was particularly notable in deictic gestures, in-keeping with our hypothesis. There was a significant effect of condition on deictic gesture number ($\chi^2(2) = 8.35$, $p = .015$, see Figure 3), with significant differences between one- and two-referent conditions ($t(94) = 2.21$, $p = .030$), and one- and six-referent conditions ($t(94) = 2.80$, $p = .006$), but not two- to six-referents ($t(94) = 0.60$, $p = .553$). Adding child vocabulary did not improve model fit (communicative gesture: $\chi^2(1) = 0.001$, $p = .973$; symbolic gesture: $\chi^2(1) = 0.05$, $p = .832$; expressive: $\chi^2(1) = 0.01$, $p = .917$). No interactions between fixed effects were found.

For representational and other gestures, there were no significant effects or interactions.

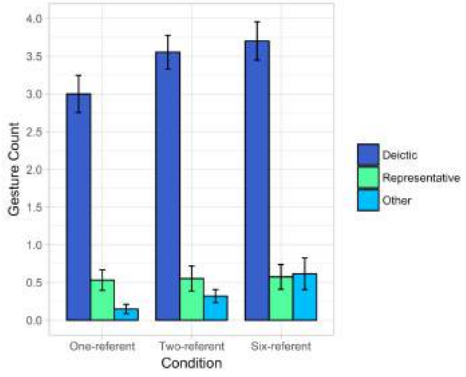

Figure 3: Mean count and standard error of gesture type generated by parents per condition.

Environmental uncertainty effects on co-occurring parental speech and gesture

When testing the co-occurrence of complementary speech with gesture, linear mixed effects models showed significant main effects of condition and child symbolic gesture vocabulary ($\chi^2(3) = 8.28$, $p = .041$; see Figure 4). There was a significant increase from one to two referents ($t(80) = 2.57$, $p = .012$), but no significant difference between one and six referents ($t(80) = 1.68$, $p = .096$) or two and six referents ($t(80) = -0.89$, $p = .376$). There were no other significant main effects of child vocabulary measures and no significant interactions between fixed effects.

When testing the co-occurrence of supplementary speech with gesture, we found condition was not significant as a main effect alone. There was a significant interaction between condition and child expressive vocabulary ($\chi^2(5) = 17.96$, $p = .003$), which showed that children with larger vocabularies were offered more information in the one- and two-referent conditions, but less in the six-referent condition, than children with smaller vocabularies. There were no other significant main effects or interactions between fixed effects.

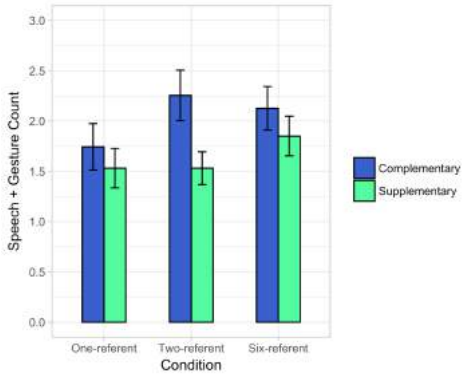

Figure 4: Mean count and standard error of types of speech with gesture generated by parents per condition.

Effect of parental gesture use on word learning

A series of binomial general linear mixed effects models (glmer; lme4 in R, v3.4.1, 2017) were used to predict accuracy. These models were built up progressively with the addition of fixed effects of condition and child vocabulary (scores of communicative gesture, symbolic gesture and expressive subscales of CDI), comparing each model to a null model or previous best-fitting model using log-likelihood comparison after the addition of each new term (Barr et al., 2013). Random effects of subject and infant age were included in each analysis.

Analysis using general linear mixed effects models revealed the addition of condition improved model fit ($\chi^2(2) = 6.08$, $p = .048$; see Figure 5), indicating a significant increase of accuracy from one to two referents ($\beta = 0.91$, $z = 2.19$, $p = .028$) and from one to six referents ($\beta = 0.86$, $z = 2.02$, $p = .044$), but no significant increase in accuracy from two to six referents ($\beta = -0.05$, $z = -0.13$, $p = .893$). However, this varied by parent, as the addition of a slope of condition per parent as a random effect removed the significant main effect of condition ($\chi^2(2) = 1.8$, $p = .406$).

Given that complementary speech with gesture was highest in the two-referent condition during training and accuracy was highest in this condition during testing (see Figure 5), we postulated that there might be some relationship between the two. However, the inclusion of total gestures, gesture subtype, and types of co-occurrence of speech with gesture did not improve model fit, suggesting there was no significant prediction of accuracy when these effects were taken into account. This did not support our hypothesis that increased parental gesture use during training would predict increased accuracy of infant word learning. A separate model examining these training response variables without an effect of condition did not demonstrate any significant improvement of model fit, suggesting any significant difference in accuracy was the result of differences in condition alone, without any demonstrable effects of training response.

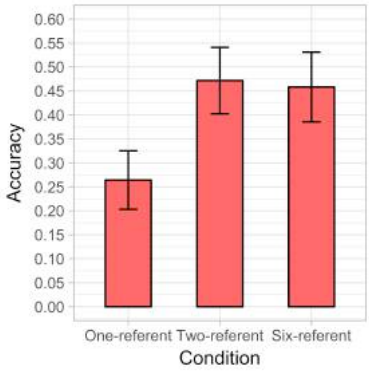

Figure 5: Mean infant word learning accuracy and standard error per condition.

Discussion

By varying referential uncertainty, we explored how parental gesture might aid infants in learning correct word-referent pairings within complex environments. Our training results demonstrated that parent gesture can be manipulated by altering the immediate environment around infant word learning. This was particularly notable in deictic gesture use. The results showed that parents use deictic gestures most in the presence of referential uncertainty, as parents gestured most in the six- and two-referent conditions compared to the one-referent condition. Deictic gestures have previously been found to be highly informative when determining word-referent pairs (Cartmill et al., 2013). Children also have been found to follow the direction of deictic gestural cues over linguistic cues in referent-selecting tasks (Grassmann & Tomasello, 2010). Thus, although it is possible that our findings related to deictic gesture use were influenced by task-demands (requesting parents to teach specific novel words for objects, and objects being out of reach), they are in line with other research that points towards the usefulness of

deictic gestures when delineating referents in naturalistic and laboratory settings.

The mechanism by which gesture adds information to speech may be a reduction of cognitive load for the infant, providing a visual component to learning resources alongside the verbal component (Goldin-Meadow, 2000; McGregor et al., 2009). This has been found particularly useful in situations of high task demands (McNeil, Alibali, & Evans, 2000) – consistent with parents using the most gestures in the six-referent condition. However, there was no significant difference in gesture use between the two-referent and six-referent conditions, which did not support our hypothesis that the higher the number of potential referents, the higher the number of parental gestures to assist the child in coping with referential uncertainty. One might also expect a higher number of potential referents to confer a higher task-demand, and thus perhaps a need for a greater reduction of cognitive load due to an increased amount of distracting information.

This result may demonstrate that the more important factor in referent-identification is whether there is referential uncertainty or not, rather than the degree of uncertainty. It is possible that the additional information conveyed in gesture is not as valuable in reducing cognitive load when there is more than one choice to be had. This interpretation is consistent with children's actual learning of novel words – infants demonstrated the highest accuracy in the two-referent condition, and performed marginally worse in the six-referent condition which had the highest frequency of parent gestural information and referent label use. Infants performed worst in the one-referent condition. This might be unexpected given the lack of referential uncertainty, although there was also the least amount of information available (provided in speech and gestural cues).

These learning results suggest that some referential uncertainty might actually be beneficial for learning, and that perhaps too much uncertainty begins to remove that benefit. In Monaghan's (2017) computational study of multiple cue integration in word learning, the model predicted that a small amount of variability in the cues available in the word learning environment yielded superior learning in comparison to conditions where cues were perfectly reliable and invariable. But when this variability became substantial, learning of novel words began to decline. In Monaghan et al. (2017), this prediction was supported in a study of adults learning novel word-referent mappings from multiple cues: variability was helpful. However, in these studies, the referential uncertainty was kept constant – in all cases, there were two possible referents from which to select. In the current study, we further show that a small degree of variability in referential uncertainty led to the best novel word learning.

The presence of two competing alternatives in the environment ties in with studies of children's application of mutual exclusivity (Markman & Wachtel, 1988). In these studies, children are shown to actively use a general principle of 'this, not that' to map unknown words to unknown objects in relation to known objects. Although this mechanism works primarily by prior knowledge, it is possible that having one choice enables some sorting of the available referents that makes word learning more efficient.

However, our results did not show a significant direct effect of parents' behaviour in driving children's word learning performance – the amount of gestural information with and without speech during training was not predictive of more accurate infant word learning as we had predicted. Any effect of condition on accuracy also disappeared with the addition of a random slope for condition per parent, suggesting that there was a high degree of variability in how parents used gestures across the conditions.

The lack of an effect may be partly due to limitations in our sample. All parents were of mid-socioeconomic status (SES), recruited from a database of families who had actively signed up to take part in child development studies. Families from mid to high SES backgrounds are known to use gesture more (Rowe & Goldin-Meadow, 2009). Kirk et al. (2013) suggest that the added benefit of gesture may be most prevalent in cases where there is general diminished parental input, providing a compensatory effect, and in mid to high SES families, parental input is less likely to be reduced. Gains in child vocabulary following training that involved increased gesture use have previously been found primarily in low SES environments (Hirsh-Pasek et al., 2015). Although parents in our study did gesture more with increased referential uncertainty, it is possible that any added benefit of gesture in this sample reached something of a ceiling effect when it came to word learning – infants were already subject to a level of parental input that meant gesture did not add to their learning.

Finally, given prior evidence that children's vocabulary and gesture use are positively related, and child gesture is linked to parental gesture (Rowe et al., 2008), child gesture vocabulary might be expected to have some effect on parental gesture use during training. However, this was not the case in our study. Our models of gesture alone did not identify an effect of child expressive and gesture vocabulary. We did find that these effects played a role in the amount of speech with gesture. We found that child gesture and expressive vocabulary were significant effects when referential uncertainty was increased. This may indicate that child gesture and expressive vocabulary are related to parental gestures co-occurring with speech, instead of parental gesture in isolation. This aligns with the idea of gesture playing a supplementary role to speech, rather than one supplanting the other (O'Neill, 1996; Iverson & Goldin-Meadow, 2005).

In summary, we found that referential uncertainty affected parents' gestures. Parents were affected by the number of potential referents in the environment, and adapted their gestures, and co-occurrences of gestures with naming of the target object, offering more cues when the child's environment became more complex. However, parental gesture use was only affected by whether there was referential uncertainty or not, rather than the degree of referential uncertainty. In terms of children's accuracy when testing their knowledge of novel labels, referential

uncertainty was again found to affect learning, and actually promoted it. The results add to a broad picture of communicative exchange where interlocutors are sensitive to the context and informational requirements of the situation, and also to growing evidence that variability, within speech and within the environment, is beneficial for learning.

Task Goals Structure Conceptual Acquisition

Seth Chin-Parker (chinparker@denison.edu)

Department of Psychology, Denison University
Granville, OH 43023 USA

Abstract

The purpose of this study is to explore the role goals play in concept acquisition. Goals motivate and shape our interactions with items, so it stands to reason that they also impact the learning that occurs as a result of those interactions. There is abundant evidence that goals orient us to particular information about the items we encounter. A more speculative claim is that goals play a more integral role in the acquired concept in that they also help to structure and cohere the acquired conceptual knowledge. Using a novel concept learning paradigm, we examined participant knowledge of attributes of the items they interacted with in an experimental task. We found evidence that the interaction of the goal with the learning situation impacted the centrality of the attribute information within their conceptual knowledge. These results support the idea that conceptual knowledge is organized in terms of goals active during learning.

Keywords: categories; concepts; goals; conceptual acquisition

Conceptual knowledge plays an important role in human cognition. Concepts help to shape our perceptions and predictions as we move through the world, and they allow access to information about entities that are not immediately present. All facets of cognitive science (e.g. philosophy, psychology, computer science, anthropology) have engaged with questions concerning conceptual knowledge, but important questions remain. This study focuses specifically on the ways that goal-directed interactions with instances from a novel category of items shape the organization and content of the acquired conceptual knowledge.

Within the psychological research, there has been on-going study of concept acquisition for over a century. Machery (2007) notes that despite significant shifts in the theoretical perspectives as to what constitutes conceptual knowledge, there has been a noticeable lack of variation in how psychologists operationalize the acquisition of a concept. Related concerns have been raised about category learning research in that the experimental paradigms are limited and potentially restrict our understanding of the processes involved in concept acquisition and how they affect acquired knowledge (Markman & Ross, 2003; Ross, Chin-Parker, & Diaz, 2005). There are also questions as to how well those experimental paradigms reflect concept acquisition as it happens in everyday life (Murphy, 2005).

In response to these concerns, there have been intentional and systematic attempts to broaden the range of learning tasks in the study of concept acquisition. The rationale is that examining learning that occurs in the course of different kinds of interactions provides a richer and more applicable sense of what conceptual acquisition is really like. Out of this, a line of research has emerged that examines how the goal of the learner affects concept acquisition. If an individual interacts with a set of items in the course of working towards a particular goal, the conceptual knowledge acquired from those interactions should be tuned such that it supports that goal (Chin-Parker & Birdwhistell, 2017; Jee & Wiley, 2007; Love, 2005). The idea that goals meaningfully intersect with conceptual acquisition has existed in the literature for several decades (see Barsalou, 1995), but only relatively recently has it been formalized within concept acquisition studies.

A basic assumption of this approach is that the goal points the individual towards features of the items that are goal relevant. Jee and Wiley (2007) and Chin-Parker and Birdwhistell (2017) have found strong evidence for this *goal-orientation hypothesis*. When participants with different goals interact with same set of items, the conceptual knowledge acquired privileges access to the attributes of the items that were critical to completion of the goal. This idea fits well with learning theories that incorporate some means for the learner to adapt to the differential importance or salience of individual attributes (e.g. Kruschke, 2003; Le Pelley, et al., 2016).

It has been suggested that goals also play a role in the representation of conceptual knowledge. Because a concept provides information as to why the instances of the corresponding category belong together, Jee and Wiley (2007) propose that the goal acts as a glue that coheres the members of the category. This idea reflects earlier work on ad hoc categories (e.g. Barsalou, 1983).

Chin-Parker and Birdwhistell (2017) provide an account that focuses on how a goal plays a role in organizing the attribute information represented within the concept. They note that in any situation there are many possibilities as to how an individual might interact with the entities that constitute that context. However, having a specific goal means that each possible interaction within that situation can be defined in terms of its goal-relevance. An interaction that moves the individual closer to, or further from, the goal can be considered goal relevant. An interaction that does not do so would not be goal relevant. If a goal-relevant interaction involves a particular facet of the item at hand, that aspect of the item becomes defined

in terms of how it relates to the goal – the way in which it facilitates (or hinders) movement towards the goal. In this view, the attributes themselves become available through the interplay between what constitutes the items and the goal-directed behaviors. It is important to remember that these interactions are situated – what constitutes a goal relevant attribute and how that attribute relates to the goal may vary across situations. Through the goal-directed interactions, a structure emerges that reflects the goal-relevance of the various components of the situation – attributes that are more critical to completing the goal become more central within the concept. For instance, if an attribute was differentiated in relation to the goal, e.g. it offered a goal-relevant decision point, then the information about its differentiation with regards to the goal would also be captured within the acquired conceptual knowledge. The *goal-framework hypothesis* proposes that the goal is more integrated into the conceptual knowledge than is implied by the goal-orientation hypothesis.

The purpose of this study is to assess the goal-framework hypothesis. Participants interacted with a set of novel items in order to complete a particular task. These items represented two different types, although the participants were not told this: They were not asked to learn about the items or to do any explicit category-based work, only to use them to complete the task at hand. In both conditions the items had two primary attributes that were goal-relevant – the participant had to attend to both attributes to complete the task. However, we manipulated the task so the relationship of one of the attributes to the goal differed across conditions. We modified whether the specific shape of that attribute was *relevant*, i.e. that shape required a decision to made about how to proceed in the task, or if it was *irrelevant*, the interaction with that attribute occurred without any consideration of its specific shape.

Because the task required the participants to differentiate between the two types of items, we expected them to naturally recognize the two categories of items. We expected all participants should be able to assess class membership of the items based on the primary attributes and to make judgments based on those categorizations. Critically, we expected that our manipulation of the relevance of the shape of one of the attributes would affect later category-based judgments indicating that it had impacted the centrality of that attribute within the conceptual knowledge.

Experiment

Methods

Participants and Design Sixty-seven participants were randomly assigned to two experimental conditions: 33 participants were assigned to the *interior shape relevant condition* (ISR condition), and 34 to the *interior shape irrelevant condition* (ISI condition). All participants used the same set of items during the initial task and completed the same transfer tasks. The presentation order of items during the initial and transfer tasks was randomized.

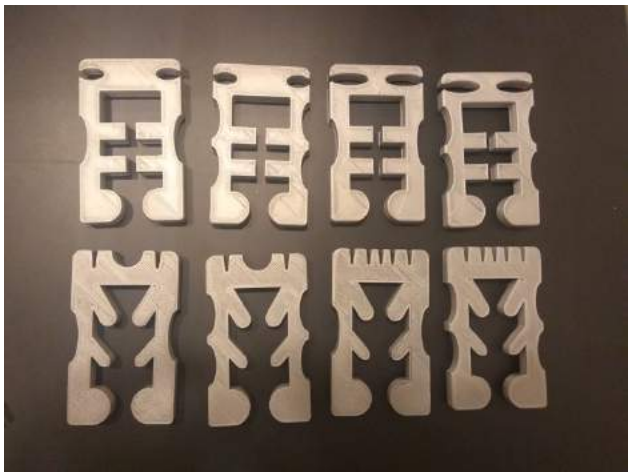

Figure 1: Keys used in the initial task. They were identified in the classification task as "alpha keys" (top row) and "zeta keys" (bottom row).

Materials and Procedure During the *initial task* of the experiment, all participants interacted with the same set of eight "keys" (see *Figure 1*). The keys had two primary attributes – the head shape and interior shape. These attributes co-varied so that there were two categories, or types, of keys defined by a particular combination of head and interior shape. The keys were made of ABS plastic and were created using a 3D printer. The keys were approximately 10 cm by 6 cm by 1 cm in size.

Participants used the keys to manipulate the task boards (see *Figure 2*). The boards were designed so the keys would be used as part of a two-step task. Each board featured a metal transport that could slide along the top surface of the board. The transport had an acrylic window that revealed a button the participant was instructed to press in order to complete the task.

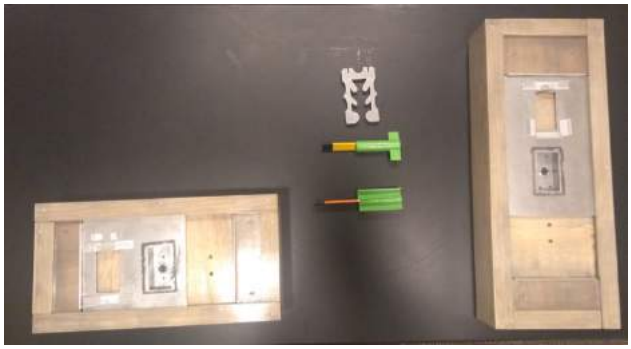

Figure 2: Set up of the initial task from the participant's perspective. The participant set the key onto the appropriate task board, slid the transport to reveal a button, then used one of the tools provided to press the button. The tools shown here were used in the ISR condition.

Figure 3: Close up of a "zeta" key placed on a task board. The shape of the key head (vertical slots on the top of the key) allowed it to fit onto the board (an "alpha" key with horizontal slots would not fit on this board). Here, the transport has been moved to its target position, so the button is accessible. To complete the second part of the task, a tool had to be inserted through the interior of the key to press the button.

The key frame on the transport was configured so that only one of the head shapes of the keys would fit into the frame for each board. Once a key had been properly placed into the frame, the transport could be moved to the target position (see *Figure 3*). This constituted the first part of the participant's task. When the transport was moved into the target position, the participant had access to the button through the interior of the key. The participant was instructed to press the button using a tool provided for that purpose (see *Figure 4*). Using one of the tools to press the button constituted the second part of the task. Once the participant pressed the button, lights built into the board turned on signaling that the task had been successfully completed.

As noted, the first part of the task required the participant to attend to and differentiate the head shape of the key being used so that the key could be correctly placed onto one of the task board transport frames. The second part of the task required the participant to attend to the interior shape of the key. In the ISI condition, the interior shape of the key was irrelevant in terms of which tool could be used. Participants in that condition could select either of the two tools available to press the button. In the ISR condition, the tools were designed so that each tool fit with the interior shape of one of the types of keys (either the alpha keys or zeta keys). Participants in that condition not only had to attend to the interior, they had to make a decision about which tool to use given the interior shape of the key.

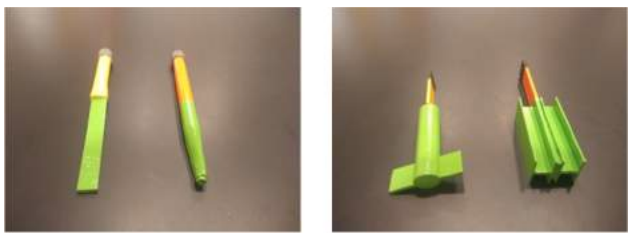

Figure 4: In the ISI condition (tools on left), either tool could be used with any key. In the ISR condition (tools on right), the tool used depended on the interior shape of the key.

At the start of the experiment, participants were introduced to the keys, task boards, and tools with a set of practice materials that allowed them to familiarize themselves with the basic aspects of the task (i.e. place a key onto the transport of one of the boards, move the transport, use a tool to press the button). However, the practice keys had different shape attributes and fit onto the transports differently (and the transports rotated on the surface of the board instead of sliding). Once the participant indicated they were comfortable with the basic idea of the task, the practice materials were replaced with the actual task boards and tools for the study. It is important to note that at no time during the initial task trials were the participants told that there were different types of keys – each trial featured one key and the instructions and communication with the participant focused solely on the completion of the task.

At the start of each trial during the initial task, the experimenter set a key (determined by a randomized order for each participant) on the table between the task boards. As described prior, the participant's task consisted of placing the key onto the proper transport, sliding the transport to its target condition, and then pressing the button using one of the tools. The participant handed the key back to the experimenter, the transport on the task board was returned to its initial position, and the trial ended. The keys were kept out of sight except for when they were being used during a trial. The participant completed two blocks of eight trials during the initial task. Each key was used once within each block.

After the initial task trials, the participants moved to a computer workstation. The computer tasks were designed and administered using PsychoPy software (Peirce, 2007). The images of the keys used in the computer tasks were created using the same computer aided design (CAD) software that was used in printing the physical keys. The 3D images of the keys used during the following tasks were identical to the physical keys the participants had used during the initial tasks, excepting for the modifications noted below.

The first task the participant completed on the computer was a *classification task*. The purpose of this task was to provide the participants with labels for the concepts they had acquired during their initial interactions with the keys. Chin-Parker and Birdwhistell (2017) showed that participants can make category-based judgments, e.g. sorting and similarity judgments, following goal-directed

tasks even without explicit labels, but as we planned to use a category-goodness rating task, the participants needed a way to explicitly differentiate the concepts. Because the general head and interior shape were perfectly correlated in the keys, the participants could use either, or both, of those attributes to guide their classification decisions. We expected the participants to look to whichever feature they already considered to be critical in terms of their knowledge of the keys, so the classification task should only reinforce the concepts they acquired during the initial task.

The initial screen of the classification task provided information about the task, and at this point the participants were explicitly told that there were two types of keys, identified for the classification task as "alpha keys" and "zeta keys". During each trial of the classification task, the image of a key was presented and the participant used the mouse to indicate whether they thought it was an alpha or zeta key. The participant received feedback on her classification, and the correct label for the key was shown with the key so that she could study it for two seconds before the next trial began. Each participant completed 16 classification trials comprised of two blocks of the eight keys used in the initial task.

After completing the classification task, the participant began the *category rating task*. Each trial consisted of an image of a key presented with a category label (see *Figure 5*). The participant was instructed to rate how good a member of the indicated category the key was. The participant could use the mouse to click on a rating scale that went from 0 (labeled with "definitely not this type of key") to 100 (labeled with "perfect example of this type of key"). The participant was encouraged to use the entire range of the scale in order to most accurately reflect her ratings of the keys shown.

Each participant completed 32 trials in the category rating task. There were eight types of items shown during the task, four instances of each type. They were balanced in terms of whether they represented alpha or zeta keys. In the *old match trials*, the key shown was one from the initial task and it was displayed with the correct category label. In the *old mismatch trials*, a key from the initial task was displayed with the incorrect category label. In the *new match trials*, new versions of keys that matched the keys from the initial task (and these keys would have functioned the same with the task boards and tools) were displayed with the appropriate label. In the *head violation trials*, the image of the key was modified so that it had the same basic shape, but it would no longer fit onto either key frame if it had been used in the initial task. In the *interior violation trials*, the interior of the key was modified so that it had a different shape that would keep any tool (from either the ISI or ISR conditions) from being able to reach the button in the initial task. The *head/interior mismatch* trials had items where the head from one type of key was matched with the interior from the other type of key, and these keys were presented with the label that matched the head of the key. Finally, there were *minor match trials* and *minor mismatch trials* where superficial aspects of the keys (e.g. whether the edges were rounded or squared off) were modified, and the key was presented with either the correct or incorrect label. These items were considered filler items.

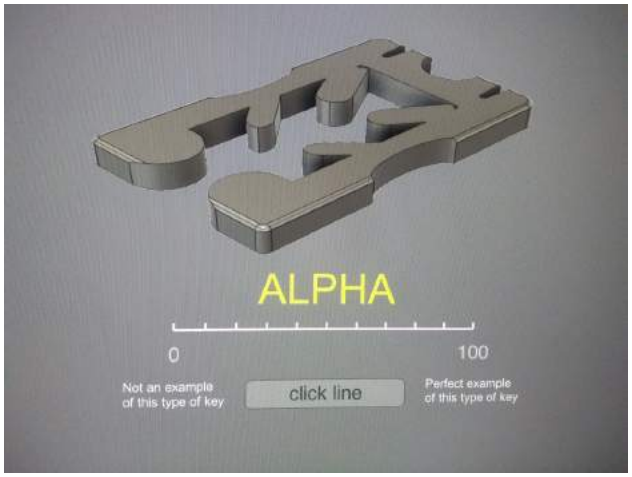

Figure 5: Screenshot of an Old Mismatch trial of the category rating task.

After the participant completed the category rating task, she was asked to move back to the task table. The task boards had been removed, and a pile of 16 "miniature" keys were in the center of the table. These keys were printed at ¼ scale and matched the keys from the initial task in terms of their attributes. Eight of these keys were identical to the initial task keys. The other eight keys were like the head/interior mismatch items from the category rating task – the head of one type of key was paired with the interior from the other type of key. The experimenter instructed the participant to "put these keys into groups that you think naturally reflect the types of keys you worked with today." The participant was free to sort the keys into any number of groups. Once the participant indicated she had completed the sorting task, the experimenter asked her to explain the sort.

Results

Initial Task Participants in the ISR condition (M = 221.03 secs, SD = 96.46) took longer to complete the first block of trials of the initial task than participants in the ISI condition (M = 162.24 secs, SD = 43.06), $t(65) = 3.24$, $p = .002$, $r_{pb}^2 = 0.14$. The difference persisted into the second block, but was much smaller in magnitude: ISR condition (M = 118.15 secs, SD = 21.59), ISI condition (M = 106.09 secs, SD = 19.82), $t(65) = 2.38$, $p = .02$, $r_{pb}^2 = 0.09$.

Classification Task There were no differences in the participants' ability to complete the classification task. The mean accuracy for the ISI condition (M = 0.95, SD = 0.07)

was nearly identical to the ISR condition (M = 0.96, SD = 0.07), $t(62) = 0.27$, $p = .78$, $r_{pb}^2 = 0.001$.

Category Rating Task The initial analysis of the category goodness ratings (see *Table 1*) was an omnibus test to determine whether the ISI and ISR conditions showed different patterns of ratings across the items. The category ratings were analyzed using a 2 (condition) X 8 (item type) mixed ANOVA. There was no main effect of the condition, $F(1, 65) = 0.07$, $p = .80$, $\eta_p^2 = .001$, but there was a significant main effect of the item type, $F(7, 455) = 78.04$, $p < .001$, $\eta_p^2 = .55$. Critically, there was a significant interaction between the condition and item type, $F(7, 455) = 2.16$, $p = .04$, $\eta_p^2 = .03$. Looking at the overall results, participants in both conditions provided similar ratings when both the head and interior of the key indicated the same category (i.e. the old match, new match, old mismatch, minor match, and minor mismatch items). The interaction appears to arise from a differential rating across items where the head and interior provided different information about the category membership.

Table 1: Mean Category Goodness Ratings (and Std. Error) Organized by Item and Condition

	Initial Task Condition	
Item	Interior Shape Irrelevant (ISI)	Interior Shape Relevant (ISR)
Old Match	85.13 (2.81)	85.52 (2.85)
New Match	73.10 (3.28)	77.61 (3.33)
Old Mismatch	10.33 (2.77)	13.77 (2.81)
Head Violation	40.38 (5.18)	50.27 (5.26)
Interior Violation	50.80 (5.87)	34.71 (5.96)
Head/Interior Mismatch	55.16 (6.47)	42.52 (6.57)
Minor Match	75.25 (3.81)	75.50 (3.86)
Minor Mismatch	13.57 (3.18)	13.82 (3.23)

As noted, we expected the manipulation of the relevance of the interior shape would affect the centrality of that attribute within the conceptual knowledge. To test this idea, we ran a more focused set of ANOVAs that assessed the conditions in terms of their ratings for the old items (as a baseline for the category ratings) compared to the items where the head and interior attributes provided different information about the category membership of the key (head violation, interior violation, and head/interior mismatch items). Across the analyses, there was a consistent effect of the item types (all ps < .001) because the old items were reliably rated as better members of the target categories compared to the items that contained inconsistent attributes. There was also no main effect of the condition in any of the analyses (all ps > .10). However, the interaction terms differed across the analyses. For the head violation items, $F(1, 65) = 1.19$, $p = .28$, $\eta_p^2 = .02$, and head/interior mismatch items, $F(1, 65) = 2.08$, $p = .15$, $\eta_p^2 = .03$, there was no interaction between the condition and item type. For the interior violation items, there was a significant interaction between the condition and item type, $F(1, 65) = 4.27$, $p = .04$, $\eta_p^2 = .06$. The interaction in the primary analysis appears to have occurred because the participants in the ISR condition dropped their ratings for the interior violation items in comparison to the old items more than the participants in the ISI condition did.

Sorting Task The participants in both groups created a variety of sorts for the miniature keys, and these sorts varied in terms of whether they reflected attention to a single attribute or multiple attributes. The sort by one participant in the ISR condition was not based on the physical attributes of the keys, so her data were removed from these analyses.

There was no difference in the number of groups created by participants in each condition (ISI condition: $m = 3.35$, $s = 2.28$; ISR condition: $m = 3.28$, $s = 1.99$), $t(64) = 0.13$, $p = .89$, $r_{pb}^2 = 0.001$. The proportion of participants that used information about the head of the keys (77% of ISI; 53% of ISR) differed between the conditions, $X^2_{(1, 64)} = 3.96$, $p = .04$, $v_c^2 = .06$. However, the proportion of participants that used information about the interior of the keys (53% of ISI; 66% of ISR) did not differ between the conditions, $X^2_{(1, 64)} = 1.10$, $p = .30$, $v_c^2 = .02$.

Forty-two participants (24 in the ISI condition, 18 in the ISR condition) sorted the items into only two groups. Those sorts provide a direct insight into what aspect of the keys was considered critical because the sort was based on a single attribute. Of this subset of participants, 66% of the participants in the ISI condition sorted the keys based on the head of the keys while 66% of the participants in the ISR condition sorted based on the interior. The primary attribute for the sort differed between the conditions, $X^2_{(1, 42)} = 4.58$, $p = .03$, $v_c^2 = .11$.

Discussion

The results of this study provide additional evidence for the goal-framework hypothesis. The participants in the two conditions were given equivalent tasks (and thus equivalent goals) to guide their interactions with the keys. In both conditions, the goals associated with their tasks oriented them to both of the critical attributes of the keys: the shape of the head and the shape of the interior. If the goal orientation hypothesis were sufficient to account for the role of the goal construct in the learning, the two conditions should have been largely equivalent in terms of how they organized their knowledge of the critical features of the keys. In some ways, they did show comparable learning. There is a striking similarity in terms of how the participants rated many of the items regardless of

condition. For instance, the mean ratings for the old match, new match, old mismatch, minor match, and minor mismatch items are nearly identical across the conditions. In all of those items, the head and interior attributes of the keys were in agreement with regard to the type of key shown. However, when the attribute information conflicted, the ratings differed between the conditions.

The participants in the ISI condition tended to consider the head shape as more critical when judging the category goodness of the items. Their ratings for the head violation items is lower than their ratings for the interior violation items. They also had a tendency to use the shape of the head of the key more consistently when organizing the keys during the final sorting task. The participants in the ISR condition tended to consider the interior of the keys as more critical to the category goodness, and they used the interior shape more consistently when sorting the keys.

As expected, the participants in the ISI condition acquired and used some knowledge of the interior shape in the category-based tasks. As noted, having to pay attention to the interior shape is sufficient to drive some learning. However, we would argue that their knowledge of the interior shape was less central to their concept of the key compared to the ISR condition, so it did not affect their ratings as much. A potentially important contribution of the notion of the goal-framework is that it explicitly connects the experiences of an individual, their interactions with objects in the world, to their conceptual knowledge.

It is not clear why the ISR participants showed less sensitivity to the head shape than the ISI participants. The head attribute played a comparable role in the task completion for both conditions. It is possible that having two goal-relevant attribute distinctions required some weighting of those attributes within the concept. This would fit with models of conceptual acquisition that have such a mechanism in place to account for the differential learning of attribute information. As suggested by an astute reviewer, it is also possible that the proximity of that part of the task to the completion of the goal might have privileged the knowledge of the interior shape in the concept. However, further study is necessary to determine why the ISR participants tended to emphasize the interior shape over the head shape.

The critical difference between the conditions was in the role the interior shape played in terms of how the participant could reach the goal. Both conditions had the same goal, to press the button, but the different tools during the second part of the task meant that the interior shape played a qualitatively different role in achieving that goal. In the ISI condition, the participant had to attend to the interior shape of the key in order to navigate the tool and press the button, but the shape of the interior of the key did not have relevance to the task beyond that. In the ISR condition, the shape of the interior was critical to differentiating the use of the tools to press the button. In this way, the differentiation of the shape of the interior was relevant to completing the task.

Chin-Parker and Birdwhistell (2017) posit that the learning process involves the development of the "goal framework" and that this framework reflects the structure that emerges as an individual interacts within a particular situation with a certain goal. In this way, the framework organizes the incoming information in terms of its goal-relevance providing structure to the acquired knowledge. They also propose that this framework is involved in organizing aspects of the basic perceptual experience of the individual when operating in a novel domain because there has to be some means to constrain the development of a feature language (see Landy & Goldstone, 2005). Although the current study was not designed to test these aspects of the goal-framework hypothesis, they fit within the experiences of the participants. When they had arrived for the study, they had no idea what the keys were or how to think about them. By the time they had completed the sorting task, they had a meaningful sense of what the keys were. As we develop this paradigm, we intend to revise the tasks so that we have the power to look at subtler indicators of the developing conceptual knowledge so we can assess these other claims.

This study examines concept acquisition in an arguably more naturalistic manner than most research in this this area. Our participants used the keys to complete an admittedly simple and arbitrary task, but in doing so, they had meaningful interactions with objects in a particular context in order to reach a goal. As a result, they developed useful ways to organize their knowledge of keys. This kind of experience invokes pragmatic constraints that are important to conceptual acquisition (Barsalou, 2017). The concept acquisition that occurs is not driven solely by the physical characteristics of the keys. Similarly, the goal of individual, in isolation, is unable to account for the conceptual acquisition. Instead, it is the interactions between the individual and environment that allow the useful structure to emerge.

Abstract

Human knowledge accumulates over generations, amplifying our individual learning abilities. What is the mechanism of this accumulation? Here, we explore how language allows accurate transmission of conceptual knowledge. We introduce a novel experimental paradigm that allows direct comparison of learning from examples and learning from language. In our experiment, a *teacher* first learns a Boolean concept from examples; they then communicate this concept to a *student* in a free conversation; finally, we test both teacher and student on the same transfer items. We find that learning from language is both sufficient and efficient: Students achieve accuracy very close to their teachers, while studying for less time. We then explore the language used by teachers and find heavy reliance on generics and quantifiers. Taken together, these results suggest that cultural accumulation of conceptual knowledge arises from the ability of language to directly convey generalizations.
Keywords: concept learning; cultural ratchet; communication

Introduction

The human species is remarkable: We are able to learn by observing the world around us, forming new concepts that support prediction and manipulation (Tenenbaum, Kemp, Griffiths, & Goodman, 2011). Yet human concept learning has limits: Life is only so long and a person can only be in one place at a time. Individual learning from observations is thus unlikely to fully explain the ecological successes of our species (Henrich, 2015). If we are able to faithfully transmit our knowledge to the next generation, then limited individual learning can accumulate over generations to arrive at powerful systems of knowledge—a process termed the "cultural ratchet" (Tomasello, 1999). How does the ratchet work? What aspects of cognition support faithful transmission?

Cultural transmission has been often studied through the lens of imitation. This mechanism is particularly useful for learning procedural knowledge and rituals (Legare & Nielsen, 2015). Reproducing the behaviors of conspecifics, however, does not easily address ideas that go beyond the here-and-now: our generalizable knowledge and intuitive theories. Language, on the other hand, is a tool by which humans can convey abstract information. It allows us to transmit knowledge that would be otherwise difficult or unsafe to observe directly (e.g., which plants are poisonous; Gelman, 2009; Tessler, Goodman, & Frank, 2017).

Prior experimental work in cultural transmission has suggested that language may be a sufficiently expressive channel for conveying hard-to-discover knowledge (Beppu & Griffiths, 2009; Morgan et al., 2015). For example, Morgan et al. (2015) found that knowledge about stone flaking and tool making were best transmitted via verbal language. This work did not examine in detail, however, the kinds of natural language expressions utilized in the transmission of knowledge, nor relate it to the concepts being transmitted. In this paper we introduce a novel experimental paradigm that allows to explore how language can support the "first crank" of the cultural ratchet: how concepts learned from examples by one person are faithfully transmitted to a second via language.

Typical concept learning experiments are structured so that a single subject is presented with examples of objects that belong to (and don't belong to) a new category (Bruner, 1956; Piantadosi, Tenenbaum, & Goodman, 2016). We extend this paradigm by asking the initial learner to convey the concept to a second person. We allow them to do so freely using language. We then separately test the initial and secondary learner on the category. This allows us to explore detailed questions about whether and how language allows faithful transmission of these concepts: Is language sufficient for conveying concepts? How efficient is language compared to directly studying examples? What aspects of language are used to convey concepts?

In the remainder of the paper we introduce our experimental paradigm and then explore the resulting data with a variety of analyses. We find that language is sufficient and efficient for concept learning, and that certain linguistic forms seem to underlie this efficacy.

Methods

Participants

We recruited 224 participants from Amazon's Mechanical Turk (MTurk). This number was chosen to yield approximately 10 dyads per concept. Participants were restricted to those with U.S. IP addresses and at least a 95% work approval rating; in addition, participants who self-reported a native language other than English or failed to partake in the experiment (accepted the hit but then discussed matters entirely unrelated to the experiment) were excluded. In total, 11 pairs were excluded on this basis. The experiment took on average 15 minutes and participants were compensated $1.25 with an additional performance bonus (described below).

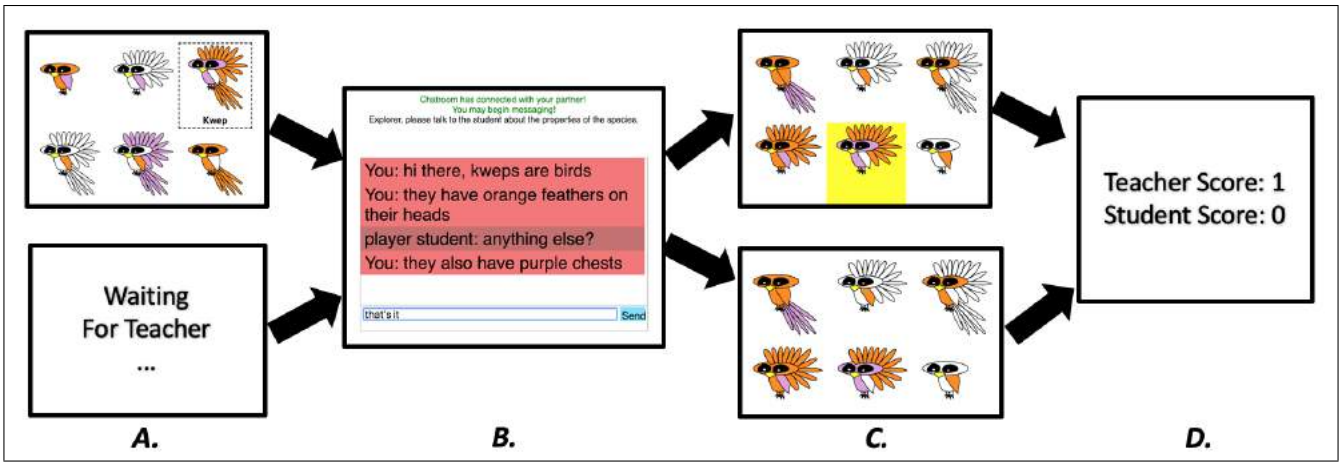

Figure 1: During the *concept learning* phase (**A**) the teacher (above) clicked through a grid of creatures, revealing the labels for creatures in the train set, while the student (below) waited. During the *concept communicating* phase (**B**), the teacher explained the concept to the student in a chatroom. During the *concept testing* phase (**C**), both participants were shown the same grid of held-out test creatures. Each selected the creatures (yellow) that they believed belonged to the concept. Finally, the participants were shown their scores for the round (**D**).

Concepts and stimuli

Participants learned concepts generated by 5 different *rules* (i.e. logical forms): Single Feature, Conjunction, Disjunction, Conjunctive Disjunction, and Disjunctive Conjunction. Rules were realized in specific *concepts* by varying Boolean properties of programatically generated images of creatures, from five different kinds: flowers, bugs, birds, fish, and trees (see Figure 1 for an example). Each kind had 5 to 7 Boolean features that we used to realize our concepts. Each of the 5 rules was realized twice in each creature kind, yielding a total of 50 concepts (listed on the axis of Figure 3). For each concept, we generated 100 specific creatures, split into 50 for training and 50 for testing. We ensured some positive examples of the concept even for very restrictive rules by first randomly selecting 6 positive instances of the concept and then adding 44 items chosen at random from all remaining items (i.e., according to the true concept base rate).

Procedure

Every pair of participants was placed in a game, where one was assigned the role of the "teacher" (initial learner) and the other was assigned the role of the "student" (secondary learner). Each game consisted of 5 rounds, each with a new concept from a new rule. Each of a game's 5 concepts used a different creature kind, and each concept was presented with a different nonce word as the species name. The ordering of concepts was randomized so that there was no standard ordering of rule types across the games.

On each round, participants went through three phases: *concept learning*, *concept communicating*, and *concept testing* (Figure 1). During the *concept learning* phase, the teacher was presented a grid of training creatures and was instructed to click on individual creatures to reveal whether or not they belonged to the species defined by the concept. Once the teacher clicked on every creature in the grid, they were presented a message advising them to review the creatures for as long as they needed. When the teacher ended the concept learning phase, they proceeded to the *concept communicating* phase, where they entered an online chatroom and were were instructed to teach the concept to the student. Participants were provided no additional instructions for the chatroom, and they were allowed to talk freely. In order to prevent a teacher from rushing through the chatroom without properly communicating with their student, only the student was given the ability proceed to the final *concept testing* phase. In the final phase both participants were (separately) given the same grid of test creatures and asked to tag the creatures that they believed belonged to the species. Neither participant had access to their chatroom messages during this phase.

Once both participants completed *concept testing* for a concept, they were provided feedback in the form of their own and their partner's score, computed as: # of hits − # of false alarms. We encouraged them to learn concepts thoroughly and communicate effectively with a monetary bonus equal to the sum of both players' scores (in cents). Participants were made aware of the task structure and bonus mechanic prior to starting the first round; they had to answer 5 comprehension questions correctly to begin to the game.

Analysis and Results

Our experiment yielded rich data for exploring whether and how concepts are learned from language, and how learning from language compares to learning from examples. We first examine performance during the *concept testing* phase for both the student and teacher participants. We then explore the time spent learning from each type of evidence. Finally,

we explore the actual language used to teach concepts in the *concept communicating* phase.

Concept learning performance

Participants assigned to be the *teacher* take part in a standard Boolean concept learning paradigm, and results are in accord with expectations. The five rule types we used in our experiment cover a range of complexity in terms of description length (Feldman, 2000), which manifests in variable performance in test accuracy across types (Figure 2).

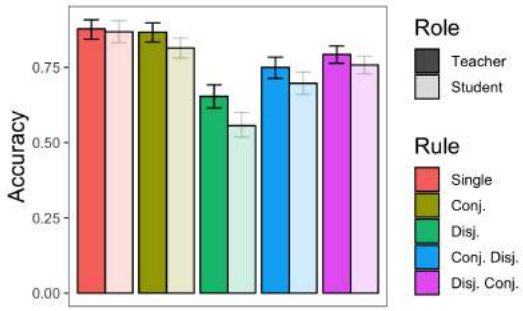

Figure 2: Average accuracy of teachers and students during the *concept communicating* phase of the experiment. Error bars denote bootstrapped 95% confidence intervals.

Students have access to the concept only through the language conveyed by their partner. The average student accuracy during the *concept testing* phase should thus be no greater than the average teacher accuracy, which appears to be true for our 5 rule types in Figure 2. To assess the potential accuracy differences between learning from examples vs. from language, we built a Bayesian mixed-effects model predicting whether or not a participant responded accurately during the *concept testing* phase as a function of the rule, the participant's role (teacher vs. student), and their interaction. We included random intercepts and effect of rule for participants and random intercepts and effect of role for each of the 50 concepts. All regression models were created in Stan (http://mc-stan.org/) accessed with the brms package (Brkner, 2017). We find a main effect of role such that students were less accurate than teachers (posterior mean and 95% credible interval: $\beta = -0.41(-0.69, -0.12)$). However, this effect is very small in absolute terms—the average difference in accuracy for students vs. teachers is just 5.3% (95% credible interval: 2.7%, 8.2%). Thus language appears to be sufficient to convey concepts; students are able to learn concepts from language, yielding performance very close to their teachers, who had access to the actual training examples.

Performance on individual concepts (rules reified in particular stimuli) reveal substantial variability in learning. Figure 3 shows the average performance of teachers and students for each of the 50 concepts along with the concept-specific chance accuracy[1]. Teachers perform above chance in all concepts, but there is significant variation in performance for concepts within a given rule. Such variation is expected given the known importance of feature salience and other stimulus properties on concept learning (Nosofsky, 1986). Notably, the gap between teacher and student performance also varies.[2] This variability cannot be attributed to stimulus features, which are shared between teacher and student, but rather reflect the language available for conveying different features. Inspection reveals that concepts with a large gap in teacher-student performance have a small number of teachers who used language in idiosyncratic ways. For example, one teacher described creatures belonging to the concept "bugs: no wings" as "like a worm ... [with a] straighten[ed] body". Another teacher described "flowers: purple petals OR thorns" as "no color ... a flower with sharp edge branches and some tails". In both cases the teacher fails to use a simple word for the relevant feature ("wings", "thorns") unlike most other participants. These cases may arise from particularly confused teachers, particularly difficult to describe features, or an interaction. We return to this question below.

Often, how well a person learns depends on the particular person they learned from. We find a strong linear relationship between average student accuracy and (corresponding) teacher accuracy across the 50 concepts ($r = .88$, $p < .001$; Figure 4). We further find that this correlation remains strong at the individual level ($r = .60$, $p < .001$; Figure 4).

While this suggests that students make mistakes when their teacher does, we may further ask whether they make the *same* mistakes. Since teachers and students are presented the same held-out test examples in the same order during the *concept testing* phase of the experiment, we can measure the similarity between teacher and student responses at the level of individual stimuli using Hamming distance (the total number of times the student and teacher responded differently). The average distance between teacher and student in our data set is 11.1 differences (out of 50 possible). To calibrate this number we computed a baseline by randomly permuting teacher-student pairings, which yields average distance 19.9 (95% CI $[19.84, 19.96]$). A second, tighter, baseline considers permutation of student-teacher pairs only within each concept (matching evidence seen by teachers). This yields average distance 13.53 (95% CI $[13.18, 13.91]$). Thus we can conclude that students' pattern of responses is more similar to their own teachers' responses than to other teachers in the same concept (and in the whole data set). Language seems to be sufficient to convey the concept as understood by the teacher, even when the teacher has learned the wrong thing.

We do not have a direct measure of teacher confidence that

[1]Chance is defined here as the accuracy achieved by guessing at random but with the base rate of positive examples shown for that concept. This is a stronger comparison than random guessing.

[2]Generally teachers do better than students. Ten concepts show the opposite trend, to varying extents. Three of these differences are driven by a few outliers where the teacher attained low accuracy in the final phase even though they properly communicated the concept. Seven of these concepts have students that are negligibly more accurate than teachers, i.e. correctly identify 1-2 more stimuli, of the 50 presented.

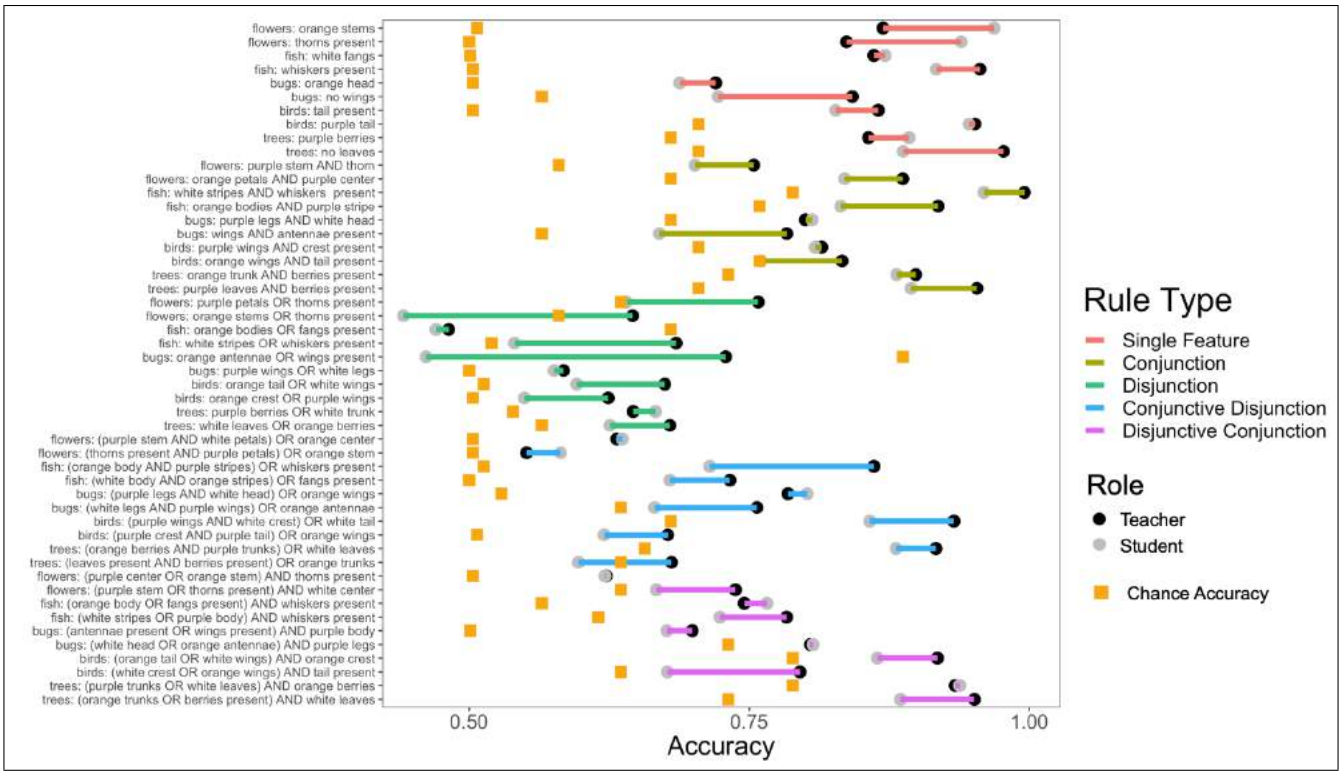

Figure 3: Accuracy on each concept. Black dots denote the average teacher accuracy on the test set; gray dots denote the average student accuracy. Gold squares denote chance accuracy.

we could use to explore the impact of confidence on the efficacy of language for transmission. Instead, we analyze an indirect measure of teacher confidence: the mean teacher accuracy within a concept. Figure 5 shows the relationship between teacher accuracy and distance from teacher to student responses. We find a strong relationship: language seems to yield stronger alignment between students and teachers when the teachers are (expected to be) confident in what they have learned ($r = -0.75, p < 001$).

Study time for observation vs. language

As we saw above, language appears to be relatively *sufficient* for conveying concepts, how *efficient* is language compared to directly learning from observed examples? We could consider efficiency in terms of amount of evidence required to learn or amount of effort required. In our experiment the amount of evidence was fixed in the *concept learning* phase, but the study time was controlled by participants. We thus consider study time as a proxy for learning effort. Since the amount of time spent in the *concept communicating* phase was similarly controlled by participants, we use time as a proxy also for effort required to convey a concept with language. Using time to measure learning effort makes it possible to directly compare effort required to learn from observations and from language.

For each concept, we recorded the amount of the time that teachers spent in the *concept learning* phase. During the *concept communicating* phase we recorded the time that elapsed between the moment a participant began typing a message into the chatbox and the moment they sent the message to their partner. Since some messages may have been unrelated to learning (e.g. pleasantries or commentary), we coded every message in the data set as "Informative", "Follow-Up", "Confirmation", "Miscellaneous", or "Social". Informative messages were those related to the concept that were sent by teachers without prompting from the student. Messages in the ensuing dialog that were relevant to the concept were labeled as Follow-Up. Social pleasantries ("hi", "hello", etc.) were labeled as Social, and messages that were unrelated to the current concept (e.g. commentary about performance on previous rounds) were labeled as "Miscellaneous". Overall, there were 1012 Informative, 1751 Follow-Up, 160 Social, and 300 Miscellaneous messages in the data set. For our time analysis, we only considered the concept-related messages: the Informative and Follow-Up messages that constituted the majority of participants' conversations.

To compare the study time of learning from examples vs. from language (Figure 6), we built a Bayesian mixed-effects model with fixed effects of rule, participant role, and their interaction; in addition, we included random intercepts and effects of rule for each participant and random intercepts and effects of participant role for each concept.[3] We observe

[3]The data was modeled as being generated from a lognormal dis-

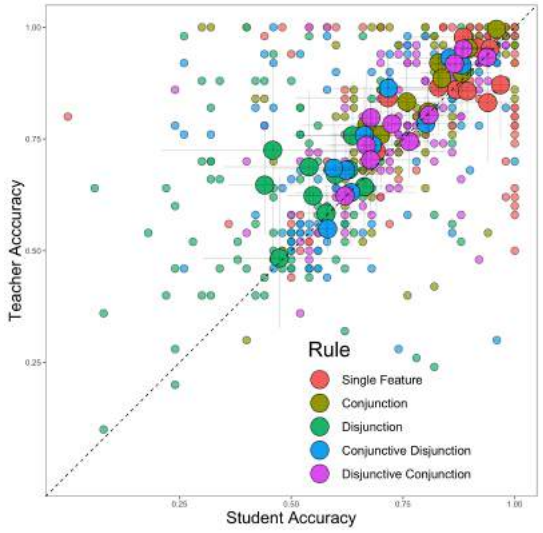

Figure 4: Accuracy of student-teacher pairs in *concept testing* phase. Small dots indicate individual teacher-student pairs, while larger dots indicate mean accuracy of teachers and students for a concept. Lines indicate bootstrapped 95% confidence intervals of teacher and student accuracy for a concept.

that the simplest rule (Single Feature) took the teacher substantially less time to study than average (comparison to the grand mean: $\beta = -0.25(-0.37, -0.12)$) and the most difficult rule took substantially more time to study than average ($\beta = 0.20(0.08, 0.31)$). Crucially, study time was systematically shorter when learning from language than from examples ($\beta = -0.64(-0.82, -0.48)$), which translated into an average 57 seconds (42, 75) less time for learning from language. There were no interactions between role and rule that were plausibly different from 0.

This suggests that learning from language may be *more*

tribution.

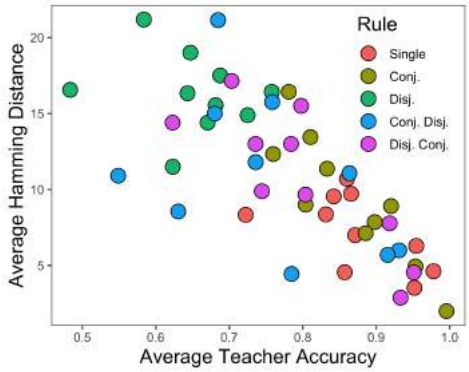

Figure 5: Average accuracy of the teacher versus the average hamming distance between student and teacher responses during *concept testing* phases of all 50 concepts.

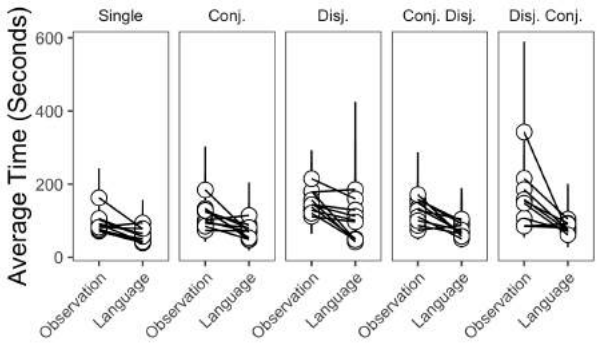

Figure 6: Time spent by teachers learning concepts from observation and time spent by teacher-student pairs communicating about concepts. Circles denote average time for a concept, error bars are bootstrapped 95% confidence intervals. Lines pair the same concept.

efficient than learning from observing examples. This conclusion warrants further study however, as our measures of study time likely depend on specific paradigm choices. For instance, teachers were forced to click on all 50 creatures during the *concept learning* phases of the experiment—it may be that not all of this time was needed for belief updating (as opposed to rote clicking of the stimuli).

Language used for knowledge transmission

We have seen that language is a sufficient and (probably) efficient means for transmitting concepts in our experiment. Now we turn to the question of what specific aspects of language were used by teachers to convey concepts. We first coded each of the messages in the game as Informative, Follow-Up, Social, or Miscellaneous, as described above. A vast majority of the messages (2763 of the 3223) were concept-relevant, i.e. Informative or Follow-up.

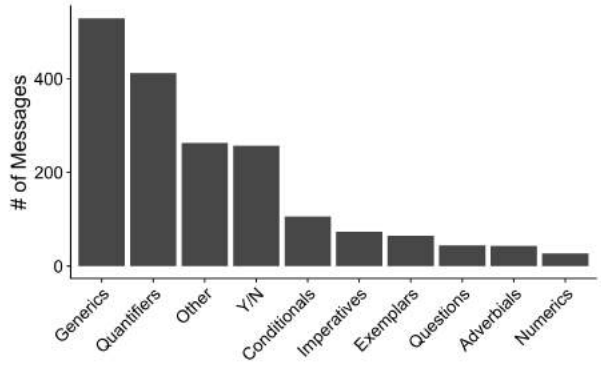

Figure 7: Distribution of concept-relevant messages.

When properties are predicated on categories, the resulting linguistic expression is typically a quantified sentence (e.g.,"All wugs have orange heads"; "Most feps have purple

Table 1: Utterance Categories & Examples

Category	Example(s)
Generics	"morseth[s] come in a variety of colors"
	"they have saber teeth"
Quantifiers	"some will have wings"
	"all morseth[s] have long whiskers"
Conditionals	"if the left wing is orange click it "
Exemplars	"12 white feathers ... no tail ..."
	"12 white feathers ... 5 white tail..."
Imperatives	"so click on the teeth!"
	"focus on orange fish..."
Adverbials	"usually their wing colors match their..."
	"stems are usually colored as well"
Numerics	"2/3 of them are the ones that qualify"
	"75% of what I clicked on was a zorb"
Yes/No	"nope", "k",
	"yes", "okay"
Other	"this sounds difficult"
	"okay idk what else to say"

wings") or a generic sentence which lacks explicit quantification (e.g., "Morseths have saber teeth" Carlson & Pelletier, 1995). Rather than talking about categories explicitly, participants could convey the actual examples they saw using numerical language (e.g., "4 of them ...") or describing individual exemplars (e.g., "white-tail with feathers, white-tail with no feathers, ...").

The first author first identified Generics consistent with other coding schemes used for generic sentences (Gelman, Goetz, Sarnecka, & Flukes, 2008), then identified Quantifiers, Numerics, and Exemplars, before grouping the remaining messages by the following linguistic constructs: Conditionals, Imperatives, Adverbials, and Yes/No statements. Remaining messages were grouped as "Other". See Table 1 for examples of messages across these categories.

Figure 7 shows label counts for concept-relevant messages in our data set. The majority of these messages use generics or quantifiers to convey information about the category, with generics being the most common. Examining this distribution within rules, we find that this pattern holds for all except disjunction, where quantifiers are more prevalent than generics. Additionally, we find that the number of generics (%G) and quantifiers (%Q) amongst concept-relevant messages does not vary appreciably across the rules: single features: (35%G, 21%Q); conjunction (34%G, 22%Q); disjunction (21%G, 26%Q), conjunctive disjunction (24%G, 21%Q); disjunctive conjunction (31%G, 22%Q).

The remainder of the responses are mostly made of other commentary about the concepts and Yes/No responses. It is important to note that teachers could have directly instructed the students what to choose (with Imperatives) or described their specific experience (e.g. "there were three morseths with blue wings"); they chose instead to use linguistic constructs that convey generalizations across categories.

Discussion

In this paper we introduce the first experimental paradigm that permits apples-to-apples comparison of learning concepts from examples and from language. We found that language is *sufficient* for faithful concept transmission, in the sense that the student who learns from language is nearly as accurate as the teacher who learned from examples (and as inaccurate, making similar mistakes). We have also seen preliminary evidence that language is *efficient* for concept transmission: that it may take less time to learn a concept from helpful language than to learn it from observations.

Most work on cultural transmission either investigates well-controlled experimental paradigms but with heavily restricted modes of transmission (e.g., sharing direct observations; Efferson et al., 2007; Kalish, Griffiths, & Lewandowsky, 2007; Griffiths, Lewandowsky, & Kalish, 2013; Kirby, Cornish, & Smith, 2008; Smith, Kalish, Griffiths, & Lewandowsky, 2008; Martin et al., 2014) or use open-ended modes of transmission (e.g., creating an instructional video) but on complex tasks where a ground-truth is difficult to establish (Muthukrishna, Shulman, Vasilescu, & Henrich, 2014; Caldwell & Millen, 2008; Morgan et al., 2015). In this paper, we chart a middle course: investigating a well-studied phenomenon (Boolean concept learning) with a relatively open-ended mode of transmission (free language production).

This allows us to perform parallel analyses of *what is being learned* and *how that knowledge is conveyed*. Recent advances in natural language processing have demonstrated potential in training and parameterizing classifiers according to language (Andreas, Klein, & Levine, 2017; Srivastava, Labutov, & Mitchell, 2018). Meanwhile, there has been a growing body of research aimed at understanding effective teaching and learning within Cognitive Science (Chi, Roy, & Hausmann, 2008; Chi, Siler, Jeong, Yamauchi, & Hausmann, 2001; Kapur, 2014). We believe that bringing the pedgagogical perspective to machine learning will be instrumental to improving models that learn from language. Importantly, our novel experimental method allows for scalable data collection of language-based instruction and provides a clear classification task, i.e. training models to learn from discourse and demonstrate understanding by predicting student responses.

In our experiment, we found substantial evidence that quantifiers and, especially, generics are used by teachers to convey their knowledge about concepts. In one sense this is unsurprising, as these linguistic constructs are *about* category generalization. Yet our results provide the first direct evidence for the connection between these aspects of language and cultural transmission of knowledge. This in turn provides initial support for a strong hypothesis about the mechanisms of knowledge accumulation: *The cultural ratchet arises specifically out of the ability of language to convey generalizations through generics and quantifiers*.

Abstract

Cognitive science is an archipelago of concepts and models, with cross-pollination between topics of interest often prohibited by incompatible approaches. Despite this, behavioral performance universally depends on information transmission between brain regions and is limited by physical and biological constraints. These constraints can be formalized as information theoretic constraints on transmission, which provide normative predictions across a surprising range of cognitive domains. To illustrate this, we describe a simple variable-length rate coding model built with Poisson processes, Bayesian inference, and an entropy-based decision threshold. This model replicates features of human task performance and provides a principled connection between a high-level normative framework and neural rate codes. We thereby integrate several disjoint ideas in cognitive science by translating plausible constraints into information theoretic terms. Such efforts to translate concepts, paradigms and models into common theoretical languages are essential for synthesizing our rich but fragmented understanding of cognitive systems.

Keywords: information theory; bayesian inference; rate coding; response time; learning

Introduction and Background

Cognitive science is home to almost as many models as phenomena they purport to describe. While this *sui generis* approach to each problem allows rich and flexible descriptions, it stands in sharp contrast to the physical sciences, in which scientists strive for and expect simple unifying principles, like Newton's axiomatic laws, from which individual phenomena arise as particular circumstantial manifestations (Chater & Brown, 2008). In cognitive science, we would say that Newton's laws are *normative*. But where are our first principles, from which we can hope to derive a coherent set of expectations about how cognition *should* operate? In this paper, we consider information transmission from the environment, through the brain, to behavior. By constraining both the channel code and each transmitted signal to be optimally inferred under normative assumptions, we can construct a message-transmission system that replicates the Hick-Hyman law (Hick, 1952; Hyman, 1953) and the Power Law of Practice (Newell & Rosenbloom, 1981), illuminates the connection between transmission rate and energy use, and produces human-like response time distributions. Our information-theoretic approach affords a principled way to connect levels of analysis (Marr, 1982) by integrating energetic resource availability, message encoding and decoding schemes, and task performance characteristics into a single framework.

Applying information-theoretic concepts to the study of cognition is not new. The years following Claude Shannon's 'A Mathematical Theory of Communication' (1948) produced a wealth of information-theoretic analyses of cognitive function, perhaps the most famous of which resulted in the Hick-Hyman law (Hick, 1952; Hyman, 1953). This mathematical approach merged with optimal control theory to become Cybernetics (Wiener, 1965), which promised to understand cognition and behavior as just another system of information transmission, feedback, and control, and subject to the same constraints. Despite their successes, enthusiasm about both information theory and cybernetics has not persisted to the present day, partly because cybernetics was abstracted away from biological and neurological characterizations, and partly because the cognitive revolution led to a focus on the nature and calculus of representation.

The development of cognitive architectures has resulted in highly successful models of a broad array of tasks (Sun, 2008; Anderson et al., 1997; McClelland, 2009). In parallel, architecture-free computational principles like Bayesian inference, prediction, credit assignment, and generalization bounds on learning have provided a rich framework for normative thinking (Shiffrin, 2010; Griffiths et al., 2008). Computational architectures form a possible hybrid (Chater & Brown, 2008), using normative computational principles to structure a cognitive architecture. However, these principles are often expressed in mathematical language disconnected from cognitive and neural architectures, leading to a pervasive difficulty in translating between mathematical formulation and plausible neural implementaiton.

The inability to translate between cognitive models directly results in a lack of knowledge transfer between domains (cognitive processes, language, tasks, etc) and levels of analysis (high-level models to low-level mechanistic details). For example, consider cognitive control as a case-in-point illustration. 'Cognitive control' refers to the deployment of attention and memory resources in the service of competing tasks. Each of these (control, attention, and working memory) are famously limited in capacity and inextricably intertwined in their roles in executive function. It is well-known that task practice lessens the effort required to do tasks, lessens attentional load, reduces response times, and decreases the amount of cognitive control required (Logan, 1985; Moors, 2016; Pierce & McDowell, 2017). These effects mirror practice

effects in perceptuo-motor skill acquisition, suggesting there should be some common principles, but it is currently difficult to transfer insights gained in the study of one phenomenon to the study of others. This lack of transferability means that cognitive science has developed a series of 'knowledge islands,' making it almost impossible to share insights across boundaries.

Even within a single topic, with the same underlying concepts, there are often many theories that are difficult to relate to each other. For example, under the shared working assumption that mental effort is treated as a cost in a cost-benefit analysis, there is considerable disagreement about the nature of the cost. Depending on the theory employed, it may represent an opportunity cost from foregone tasks, a loss of the intrinsic reward of cognitive leisure, the tendency of mental effort to discourage use of limited-capacity resources like working memory, or simply the effort of cognitive control as a cost per se. Although Shenhav et al. (2017) show that these ideas share common computational principles, they also leave it as an open question how to compare them directly. The difficulty is that cognitive costs are exogenous to the computational architecture, which means there are many non-equivalent ways to import them. Without further normative constraints, there are many rational ways to import computational modeling ideas (like costs), which means each new model multiplies the translational difficulties for integrating and relating existing models, constraints and concepts.

Like Shenhav et al. (2017), we take as foundational that the brain is an information-processing organ, ultimately transferring information from the environment via sensation, through the brain, and back into the environment as behavior. Although high level theories of behavior are most easily expressed in decision- and control-theoretic terms, re-expressing these theories in information-theoretic terms affords the incorporation of constraints on information processing, as illustrated by work on bounded rationality (Ortega et al., 2015). Biological constraints involving energy availability and noise, when translated into information theory formalism, become *normative bounds* on the ability to transfer information. Similarly, limitations on information available to the organism provide bounds on task performance. In essence, information theory provides a well-known, well-understood and sophisticated language for translating models and theories that has largely untapped potential. We illustrate this potential by demonstrating its capacity to use common computational principles to reveal relationships between the seemingly unrelated phenomena of learning rates, response time distributions, and energetic resource utilization.

Framework

Whatever the task at hand, neurons performing task-related computations must infer, in a continuous-time and streaming manner, which 'messages' are being transmitted from other brain regions (Rieke et al., 1999). This inference process is noisy, imperfect, and time-dependent. We model this process by performing continuous-time inference about the configuration of stochastic processes, with a stopping criterion based on a posterior entropy threshold. This approach produces normative predictions that match the behavioral characteristics so commonly observed in experimental paradigms, including the shape of response-time distributions and the decrease in response times and mental effort as a function of practice.

Characterizing the relationship between inferential constraints and transmission efficiency is the domain of information theory (Cover & Thomas, 2012). Information theory has been transformative in its applications to electronic communications, and has provided useful normative predictions for neural characteristics (Bialek, 2012). In particular, information theoretic constraints underlie the Efficient Coding Hypothesis (Barlow et al., 1961; Simoncelli & Olshausen, 2001), which suggests that neural connectivity is structured in such a way as to encode information from the natural environment with maximum efficiency. Despite widespread evidence for the general validity of this hypothesis in early sensory systems (e.g. Laughlin (1981); Vinje & Gallant (2000); Pitkow & Meister (2012)), there is still significant uncertainty as to whether information theoretic principles are relevant at the level of cognitive processing. Central to this reservation is a concern that Shannon's proofs of the existence of arbitrarily efficient binary codes rely on his use of 'block codes,' in which several messages are combined into a single string in a way that increases the likelihood of error-free transmission (Shannon, 1948; Cover & Thomas, 2012). For example, Luce (2003) writes "Shannon's way of defining the concept [of channel capacity] requires that not individual signals be transmitted but rather very long strings of them so as to be rid of redundancies. That is rarely possible within psychological experiments." Another recent paper raises similar concerns that Shannon's method of encoding "requires complex computation and long delays to encode and decode in ways that achieve optimality," and that it only "applies to settings of perfect signal recovery, which may not be possible or even desirable in biological settings" (Park & Pillow, 2017).

Concerns about the applicability of Shannon's proofs to information transmission in the brain confuse levels of analysis (Marr, 1982). It is true that Shannon's reliance on block-coding to achieve efficient information transmission is an implementation-level detail applicable to discrete-time codes and not to the communication of information between neurons. However, the core conceptual contribution of information theory lies not in coding techniques but in providing a method for quantifying uncertainty. More broadly, the theory serves to characterize the ways in which noise and redundancy affect the reliability, efficiency, and rate of inference. From this broader perspective, it is surely applicable to the study of cognitive function. That an understanding of these factors can lead to the design of optimal codes is important, but the specifics of code design in a discrete-time system do not invalidate the application of general principles to the study of cognition.

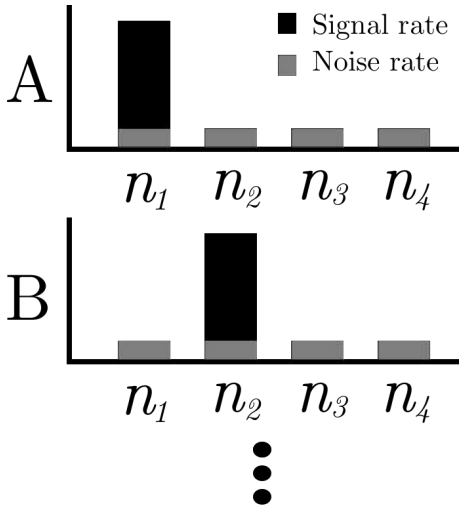

Figure 1: A codebook converts symbols A, B, etc. from a symbol alphabet into configurations of firing rates across Poisson processes $n_1, n_2, \ldots$. In this simple model, the codebook assigns a signal rate λ_S to a single Poisson process for a given symbol. Each Poisson process also emits spikes at a noise rate λ_N. As Poisson process rates are additive, this results in a total emission rate of $\lambda_N + \lambda_S$ for the 'activated' process.

In the remainder of this paper, we show an example of a continuous-time variable length coding mechanism, built using entropy and inference, that adheres to the principles of information theory while providing normative predictions of signal transmission time and accuracy. We emphasize that the continuous-time nature of the code means that signals are not discretized. Because of this, we are able to transmit messages such that transmission time is linearly related to message surprisal, replicating the Hick-Hyman law. By presenting such a code, we show that appropriate information-theoretic concepts can be applied to the study of neural information transmission.

Implementation

We model information transmission by having a sender encode a message into a configuration of Poisson process firing rates, and a receiver watch the generated spikes until they are confident about the configuration of underlying rates, and thus about the content of the encoded message (see Figure 2 for a schematic of the architecture). In more detail, the transmission mechanism consists of an encoder, a transmitter, a receiver, and a codebook. The transmitter is an array of Poisson processes, each continuously producing points or 'spikes' independently at a given noise rate λ_N. This can be viewed as a basic model of a neural rate code, as neural spikes trains are often modeled as Poisson processes (Rieke et al., 1999). The symbols to be communicated are taken from an alphabet of discrete symbols $\mathcal{A}$. The codebook describes a mapping between each symbol and a configuration of Poisson rates,

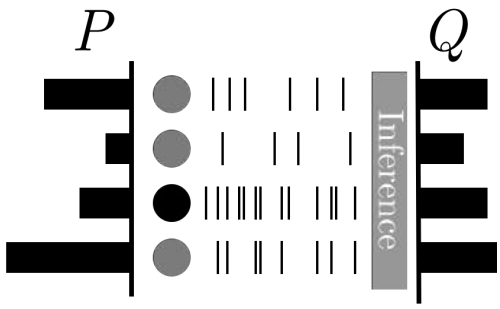

Figure 2: Messages are selected from a source distribution P. The codebook translates each message into a higher firing rate for a single process (a simplifying, but not restrictive, assumption). Poisson processes stochastically emit spikes, which are observed by the inference process. Bayesian inference combines the prior distribution Q with the likelihood of each message given the accumulated observations to produce a posterior distribution over possible messages.

and the mapping from a given symbol to rate configuration is carried out by the encoder. For the sake of expositional simplicity, we restrict the codebook to increasing the rate for a single Poisson process from the noise rate λ_N to a signal rate $\lambda_N + \lambda_S$, as shown in Figure 1. The neural analogue is that each Poisson process is 'tuned' to 'prefer' a particular symbol in a 1-hot manner, resulting in a sparse code.

The receiver observes the sequence of spikes emitting from each Poisson process and continuously attempts to infer which rate configuration is producing the spikes it observes, and thereby which symbol is being transmitted. We assume, again for simplicity and consistent with common information-theoretic analysis, that the receiver knows the values of both λ_N and λ_S. In standard binary or Gaussian channels, transmission is a discrete vector of amplitudes that takes a fixed time to transmit. Because of this, practitioners typically speak in terms of transmitting bits-per-signal, or bits-per-second (which are a constant multiple of each other). In our case, the receiver accumulates information about each transmission gradually, over time. In effect, observing for a longer period of time adds redundancy to the signal.

As observations continue, the receiver calculates and continuously updates a posterior probability distribution over possible messages, and stops decoding when the entropy of the posterior reaches a pre-specified stopping threshold. Let transmitted symbols be treated as realizations of a random variable X. The receiver begins each transmission at time $t = 0$ with an initial uncertainty $H_Q(X)$ regarding the symbol being transmitted, reflecting its prior distribution $Q(X)$ of the possible codewords. As time passes and observations $Y_t = \{y_1, \cdots, y_t\}$ are made, the receiver uses Bayesian inference to update the prior to obtain a posterior distribution $Q_t(X|Y_t)$ over messages according to Bayes rule, which yields an updated posterior entropy $H_{Q_t}(X|Y_t)$. The posterior entropy decreases non-linearly with time and reflects the de-

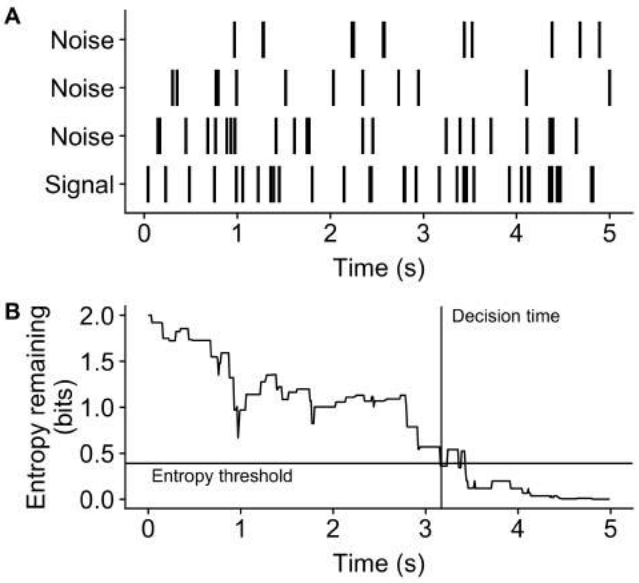

Figure 3: (A) Spikes are randomly emitted by each Poisson process as a function of time. The lower-most Poisson process is firing at a higher $\lambda_N + \lambda_S$ rate, while the others are firing at rate λ_N. (B) The receiver observes the spikes and infers which process is firing at rate $\lambda_N + \lambda_S$. The initial entropy is 2 bits, indicating a weak belief in equal probabilities for each of the 4 possible signals. The receiver's remaining entropy changes as the processes are observed and the posterior probability of each signal is calculated.

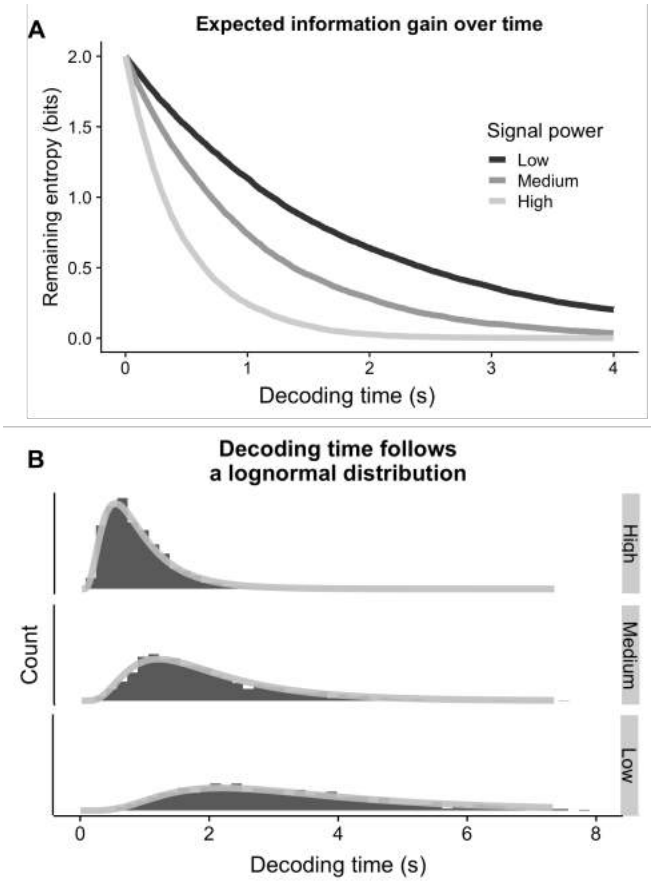

Figure 4: (A) The expected value of the receiver's entropy regarding four possible messages decreases as spikes are observed. Increasing the signal power λ_S changes the information transmission rate. (B) Response time distributions vary as a function of signal power λ_S, and in each case are well-fit by a log-normal distribution.

gree of confidence that a message has been correctly received. Transmission stops when $H_{Q_t}(X|Y_t)$ reaches a threshold. Figure 3 shows the change in posterior entropy over time for an example transmission.

Variable length transmissions

In the coding scheme introduced here, messages are *variable-length*: transmissions of messages with higher surprisal takes more time than messages with low surprisal, where surprisal is calculated using the prior probability distribution $Q(X)$ of the receiver. Recall that the surprisal $h(x)$ of a message x drawn from a distribution $P(X)$ is the logarithm of the inverse probability of the message, $h(x) = \log_2 \frac{1}{P(X=x)}$.

In 'entropy codes,' codeword length (and thus transmission time of each codeword) is roughly proportional to the surprisal of the encoded symbol in the absence of noise. When symbols are independently drawn according to a categorical probability distribution, this can manifest in two ways. In the first, increasing the number of possible symbols increases the surprisal of each individual symbol, and consequently the length of the code needed to encode its value. In the second, symbols drawn from a categorical distribution with unequal probabilities will have different surprisal values: more frequently transmitted messages will have lower surprisal and shorter codes than less frequent messages. We performed simulations to explore these scenarios in turn using our transmission model.

First, we varied codebook sizes and recorded transmission times using a fixed entropy threshold and a uniform source distribution. The nonzero entropy threshold occasionally results in transmission errors, as we see in human subjects. Information transmitted is thus less than the surprisal of each individual message, on average. We computed actual information transmitted by calculating the mutual information between transmitted symbols and received symbols, for each codebook size. The results are shown in Figure 5 and are a close qualitative match for the Hick-Hyman observations of human response times reported by Hick (1952) and Hyman (1953).

We next transmitted messages drawn from a non-uniform distribution $P(X)$ and measured transmission time for each message. For each transmission, we measured the information transmitted by comparing the receiver's prior probability distribution $Q(X)$ (which equals the source distribution

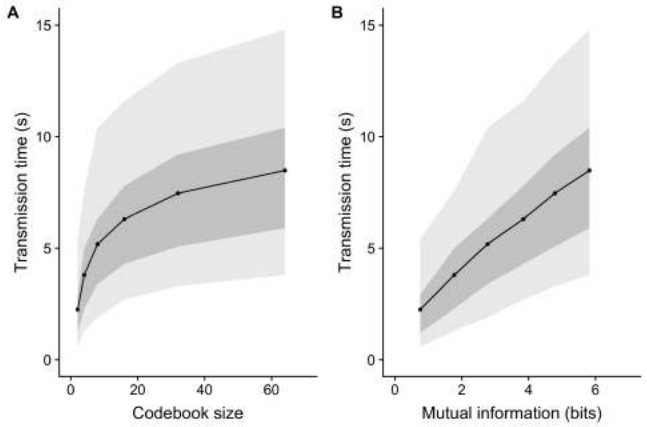

Figure 5: Mean transmission time increases logarithmically with codebook size and linearly with information transmitted, mirroring the Hick-Hyman law. Points represent mean transmission times and shaded regions represent the 50% and 90% high-density interval of the transmission time distribution. In each case, messages were transmitted according to a discrete uniform distribution $P(X)$ over messages, and the receiver maintained a uniform prior distribution $Q(X) = P(X)$ of the same dimensionality. For each transmission, an entropy threshold of 0.3 bits was used, with $\lambda_S = 4$ and $\lambda_N = 10$.

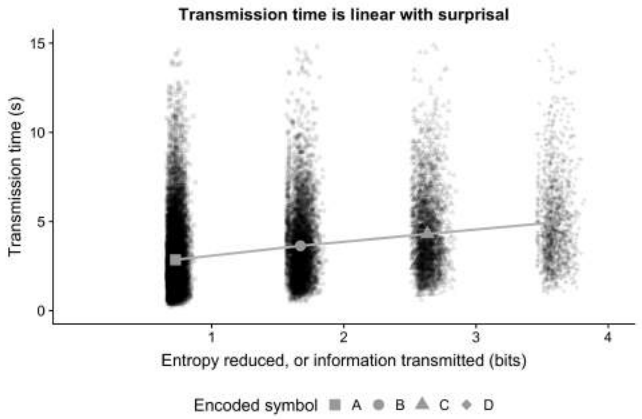

Figure 6: Mean transmission time increases linearly with actual information transmitted, echoing similar findings in humans by Hyman (1953). The quantity of information transmitted is calculated as the the KL-divergence between the prior distribution $Q(X)$ and the posterior distribution $P(X|Y)$ at decision time. Messages were drawn from a non-uniform source distribution $P(X)$. The receiver is assumed to know this source distribution and maintains a prior distribution $Q(X) = P(X)$. For each transmission, an entropy threshold of 0.3 bits was used, with $\lambda_S = 4$ and $\lambda_N = 10$.

$P(X)$, an assumption we relax below) with their posterior distribution $Q(X|Y)$ at decision time. We measured the difference in these distributions using the Kullback–Leibler divergence between the two distributions, $D_{KL}(Q(X|Y)||Q(X))$. The change between the receiver's prior and posterior distributions is equivalent to the decrease in the receiver's subjective uncertainty about which message is being transmitted. From the point of view of the receiver, this is equivalent to the amount of information transmitted, in bits. Figure 6 shows a linear relationship between message surprisal and transmission time, again qualitatively matching Hyman's reported results from human subjects.

Learning to efficiently transmit

As with source-coding systems, expected message transmission times are faster when more frequently transmitted messages are transmitted in less time than less frequently transmitted messages. In the our system, this is implemented by tailoring the receiver's prior distribution Q to match, as closely as possible, the source distribution P. This reveals an epistemic problem from the perspective of the receiver, which has no *a priori* knowledge of the source distribution: the prior must be learned and updated by observing message transmissions. The work of Hick and Hyman has been legitimately criticized for omitting this discussion (Laming, 2010).

Suppose we allow a receiver with an incorrect uniform prior message distribution Q_{init} to update its distribution to Q_{obs} in a Bayesian manner each time a message is received, so that the subsequent message transmission starts with the updated prior. As the receiver observes which messages are transmitted and at what relative frequency, Q_{obs} will become an ever-closer approximation to P, shrinking both $D_{KL}(P||Q_{obs})$ and the expected transmission times. Figure 7 shows message transmission times resulting from a uniform (naive) prior, a prior equal to the true source distribution, and an intermediate distribution, as might be expected to develop from a moderate level of experience with the task. In each case, response time is linearly related to message surprisal as calculated using Q. The slope depends on the amount of experience with the task: as experience accrues and Q_{obs} approaches P, response times more closely reflect the transmission frequencies of each message. The varying slopes are reminiscent of the subject-specific slope found by Hyman (1953).

As observations accumulate, the rate at which response times decrease as Q approaches P mirrors the Power Law of Learning (Newell & Rosenbloom, 1981). The Power Law of Learning is a ubiquitous finding that task response times have a power-law relationship with the number of practice episodes, when averaged across many subjects. We constructed a categorical source distribution P with $k = 16$ categories, but with most of the probability mass in two categories. We initialized Q_{init} to have a Dirichlet prior with concentration parameters 2, representing a weak prior belief that the source distribution is uniform. We simulated N message transmissions, for $N = 2$ to $N = 1024$, taken evenly in log space. For each value of N, we averaged the results across 1,000 simulated observers, resulting in an expected posterior

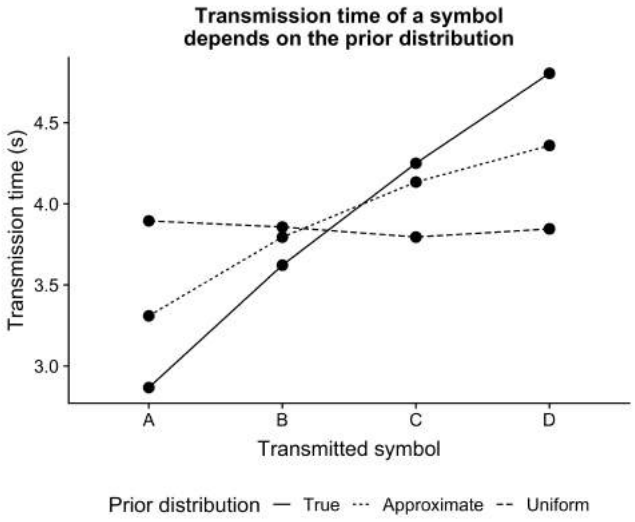

Figure 7: Mean transmission time is a function of the receiver's prior belief $Q(X)$ over messages, rather than the source distribution $P(X)$. In each case, messages were transmitted from the identical source distribution, where A was most frequent, followed by B, and so on. Each line connects response times arising from the same prior distribution. A uniform $Q(X)$ results in a flat line, while a $Q(X) = P(X)$ results in the steepest slope. In each case, the relationship between subjective surprisal and response time is approximately linear. For each transmission, an entropy threshold of 0.3 bits was used, with $\lambda_S = 4$ and $\lambda_N = 10$.

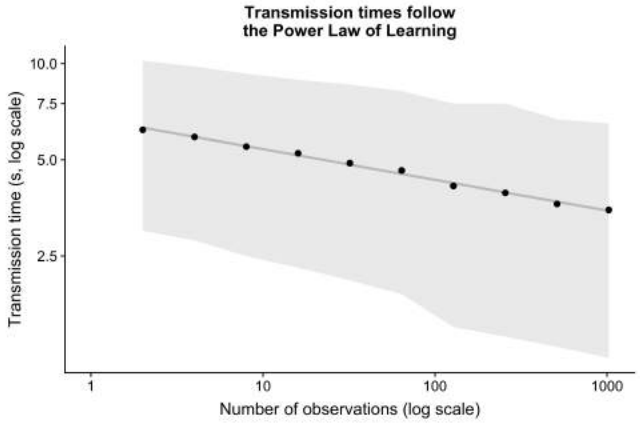

Figure 8: Simulated message transmission time decreases as a function of observations, as the prior Q approaches the source distribution P. Signals are transmitted with signal strength $\lambda_S = 4$, noise power $\lambda_N = 10$, and an entropy threshold of 0.3. Points represent mean transmission times, and the shaded region represents the 80% high-density interval of the response time distributions.

distribution Q_{obs} after N observations. For each Q_{obs} we then simulated more 2,000 message transmissions, with messages drawn with frequency defined by P, and calculated the transmission time for each. As illustrated in Figure 8, the relationship between observations N and transmission time is linear in log-log space, matching the Power Law of Learning.

The energy connection

Implicit in the above discussion is the notion that information transmission costs energy: transmission is initiated when an encoder assigns signal power λ_S to a Poisson process. If each spike costs energy, this implies a rate of energy expenditure. As shown in Figure 4, signal power has a direct effect on the rate of entropy decrease and the resulting transmission times. The framework introduced here allows us to explicitly describe the relationship between energy use (in terms of spikes), task novelty (in the form of naive Q estimates), task practice, and response times. If mental effort is a phenomenological correlate of signal transmission costs, it also provides a normative explanation for effort decrease as a function of practice, and provides weight to the currently tenuous relationship between mental effort and the utilization of metabolic resources.

Indeed, neural spikes are not free: an estimated 10% of an adult body's energy budget is allocated to neural information processing (Stone, 2018). In light of this, we might expect the brain to adopt a strategy of driving energetic efficiency by tailoring codes (represented by codebooks and Q distributions) to individual tasks. As stimulus distributions P are not equivalent between tasks, this would necessitate the creation and maintenance of a bank of task-specific codes, with a power-law response time trend repeated during the practice of each separate task (Newell & Rosenbloom, 1981). However, the power-law describes severely diminishing returns between task practice and transmission efficiency, and tasks in the world are not as discrete as in laboratory experiments. Because of this, in a naturalistic setting we might instead expect the brain to implement some 'universal' code (Cover & Thomas, 2012) that provides moderately efficient transmission across range of tasks (Vera et al., 2018). If this is the case, the brain would sacrifice efficiency to achieve flexibility, which is, after all, a chief characteristic of human cognition.

Conclusion

We have applied the principles of information theory to a simple rate-coding model of neural information transmission. We showed that placing normative bounds on the inference of both source distributions and the content of individual signals results in a coding mechanism that predicts the Hick-Hyman Law and the Power Law of Practice, describes a principled connection between information transmission and energy use, and produces realistic response-time distributions. By utilizing the information-theoretic principles relevant to a continuous-time system (in particular entropy and inference), and avoiding those that are not (block-coding), we have produced a simple and parsimonious explanation of a wide range of phenomena.

The everyday statistics of objects and their names: How word learning gets its start

Elizabeth M. Clerkin (emclerki@indiana.edu)
Linda B. Smith (smith4@indiana.edu)
Department of Psychological and Brain Sciences, Indiana University
1101 E. 10th Street Bloomington, IN 47405

Abstract

A key question in early word learning is how infants learn their first object names despite a natural environment thought to provide messy data for linking object names to their referents. Using head cameras worn by 7 to 11-month-old infants in the home, we document the statistics of visual objects, spoken object names, and their co-occurrence in everyday meal time events. We show that the extremely right skewed frequency distribution of visual objects underlies word-referent co-occurrence statistics that set up a clear signal in the noise upon which infants could capitalize to learn their first object names.

Keywords: word learning; natural statistics; egocentric vision

Introduction

Infants begin learning object names before their first birthday. We know they can do this because infants look to the pictures of an object upon hearing the name (Bergelson & Swingley, 2012). By these measures, individual infants do not know many object names, and their knowledge is fragile. Still, it is clear that the start of learning object names begins well before infants produce words. By consensus, these novice learners must begin learning object names by linking the heard word to visually present objects. The ability to do this has been demonstrated in experimental studies (e.g., Smith & Yu, 2008). The problem is that the everyday visual world is much noisier and cluttered than the learning tasks presented in the laboratory (Clerkin, Hart, Rehg, Yu, & Smith, 2017). Laboratory studies also show that in the period just prior to the first birthday, infants have limited attention skills and quite limited memories for the learned object-word pairings taught in a single laboratory session (Vlach & Johnson, 2013). Accordingly, the field lacks a complete understanding of how object name learning gets its early start.

Learning depends on both the internal learning mechanisms and the data for learning. There are critical gaps in current knowledge about the everyday experiences that comprise the data for early object name learning. We know that parent-naming events are often ambiguous as the visual world is cluttered (Cartmill et al., 2013), parents often do not talk to the child in the home during natural activities (Tamis-LeMonda, Custode, Kuchirko, Escobar, & Lo, 2018), and parents only sometimes name the objects in the child's view during naturalistic play (Yurovsky, Smith, & Yu, 2013). Still, we know little about the statistical structure of everyday experiences across multiple naming events (but see Bergelson & Aslin, 2017 for recent work on this topic). Here we provide evidence-based estimates on three key statistical properties of the learning environment: the frequency distribution of heard object names, of seen visual objects, and their co-occurrence.

Rationale

The frequency distributions of words in parent talk to children are known to be extremely skewed with a small set of extremely frequent words and a much larger set of very rare words (Montag, Jones, & Smith, 2018). A small set of words that are heard pervasively – day in and day out – might define a constrained set upon which object name learning could get its start. Analyses of one large corpus of child-directed talk, however, suggests that the frequency distribution for object names in parent talk is not as skewed as other grammatical classes such that there are less dramatic differences between the most and least frequent object names (Sandhofer, Smith, & Luo, 2000). However, these analyses considered all parent talk – not talk within a particular context. Parent talk, and the words infants hear, are context bound (Montag et al., 2018). The child should be much more likely to hear the words "spoon" and "table" at mealtime than to hear the words "bat" or "ball." Thus, the key question for the role of very high frequency objects names at the start of object name learning may lie in the pervasiveness of a select set of objects names within a context.

There is very little evidence on the frequency distribution of visual objects in the natural environment generally or in infant everyday experiences in which these objects that must be linked to heard names. The evidence that does exist about the natural visual environment – from analyses of large corpora of photographs (Salakhutdinov, Torralba, & Tenenbaum, 2011) and from one analysis of head camera images collected by infants in their home (Clerkin et al., 2017) – suggests that the frequency distribution of object categories will be extremely skewed. The latter evidence further suggests that the very high frequency categories will correspond to the object names that are learned early by infants. Common sense and extant evidence from photography corpora (Sadeghi, McClelland, & Hoffman, 2015) also suggests that visual objects will be context dependent, with spoons and tables more likely in the immediate visual scene at mealtime than bats and balls.

For novice learners to learn object names, heard names must co-occur with referents in their experience. If a few object categories and their names are concurrently pervasive in infant everyday experiences, then there is a clear statistical solution to how object name learning starts – with the learning of the names of those few pervasive objects in infant experiences. Here we provide direct evidence on this possibility and show that the pervasive objects and pervasive

Figure 1. Example (non-consecutive) images from the videos recorded during infant mealtimes.

names in infant language learning environments *do not correspond* well, but that the learning environment offers a different statistical solution to the start of object name learning based on the 1) the skewed distributions of visual objects and 2) the quantity and quality of word-referent co-occurrences.

Method

The Corpus

We chose the mealtime context for three reasons: it is frequent, occurring on average 5 times a day for infants in this age group, the names for objects likely present at mealtimes are among the earliest learned concrete nouns by normative age of acquisition, and it is a potentially challenging context for learning given the sparsity of parent talk (Tamis-LeMonda et al., 2018) – very unlike contrived play contexts in laboratories. These mealtime events were selected from head cameras[1] embedded in hats worn by 14 infants aged 7 to 11 months at home as they went about their daily activities with no experimenters present (see Clerkin et al., 2017; Jayaraman, Fausey, & Smith, 2015 for details). Parents were not told specific activities to record and were told to record any and all activities during the times their infants were awake over a period of several days.

Figure 1 shows example images extracted from the video. Critically, the video collected from the head cameras is from the infants' ego-centric view. Thus, we have captured the visual environment directly in front of the infants' faces and the objects in it to which infants could be attending in any given moment. This ego-centric perspective is highly dependent on the infants' motor abilities, their interests, and their location and posture in any given moment. In sum, not only are we studying the natural word learning context at scale, but we are doing so with reference to the infants' own point of view.

Any video that included eating or meal preparation was included in the mealtime corpus which totaled 16.99 hours of footage and consisted of 344 mealtime events with 24.57 per subject on average (SD = 20.02).

Coding

Visual Objects Still images were down-sampled from the video recordings at a rate of 0.2hz (1 image every 5 seconds). The 11,549 down-sampled images were then coded by naïve adult coders for the 5 most obvious objects in the scene using basic level nouns; (see Clerkin et al., 2017 for more details). Each image was coded by 4 coders. These adult judgements of objects that are in view do not necessarily align with what the target infant's visual attention in the moment; however, we use these adult judgements as a way of describing the clutter of the natural environment from which infants are presumably visually sampling.

We chose to keep the coders' responses as intact as possible to avoid biasing the data; however, we did clean the data in the following ways. First, extraneous adjectives were removed (e.g., "baby spoon" was reduced to "spoon"); however, if an adjective-word combination was listed in the dictionary (e.g., "high chair"), it remained as a unique object. Also, different forms of the same object name were collapsed (e.g., "cup" and "cups" were both counted as instances of "cup"). Finally, words that were overly general (e.g., "food") or clearly did not refer to a concrete object (e.g., "color") were removed entirely. The frequencies of visual object categories are reported as the proportion of frames in which the object category occurred.

Object Names All speech in the target infants' environment was transcribed for each mealtime using Datatyvu (Datavyu Team, 2014). The audio data was broken down into 5 second intervals for ease of coding and to have an appropriate comparison to the visual data coded at 1 image every 5 seconds. It should be noted that infants this age do not talk, and thus none of the transcribed speech is the target infants' own vocalizations. Naming events (defined as any moment an object name was said) were extracted from the speech stream for object names that referred to objects which were reported as occurring at least once in the visual scenes. The speech transcripts were cleaned as described above for visual objects. The frequencies of object names are reported as the number of naming instances for each name across the corpus

[1] The Looxcie 2 weighs 22 grams and has a 75° diagonal field of view.

as a proportion of the number of 5 second intervals containing any speech.

Age of Acquisition Categories In order to understand how the statistics of the natural learning environment relate to learning first words, objects were broken down into two age of acquisition (AoA) categories. Objects in the First category were those named by nouns on the MacArthur Bates Communicative Developmental Inventory – MCDI (Fenson et al., 2007) and are present in the receptive vocabulary of 50% of 18-month-old children in the Wordbank repository of thousands of MCDI administrations (Frank, Braginsky, Yurovsky, & Marchman, 2016). Later objects were all other objects given by the coders.

Co-Occurrence Co-occurrence was coded by three trained raters in the laboratory. Each naming instance was located in the video, and if during the 5 second interval surrounding the naming instance an object which could be called by that name was visually present, then the coder recorded there was a co-occurrence. Approximately 20% of the naming instances were coded by all 3 coders. The final judgment for those instances was the response recorded by at least 2 of the 3 coders. The overall percentage agreement between the coders was 76.2%, but there were no naming instances on which at least 2 coders did not agree. Co-occurrence is reported as the proportion of naming instances during which a corresponding object was visually present.

Table 1: Summary of data coded.

	Num Frames	Num Speech Intervals
Total	11549	12237
With Talk	–	6833
Without Talk	–	5404

Table 2: Object and object name counts

	Num Unique Objects	Num Unique Object Names
Total	1095	350
First	118	97
Later	977	253

Results

Table 1 provides the number of fames coded for visual object and the total number of 5 second speech intervals, the number containing any speech, and the number containing no speech. Table 2 provides the number of unique visual objects and unique object names. As is apparent, there are many more objects than object names, showing considerable selectivity in parent talk relative to the wide variety of objects in view.

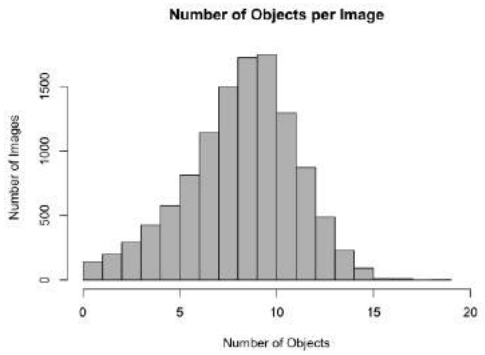

Figure 2. The frequency distribution of the number of objects per image across the corpus.

We consider the statistical regularities characterizing the visual objects, then the object names, and finally, their co-occurrence.

Visual Objects

The number of objects coded in each scene is an indication of the clutter present in the natural visual environment. Because 4 coders named a maximum of 5 objects each per image, the number of possible objects recorded as visually present in a scene ranged from 1 to 20. Figure 2 shows the frequency distribution of the number of objects per image. On average, images contained 8.63 objects (median = 9), which supports the long-held idea that the visual world is cluttered and that for most naming events there are multiple possible referents that a novice learner could consider.

In total, coders recorded 1,095 unique objects with a total of 97,407 object instances. Only 351 of these visual objects also occurred as object names in speech, and the reported analyses focus on these 351 objects that occurred in both modalities[2]. There were 72,446 total object instances for this smaller set. Figure 3a shows the proportion of images in which each object category appeared plotted against its rank frequency. As in Clerkin et al. (2017), visual objects occur in these natural scenes with a right skewed frequency distribution[3]. A small number of objects were pervasively present and a large number of objects occurred rarely with the 20 most frequent object categories (see table 3) accounting for 65.47% of all object tokens and the 37 most frequent object categories (that is, 10.5% of the 351 objects) accounting for 80.18% of all object tokens (see Figure 4).

Further, the AoA category of an object name is significantly related to the frequency of its corresponding visual object in the corpus. 97 of the visual objects reported by coders (that also appeared in the speech modality) were First objects and 253 were Later objects. Mann-Whitney-Wilcoxon tests were used to compare the frequencies of objects in these categories due to the non-normality of the

[2] All analyses follow the same statistics pattern when all 1,095 visual objects are analyzed.

[3] The distribution is referred to as right-skewed based on a histogram of the frequency distribution in which the placement of the most frequent objects is reversed on the x-axis as compared to Figure 3. We find the rank order plots better visualizations for our purposes.

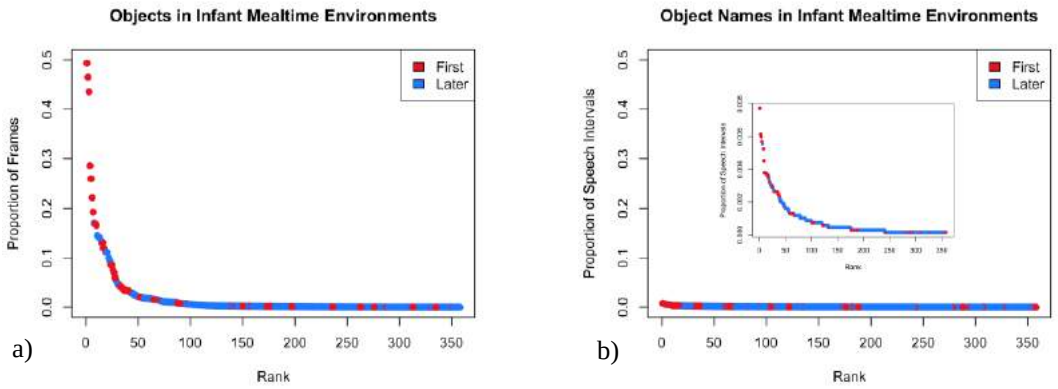

Figure 3. a) The proportion of images in which each visual object category appeared against its rank. b) The number of naming events for each object name as a proportion of the number of 5 second intervals containing any speech. Inset is the same information plotted with a smaller y axis.

data. Objects named by words in the First category (mean = 4.50%; Mdn = 0.55% of images) were significantly more frequent than objects named by Later words (mean = 0.75%; Mdn = 0.10% of images), U = 17609.5, $p < 0.0001$[4]. 11 of the 15 most frequent objects belonged to the First category. In sum, infants' visual experience during mealtime is dominated by a small set of objects named by very early learned words. These results suggest that day-in and day-out experience with these visual objects may be important for learning their names.

Object Names

Talk overall was extremely sparse in these mealtime scenes. Any speech, not just speech including object names, only occurred in 55.83% of the total video time (see table 1).

Table 1: Top visual objects, object names, and their AoAs.

Object names in speech occurred even more rarely; 117 mealtime events contained some speech but none of the target object names. The overall lack of talk and object names appears quite ordinary and typical when watching and listening to content these natural videos. These infants do not yet talk themselves, and the speech stream thus often contains terms of endearment and comments directed to the baby, talk between adults, and periods of silence as the parents and their infants go about their daily lives.

Nonetheless, 351 unique object names were said during mealtime activities across 1,941 naming events. It should be noted that only a small number of object names were said – about a third of those possible based on the list of visual objects. Figure 3b shows the number of naming instances as a proportion of the 5 second intervals containing any talk for each object name plotted against its rank frequency. Though the distribution of object talk is not uniform, it does not follow the pattern of extreme skewness as does the objects or might be predicted by the statistics of natural language more generally. The 40 most frequent object categories accounted for only 48.79% of all object name tokens, and the 123 most frequent object names (that is, 35.04% of all object names) were required to account for 80.06% of all object names tokens. Though object names do not appear equally frequently, there is not a clear set of object names that dominate talk about objects in this natural mealtime context. Note in Figure 4 the difference in the shapes of the curves for the proportions of unique visual objects and object names that account for all tokens.

A large proportion (97 out of 118) of the First words whose visual objects appeared in the images occurred in the auditory domain as well. Proportionally fewer of the possible Later objects had names that were said during mealtime; only 253 of the 977 Later object names were spoken in the corpus. As with the visual objects, object name frequency is significantly related to AoA. Object names from the First category (mean

[4] All reported p-values have been corrected for multiple comparisons using the Holm correction.

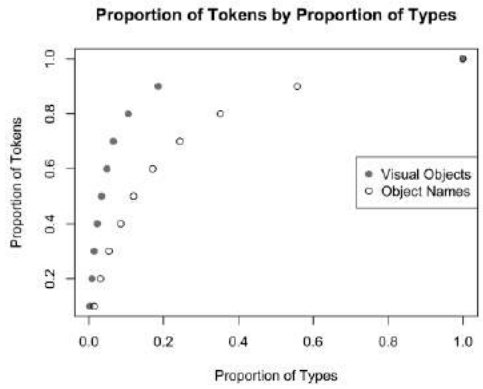

Figure 4. The proportion of types accounting for the proportion of tokens at intervals of 0.1.

= 0.14%; Mdn = 0.07% of speech intervals) were spoken more frequently than object names from the Later category (mean = 0.06%; Mdn = 0.03% of speech intervals), U = 16765.5, $p < 0.0001$. 12 of the 15 most frequent object names belonged to the First category. This, unsurprisingly, supports the idea that hearing objects names is important for learning them.

Correspondence and Co-occurrence

If the objects present most frequently in the visual environment were those whose corresponding names occur frequently in the environment, it would seem that the problem of breaking into learning first object names is solved. However, while there is a highly significant positive relationship between visual frequency and spoken frequency for object-name pairs, the relationship is very weak[5], τ_B = 0.17, $p < 0.0001$. As a demonstration, the 40 most frequent objects and the 40 most frequent object names only have 11

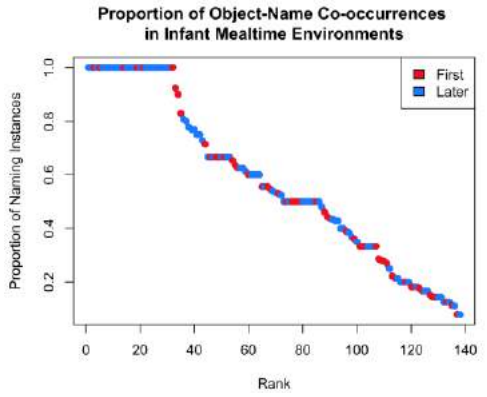

Figure 5. The proportion of naming instances in which a corresponding object was visually present. Only object-name pairs which ever co-occurred are shown.

items in common, and only 1 object name appears in the top 10 for frequency in both modalities. In sum, the pervasive visual objects are not named by words that are especially frequent in this context.

The number of co-occurrences between objects and their names even by our generous measure was very low. 213 of the 351 object-name pairs never occurred in the same 5 second interval. For the 138 that co-occurred at least once, the maximum number of co-occurrences was 34 (mean = 4.43; Mdn = 2). Because raw co-occurrence is so rare and the timescales of visual objects and spoken words are so different, we turned co-occurrence, reported here as the proportion of naming instances in which a corresponding object was visually present.

Figure 5 shows the co-occurrence proportion by rank order for the 138 object-name pairs that ever co-occurred. For co-occurrence, we do not find a right skewed frequency distribution but rather one that is bimodal. Further, co-occurrence proportion shows a statistical relationship with AoA that is opposite to those found for visual objects and object names individually. The co-occurrence proportion of the Later category (mean = 60.55%, Mdn = 62.95%) was significantly higher than that of the First category (mean = 48.83%, Mdn = 50%), U = 1662, $p < 0.01$. In fact, 26 Later objects co-occurred with their corresponding names 100% of the time whereas only 6 First objects did so. This result on its face seems surprising because there is a strong theoretical and empirical basis for the idea that co-occurrence is key to learning object-name mappings.

However, when the frequency of object names in the corpus are considered, it becomes clear why co-occurrence proportion was related to AoA in this direction. Co-occurrence proportion is in fact negatively correlated with word frequency, $\tau_B = -0.41$, $p < 0.0001$. This means that for many object names which were said perhaps only once, the corresponding visual objects were likely to be present during that naming instance. It makes sense that objects that are unusual in the context would be more likely to be present in the moment when those objects' names are said. For example, "fire extinguisher" (which is logically an unusual item for the mealtime context) was named once and the object was present, giving it a co-occurrence proportion of 1. This result suggests that it is important to consider not only the quantity of the co-occurrences (frequency) but also the quality of co-occurrence between object-names pairs (co-occurrence proportion) as it is unclear how much very young infants could learn from a single co-occurrence.

Quantity and Quality: Strength

To assess the quantity and quality of the co-occurrence of object-name pairs, we created a new compound measure of co-occurrence strength which was the proportion of naming instances during which the visual object was present - multiplied by the number of mealtime events in which both

[5] Kendall's rank correlation used instead of Pearson's product moment correlation due to the non-normality of the data.

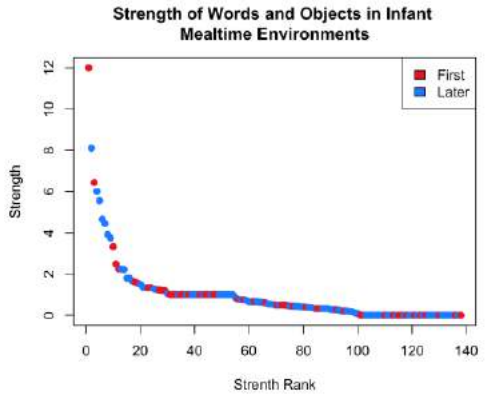

Figure 6. The strength of the co-occurrence of the object-word pair against its rank. Only object-name pairs which ever co-occurred are shown.

the visual object and the object name ever occurred. This measure allows us to approximate the potential learnability of an object-name pair.

Figure 6 shows the strength of the object-name pairing plotted against rank strength. Here we see again the skewed distribution with a small number of object-name pairings with relatively high strength values and a large number of object-name pairings with low strength values. We also again find a significant difference between strength of First object-name pairs (mean = 1.69, Mdn = 1) and Later object-name pairs (mean = 0.51, Mdn = 0.35), U = 3203, $p < 0.0001$. 13 of the 15 highest strength values belong to object-naming pairing for the First AoA category. This result suggests that the quality and quantity of co-occurrences between object-name pairs may be important for infants breaking into object name learning. Critically, the strength of the co-occurrence is underlain by the skewed frequency of visual objects.

Discussion

The results taken together do not support the hypothesis that many may have theorized: object names that occur frequently have pervasive referents, and these word-referent pairs occur frequently and simultaneously, thus providing a simple statistical solution for how infants can learn their first object names. Instead, the evidence of the present study suggests a different solution underlain by the pervasiveness of a few object categories in the visual environment. Object names that refer to visually pervasive objects may be said relatively rarely, but because the objects are visually pervasive, whenever the object name is said, the object is likely in the infants' view. The extremely skewed frequency distribution of objects in view in the mealtime context thus makes each naming event for those objects count – as demonstrated by our measure of co-occurrence strength.

Studies of the word-learning environment for children have typically focused on the frequency and diversity of the words (Hart, 1991; Montag et al., 2018). However, investigations of the natural environment including the visual domain are taking off with the advent of small, wearable cameras. Another recent at-home study which also examined the frequency of objects and their names in the natural environment found that the overall proportion of object-name co-presence predicts 6-month-olds' performance in an in-laboratory word comprehension task (Bergelson & Aslin, 2017). This result supports the idea that the statistical structure of the learning environment is directly related to word learning. Our results further suggest that the visual side of the learning problem specifically may be critical to the start of object name learning because it sets up the opportunities for learning moments.

The frequency distribution of visual objects during a particular context (mealtime in the present case) partitions potential referents into two potential classes for young learners –those that are typically present in this context and those that are not; classes that will be different for each context. Those that are persistently present provide a *selective* visual foundation to linking the objects to their referents.

The foundation for the *early* learning of object names may be contexts – such as mealtime, dressing, getting into the car – that occur day-in and day-out and are characterized by the same object categories repeatedly and pervasively present. These routines may bias the linking of even sparse naming events to those visually pervasive objects. Contexts that repeat in this way, along with the statistical structure of visual objects in those contexts, may be a critical contributing factor for early learning. This idea is consistent with the evidence on the value of repeatedly reading infants their favorite pictures books in supporting word learning (Horst, Parsons, & Bryan, 2011). For older children, the diversity of words in the learning environment may matter most for vocabulary development (Montag et al., 2018), but for the earliest learners, consistency of the visual content of repeated contexts may be the key.

In sum, the co-occurrence statistics of object names and their referents in the contexts comprising the early natural learning environment, as underlain by the extremely right skewed frequency distribution of visual objects, set up a clear signal in the noise which infants may use to learn their first object names.

Frequency Effects in Decision-Making are Predicted by Dirichlet Probability Distribution Models

Astin Cornwall, Hilary Don, & Darrell Worthy
Texas A&M University, Texas, USA

Abstract

Frequency of reward and average reward value are two types of reward information we utilize when making decisions between two alternative options. Often, these two pieces of information coincide with the highest value option, however, when a slightly less valuable option is presented more frequently, standard reinforcement learning models such as the Delta model can make incorrect predictions. This paper explores the discrepancy in these predictions by way of simulating relevant behavioral tasks with the Delta model, the Decay model, and a novel Bayesian model based on the Dirichlet distribution. We then compare model predictions to behavioral data from some of the same tasks that were simulated. The Delta model provides a poor fit to the data for each of the three presented tasks when compared to the Decay model and the two Bayesian learning models, because it predicts a bias toward options with higher average reward, while the Decay and Bayesian models predict a bias toward reward frequency. The Decay and Bayesian models show a distinct similarity in prediction and fits to the data for most of the tasks. This is because both models predict a bias toward reward frequency rather than average reward magnitude, despite different computational formalisms. However, we also note some interesting discrepancies between the Decay and Bayesian models which will show that in some cases, the frequency of reward may be more important than the reward value.

Keywords: Frequency Effect; Reinforcement Learning; Bayesian Learning

Introduction

A wide variety of decisions we make on a day-to-day basis are repetitive in the sense that we may choose one option over another fairly consistently. Whether these decisions are about choosing name-brand over store-brand items, restaurant A or B, or taking the freeway versus the side roads to work, it's possible that all of these decisions are computed by common algorithmic mechanisms. These decisions could be based on the average outcome of each option, for example, taking the freeway to work is nearly always faster than taking the side roads. However, supposing that a new bypass opens that is predicted to greatly reduce travel time, a person may still be inclined to choose the freeway since they have had many more experiences with the freeway being adequate enough.

Learning rules in formal models of cognition allow us to make sense of human decision-making processes and get a glimpse as to why people make the decisions they do in situations such as the examples above. In this paper, we compare the choice predictions of four learning models: the Delta rule, the Decay rule, and two Dirichlet distribution-based models, on a set of decision-making tasks.

The Delta rule, in particular, is a widely used learning rule across many domains of cognition. This model predicts that people will have a preference for options that have the greatest expected value, based on representations of the *average* reward for each option, amongst alternative options (e.g. Busemeyer & Stout, 2002; Daw et al., 2006; Gluck & Bower, 1988; Jacobs, 1988; Rescorla & Wagner, 1972; Rumelhart & McClelland, 1986; Sutton & Barto, 1981; 1998; Widrow & Hoff, 1960; Williams, 1992).

In contrast to the Delta rule's average value representations, the Decay rule learns to represent the *cumulative* value of each option based on the frequency with which it has been rewarded. Psychologically, the Decay model assumes that that decision outcomes are stored in working memory and decay over time. The Decay model utilizes a decay parameter which diminishes the expected value of each option at each timepoint. Therefore, the option with the greatest expected value in this model would be the option which is most frequently rewarded; in most cases (Erev & Roth, 1998; Yechiam & Busemeyer, 2005; Yechiam & Ert, 2007).

In a departure from these two standard learning models, this paper presents a Bayesian model which simply learns how many times each option has a positive outcome rather than learning expected values. The Dirichlet Probability Distribution (DPD) model holds in memory a representation of how many times each option has produced a reward, regardless of value. Each of these values are used as the concentration parameter values in the distribution which allocates more probability mass to the options which have been rewarded most frequently. Thus, when attempting to choose between options, the option more frequently rewarded will have a higher probability of being chosen.

The sole use of the Dirichlet distribution as the base for this model may seem atypical considering it is more often used in Bayesian data analysis for determining the clustering, or categorization, of data (e.g. Griffiths, Sanborn, Canini, & Navarro, 2008), or in Dirichlet Process or Mixture models (Navarro, Griffiths, Steyvers & Lee, 2006; Gershman & Blei, 2012; Sims, Neth, Jacobs, & Gray, 2013), or as the prior for

another Bayesian model. However, choice outcomes and options map nicely onto the Dirichlet distribution concentration parameter and categories respectively. Simply, the categories are effectively predetermined by the number of choices and the probability mass for each category is distributed as a function of the number of rewarding observations.

As an attempt to design a Bayesian analog to the Decay model, the DPD model was extended to include a decay parameter. The Dirichlet Probability Distribution Decay (DPD-Decay) model decays the memory representations of the total number of rewarded outcomes at each timepoint. Critically, this means that additional uncertainty is introduced into the probability distribution. As the memory of rewarded outcomes for each option tends towards 0, all options would have an equiprobable chance of being selected.

While Bayesian models have been criticized in prior research for being simple vote-counting models (Jones & Love, 2011), it's possible that, if each rewarding event is considered a vote, the DPD model will predict similar behavior as the Decay model. This could allow the DPD model to predict a bias toward frequency of reward rather than average reward magnitude, and recent work suggests that reward frequency exerts a larger effect on behavior than average reward magnitude (Worthy, Otto, Cornwall, Don & Davis, 2018). Thus, DPD models with sparse priors may represent a cognitive process of predicting the probability of a rewarding event, based solely on reward frequency. Our goal in the present work is to verify these predictions and examine the degree to which they are consistent with human behavior.

Difference Between Models

The key difference between the Delta model and the reward frequency models (Decay and Dirichlet) is in how each type of model utilizes reward information to make predictions about future choices. The Delta model uses average reward information whereas the Decay and Dirichlet models utilize the frequency of rewards to formulate a cumulative representation of reward. This is important as, per Estes (1976), probability judgements about the choices are heavily influenced by the frequency that each option produces a reward, rather than the average reward value. As such, it would be expected that the when rewarding options are shown in disproportionate frequencies, the predictions of the Delta model and the Decay and Dirichlet models will diverge. It would be expected that tasks which consist of rewards of varying frequency and value would show differences in each models' predictions.

To ascertain the general predictions of each model, and determine the differences therein, three tasks which have previously examined the effect of reward frequency and value were selected to be simulated using each model. To verify the predictions made by each model and task combination, each of the models were fit to human data collected from each of the three tasks.

Experimental Tasks

Iowa Gambling Task. The Iowa Gambling Task (IGT; Bechara, Damasio, Damasio, & Anderson, 1994) allows four options to be chosen from, each with their own reward schedule over the course of 100 total trials. The reward schedule for the IGT can be found in Table 1 below. Traditionally, the task consists of two options which result in a net loss of points, and two options which results in a net gain. Options A and B offer participants larger rewards on gain trials, but also larger losses on loss trials resulting in an overall net loss for both options. In contrast, Options C and D give smaller rewards and losses resulting in an overall net gain for these two options. Within each 10-choice block for each option, the frequency of gains differs between options. Options A and C show infrequent gains relative to Options B and D which are more consistent. Strictly looking at the net positive options, Options C and D should be the favored decks. However, as Bechara et al. observed, there is a preference for choosing Options A and B which have a higher frequency of larger rewards, but results in a net loss of points.

	A		B		C		D

Table 1: Reward schedules for both the IGT and SGT by Option Letter. This reward schedule is repeated over the total 100 trials.

Soochow Gambling Task. The Soochow Gambling Task (SGT; Chiu et al., 2008) is a task similar in procedure to the IGT aside from a change in the reward schedule of each option. The reward schedule for each option in the SGT can be found in Table 1 below. Similar to the IGT, over the course of 100 trials, participants are able to select one of four options. Options C and D are still the options with an overall net reward gain, and likewise with Options A and B having a net reward loss. Both Options A and B offer participants consistent gains of 200 or 100 points, respectively, followed by a large loss which results in a net loss for both options. Inversely, Options C and D show consistent losses followed by a large gain resulting in a net gain. The gains and losses shown in Options A and B are exactly opposite in terms of sign. Where A and B show consistent rewards followed by a large loss. Importantly, the best options according to overall gain are also the options with the most consistent losses.

Similar to the IGT, there is a large preference for Options A and B indicating that frequency of rewards, despite losses, is a good predictor of choice preference(Byrne & Worthy, 2016).

Binary Choice Task. This task, as presented by Worthy et al. (2018), assesses the effect of reward frequency in a different manner. The task consists of four options, A, B, C, and D, where each have a respective probability of giving a reward of .65, .35, .75, .25. The possible rewards for this task were binary in that the reward totals were either 1 or 0. The task pairs Options A and B, and Options C and D, together and presents them randomly interspersed during training. Importantly, there are 100 AB trials and 50 CD trials which creates a situation where frequency of reward and average reward are in opposition if it is learned that Option A and C are the most rewarding within the respective pairs. The task then consists of 25 transfer trials for each of the remaining pairs of A, B, C, and D and bars further reward feedback. Worthy et al. observed that human participants were more likely to prefer Option A over C on AC pairing trials indicating that despite having a smaller average reward, option A is preferred over option C because of more frequent, and therefore higher cumulative reward.

Method

Model Formalisms

The Delta and Decay rule used in this paper are identical to those described in Worthy et al. (2018). Reward (*r*) and the expected value (*EV*) is calculated for each *j* option on each *t* trial. The Delta rule is described in Equation 1 as:

$$EV_{j,t+1} = EV_{j,t} + \alpha \cdot (r_t - EV_{j,t}) \cdot I_j \quad (1)$$

Where I_j is a variable which indicates option choice via a value of 1 if *j* option is chosen on trial t, and 0 otherwise. This formulation ensures that only the expected value for the chosen option is updated, and the other options, whether seen or not, are not updated. Alpha (α) is denoted as a learning rate parameter where $\alpha \in (0,1)$. For the Delta model in particular, α modifies the $(r_t - EV_{j,t})$ prediction error by giving greater weight to more recent outcomes with higher α values, and lower α values giving less weight to recent outcomes and producing little change in the expected value on each trial.

Similarly, the Decay model tracks changes in expected value, but instead of updating the expected value by way of a prediction error the raw reward value is used. However, this does not mean that expected value consistently increases for each chosen option. On each trial, each *j* option will be modified by a decay parameter (*A*; $A \in (0,1)$) regardless of whether the *j* option was seen or chosen. Critically, this means that the expected value for each option will decay over time and only increase when a reward for that option is received. Thus, the more frequent the reward, the greater the expected value. The formula for computing the change in expected is described below in Equation 2:

$$EV_{j,t+1} = EV_{j,t} \cdot A + r_t \cdot I_j \quad (2)$$

As mentioned above, the DPD model focuses solely on the number of times each *j* option is rewarded (*r*) and uses that information to update a Dirichlet probability distribution. Simply, a Dirichlet distribution takes *k*, the total number of *j* options, and their respective number of rewarded trials (γ_j) and produces a probability density (x_j) for each *j* option where $x_j \in (0,1)\ and\ \sum_{j=1}^{k} x_j = 1$. In other words, the updating of the distribution occurs in two steps as described in Equations 3 and 4:

$$\gamma_{j,t+1} = \gamma_{j,t} + r_t \cdot I_j \quad (3)$$

$$f(x_{1,t+1} \ldots x_{k,t+1} | \gamma_{1,t+1} \ldots \gamma_{k,t+1}) = \frac{1}{B(\gamma)} \prod_{j=1}^{k} x_{j,t}{}^{\gamma_{j,t}-1} \quad (4)$$

$$\text{where } B(\gamma) = \frac{\prod_{j=1}^{k} \Gamma(\gamma_j)}{\Gamma(\sum_{j=1}^{k} \gamma_j)}$$

On each *t* trial, the reward value for one option is added to the chosen option which will distribute slightly more probability density to the chosen option. To determine choice with this model, a random sample is taken from the Dirichlet distribution which results in a simplex, or a vector of probabilities which sum to 1. Critically, this implies that as one option is rewarded more frequently, the probability value sampled from the distribution will tend to be of greater value, and thus the option is more likely to be chosen. Taking a single sample, rather than integrating over the posterior, was a decision made with the assumption that this would better reflect human performance as the beliefs surrounding each option is uncertain. As more information is learned about an individual option, the belief about the positive outcomes of that option will become more certain, and thus the probability of choosing that outcome will be more consistent.

An extension of the DPD model presented above, the DPD-Decay model includes the decay parameter (*A*) which decays the total number of rewarded trials (γ_j) for each option on each trial similar to how the Decay model functions. By decaying the rewarded trial values, the model increases the amount of uncertainty and allows a greater range of possible values to be randomly sampled. This also implies that the more frequently an option is seen the more likely it is to overcome the consistent decay, such that it is granted more probability density over time. Expressly, the decay parameter in this equation will weigh the model for or against more recent outcomes. In Equation 5, $\gamma_{j,t+1}$ is computed for every *j* option and are subsequently inserted into Equation 4.

$$\gamma_{j,t+1} = \gamma_{j,t} \cdot A + r_t \cdot I_j \quad (5)$$

For the Delta and Decay models, the predicted probability that any given option *j* is chosen *C* on a particular trial *t*, P($C_{j,t}$), is calculated by way of a Softmax choice function shown in Equation 6 below:

$$P\left|C_{j,t}\right| = \frac{e^{\beta \cdot EV_{j,t}}}{\sum_{1}^{N(j)} e^{\beta \cdot EV_{j,t}}} \quad (6)$$

Like the Yechiam & Ert (2007) Softmax application used in Worthy et al. (2018), $\beta = 3^c - 1; c \in (0,5)$, where c is an inverse temperature parameter which dictates how often the option with the higher expected value is chosen. When c approaches 0, choices are more random. Inversely, choices are weighted more heavily towards the options with the

highest expected value as c approaches 1. Simply, this choice function determines the probability of choice by computing the proportion of the scaled chosen option divided by the sum of the scaled choice and alternative choices.

Simulation and Behavioral Methods

For each task, 10000 simulated participant datasets were created with randomized model parameters of α, A, and c, for applicable models, for each participant. Each of these parameters were drawn from a uniform distribution: $U(0,1)$ for learning and decay rates, and $U(0,5)$ for the inverse temperature parameter. These parameters were kept consistent across models within each simulation, but each model ran independently in regard to the choices made and corresponding output. The output for each of these simulations was the probability of choosing each outcome, the expected value of each option, and the choices made on each trial.

For each task, human behavioral data was collected from an undergraduate population with sample sizes of ~50 for each task. Each participant completed the experiment in a Psychtoolbox 2.54 environment on a Windows computer running Matlab. The general procedures used in the simulations were identical to the computerized version of the tasks that participants completed, however graphical and counterbalancing considerations were needed for real participants that are detailed below for each experiment.

In both the IGT and SGT, the options were displayed onscreen as a deck of cards, each with their own random color. The onscreen location of each individual deck was displayed from left to right in a random arrangement of Options A-D for each participant. Upon selecting a deck, the participant would be shown the card being overturned and the amount of reward. Additionally, participants were given a set amount of points in an onscreen bank that would increase or decrease depending on the outcome.

For the Binary Choice Task, each of the four options were randomly assigned a fractal image randomly drawn from a pool of 12 images. Like the IGT and SGT, the order of the 4 selected images were randomly arranged on screen from left to right. However, Options AB and CD were always together as a pair, but the order of each pair varied for each participant. As an example, some potential orderings of the option could include: ABCD, CDAB, BACD, etc. Each selection of an option showed the option turning over to reveal the outcome of that trial. Importantly, and consistent with the simulations, reward feedback only occurred during the initial 150-trial training phase, but the transfer phase, participants were only shown a gray outline around the option they chose instead of the point value they would have seen on the training trials.

Results

Simulation Output

For the IGT and SGT, the simulation metric that will be reported is the overall performance on the task as computed by subtracting the sum of the net loss options from the sum of the net gain options: (A+B)-(C+D). For both the IGT and SGT, the performance of each model, and the actual participant data for comparison, is plotted over all 100 trials in Figures 1 and 2. In the IGT the Delta model was more likely to choose the net gain options over the more frequently rewarding net loss options. The Decay model also showed a preference for the net gain options overall. Both the DPD and DPD-Decay models showed no preference for either the net gain or loss options, but this behavior also seems to be reflected, albeit slightly, by the actual participant data which rapidly varies in preference for either the net gain or loss options over time.

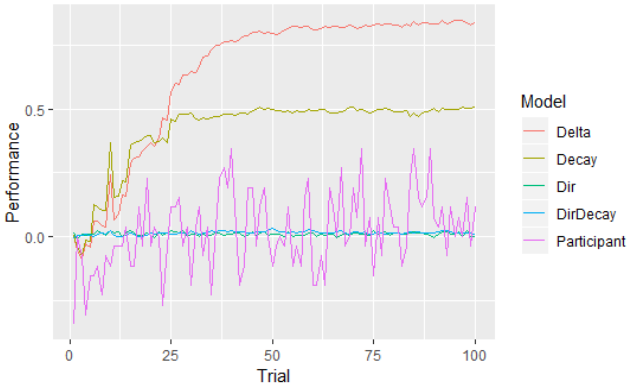

Figure 1: Average performance on the IGT by model and actual participant data.

In the SGT, the Delta model again showed a preference for the net gain options, but the Decay model now shows behavior that greatly reflects the behavior shown by actual participants. Both the human and simulated Decay model datasets showed an initial preference for the net loss options, but over time began to tend towards the net gain options which is consistent with prior research as previously discussed. The DPD and DPD-Decay model again showed similar results, but in the SGT, they show a large preference for the more frequently rewarding net loss options.

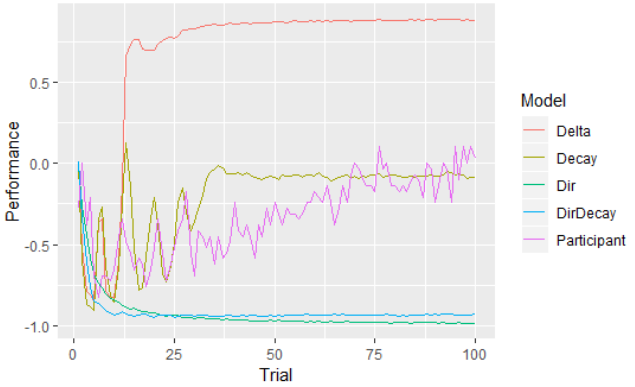

Figure 2: Average performance on the SGT by model and actual participant data.

For the Binary Choice Task, as shown in Figure 3A-B, each model was able to learn that there is a more rewarding option in each option pair. However, the rate at which the most rewarding, or best, option was identified and overall

preference for the best option differed between models. The Delta model showed the greatest preference for the best options out of the four models, followed by the DPD, Decay, and DPD-Decay. When solely learning which option has the largest average reward, it is no surprise that the Delta model outperforms the other three models. However, when looking at the choice predictions for the remaining option pairs, as shown in Figure 3C, a difference between the models emerge. The Delta model predicts more C choices, whereas the Decay, DPD, and DPD-Decay models all predict more A choices. The remaining option pairs showed relatively similar predictions since there was not as big of a discrepancy between an options' expected value and number of observations. The large peaks in the DPD model are indicative of the frequency of outcome observations for each pair. The more outcomes observed, the more likely the model will choose the same option.

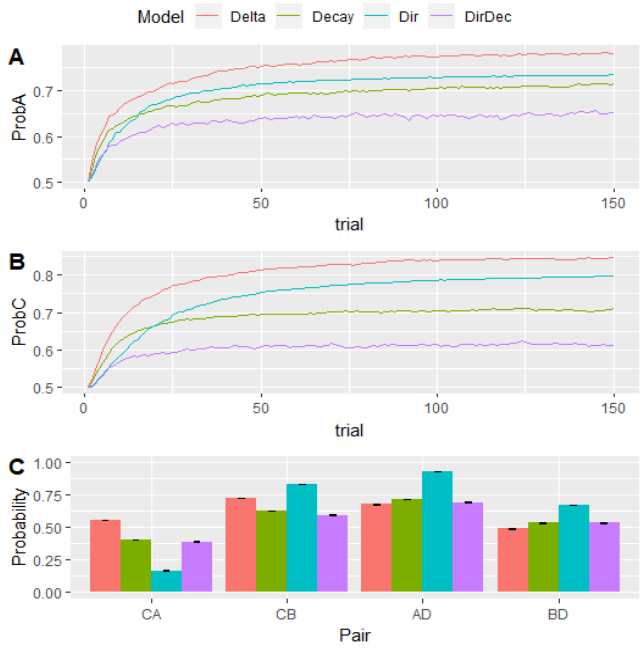

Figure 3: A and B show the probability of choosing the best option, either Option A or C respectively, over the course of 150 trials. C shows the predicted probability of choosing the best options if the simulated participant were to see the remaining pairings of options.

Behavioral Fits and Comparisons

Participants were independently recruited for one of the three tasks from an undergraduate sample. Each participant was reimbursed for their time with partial completion of course credit. For each task we recruited comparable sample sizes: 52 participants for the IGT; 58 participants for the SGT; 50 participants for the Binary Choice Task.

Each of the models were directly fit to the behavioral data by maximizing the likelihood of each model via the 'optim' function with a 'L-BFGS-B' method in R. The decay and inverse temperature parameters were included as free parameters for the respective models. The Delta and Decay models utilized two free parameters while the DPD-Decay model used only the decay parameter. No free parameters were used in the DPD model for the IGT and SGT. When fitting the Binary Choice Task data alone however, the DPD and DPD-Decay model included an inverse temperature parameter. In this task, for both models, the probability simplex was drawn from the Dirichlet distribution, as previously discussed, but the values relevant to the two observed options were used in the softmax function to compute a choice probability for each option which summed to 1.

A Bayesian Information Criterion (BIC; Schwarz, 1978) value was computed for each individual participant within each model and used to calculate the average BIC and subsequent BIC differences between each model. BIC was calculated by calculating the deviance of the model and adding additional error based on the number of free parameters k and number of trials t: $-2ln(L) + (k \cdot ln(t))$. Lower BIC values indicate a better fit to the behavioral data. As per Wagenmakers (2007), the BIC difference between the models can additionally be used to calculate a Bayes Factor which would show evidence for one model over another: $BF_{10,Model1}=exp((BIC_{model2}-BIC_{model1})/2)$.

Table 2 below details the BIC values of each model for each task along with the best fitting parameters for each model. For the IGT and Binary Choice Task, the Decay model shows an advantage over the other models. For the IGT, the next best fitting model was the DPD with a BIC of 268.9 which is shown to be significantly different from the Decay model with a Bayes Factor (BF) of 3.33. BFs with values greater than 3, or less than 1/3, are believed to have adequate evidence to reject the null hypothesis that the models are equal. The Decay model in the SGT was the next best fitting model behind the DPD-Decay model with BIC values of 269.8 and 267.8 respectively. This difference, with a BF of 2.7416, shows that both models are similar in their fits of the SGT data. In the Binary Choice Task, the Decay model BIC (279.7) is closely followed by both the DPD and DPD-Decay models; 282.8 and 280.5 respectively. The difference between the Decay and DPD model is significant with a BF of 5.1984, but there is not enough evidence to say that the Decay and DPD-Decay models are different, BF = 1.5115.

Table 2: Average Model Values

		Best a or A	Best c	BIC
IGT	Delta	.1009	.3756	278.0677
	Decay	**.6857**	**.00538**	**266.4658**
	DPD	N/A	N/A	268.8740
	DPD-D	.0218	N/A	273.8372
SGT	Delta	.4613	.3564	274.4863
	Decay	.5268	.0019	269.7714
	DPD	N/A	N/A	282.9299
	DPD-D	**.1454**	**N/A**	**267.7543**
Binary	Delta	0.3821	1.5120	296.2498
	Decay	**0.1765**	**0.4978**	**279.7178**
	DPD	N/A	1.3088	282.8315
	DPD-D	0.8770	1.5673	280.5440

It was also of interest to determine the proportion of participants whose data were best fit by each model. To do this, each non-redundant combination of models for each task was examined to figure how many participants' data were best fit by each model. Table 3 presents the proportion value for each model combination by task. The first model listed in the pair is the reference model. Values shown in bold represent that the reference model was the best fitting model of the pair.

As expected from the data in Table 2 for the IGT, the Decay and DPD model best fit the largest proportions of participants, and the DPD model showed the best fit overall. For the SGT, despite showing a large average BIC value, the Delta model showed a better fit slightly more participants than the Decay model, but not the DPD-Decay model. Additionally, the Decay model, rather than the DPD-Decay model, was the best fitting model for most participants. In the Binary Choice Task, the DPD models better fit more participants than the Decay model which showed the better fit on average. The DPD model showed the overall highest proportion best fit on this task as well.

Table 3: Proportion Best Fit

By Model	**IGT**	**SGT**	**Binary**
Delta<Decay	.44	**.54**	.38
Delta<DPD	.06	**.54**	.30
Delta<DPD-D	.44	.48	.38

DPD-D	.07	.19	.14

Discussion

The simulations and experiment presented in this paper examined the influence of reward frequency and probability on choices made in a decision-making task. Four models were compared that made both convergent and divergent predictions about which option was more valuable in three tasks which examine the effect of reward frequency. As similarly described by Worthy et al. (2018), there were divergent simulation predictions between the Delta rule and the reward frequency models where the Delta rule more often chose the options with the higher value rewards, whereas the reward frequency models, the Decay, DPD, and DPD-Decay, tended to choose the options which resulted in the most frequent rewards. The data from the experimental tasks showed that human participants more often chose the more frequent options in most cases. This behavior is in support of the predictions of all three of the reward frequency models. This is shown in which models where the best fitting model on average. For all three tasks, the best fitting model was a model which attended more towards the frequency of reward rather than the average value of reward. However, there also seems to be some individual differences in people who attend more towards average reward value instead of the frequency of reward. This can best be seen when looking at the SGT and Binary Choice Task. For both of these tasks, there was a sizable subset of participants who were best fit by the Delta model than the other three models.

There also exists some important differences in the reward frequency models despite their similarities. One of which is between the DPD and DPD-Decay models and the Decay model. When looking at Figure 1, the performance values for the DPD and DPD-Decay model are fairly constant about 0. This is most likely due to how the Dirichlet models compute reward. These models do not consider reward value, only the observation of a reward. Looking back to the reward schedules for the IGT, one net gain and one net loss option have fairly frequent rewards. With how the performance calculation considers the number of choices, and how the Dirichlet models determine choice by the number of observed rewards, you can begin to see how the number of net gain and loss choices would be about equal, and thus result in a performance of ~0. This can also be seen in the simulation of the SGT as well in Figure 2. The two Dirichlet models show an overwhelming preference for the net loss options. Again, looking at the reward schedule, the net loss options are the only options that have a frequent occurrence of reward as the net gain decks only give a reward every 5 successive picks. These two Dirichlet models may aid in making sense of the "Deck B" phenomenon in the SGT where people tend to choose the net loss options since the reward most frequently. However, the average fit for the DPD model was quite large. Which suggests that pure frequency of reward is not entirely predictive of choice on the SGT. With the DPD-Decay model showing the best average fit, this suggest that the frequency of reward is predictive, but that the overall representation of the total number of rewarded outcomes decays over time.

For the DPD model in particular, another difference be seen in Figure3C with the large peaks in the option pair predictions relative to the other models. Like detailed for the IGT and SGT, these peaks can be explained by looking at the rate of reward and frequency of observing the option pair. For these option pairs the best option is the one that is either the most frequently seen and/or rewarded. Thus, the model would be more likely to choose these options.

However, this also ties in to the major conclusion of this paper, that despite not utilizing any reward information, these Dirichlet models are able to fit human behavioral data on three tasks relatively well solely using a count of rewarding outcomes. Generally, choice selection may depend on reward value when all other factors are equal, but if rate of reward changes or if there is knowledge of number of previously rewarding outcomes, frequency of reward may take precedence over reward value. Though, like shown by the proportion of best fitting models, there may be a subset of people who focus on the overall reward value regardless of the frequency of the outcomes.

Differences in learnability of pantomime versus artificial sign: Iconicity, cultural evolution, and linguistic structure

Abstract

One of the central goals of language evolution research is to explain how systematic structure emerges. A cultural evolutionary approach proposes that the systematic structure of language arises from the use and transmission of language. Motamedi and colleagues (2016) investigated the influences of these forces on the evolution of language by generating an artificial sign language in the lab. Over several generations of new learners and their interactions, an initially unsystematic set of silent gestures developed markers for functional categories of person, location, object, and action. Here we describe results of two studies that compared the learnability of solo-produced pantomimes versus signals that had been transmitted and used by interlocutors. In these studies, participants saw an artificial sign and judged whether an English translation matched or mismatched the meaning of the sign. In an event-related potential (ERP) study, we found that mismatches elicited larger negativities in the ERP than matches. However, those effects were most reminiscent of the classic N400 response in the evolved signs. This study provides a clearer view on how the mechanisms that drive language evolution change language to adapt to a learner's brain.

Keywords: artificial language learning; gesture comprehension; iterated learning

Introduction

All languages demonstrate systematic structure. From the smallest units of sound, to words and phrases, the elements of language are not independent. These elements are part of a structured system that allows infinite expressive power through the reuse and recombination of those elements. Systematicity is a property found across the world's languages, but how does this systematic structure of language emerge?

One answer to this question appeals to the forces of cultural evolution. Languages, like species, change over time and are subject to similar evolutionary processes found in biological evolution, such as variation, selection, and inheritance. In this view, language is under selectional pressures from human cognitive biases and adapted to suit the human brain (Christiansen & Chater, 2008). The nature of linguistic structure would then be a product of the learning and processing constraints that derive from underlying neural mechanisms.

One avenue for investigating the emergence of linguistic structure is to examine natural languages in the early stages of linguistic development. Although most communities have long-established languages, emerging sign languages such as Nicaraguan Sign Language (NSL) provide us with the opportunity to observe how linguistic features arise in a new human communication system. In the 1970s, the Nicaraguan government established a school for deaf children. These children, who communicated with their families via idiosyncratic systems of home sign, were brought together and organically created a novel sign language (Kegl, 1994).

In the case of NSL, each incoming cohort to the school has shaped the language and furthered its development (Goldin-Meadow et al., 2014). One example of the emergence and development of grammatical structure in NSL can be found in the use of spatial modulation to mark semantic roles in sentences expressing events with both an agent and a patient. Senghas (2003) found that signers from the earliest generation did not use the direction of spatial modulation in their interpretation of such sentences, whereas signers from the next generation made systematic use of spatial location to determine who the patient of the event was. The properties and structure of NSL thus changed as a function of transmission to learners of the next generation, as well as its use between signers who had already acquired the rules of the grammar.

Recent laboratory studies of artificial languages likewise suggest that the cultural evolutionary mechanisms of transmission and interaction play pivotal roles in the emergence of language and its change over time (Kirby, Cornish & Smith, 2008; Kirby, Griffiths, & Smith, 2014;

Tamariz, Cornish, Roberts, & Kirby, 2012). Motamedi and colleagues (2016) investigate the impact of interaction and transmission on the evolution of language by generating an artificial sign language in the lab.

In their study, participants in an initial "seed" generation were asked to innovate gestures for concepts that vary across six themes and four functional dimensions. These concepts were selected to share salient semantic features across a thematic category (Figure 1). Signs from the initial seed generation demonstrate high iconicity, use a lot of space, require a lot effort, are redundant, and use similar salient features of the theme (e.g. handshape that represents scissors cutting). Moreover, the seed generation signs do not contain features to distinguish across functional categories within a theme.

Functional Dimension

Thematic Dimension	Person	Location	Object	Action
Food	chef	restaurant	frying pan	to cook
Church	priest	church	bible	to preach
Photography	photographer	dark room	camera	to take a photo
Concert	singer	concert hall	microphone	to sing
Hair	hairdresser	hair salon	scissors	to give a haircut
Police	police officer	prison	handcuffs	to make an arrest

Figure 1: Chart of the 24 concepts from Motamedi et al. (2016)

In an iterated language learning paradigm, new sets of participants came into the lab and were trained on the gestures produced by the seed generation, and played a communication game using those gestures. The signs produced by one of these participants in a dyad was then passed on to two new participants as the training set. The process was repeated for five generations in a transmission chain. This design was intended to create pressure for participants to develop a way to communicate the different dimensions of category structure. Concepts from within a thematic category were similar such that a pantomime of each might be difficult to distinguish across the functional categories.

Motamedi and colleagues (2016) show that under the pressures of communication and transmission, highly iconic and lengthy manual signals signs change to become more efficient and less iconic. After several generations of interaction, the authors also found the recycling of gestures within a theme. Most impressively, Motamedi and colleagues (2016) found the emergence and retention of functional markers that make it possible to distinguish between concepts within a theme. For example, in one dyad, signers pointed at themselves to indicate that the subsequent gesture depicted a person.

Despite their iconic origins, many of the functional markers are not transparent to new learners, and must be learned as arbitrary constructs. In one artificial sign system, for example, the marker for action involved the raising of the right hand with the palm facing out. The emergence of functional markers after several generations of learners in this study is used as a proxy of the emergence of systematicity in linguistic structure.

The Present Study

Here, we examine whether the communicative advantages of the final generation signs outweigh the benefit of the iconicity in the signs from the seed generation. Accordingly, we present videos of gestures from Motamedi et al. (2016) in a word learning task in which we compare participants' ability to learn the meanings of the iconic seed generation signs versus those of the more language-like final generation signs. We are interested in the processing and learning of language-like artificial signs, thus we applied methods typically used to study processing of natural languages.

In our study, participants viewed signals from the artificial sign language followed by English words that either match or mismatch the signal's meaning. We focus on two different ways in which the word presented can mismatch the meaning of the sign. A Thematic Mismatch is a violation of the thematic category, (e.g. present the sign for hairdresser, then display the word "chef" on the screen), whereas a Functional Mismatch is a violation of the functional category (e.g. present the sign for hairdresser, followed by the word "scissors").

In manipulating the generation that the sign comes from, we are able to see if there are differences between learning improvised pantomimes versus the signs evolved in the lab. We expect that identifying a mismatch in the thematic violation cases would not be difficult for either seed signs and evolved signs, as all signs displayed some degree of iconicity, and were readily distinguishable between thematic categories, (e.g. food versus photography). However, we expect that identifying a functional violation would be more difficult because signs within a theme share many iconic features associated with their thematic category, and may not provide features that would allow a learner to distinguish between the four potential meanings.

In Experiment 1, we measured response times and accuracies in a behavioural artificial language learning task. In Experiment 2, participants complete the same task as in Experiment 1, while we measure event-related potentials (ERP) time-locked to the onset of the English translation of the sign. We are particularly interested in the N400, ERP component known to index difficulty associated with meaning processing or retrieval from semantic memory, and is produced reliably across a range of stimuli (Kutas & Federmeier, 2011). Even within 14 hours of instruction, second language learners show larger N400 responses to pseudowords compared to real words that were semantically related or unrelated to primes, indicating that limited exposure is sufficient for new language learners to gain sensitivity to lexical status and word meaning (Mclaughlin, Osterhout, & Kim, 2004). ERP studies allow for real-time

indexing of brain activity and provide multidimensional data about stages of processing. Thus, the N400 component is an appropriate dependent measure to more precisely examine the learning of an artificial language, in such a way that is comparable to studies investigating the processing of natural language.

Experiment 1

In Experiment 1, we taught participants signs from the Motamedi et al. (2016) in an explicit language learning paradigm. We used a within-subjects design in which each participant learned 12 signs from the seed generation and 12 signs from the final generation. In this behavioural experiment, we measured accuracy and reaction time in making judgements about whether the sign and word presented on the screen matched. We predict that accuracy will be greater for final generation signs after participants have learned the mappings, and reaction times will decrease as participants learn the system. We also expect lower accuracy rates and slower response times for Functional Mismatches.

Methods

Participants

We recruited 38 healthy undergraduates (15 M, 23 F). All gave informed consent and received course credit for participating. English was the primary language of all participants. One participant was excluded for not completing the experiment.

Materials and Procedure

Each trial began with a fixation cross for 500ms, followed by the video that varied from 2 - 7 seconds depending on signal length. A word then appeared until a key press was made, with feedback displayed on the screen for 500ms until the next fixation cross. We used two different stimulus lists varied across participants so that each concept was conveyed once with a seed gesture, and once with a final gesture. Participants watched videos of signs from either the seed generation or final generation. After each video was played, a word was displayed on the screen. The word either matched or did not match the meaning of the previously shown sign. When the word was displayed on the screen, participants pressed a key to indicate whether or not the word matched the sign. Participants received immediate feedback after every response they made. Feedback was given by the words "correct" or "incorrect" presented on the screen, and an accompanying tone. The experiment comprised 4 blocks of 48 trials each.

Figure 2: Example of a single trial.

Results and Discussion

Accuracy

A mixed effects logistic regression model was used to analyze the accuracy rate data. Models were constructed with the *lme4* package in R (R Core Team, 2013; Bates et al., 2015). Analysis involved construction of a generalized linear model to predict accuracy with experimental Block (First, Second, Third, Fourth), Generation (Seed, Final), and Condition (Match, Thematic Mismatch, Functional Mismatch) as categorical predictors, and all interactions. Models were fit with random intercepts for participants and for items (i.e. the videos that were played). Mean accuracy rates in each experimental category are shown in Figure 3. Model estimates are listed in Table 1. Analysis suggests accuracy rates improved as the blocks progressed. Experimental condition also impacted performance as accuracy rates were highest for Thematic Mismatches, lower for Functional Mismatches, with intermediate performance on the matches. The interactions between Condition and Block result because the learning curve was steeper for the more difficult Functional mismatches than the Thematic mismatches.

Participants' performance show that Functional Mismatches are more difficult to judge as being mismatches. The signs within a thematic category share many of the same features with respect to handshape and movement, such that differentiating between signs within a theme is ambiguous. Initially, participants perform worse in trials with final generation signs, which suggests that the markers contained in these signs are not transparent to new learners. There appears to be more arbitrariness to the form of a marker, i.e. an open hand facing palm forward denoting an action would not be considered an obvious association. However, after several trials participants quickly learn to map the marker to action verbs, as demonstrated by the increase in accuracy by the second block.

Table 1: Mixed effects logistic regression for accuracy rates.

	Estimates	t-value
Mismatch Type:		
Functional	-0.251	-8.94
Thematic	0.186	6.86
Generation	0.0134	0.600
Block	0.0520	9.10
Functional:Block	0.0554	5.51
Thematic:Block	0.0456	-4.51

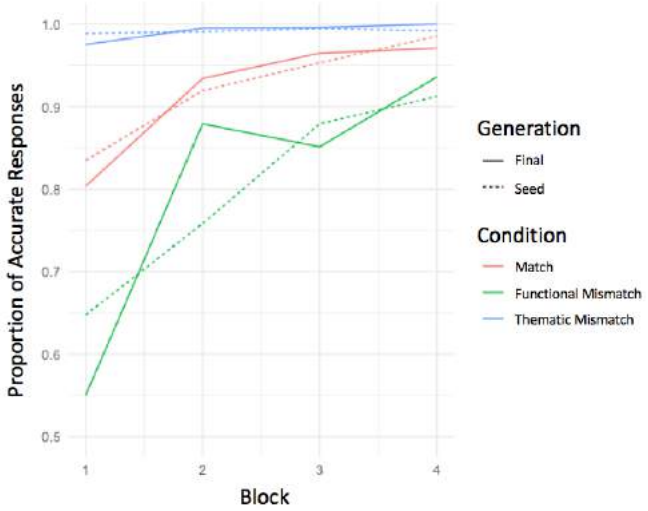

Figure 3: Accuracy rates between generation and condition across blocks.

Response Latency

To predict response latencies, we fit a linear mixed effects model in R (R Core Team, 2013) using the *lmer()* function of the *lme4* package (Bates et al., 2013). Predictor variables again included sign Generation (Seed, Final), Condition (Match, Thematic Mismatch, Functional Mismatch), and experimental Block (First, Second, Third, Fourth) and all interactions. Random intercepts were included for participants and item videos. Mean response latencies from each experimental category are shown in Figure 4 with model estimates listed in Table 2. Analysis revealed an interaction between Condition and Block, due to reaction times decreasing over the course of experimental blocks. Mismatch type also impacted performance as response latencies were consistently fastest for Thematic Mismatches, slower for Functional Mismatches, with intermediate performance for the Matches. Functional Mismatches also displayed the slowest average response latency across blocks, especially in the case of judging signals from the seed generation.

The results show that most of the learning of the mappings between sign and concept occurs during the first block of the experiment, as demonstrated by the slope of the response latencies from Block 1 to Block 2. As expected, participants respond faster to Thematic Mismatches since mismatches are easier to detect when the gestures produced clearly relate to different themes. Responding to seed signals is slower overall, which suggests that more processing occurs in deciding whether the signal matches the word presented. Seed signs are characterized as being longer in length, repetitive, pantomime-like, and lacking in defining features that would differentiate them from similar concepts. Between Blocks 3 and 4, there is a decrease in reaction time for decisions about final generation signals, suggesting that participants have mastered the meaning of the functional markers.

Table 2: Linear mixed effects model for response latency.

	Estimates	t-value
Condition	-0.573	-7.57
Generation	-0.573	0.726
Block	-0.208	-10.4
Condition:Block	0.132	4.91

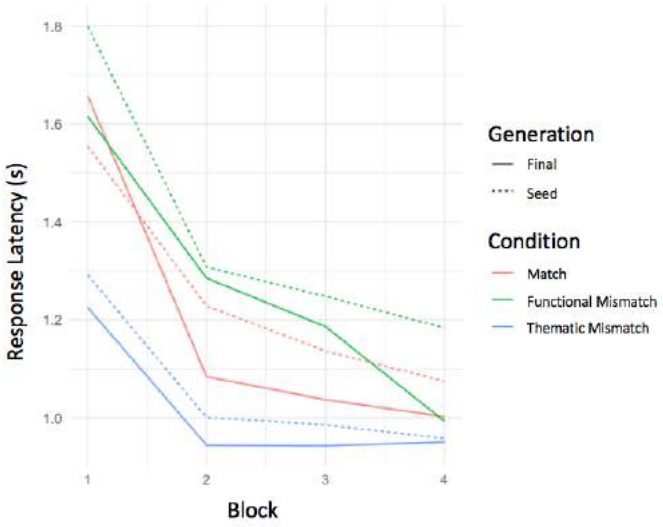

Figure 4: Mean response latencies between generation and mismatch type across experimental blocks.

Experiment 2

In Experiment 2, we measured neural responses in an artificial language learning paradigm. If the participant has learned the sign, we would expect mismatches to elicit a larger N400 response than matches. If final generation signs are indeed more learnable than those from the seed generation, we might expect to see larger amplitude N400 effects on words following the final generation signs than those following words from the seed generation.

Methods

Participants

We recruited 34 healthy undergraduates at UCSD (12 M, 22 F). All gave informed consent and received course credit for participating. English was the primary language of all participants. Two participants were excluded, one for excessive sneezing and sniffling, and one who was unable to complete the experiment within the allotted two hours. Participants completed surveys on handedness, neurological damage, and medication.

Materials and Procedure

Materials and procedure were adapted from the behavioural study outlined in Experiment 1.

EEG Data Collection

EEG was collected from 29 scalp sites using an ElectroCap mounted with electrodes. Scalp electrodes were referenced to the left mastoid. Blinks were monitored from an electrode below the right eye and referenced to the left mastoid. Horizontal eye movements were monitored via two electrodes placed beside each eye. Electrical impedance was reduced to less than 5 kohms. EEG was recorded and amplified using SA instrument bioelectric amplifier. The EEG was digitized at a sampling rate of 512 Hz. Recording took place in a dimly lit, sound-attenuated, electrically-shielded chamber. Participants were seated in front of a CRT monitor for stimulus presentation.

Results and Discussion

ERPs were time locked to the onset of potential meanings (viz. English words) presented after each signal. Mean amplitude was measured relative to a 100ms pre-stimulus baseline in two time windows: 300-500ms post-onset, intended to capture the N400 component, and 500-700ms post-onset, intended to capture the P600. In each interval, analysis involved repeated measures ANOVA with factors Condition (Match, Thematic Mismatch, Functional Mismatch), Generation (Seed, Final), Block (First, Second, Third, and Fourth), and two factors intended to capture the location of electrodes across the scalp, Hemisphere (Left, Right), and Region (Frontal, Frontocentral, Central, Centroparietal, Parietal, Occipital). Where relevant, the Greenhouse Geisser correction has been applied to p-values; however, for clarity, we report the original degrees of freedom.

Omnibus analyses revealed (among other effects) the presence of significant complex interactions with Block in both intervals (*N400:* Condition x Generation x Block x Hemisphere $F(6, 186) = 3.36$, $p < 0.05$; *P600:* Condition x Generation x Block $F(6, 186) = 2.76$, $p < 0.05$, Condition x Generation x Block x Hemisphere $F(6, 186) = 2.5$, $p < 0.05$), motivating separate follow-on analyses within each block.

N400 Analysis of ERPs in the first block revealed a main effect of Condition ($F(2, 62) = 8.2$, $p<0.05$), but no interaction with Generation ($F(2,62) = 1.03$, n.s.). By contrast, analysis of the second block suggested condition effects differed for signs from the seed versus the final generation (Condition, $F(2,62) = 18.4$ $p<0.001$; Generation, $F(1,31) = 4.2$, $p<0.01$; Condition x Generation, $F(2,62) = 3.26$, $p<0.05$; Condition x Generation x Hemisphere, $F(2, 62) = 7.8$, $p<0.01$). In the third block, Condition effects were present ($F(2,62) = 14.3$, $p<0.001$, but were similar for seed and final generation signals (Condition x Generation, $F(2,62) = 1.2$, n.s.). In the final block, Condition effects ($F(2,62) = 7.3$, $p<0.01$) displayed a different topographic profile following seed versus final generation signs (Condition x Generation x Region, $F(10,310) = 3.48$, $p<0.01$).

Figure 5 shows the topography of ERPs in the N400 interval for each type of mismatch following seed (upper panel) and final (lower panel) generation signs. Whereas the seed generation mismatches display a right frontal maximum reminiscent of ERPs to imageable words (see, e.g., Swaab, Baynes, & Knight, 2002), the topography of the final generation mismatches resembles the classic N400 that results from associative priming (e.g., Steinhauer, et al., 2017).

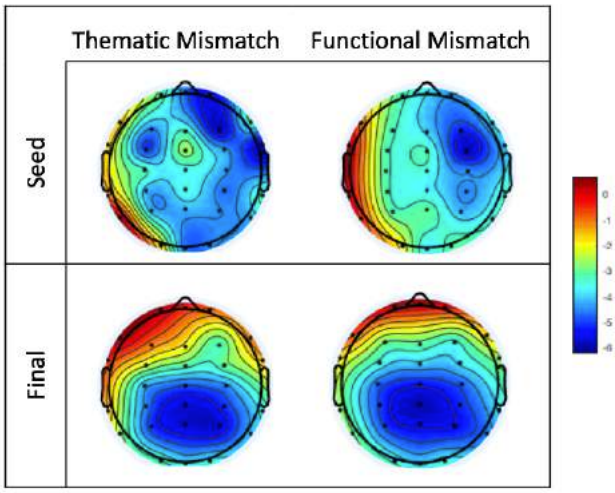

Figure 5: Difference in amplitude for latency between 300-500ms.

P600 Among other effects, follow up analyses revealed the presence of complex interactions between Condition, Generation, and topographic factors in blocks 1, 2, and 4 (*Block 1:* Condition x Generation, $F(2 ,62) = 4.55$, $p<0.01$; *Block 2:* Condition x Generation, $F(2,62) = 4.27$, $p<0.05$, Condition x Generation x Hemisphere, $F(2,62) = 7.23$, $p<0.001$; *Block 3:* Condition x Generation x Region $F(10,310) = 1.99$, n.s.; *Block 4:* Condition x Generation x Region, $F(10,310) = 6.96$, $p<0.001$). Figure 6 shows the topography of mismatch effects (match – mismatch) 500-700ms following seed and final generation gestures.

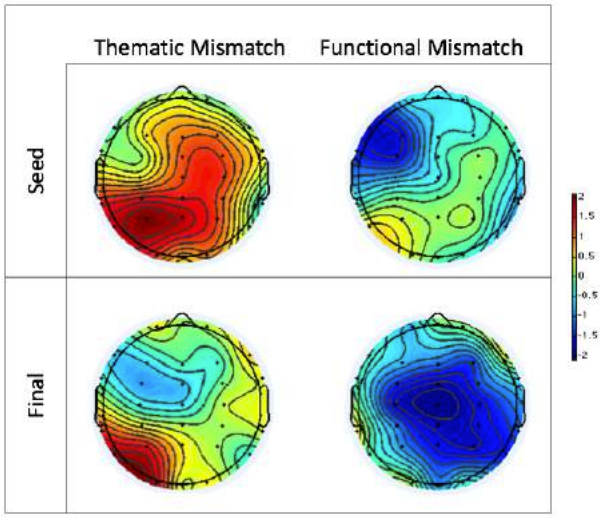

Figure 6: Difference in amplitude for each condition compared to the matches in the 500-700ms window

Figure 7 shows ERPs recorded at Pz, a parietal site where N400 and P600 are typically prominent. In the first half of the study, the N400 dominates the ERP response to these words, with more clear differentiation between the three conditions being evident in the seed generation signs. In the latter half of the study, N400 effects are overlapped by late positivities related to the task of classifying the word as a match or a mismatch. Following both seed and final generation signs, matches elicit a positivity that peaks earlier than the thematic mismatches (viz., seeing "chef" after the sign for hairdresser). For functional mismatches (viz., seeing "hair salon" after the sign for hairdresser), however, ERPs in the seed generation are more similar to the matches, whereas functional mismatches in the final generation are more similar to the thematic mismatches.

General Discussion

Here, we examined the ways in which a culturally-evolved artificial language may be advantageous to learn, in comparison to a system of individually iconic communication signals that lack internal systematicity. We found that signs from the more evolved system included both a consistent and concise iconic gesture to indicate thematic category, and a gesture that indicates whether the concept is a person, place, object, or action. Although the behavioral study suggested participants readily learned both the evolved final generation signs and the less systematic seed ones, the real-time brain response revealed processing differences for the two kinds of signs.

Our ERP study revealed a classic N400 response to signs from the final generation, indicative of semantic processing. By contrast, the iconic seed generation signs elicited concreteness effects that suggested participants exploited a learning strategy that involved mental imagery. Moreover, the brain response to final generation signs suggested participants could distinguish between closely related concepts such as hairdresser and scissors, whereas such concepts were treated identically in the seed generation.

Previous studies have also found that when used in a referential or communicative game, signs representing concepts from a set of shared semantic relations become more arbitrary, schematized, and systematized across dimensions (Theisen, Oberlander, & Kirby, 2010). We see that the introduction of a system of schematized signs influences how the meaning signs are retrieved from memory via ERPs to violations in signal-meaning pairings.

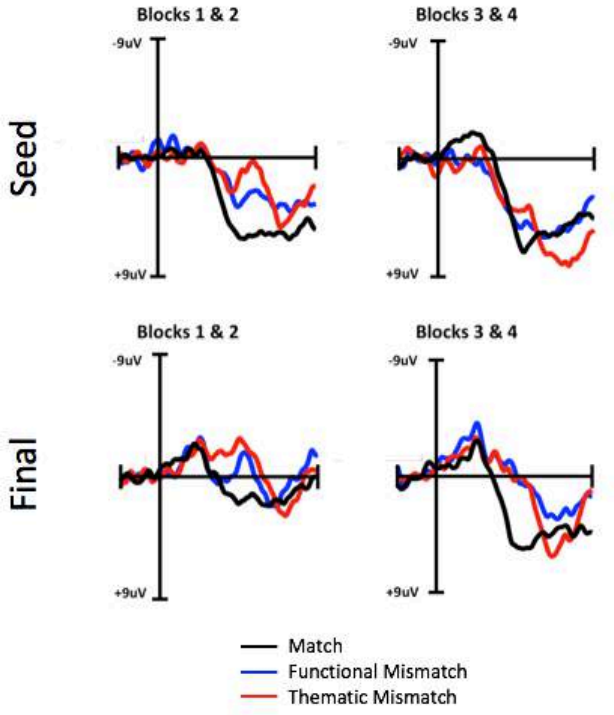

Figure 7: ERP waveforms recorded at electrode site Pz.

A recent study by Nölle and colleagues (2018) demonstrated how individuals use context and the environment to shape the signals they use together. The authors found that interlocutors were more likely to produce systematically-related signals rather than signals that refer to some idiosyncratic feature of the referent, even when both strategies were afforded by the environment. In the present study, we found that the brain's real time response displayed a greater sensitivity to subtle distinctions within a thematic domain for meanings conveyed by final generation signs that contained the functional markers. Systematic signs are easier to remember and rely more on abstraction to identify like features that can be referred to similarly.

Our current design adapts videos generated in a previous study as stimuli. This choice may introduce confounds relating to processing and working memory, as all seed generation signs were longer than the final generation signs. The seed signs are highly iconic pantomimes of actions associated with the theme, thereby resulting in longer signals that lack specificity. Consequently, the differences we found between learning seed and final signs might reflect differences in length of seed versus final generation signs, differences in the degree of structure, or some combination. Future research should seek to unconfound these factors.

Results of the present study support that artificial language shaped by interaction and transmission is more learnable. As such, it is in keeping with research that reports differences in the brain response in learners of another culturally-evolved artificial language (Verhoef, Walker, Marghetis, & Coulson, 2018). Signs evolved through interaction and transmission

display systematic structure, and this systematic structure better suits the learner's brain.

Abstract

Do people adjust their conversational strategies to the specific contextual demands of a given situation? Prior studies have yielded conflicting results, making it unclear how strategies vary with demands. We combine insights from qualitative and quantitative approaches in a within-participant experimental design involving two different contexts: spontaneously occurring conversations (SOC) and task-oriented conversations (TOC). We systematically assess backchanneling, other-initiated repair and linguistic alignment. We find that SOC exhibit a higher number of backchannels, a reduced and more generic repair format and higher rates of lexical and syntactic alignment. TOC are characterized by a high number of specific repairs and a lower rate of lexical and syntactic alignment. However, when alignment occurs, more linguistic forms are aligned. The findings show that conversational strategies adapt to contextual demands.

Keywords: conversational dynamics; common ground; interactive alignment; backchannels; repair

Introduction

How do we continuously update mutual knowledge and coordinate behaviors in conversations? The issue has been defined as grounding: a constant evaluation of whether we share mutual beliefs, knowledge, and understanding sufficient for the purpose of the situation. (Clark & Brennan, 1991). A diverse set of disciplines have approached this issue, from psycholinguistics to conversation analysis, highlighting several conversational strategies for coordinating interactions. Interlocutors might ensure common ground by subtly confirming their understanding (*backchanneling*), more explicitly signaling misunderstanding and correcting each other (*conversational other-repair*), or by re-using each other's linguistic forms (*linguistic alignment*). Even if such conversational strategies are often viewed as ubiquitous in interaction, one might expect them to vary considerably across individuals, and more importantly across different types of contexts. Conversations involve a plurality of linguistic and social games, from exchanging specific information to maintaining a social reputation; from coordinating decisions to ensuring a comfortable emotional environment (Fay et al., 2018; Fusaroli, Rączaszek-Leonardi, & Tylén, 2014; Fusaroli & Tylén, 2016). Thus, different contexts of conversation might afford different grounding strategies. For instance, conversations between pilots and airport control towers require a higher need of referential precision, and therefore more strict monitoring of the common ground (Prinzo & Britton, 1993). On the contrary, small talk and dinner conversations are arguably more focused on building and maintaining social relations, possibly not necessitating the same need for detailed and continuously monitored referential precision. Indeed in more casual chats people have been observed to not always realize that they are talking about different things, or even that they shift partners mid-conversation in an instant messaging system (Dunbar, Marriott, & Duncan, 1997; Galantucci & Roberts, 2014). Thus, different conversational contexts may require different dimensions and degrees of coordination.

Understanding how the joint use of multiple conversational strategies adapts to the activity at hand is crucial. Cognitive science, management, and other disciplines are increasingly focusing on how to promote effective team coordination and the conversational patterns underlying it (Fusaroli & Tylén, 2016; Pentland, 2012; Wiltshire, Butner, & Fiore, 2018). Clinical research is investigating how social impairment develops and unfolds across a wide spectrum of neuropsychiatric conditions, and atypical conversational strategies are likely to play a role in impaired social

functioning (Bolis, Balsters, Wenderoth, Becchio, & Schilbach, 2017; Lavelle, Healey, & McCabe, 2014; McCabe & Healey, 2018; Wadge, Brewer, Bird, Toni, & Stolk, 2018). Further, effective human-computer and human-robot interactions also require a detailed understanding of when and how grounding happens (Loth, Jettka, Giuliani, & De Ruiter, 2015). However, conversational strategies have traditionally been investigated across different disciplines, with varied methodological approaches and foci. Only recently the field has started combining qualitative insights with quantitative methodologies (De Ruiter & Albert, 2017; Dingemanse & Enfield, 2015) and systematically assessing the role of contexts and activities (Fusaroli et al., 2017; Healey, Purver, & Howes, 2014; Reitter & Moore, 2006). In the following, we define the relevant conversational strategies and how they might be adjusted to different contextual demands, and then present a study systematically assessing them across two different contexts: Spontaneously Occurring (SOC) and Task Oriented Conversations (TOC).

Conversational strategies and context

By conversational strategies, we here refer to a heterogeneous set of linguistic behaviors often investigated separately under the headline of *backchannels*, *repair* and *alignment*. Backchannels are defined as head nods or short utterances consisting of a word (e.g. *'uh-huh, 'yes', 'okay'*), or short sentences, often repeating the previous turn (e.g. A: *'let's meet Monday at 10', B: 'Monday at 10'*). They do not take the floor in a conversation, but are used to exhibit interest, understanding, and perhaps even agreement with the speaker's utterance. Thus, backchannels signal a shared common ground and that the speaker can continue with their speech turn (Bangerter & Clark, 2003; Jurafsky, Shriberg, Fox, & Curl, 1998; Schegloff, 1982; Yngve, 1970). Therefore, (Hypothesis 1, H1) we would expect that TOC involve a higher occurrence of backchannels than SOC. This hypothesis is supported by previous observational work (Fusaroli et al., 2017). Note that here we focus on vocal backchannels only.

The second strategy that we examine, conversational repair, also creates feedback on the level of mutual understanding between interlocutors. However, while backchannels mainly provide positive feedback, conversational repair works by providing negative feedback, signaling impending communicative trouble and a need to re-establish common ground. Repair can take different linguistic forms and levels of specificity in the feedback to the interlocutor. Here we focus on other-initiated repair, where a listener indicates trouble in hearing or understanding. The listener can use a repair request to signal that there is a problem with understanding, and thereby invite the speaker to clarify what was said and "repair" mutual understanding. Previous studies have defined three categories of repair (Dingemanse et al., 2015; Fusaroli et al., 2017). Open repair refers to problems on a general level of understanding, where the repair initiation does not specify what or where the problem is (e.g., *huh?*, *what?*, *what did you say?*). In contrast, restricted repair points to specific parts of the previous sentence that need clarification (e.g., *'who?'* or *'where*?'). Restricted suggestions are even more specific, pointing to the specific source of uncertainty and offering a suggestion as to how to repair it (e.g., '*did you say Monday?'* or '*X or what?*'). A previous study has found that repair is more frequent in TOC, due to the higher demand for precision in mutual understanding (Colman & Healey, 2011). Therefore, we also expect (H2) repair to occur more often in TOC than in SOC. Further, we expect (H3) the more specific forms of repair to be driven by the need for accuracy: restricted suggestion repairs should be higher in TOC, with restricted request and open repairs being frequent in SOC. Both hypotheses have preliminary support in a previous study (Fusaroli et al., 2017).

A third strategy is the reciprocal alignment of linguistic forms. As interlocutors hear each other using, for instance, specific words, they prime each other to re-use them. Linguistic alignment is argued to implicitly increase similarity of interlocutors' mental situation models, and thereby catalyze increased rapport and interpersonal coordination (Dale, Fusaroli, Duran, & Richardson, 2013; Pickering & Garrod, 2004). In particular, here we focus on lexical, syntactic and semantic alignment. Lexical alignment indicates the tendency to re-use an interlocutor's lexical choices ("do we *ignore it*?", "yes, let's *ignore it*"). Syntactic alignment indicates the tendency to reuse the interlocutor's syntactic constructions beyond lexical choices ("*you have passed* the youth hostel?", "yes and *I have reached* the top of the map", where the sequence of subject and verb forms are repeated). Semantic alignment indicates the tendency to keep talking about the same topics, beyond lexical and syntactic alignment. Since linguistic alignment is argued to facilitate joint task performance, we expect (H4a) it to be higher in TOC than SOC. Two studies support this hypothesis: syntactic alignment is observed to be higher in task oriented conversational corpora than in more spontaneous conversational corpora (Healey et al., 2014; Reitter & Moore, 2006). However, given that alignment is often associated with building and maintaining rapport (Ireland et al., 2011), one could also expect (H4b) it to be higher in SOC than TOC. Indeed, one previous study supports this second hypothesis (Fusaroli et al., 2017).

In summary, SOC and TOC involve different contextual demands and therefore may emphasize different aspects of the common ground. SOC have a more marked social function in the maintenance of relations, and a lower need for detailed and accurate referential understanding than TOC. We therefore expect TOC to display more precise building and assessment of shared situation models through backchannels, repair, and perhaps alignment.

The current study

While previous studies support at least some of our hypotheses, they mostly investigate one conversational strategy at a time, often with widely different methods or data. Further, all previous studies rely on cross-sectional

conversational corpora, that is, the individuals included do not overlap across corpora, making it harder to assess whether any observed differences are indeed a function of different contexts. Additionally, the corpora were often collected in a heterogeneous fashion, with varying numbers of interlocutors and different ongoing activities. Here we aim to more rigorously investigate the role of conversational strategies by controlling these contextual variables. We experimentally elicited multiple SOCs and TOCs in a within-subject design. This allowed us to get a more detailed picture of how participants use conversational strategies in different interactional settings, assessing both contextual, pair and individual variability, as well as their reciprocal relations.

Besides the hypotheses sketched above, we also explore how the three conversational strategies relate to each other, and how they are affected by the contrast between conditions. It has been argued that social interactions display signatures of self-organization dynamics, that is, conversational behaviors become interdependent within and between interlocutors, so that the increase in one strategy might result in decrease in another. For instance, a high rate of lexical alignment provides high informational redundancy and might make repairs less necessary. Further, these relations are likely to be modified by contextual demands, such that different types of conversations might result in very different interrelations. (Dale et al., 2013; Fusaroli et al., 2014).

Methods

We elicited conversations from 39 dyads (78 Danish individuals). All participants were native speakers of Danish (M age = 23.19, SD = 3.58, males = 33, females = 45). The dyads were composed of 15 female dyads, 9 male dyads, and 15 mixed-gender dyads. The participants in 8 of the 39 dyads knew each other prior to the experiment. Each dyad produced two SOCs and two TOCs. The members of each dyad were first offered a sheet of open-ended conversation prompts (e.g. "find two tv-series that your interlocutor would like to watch") and asked to freely chat while the experimenter was busy elsewhere (first SOC). Participants were then asked to engage in two joint problem-solving tasks: the map task (Anderson et al., 1991) and a categorization task (the alien game; Tylén, Fusaroli, Smith, & Arnoldi, 2016). Both tasks require participants to collaborate to solve the tasks effectively (2 TOCs). Finally, the participants were asked to freely chat again, or to use the conversation prompts (second SOC). Note that SOCs were elicited in an experimental context, which limits the degree of spontaneity of the conversations. They are nevertheless more spontaneous than TOCs. Each conversation lasted approximately 10 minutes, for a total of 40 minutes per dyad (2 SOCs and 2 TOCs). In the SOC condition, we had a total of 34,544 speech turns and an average of 443 speech turns per conversation. In the TOC condition, we had a total of 45,607 speech turns, with an average of 585 turns per conversation. All conversations were transcribed orthographically using ELAN (Brugman & Russel, 2004) and manually coded for backchannels and the three different types of repair by independent coders naïve to the purpose of the study (intercoder reliability: kappas > 0.6). Coding schemes were developed based on prior work (Dingemanse, Kendrick, & Enfield, 2016; Yngve, 1970) and are available at https://bit.ly/2LtUmax. Alignment was calculated as cosine similarity between successive conversational turns. Lexical alignment was based on lemmatized words, syntactic alignment on 2-grams of part-of-speech tags, and semantic alignment on FastText word2vec representations of Danish (Bojanowski, Grave, Joulin, & Mikolov, 2017; Duran, Paxton, & Fusaroli, accepted). While 2-grams are only a rough proxy for syntax, exploratory analyses of 3- and 4-grams yielded similar results. Previous work has also used comparisons to surrogate pair baselines, created by artificially interleaving the utterances of interlocutors from different pairs (Healey el al. 2014). Since the current work is focusing on a within pair manipulation, we leave such baselines for future work.

Bayesian multilevel models with weakly informative priors were used. Backchannel and repairs were modelled according to a Bernoulli likelihood function. Specific types of repairs were analyzed within the subset of repair utterances only. Alignments were fit to a Zero Inflated Beta likelihood function to account for the high amount of turns with no alignment (zero-inflation, see distribution plots here: https://bit.ly/2LtUmax). Note that we report alignment rate as the negative of the inflation term, thus indicating the log odds rate of any alignment instead of the rate of no alignment, and the alignment level as the log odds of the cosine similarity when there are occurrences of alignment.

All parameters were modelled as correlated and predicted by task, including varying effects by interlocutor nested within pair. LOOIC-based stacking weights assessed the relevance of the predictors (Vehtari, Gelman, & Gabry, 2017). Evidence ratio (ER) was used to test evidence in favor of our hypotheses. While ER is a continuous scale, indicative thresholds have been proposed with values of 3 corresponding to moderate evidence for the hypothesis and values of 0.3 to moderate evidence against the hypothesis. Full posterior distributions of varying effects were used to exploratorily estimate and visualize correlations between backchannels, repair and alignment as *r* Pearson coefficients[1]. Only correlations with an absolute coefficient above 0.2 and credibility intervals not overlapping with 0 were included. Global strength was calculated as the sum of the absolute value of all edges in the network. The implementation relied on brms, ggplot, igraph, Stan and R (Bürkner, 2017; Carpenter et al., 2017; Csardi & Nepusz, 2006).

[1] We also built a multivariate outcome model including all previous models and the correlation between outcomes in the same model. However, the model could not be fit due to its complexity.

Results

Estimates of the occurrence rate of the conversational strategies by condition are reported in Figure 1. Detailed results of the effects of task are reported in Table 1 and Figure 1.

Table 1: Conditional effects on conversational strategies. *Estimates represent the log-odds probability of the behavior in question, separately for each condition. Evidence ratio (ER) indicates the relative evidence in favor of our hypotheses as specified in "The current study" (against the alternative hypotheses). "Lex", "Syn" and "Sem" stand respectively for lexical, syntactic and semantic alignment.*

Outcome	Spontaneous	Task-Oriented	ER
Backchannel	-0.69 (-0.8, -0.58)	-1.45 (-1.57, -1.33)	*< 0.001*
Repair	-3.55 (-3.91, -3.17)	-2.86 (-3.11, -2.51)	*> 1000*
- Open	-0.79 (-1.08, -0.48)	-2.20 (-2.45, -1.97)	*> 1000*
- Restricted	-1.32 (-1.61 -1.02)	-1.80 (-2.05 -1.54)	= 132
- Suggestion	0.01 (-0.25 0.27)	1.02 (0.78 1.26)	> 1000
Lex Rate	0.22 (0.11, 0.33)	0.06 (-0.04, 0.16)	*= 332.3*
Lex Level	-0.79 (-0.83, -0.75)	-0.68 (-0.72, -0.64)	*> 1000*
Syn Rate	0.65 (0.52 0.77)	0.50 (0.40 0.59)	= 73.07
Syn Level	-0.78 (-0.83 -0.74)	-0.75 (-0.78 -0.73)	= 6.49
Sem Rate	1.47 (1.13 1.79)	1.61 (1.25 1.96)	= 2.93
Sem Level	0.36 (0.15 0.54)	0.34 (0.16 0.51)	= 1.3

Conversational strategies vary considerably across individuals and pairs. For instance, some pairs consistently show use of backchannels above average, while others consistently below. Analogously, some individuals consistently show higher use of, for instance, backchannels than their interlocutor. Further, the use of conversational strategies is interrelated, as shown in Figure 2. Alignment strategies are strongly and positively related (except for levels of lexical alignment), while repair and backchannel seem less related. Interestingly, the type of conversation seems to affect the relations between strategies, with task-oriented conversations displaying weaker relations (global strength of SOC = 2.91, TOC = 1.67).

Discussion

This study aimed to assess the impact of different contextual demands (SOC vs. TOC) on three conversational strategies and their interrelations. It used a more rigorous within-subject design than previous studies. We hypothesized that backchannel (H1) and repair (H2) would be used more in TOC than SOC, and that the specificity of the repair would also be higher in TOC than SOC (H3). We contrasted two hypotheses for linguistic alignment (H4a-b), as the previous evidence was contradictory, indicating sometimes higher alignment in SOC, sometimes in TOC.

We found high occurrence of backchannels, however, contrary to H1 this was higher in SOC (33.4% of utterances) than TOC (19%). While backchannels certainly play a role in grounding given their high occurrence in TOC, the findings suggest that they might be even more important in free conversation and thus related to, for instance, the maintaining

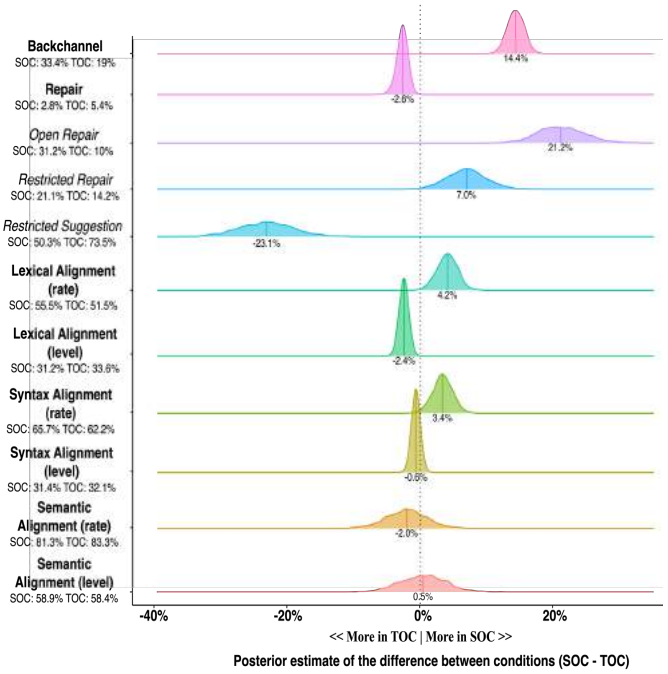

Figure 1 - Effects of task on the conversational strategies of interest. *The column on the left includes posterior estimates of the proportional use of the strategies across the two conditions, the ridge plots indicate the posterior estimates of the differences between conditions. Note that backchannels and repairs are calculated on the total number of speech turns, while repair types are calculated on repair turns.*

of social relations. Indeed, backchannels have been argued to strengthen the social relationship by making both interlocutors part of the conversation even though one speaker holds the floor (Duncan & Fiske, 1977), as well as by consistently displaying interest and attention to the speaker (Levinson, Brown, & Levinson, 1987). The large variation in the use of backchannels is in line with a previous study (Heldner, Hjalmarsson, & Edlund, 2013).

We found that conversational repair is less frequent than backchannelling. In line with H2 and H3, we found that repair was more frequent in TOC (5.4% of utterances) than in SOC (2.8% of utterances), and that the relative frequency of types of repair was affected by contextual demands. More specific repair was more frequent in TOC than SOC, while less specific repair was more common in SOC than TOC. This supports our prediction that in SOC, referential precision is less important than in TOC, where attention to details and accuracy of the information is crucial to solve the collective task at hand (Dingemanse et al., 2015; Fusaroli et al., 2017). Thus, in TOC interlocutors more carefully monitor potential misunderstandings and, given the higher attention to details, tend to prefer the strongest (in this case, most specific) repair form they are able to use in that situation (Clark & Schaefer,

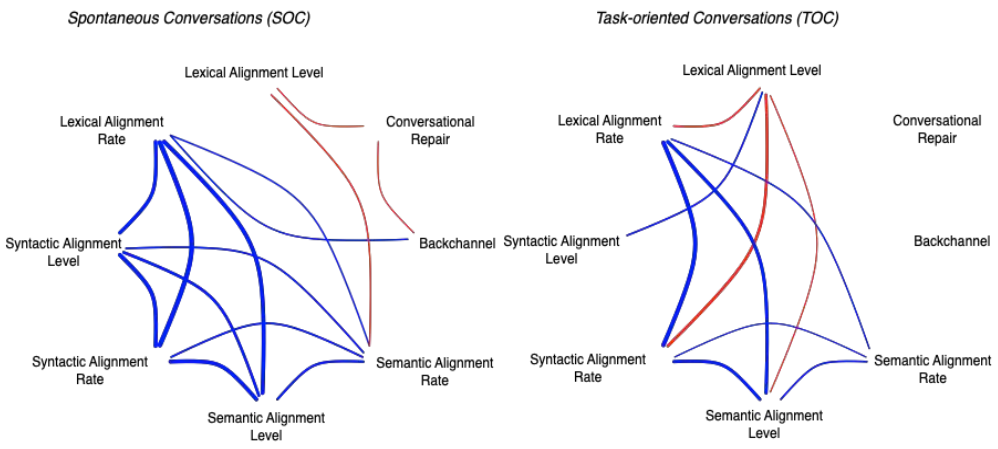

Figure 2 - Exploratory correlation network between individual usage of conversational strategies. Blue lines indicate positive correlations, red lines negative ones. Thickness of the line is proportional to the strength of the correlation, from 0.2 (backchannel and repair in SOC) to 0.9 (rates of syntactic and lexical alignment in SOC).

1987). Our findings suggest that interlocutors use repair as an adaptive strategy, adjusted to target the optimal way of grounding in order to meet specific contextual demands. We found partial support for both H4a and H4b. More than 50% of utterances displayed some lexical alignment, more than 60% syntactic alignment, and more than 80% semantic alignment. However, pervasive, the rate of lexical and syntactic alignment was affected by the type of conversation: higher in SOC than TOC (H4b). While the small effect size should warrant caution, alignment rate might be more related to building and maintaining social relationships. Previous studies have indeed argued that high rates of alignment can lead to informational redundancy, which might hamper task-oriented coordination, in situations that afford interlocutors to provide complementary information in a more synergistic fashion (Fusaroli et al., 2012; Fusaroli et al., 2014; Fusaroli & Tylén, 2016). When interlocutors do align, we find that a relatively high number of linguistic forms is aligned (alignment level): more than 30% of lexical and syntactic choices, and more than 50% of semantic variance. However, lexical and syntactic alignment levels are higher in TOC than in SOC (H4a), indicating that TOC presents fewer instances of alignment, but once alignment is there, more forms are aligned. This might again be due to the demand for precision affording more specific alignment strategies (as in the case of repair). Together with the zero-inflated distribution of alignment, this seems to suggest that we are confronted by two different alignment phenomena that have so far been conflated. The lack of clear differences in semantic alignment between SOC and TOC also seems to indicate that in both types of conversations interlocutors do speak about similar topics, although the specific strategies (lexical and syntactic choices) differ. Future work will include exploration of the effect of 3- and 4-grams on parts-of-speech tags and whether stratifying syntactic by lexical alignment preserves the same pattern of results.

The different conversational strategies, backchannels, repair and alignment, form a dense network of interdependencies (Figure 2). We show that the different forms of alignment are strongly related: interlocutors using alignment do so consistently for all forms of alignment, with the interesting exception of levels of lexical alignment (suggesting that verbatim lexical repetitions might play a different role; e.g., Fusaroli et al., 2014). However, contextual demands affect this network: while backchannels and repairs are negatively related to each other and connected to the rest of the network in SOC, in TOC they are isolated and generally the network displays sparser and weaker connections. This was an unexpected result that requires follow-up work.

In this study, we attempt to develop a more theory-driven and cumulative approach to the study of conversational strategies. Increased control enabled us to more robustly infer how contextual demands change the use of conversational strategies and affect their relations, with results at least partially different from previous less-controlled studies. This provides new insights into how we build effective coordination in conversations, and may illuminate some of the mechanisms underlying social impairment. We are aware of the limitations of this initial work. We have contrasted two macro-categories of conversation: task-oriented and spontaneously occurring. These categories are heterogeneous. The two tasks employed in TOC have somewhat different contextual demands. The two spontaneous conversations in SOC happen at the beginning and end of the experimental setup, influencing interlocutors' feeling of familiarity. Pairs display a high variability in joint performance in the tasks and rapport. This highlights the importance of considering differences across individuals and pairs in studies of conversations (which is also receiving increased attention in other areas of psycholinguistics; Kidd, Donnelly, & Christiansen, 2018). Future work will further explore these dimensions: analyzing differences between interlocutors who know or do not know each other in advance, introducing measures of performance and rapport, as well as accounting for progress familiarity and assessing how conversational strategies evolve over time as interlocutors become familiar with each other and with the tasks. A more direct manipulation of contextual demands, for instance, more continuously varying the need for accurate mutual understanding, is a necessary next step. Future work

will also further articulate the interrelations between strategies and contextual demands.

Conclusion

In a controlled within-participant design, we show that contextual demands afford diverse uses of conversational strategies. Spontaneously occurring conversations display higher frequencies of backchannels and a higher rate of lexical and syntactic alignment, possibly related to higher needs for relation building and maintenance. Task-oriented conversations display higher occurrence of repair (in particular of specific repairs) and levels of lexical and syntactic alignment, possibly related to needs for high precision. Our results suggest that backchannels, repair and alignment serve complementary functions, and that interlocutors flexibly adapt these grounding strategies contingent on current contextual demands. By focusing on how pairs and individuals adjust their strategies to contextual demands, we can better understand the patterns of effective communication, and how communication might fail. Future work might extend this approach to include measures of coordination success as well as investigation of these phenomena in contexts of social impairment.

Acknowledgments

We thank Katrine Garly and Jakob Steensig for their help in developing the coding schemes for repair and backchannel. The project was supported by the Danish Council for Independent Research (FKK) Grant DFF-7013-00074 awarded to Morten H. Christiansen and a seed grant from the Interacting Minds Center, Aarhus University.

Abstract

In language, speakers are more likely to mention the goals, or endpoints, of motion events than they are to mention sources, or starting points (e.g. Lakusta & Landau, 2005). This phenomenon has been explained in cognitive terms, but may also be affected by discourse-communicative factors: For participants in prior work, sources can be characterized as given, already-known information, while goals are new, relevant information to communicate. We investigate to what extent the goal bias in language (and memory) is affected when the source is or is not in common ground between speaker and hearer, and thus whether it is discourse-given or -new. We find that the goal bias in language is severely diminished when source and goal are discourse-new. We suggest that the goal bias in language can be attributed to discourse-communicative factors in addition to any cognitive goal bias. Discourse factors cannot fully account for the bias in memory.

Keywords: Source-Goal Asymmetry; Language Production; Goal bias; Discourse; Common Ground

Introduction

At their core, motion events involve movement of an object (i.e. the Figure) from a starting location (i.e. the Source) to an endpoint (i.e., the **Goal**; Talmy, 1983; cf. *A butterfly flew from a lamppost **to a chair***). Prior work has shown, though, that all these parts may not be "created equal". When talking about motion events, speakers are much more likely to mention the goal, or endpoint, of motion than they are to mention the source, or starting point (Lakusta & Landau, 2005, 2012; Papafragou, 2010; Regier & Zheng, 2007). This goal bias in language holds across ages (Papafragou, 2010; Lakusta & Landau, 2012; Lakusta, Muentener, Petrillo, Mullanaphy, & Muniz, 2016); different types of motion events (Lakusta & Landau, 2005, 2012); typologically different languages (e.g., Regier & Zheng, 2007; Johanson, Semilis, & Papafragou, in press); and even among deaf homesigners who lack exposure to conventional language (Zheng & Goldin-Meadow, 2002).

A similar goal bias has been shown in non-linguistic domains of cognition, such as memory, where goals have been shown to be more accurately encoded in memory than sources (e.g., Papafragou, 2010; Regier & Zheng, 2007; Regier, 1996). As in language, the goal bias in memory has been demonstrated across different types of motion events (Lakusta & Landau, 2012). And, has also been observed in pre-linguistic children (Lakusta, Wagner, O'Hearn, & Landau, 2007; Lakusta & Carey, 2015; Lakusta & DiFabrizio, 2017), suggesting that goals occupy a privileged, more salient status in non-linguistic as well as linguistic event representations.

Thus, in conjunction with a large body of work showing that infants attend to the goals or intentions of an event (e.g., Meltzoff, 1995; Bekkering, Wohlschläger, & Gattis, 2000), the presence of the goal bias in language and memory for *motion* events, also provides some basis to suggest that the linguistic bias has cognitive roots (e.g., Regier, 1996, Regier & Zheng, 2007; Srinavasan & Barner, 2013). Complicating this picture, though, is the fact that the goal bias in memory seems noticeably less robust compared to the goal bias in language. This is especially true when events no longer depict a prototypical *animate* agent moving from one inanimate reference point to another (Lakusta et al., 2007; Lakusta & Landau, 2012; Lakusta & Carey, 2015; Lakusta & DiFabrizio, 2017). In cases like these, some researchers have failed to find evidence of the goal bias in memory – even when the same studies have found a clear goal bias in language and even when the same materials have been used across linguistic and non-linguistic tasks (Lakusta & Landau, 2012).

The discrepancy between the strength of the goal bias in language and memory has been difficult to reconcile with claims that the goal bias is fundamentally rooted in the same (cognitive) mechanism in both domains. In particular, if the mechanism responsible for the goal bias in language is also responsible for the goal bias in memory, why doesn't the bias appear to work in precisely the same way across domains?

The present work proposes a novel explanation for the observation that the strength of the goal bias in linguistic production tasks is more robust than in non-linguistic tasks. We posit that the comparatively more robust goal bias in language may be attributable to an *additional* discourse/communicative asymmetry: When individuals are asked to describe video clips of simple motion events, the initial state of affairs – including the source (i.e., starting point) of the motion – is reasonably assumed to be given. By

contrast, the goal of the motion event (i.e., the endpoint) is considered 'the news' that is relevant to communicate. This makes sources less likely to be mentioned (see Lakusta & Landau, 2012 for a discussion of this possibility). To preview our results, we find evidence in support of this discourse/communicative account: Changing the discourse/communicative status of the source in motion events severely weakens (but does not eliminate) the goal bias in language. We conclude that in language, discourse/communicative factors operate over and above the more general cognitive factors that might drive the goal bias observed in memory.

The Current Study

Prior work on linguistic aspects of the goal bias has typically involved a single participant, who (i) sees a figure located at or near the source (i.e. starting point) of the motion event, (ii) presses a button to watch the event unfold, and then, (iii) describes the event out loud to either no one in particular or a physically co-present, but conversationally unengaged experimenter. Because motion clips in these paradigms typically begin with a scene that sets up the start of the event, the source can be considered already known, 'discourse-old', information, while the goal is considered the 'discourse-new', relevant piece of the event.

Given that speakers have a preference to mention discourse-new over discourse-old (i.e. "given") information in their utterances (Arnold, Wasow, Losongco, & Ginstrom, 2000), a consequence of this single-speaker paradigm may be that it inadvertently creates the conditions for a goal bias both in speakers' descriptions and their representations of motion events in memory. Specifically, participants who do not have to take into account the knowledge state of their interlocutor prioritize mentioning only what is new and relevant to themselves or a 'generic' addressee – in this case, the goal or endpoint of the motion event.

Unlike prior work, the current study asks participants to describe motion events to an attentive, engaged confederate addressee. The presence of an engaged addressee allows us to probe whether the goal bias in language can at least partially be attributed to an asymmetry in the *discourse/communicative status* of sources (typically presented as known, discourse-given entities) versus goals (typically unknown, discourse-new entities) in motion events. This is because the introduction of an addressee allows speakers to consider not only what is discourse-new to themselves, but also what is discourse-new (and presumably relevant to communicate) to their interlocutor.

This discourse/communicative account of the goal bias predicts that changes to the discourse status of the source should affect the magnitude of the goal bias in language. In particular, we expect the goal bias to weaken when sources are also made discourse-new. Alternatively, if the goal bias in language and memory is *purely* driven by a more general cognitive bias towards goals, then changing the communicative setting in which motion events are described should not affect the magnitude of the goal bias in language.

To test the discourse/communicative account, we manipulated the context in which participants described motion events. Participants in our Common Ground condition were asked to describe the motion event to a confederate addressee for whom information about the starting point of the motion was already known – that is, the source constituted discourse-given information. By contrast, participants in our No Common Ground condition were asked to describe the motion event to a confederate addressee that knew nothing about the upcoming motion event – that is, both the source and goal constituted discourse-new, relevant information to communicate about.

Following prior work, we investigated the goal bias in *language* by comparing the proportion of source versus goal mentions as participants describe motion events. We investigated the goal bias in *memory* using an adaptation of the change detection paradigm; we compared how accurately speakers remember sources versus goals *after describing events to an addressee*.

Methods

Participants Fifty-four native speakers of American English (mean age = 20; 28 male, 32 female) participated in the experiment for course credit or $10/hour – 27 in the Common Ground and 27 in the No Common Ground group. The number of participants was determined based on a power analysis of previously reported effects in the literature.

Materials We created 18 test clips, each of which depicted an animate entity moving from an inanimate source landmark (i.e. the starting point of motion) to an inanimate goal landmark (i.e. the end point of motion). (Clipart images were used. See Figure 1a for an example of a butterfly moving from a lamppost (the source) to a chair (the goal)). Each clip was roughly three seconds in length.

Clips were left-right counterbalanced such that half of our clips showed a figure moving from a source on the left to a goal on the right and the other half showed a figure moving from a source on the right to a goal on the left. Source and goal landmarks were also counter-balanced across lists such that objects which were the source of motion in one list were the goals of motion in another. This was done to ensure that our results would not be confounded by the inherent perceptual or conceptual salience (and by extension, salience in linguistic mentions or memory) of one landmark over the other. We also included 18 filler motion events, which did not involve motion between a source and a goal. These filler items were designed such that participants were not able to predict, based on the first frame of the video, whether the clip would eventually involve a source-to-goal motion event.

We probed speakers' encoding of these events in memory using a version of the change detection task used by prior work (Regier & Zheng, 2007; Lakusta & Landau, 2012; Papafragou, 2010). For this, we constructed a second set of videos that involved: (i) Changing the Source (ii) Changing the Goal; or (iii) No Changes (i.e., participants saw a video identical to the one they had previously described). Source and goal changes were always replaced with within-category

variants (e.g., the chair was changed to a different example of a chair; Figure 1) to control for the semantic distance between the original and changed object.

(Figure 1a)

(Figure 1b)

Figure 1. (a) Sample first frame of the 'butterfly flying from the lamppost to the chair' clip. In Common Ground conditions, both participant and addressee saw the first frame; in No Common Ground conditions, only participants saw this. Only participants saw events unfold. (b) Sample goal change in the memory task. The original chair was replaced with a slightly different chair.

Procedure Participants were told that they would be performing the experiment with a partner (in reality, a confederate addressee). Participants were told that they would be watching brief video clips and then describing them to their partner. Their partner would see a simple question about the clip on a separate screen and would answer those questions based on the participant's descriptions.

To demonstrate that the addressee was engaged in the experiment, participant and confederate addressee completed a Tower of Hanoi task together. Afterwards, participants performed two practice trials before moving on to the main experiment. Because prior work has shown that the level of engagement of an addressee can affect how much information speakers choose to include in their utterances (Clark & Wilkes-Gibbs, 1986; Bavelas, Coates, & Johnson, 2000) and may also affect speakers' later memory for the event (Pasupathi, Stallworth, & Murdoch, 1998), confederate addressees maintained eye-contact during event descriptions and verbally indicated when they were ready for the next trial (i.e., 'mhmm', 'ok', 'yup', 'I'm ready'). Critically, confederates maintained the same level of engagement in all conditions and used the same verbal indicators regardless of the utterance produced by participants.

Participants were seated in one of two experimental configurations. In the Common Ground condition (Figure 2), both speaker and confederate addressee were seated side-by-side in front of a centrally-located computer screen. Each trial began with the first frame of the video clip shown on this screen. Thus, both speaker and confederate addressee saw the figure's location relative to the source and the goal landmarks; more specifically, they saw where the animate figure started out in each clip. After briefly inspecting the scene, the addressee turned the participants' screen away so that the addressee was not able to watch the clip unfold.

In the No Common Ground condition (Figure 3), speaker and confederate addressee were seated across from each other so that neither could see each other's screens. Speakers were thus led to believe that addressees in this condition were unable to see *any* part of the video clip.

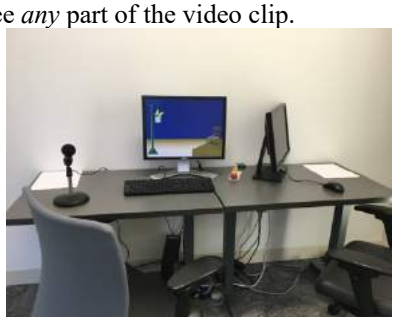

Figure 2. Common Ground configuration. Participants were always seated on the left, confederate addressees on the right. Confederate addressees were shown the first frame of the clip on the participant's screen before turning the screen away.

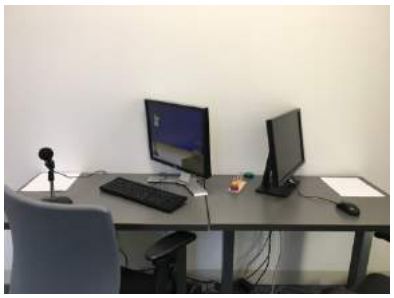

Figure 3. No Common Ground configuration. Participants were always seated on the left, confederate addressees on the right. In the No Common Ground condition, confederate addressees were not permitted to see any part of the participant's computer screen.

In both Common Ground and No Common Ground conditions, participants received the same set of video stimuli and participants performed the same tasks. They were told in all cases that confederate addressees would be answering a simple question about each video clip based on the speakers' description of what happened in each clip.

After finishing the description portion of the experiment, participants were separated from the confederate and participants were given a surprise memory task. During this portion of the experiment, participants were shown the (i) Source Change, (ii) Goal Change, or (iii) No Change variants of the test videos. This was a within-participant manipulation such that six items were randomly assigned the Source Change condition, six to the Goal Change, and six the no Change. Participants were told to circle 'Yes' on their answer sheet if the second video clip was 'exactly the same' as the clip that they had originally described; they were told to mark 'No' otherwise. Thus, correct responses in the Source and Goal Change conditions were always 'No' (i.e., they correctly rejected), but correct responses in No Change condition was always 'Yes' (i.e., they correctly failed to reject). Participants were only tested for memory of target items; clips in the memory portion of the study were presented in the same order as in the scene description portion

of the study.

Predictions

In the Common Ground condition, where the addressee was allowed to see the starting point of the motion event, the source (as in prior work) was discourse-given. However, in the No Common Ground condition, where the addressee was not privy to any information about the motion event, both source and goal were discourse-new.

On a purely cognitive account of the goal bias, the discourse status of entities in a motion event should not affect the frequency of mention of sources and goals. By contrast, on a discourse/communicative account of the goal bias, the goal bias in language should be severely weaker in the No Common Ground condition – where both sources as well as goals were discourse-new – than in the Common Ground condition – where only the goal was discourse-new.

A somewhat independent question is how linguistic descriptions of motion should affect later memory of that motion event. One possibility is that the generation of more informative linguistic representations implies the prior generation of more informative non-linguistic representations. If so, then we expect the patterns in the linguistic description portion of our study to largely correspond to the patterns that emerge in the memory portion of the study. That is, memory for sources should be more accurate in the No Common Ground condition than in the Common Ground condition, where relevant information was not just limited to the goal of motion. It is also possible, though, that there may be no direct relationship between what is mentioned in the motion event and what is subsequently remembered. For instance, even if speakers were more likely to talk about sources in the No Common Ground condition, memory for sources might nevertheless remain relatively impoverished compared to memory for goals.

Results

Language Productions We were primarily interested in how frequently speakers would mention sources relative to goals in their event descriptions. We coded whether each utterance included mention of the source and/or goal of the motion event. Following prior work (e.g. Lakusta and Landau, 2012; Papafragou, 2010), all mentions of sources and goals within (i) a prepositional phrase (e.g. 'from the chair'; 'off the chair'; 'to the chair'; etc.), (ii) within the verb + NP structure (e.g. 'left the cave'), or (iii) within a verb + particle structure (e.g. verb + 'away from the tree') were included.

Statistical analyses of the rate at which sources and goals were mentioned were done using a logistic mixed effect model. Ground Type (Common Ground vs. No Common Ground) and Mention Type (Source vs. Goal) were included as fixed effect factors. Mention Type was included as part of the by-subject and by-item random effects; Ground Type was only included as part of the by-item random effects. We simplified the model only if it failed to converge or if random effects did not significantly improve model fit.

As can be seen in Figure 4, in both the Common Ground and No Common Ground conditions, we replicated the goal bias observed in prior work (Lakusta & Landau, 2005, 2012; Papafragou, 2010). In the No Common Ground condition, though, the goal bias was severely weakened: The preference to mention the goal over the source was greater in the Common Ground condition than in the No Common Ground condition. Consistent with this, we detected significant main effects of Mention Type (ß= 3.26, SE= 0.59, $|z| = 5.51$, $p < .01$) and Ground Type (ß= 1.58, SE= 0.75, $|z| = 2.11$, $p < .05$), but these were modulated by a reliable Ground x Mention interaction (ß= -3.06, SE= 0.99, $|z| = 3.11$, $p < .01$).

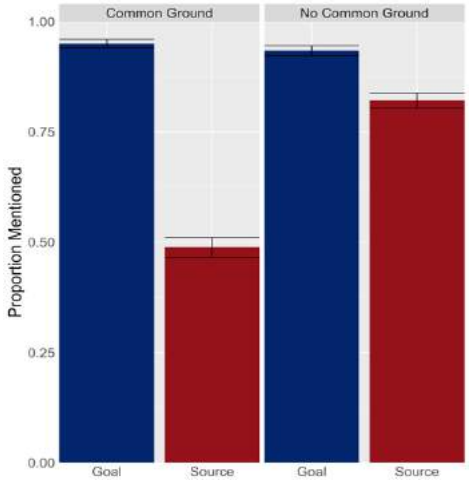

Figure 4. Proportion of Source (Red) and Goal (Blue) mentions in Common Ground and No Common Ground conditions. Error bars represent +/- 1 standard error.

Memory for Sources and Goal Accuracy in the memory task was analyzed using logistic mixed effects regressions. We included Ground Type and Change Type (Source Change or Goal Change) as fixed effects. Random effects were structured as before. The No Change condition was omitted from this analysis because it served only as an indicator of baseline performance and indeed, was similar in both Common Ground and No Common Ground Conditions (Figure 5; yellow).

Overall, participants were more accurate in the No Common Ground than in the Common Ground conditions, resulting in a significant main effect of Ground Type (Figure 5; ß = 1.07, SE = 0.38, $|z| = 2.82$, $p < 0.01$). Participants were significantly better at detecting changes to the Goal (Blue) than to the Source (Red) in both the Common Ground and No Common Ground conditions (ß = 0.90, SE = 0.22, $|z| = 4.19$, $p < .001$). However, the failure to detect a significant Ground x Change interaction (ß = -0.17, SE = 0.42, $|z| = 0.39$, $p = 0.69$) suggests that the strength of the goal bias in the Common Ground vs. No Common Ground conditions did not differ statistically. In other words, speaking to an addressee in the No Common Ground condition only had the effect of boosting speakers' memory for the event *more generally*. Unlike in the description task, it does not appear to weaken any goal bias that exists in memory encoding processes.

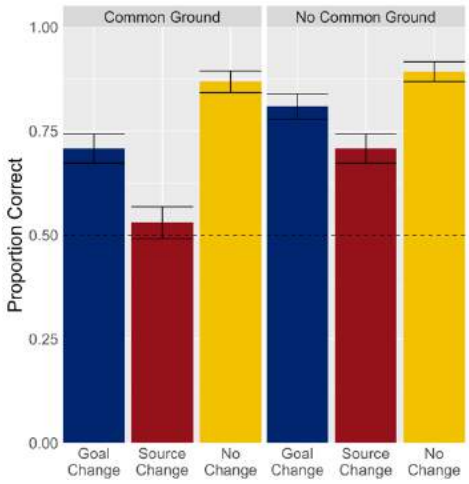

Figure 5. Proportion of Correct Responses in Memory Task. Error bars indicate +/- 1 standard error. Dashed horizontal line indicates chance performance in each condition.

The 'Source Mention Benefit' We used a logistic mixed effect regression to determine whether the rate at which speakers mentioned sources in the language task would predict how accurately they detected source changes in the later memory task. Ground Type and Source Mention (yes, no) were included as fixed effects. Source Mention was included in both by-subject and by-item random effects; Ground Type was only included by-items. Models were reduced and selected as before.

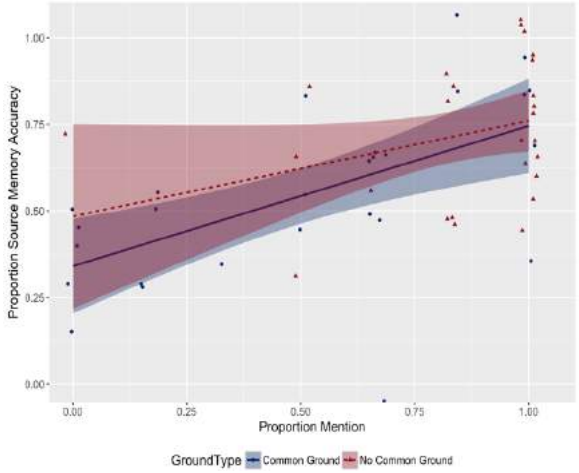
We found that speakers were more likely to accurately encode sources in memory if they had previously mentioned the source in their descriptions (Figure 6). This was indexed by a significant main effect of Source Mention (ß = 1.17, SE = 0.43, |z| = 2.73, p < .01). There was a marginally significant main effect of Ground Type (ß = 1.08, SE = 0.56, |z| = 1.94, p = .053), suggesting that speakers' memory for sources trended towards being more accurate in the No Common Ground than in the Common Ground condition. There was no significant Ground x Source Mention interaction (ß = 0.16, SE = 0.83, |z| = 0.20, p = 0.84). This latter finding suggests that mentioning the source provided the same benefit to source accuracy in the memory task, regardless of Common Ground or No Common Ground condition.

Recall that in the memory task participants were also better at detecting changes to the goal in the No Common Ground as compared to the Common Ground Condition (the two blue bars in Figure 5). This is surprising given that participants mentioned the goal to the same extent in the Common Ground and No Common Ground conditions. One possibility is that goals were remembered more accurately in the No Common Ground condition because mentioning the source (which happened more in this condition) helped to create a more coherent representation of the event as a whole.

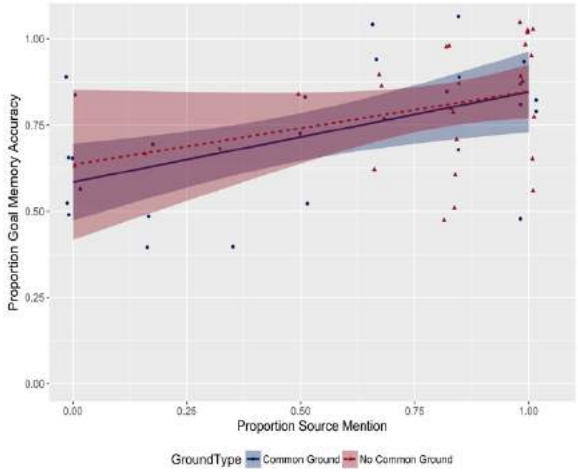
To investigate this, we analyzed whether the rate of source mention would also predict *goal* accuracy in the memory task. We found that participants who mentioned sources more frequently also tended to remember goals more accurately (Figure 6b; ß = 1.09, SE = 0.35, |z| = 3.10, p < .01). No other effects were significant, meaning that the magnitude of the source mention benefit on goal memory did not differ across Common Ground and No Common Ground conditions. Thus, mentioning the source had the secondary benefit of reinforcing memory for other aspects of the motion event – namely, the goal – as well.

Discussion

Prior work has shown a robust goal bias in language: Speakers are much more likely to mention the goal (i.e. endpoint) of a motion event than they are to mention the source (i.e. starting point) of that event. A goal bias has also



(Figure 6a)



(Figure 6b)

Figure 6. Performance in the description and memory task for each subject in the Common Ground (Blue circles) and No Common Ground (Red Triangle) conditions. The x-axis represents proportion of times sources were mentioned during the description task. The y-axis of Figures 6a and 6b show the proportion of accurate responses in the Source Change and Goal Change conditions, respectively. Shaded areas represent +/- 1 standard error.

been observed in non-linguistic cognitive domains, such as memory, suggesting that the goal bias may operate across domains of cognition. An open question and central challenge for such cognitive accounts, though, is how to account for the fact that the goal bias is much more robust across contexts in language than in memory.

We suggest that the discourse/communicative context in which motion descriptions were elicited in prior work exacerbated the goal bias in language: On top of any underlying cognitive goal bias, speakers were additionally more likely to mention the goal than the source because they were describing events in a discourse context that made mentioning the source unnecessary. In our Common Ground condition, where information about the source was discourse-given, we replicated the goal bias in prior work. When we equalized the discourse/communicative status of sources and goals (our No Common Ground condition), this goal bias was drastically weakened. These results are expected if the goal bias – at least in language – is not a reflection of cognitive factors alone.

It is work noting that other work (e.g., Stevenson, Crawley, & Kleinman, 1994) has independently reported a bias for the goal in transfer-of-possession events (i.e., *Leslie handed a book to Ann.*). There, work by Rodhe, Kehler, & Elman (2006) has similarly argued that discourse factors – like different types of coherence relations – can also modulate the goal bias in transfer-of-possession events. We do not manipulate factors like coherence here, but our results also demonstrate the way that discourse factors can interact with event representations in language. Further, our work suggests that (in addition to coherence relations) the goal bias in those cases may also be partially attributed to the givenness of the source in transfer-of-possession events.

Importantly, our results do not rule out the possibility of a cognitive bias towards goals/endpoints: Across tasks and conditions, we found a residual preference to mention goals over sources. Even in the No Common Ground condition, speakers were still more likely to mention goals over sources; and, though participants performed more accurately on the memory task in general, they nevertheless remembered goals more accurately than sources.

By contrast, the discourse status of the source did not *directly* influence the goal bias in memory. However, we did find evidence of an *indirect* 'source mention benefit' that affected how accurately goals, as well as sources, were encoded in memory: Speakers who were more likely to mention the source in their event descriptions were more accurate in remembering *both* goals and sources of motion events. For these participants, mentioning sources improved memory for sources themselves, but also helped to create a more accurate representation of the event more generally.

More broadly, we conclude that discourse/communicative factors should be incorporated into theories about the relationship between language and event cognition. Moreover, our results are consistent with prior work (e.g. Clark & Wilkes-Gibbs, 1986) showing that the extent of the addressee's knowledge has a direct effect on what information speakers choose to include in their utterance.

One question raised by our results is whether the discourse/communicative status of *goals* can modulate the mention of goal phrases in language. Is it possible, for instance, to reverse the goal bias (i.e., produce a source bias) strictly by manipulating the givenness vs. newness of goals? We are currently exploring this direction in ongoing work.

Abstract

During reading, readers intentionally do not fixate a word when highly confident in its identity. In a rational model of reading, word skipping decisions should be complex functions of the particular word, linguistic context, and visual information available. In contrast, simple heuristic of reading only predicts additive effects of word and context features. Here we test these predictions by implementing a rational model with Bayesian inference, and predicting human skipping with the entropy of this model's posterior distribution. Results showed a significant effect of the entropy in predicting skipping above a strong baseline model including word and context features. This pattern held for entropy measures from rational models with a frequency prior but not from ones with a 5-gram prior. These results suggest complex interactions between visual input and linguistic knowledge as predicted by the rational model of reading, and a dominant role of frequency in making skipping decisions.

Keywords: eye movements; reading; word identification; rational analysis; skipping

Introduction

To achieve comprehension in reading, readers move their eyes across the text to obtain the information needed to identify the words. In the past decades, research on eye movements in reading has provided ample evidence that word identification can be seen as the primary driver of eye movements. The reasoning behind this conclusion, however, is based on relatively coarse observations, such as demonstrating that eye movements are sensitive to aggregate variables that are important in word identification (e.g., word length and frequency). Although such a coarse linking hypothesis between word identification and eye movements successfully predicts several reading behaviors, a model of reading that connects eye movements to ongoing language processing in a deeper way could lead to more precise predictions, improved data analysis, and an overall fuller utilization of the eye movement record to advance theories of sentence processing.

One promising model of this type comes from a perspective of rational analysis. The idea is to consider the reading process as one that combines information from various sources to identify words and then makes eye movement decisions to maximize identification efficiency (Bicknell & Levy, 2010, 2012; Legge, Klitz, & Tjan, 1997; Legge, Hooven, Klitz, Mansfield, & Tjan, 2002). In previous rational models of reading, text identification process is modeled using Bayesian inference that combines two sources of information: (1) probabilistic knowledge of the structure of the language, serving as the prior, and (2) uncertain visual evidence, serving as the likelihood. Given a prior and a particular set of visual evidence, probabilistic inference yields a posterior distribution on the text, which specifies the probability of each possible identity of the text. The role of eye movements in this analysis is to obtain particular pieces of visual evidence, and the most efficient, rational reading behavior will be to use the current posterior distribution to determine the most useful time and place to move the eyes next. Therefore, any eye movement behaviors explained by this model of reading can be seen as naturally born from one simple origin: the rational gathering of visual evidence for text identification.

In contrast, the dominant models of eye movement control in reading tend to use heuristic linking hypothesis between text identification and eye movements (e.g., E-Z Reader, Reichle et al., 2009; and SWIFT, Engbert et al., 2005). In these models, eye movements are driven by a word identification process that is represented with discrete states (e.g., not identified, partially identified that leads to saccade programming, fully identified), the transitions between which depend on a certain amount of durations computed from a few coarse visual and linguistic variables of the word. For example, in E-Z Reader the duration of L1 and L2 depend on a stochastic function of two linguistic variables, the word's frequency in the language and its predictability in context, and one visual variable, the average distance from each of its letters to the point of fixation. After spending the pre-computed duration needed to achieve a certain stage of word identification to begin programming a saccade and then achieve complete identification of the current word, the model moves eyes to (roughly) the center of the next word to be identified. The role of eye movements in this heuristic model is a direct reflection (with stochastic noise) of cognitive process identifying a word, the difficulty of which depends on coarse properties of the word as a whole.

There are situations where word identification can be completed with more fine-grained knowledge about the particular word than merely coarse information, and we would like to make precise predictions about eye movement behaviors accordingly. Consider situations where visual information about only the beginning of some words is enough for identification, e.g., seeing the initial letters 'xyl' of the word 'xylophone' (Hyönä, Niemi, & Underwood, 1989). Similarly, in certain linguistic contexts, a reader only needs to see a few of

the initial letters of a word to be confident in its identification, such as in 'The children went outside to pl…'. Do readers in fact combine more fine-grained information than simply word frequency and word length in the way as predicted by rational models of reading?

As illustrated in the preceding examples, an ideal testbed for these predictions of a rational model is when a word is identifiable with visual information about only part of the word. In natural reading, this situation occurs often in the eye movement behavior of skipping, when a reader move their eyes past a word without ever having directly fixated it. Intentionally skipping a word is generally modeled as a case in which the reader has identified the word (possibly incorrectly) while still looking at a prior word, and thus makes a saccade that takes the eyes past the word, skipping over it. Since this (implicit) decision about whether to skip the word is made when the reader is fixating a prior word, this is a case when the reader has high quality visual information about only some of the word's initial letters but does not yet have high quality visual information about the whole word. The amount of visual information the reader has at this time is a function of the *launch site*, the distance from the fixation position to the beginning of the word. In such a situation, both the rational model and the heuristic model predict that how likely a reader is to skip a word should be a function of launch site (amount of visual input), and also of linguistic knowledge (which words are common, and which words are likely in this position). The rational model alone additionally predicts that readers' likelihood of skipping the word will vary depending on the *particular* visual information obtained, and whether that information distinguishes it strongly from its (likely) visual neighbors. Therefore, skipping should be observed to be a complex function of the launch site, the particular word, and linguistic knowledge, in contrast to the heuristic model's predictions of skipping as well-described by coarse visual and linguistic information about the whole word.

Previous empirical research finds that readers' likelihood of skipping a word increases with short word length, close launch sites to the word, high word frequency, and high contextual predictability (Rayner, 1998). Regarding how different sources of information may interact in skipping, studies of skipping short words and especially the word *the* suggest that visual information and word frequency information trump information from the sentence context (Angele & Rayner, 2013; Angele, Laishley, Rayner, & Liversedge, 2014). Despite these findings, the fine-grained predictions of a rational model can be better tested with a set of eye movement decisions that happen in natural reading and that have wide variation in visual and linguistic information available to the reader. The goal of the current paper is to directly test the fine-grained predictions using word skipping, and to gain insights into the role of different sources of information in making skipping decisions.

Related work

Empirical findings about skipping

At the aggregate level, the effects of visual and linguistic variables on skipping are very robust. Word length is considered to play a more important role than any other factors, as found in a meta-analysis showing that word length explained more variance than word frequency and predictability in regression models predicting skipping rate (Brysbaert, Drieghe, & Vitu, 2005). The effect that close launch sites increase skipping rates is also strong and robust (Brysbaert et al., 2005). As for linguistic variables, there is abundant experimental evidence that skipping rate increases as word frequency increases (Rayner, Sereno, & Raney, 1996; Angele et al., 2014), and that high predictability leads to high skipping rate (Balota, Pollatsek, & Rayner, 1985; Rayner, Slattery, Drieghe, & Liversedge, 2011). Predictability is usually measured as cloze probability, varying across conditions either with different sentential frames or target words (Balota et al., 1985; Rayner et al., 2011). The effects hold in corpus analysis as well, as Luke and Christianson (2016) find that high target predictability lead to more word skipping for both content and function words. Kliegl, Grabner, Rolfs, and Engbert (2004) also find significant effect of predictability, word length, and word frequency on skipping rate using regression analyses on Potsdam Sentence Corpus, though not including any interactions among these factors.

Several studies have looked into the interactions between visual and linguistic factors on a coarse level. One approach is to analyze linguistic effects on data split in launch sites in post-hoc analysis. For example, Rayner et al. (1996) observe reliable frequency effect on skipping rate at near launch sites (> -5) but not at far launch sites, and White, Rayner, and Liversedge (2005) find significant interaction between predictability and word length preview overall, which diminish to non-effect for far launch sites (near launch sites are defined as those ≥ -3, while far launch sites are those ≤ -4). Another approach to study the interaction of visual and linguistic information is to manipulate parafoveal preview. A preview of the definite article *the* increases readers' skipping rate, even when syntactic constraints do not allow for articles to occur in that position (Angele & Rayner, 2013; Angele et al., 2014). Skipping rates are higher for the preview of a highly predictable word or its visually similar nonword counterpart than the preview of a low-predictability word (Balota et al., 1985), and for the preview of a predictable word than for a visually similar nonword (Drieghe, Rayner, & Pollatsek, 2005). Staub and Goddard (2019) observe that frequency effect on skipping rate is maintained with both valid and invalid preview, but predictability influences skipping only with valid preview. Additionally, English readers only benefit from the preview of a semantically similar neighbor in highly-constraining context but not in moderate-constraining context (Schotter, Lee, Reiderman, & Rayner, 2015).

In sum, previous research have identified visual and linguistic factors that influence skipping by conducting reading

experiments and corpus studies. There is also evidence for interactions between visual and linguistic factors, but they are constrained to a small set of well-controlled language materials and analyzed on a coarse level. A systematic analysis with skipping made for a variety of words in a variety of contexts with a variety of launch sites would help gain insights into how visual and linguistic variables interacts to identify a word before fixating it and skip at a fine-grained level.

Other instances of rational models of reading

Previous instances of the rational models of reading have provided explanation for several eye movement phenomena. For example, they explain why the initial fixation tends to land near word center and is affected by the launch distance (Legge et al., 2002), why readers often make regressions to previous words (Bicknell & Levy, 2010), and why high-frequency and low-surprisal words yield lower reading difficulty than low-frequency and high-surprisal words (Bicknell & Levy, 2012). In the field of single word identification, Duan and Bicknell (2017) implement a rational model of refixations, and find that readers rationally make refixations to seek visual information from parts of the word that the readers are uncertain.

The rational model of skipping presented in this paper has different focuses than previous models. Instead of setting the goal to be identifying a whole sentence, the rational model of skipping focus on identifying a single word before directly fixating it. Previously, the computational cost is high due to recomputing posterior beliefs about an entire sentence after each new piece of visual evidence. The model of skipping is computationally simple, enabling the incorporation of sophisticated models of language knowledge and visual evidence.

Rational model of skipping

Word identification as Bayesian inference

In our rational model of skipping, word identification uses Bayesian inference, in which a prior distribution over possible identities of the word given by the language model is combined with a likelihood term given by 'noisy' visual input conditional on the fixation position to form a posterior distribution over the identity of the word. Formalized with Bayes' theorem,

$$p(w|\mathcal{I}) \propto p(w)p(\mathcal{I}|w) \tag{1}$$

where the probability of the true identity of the word being w given uncertain visual input $\mathcal{I}$ is calculated by multiplying the language model prior $p(w)$ with the likelihood $p(\mathcal{I}|w)$ of obtaining this visual input from word w, and normalizing. Since the shape of the posterior distribution depends on the probability of each word relative to probabilities of other words in the vocabulary, it contains information about how well a word is distinguished from its neighbors.

In general, the prior $p(w)$ represents reader expectations for the next word, and for the present paper, we compare two representations of the prior: a word unigram model (i.e., using word frequency information), which ignores any context information, and a 5-gram model, which conditions on the previous four words of context. The likelihood $p(\mathcal{I}|w)$ represents how likely a piece of visual input is from a word w. For the present paper, we assume that all visual input is obtained only from the final fixation position prior to either fixating the word or skipping it (i.e., the launch site). The visual input obtained about a word consists of independent visual input obtained from each letter in it. Each letter is represented as a one-hot 52-dimensional vector (distinguishing 26 lower- and upper-case letters), with a single element being 1 and the rest being 0. Visual input about each letter is accumulated iteratively over time by sampling from a multivariate Gaussian distribution centered on that letter with a diagonal covariance matrix $\Sigma = \lambda^{-1}I$, where λ is the reader's visual acuity for that letter. Visual acuity depends on the location of the letter in relation to the point of fixation, or eccentricity, which we denote ε. Similar to Bicknell and Levy (2010), we assume that acuity is a symmetric, exponential function of eccentricity:

$$\lambda(\varepsilon) = \int_{\varepsilon-.5}^{\varepsilon+.5} \frac{1}{\sqrt{2\pi\sigma^2}} \exp(-\frac{x^2}{2\sigma^2})dx \tag{2}$$

with $\sigma = 3.075$, the average of two σ values for the asymmetric visual acuity function ($\sigma_L = 2.41$ for the left visual field, $\sigma_L = 3.74$ for the right visual field) used in Bicknell and Levy (2010). In this paper, we take σ, the effective width of the visual field, as a free parameter, and experiment with a set of σ values. In addition, we introduce another free parameter Λ to scale the overall quality of visual information by multiplying it with each acuity λ (see the Experiment section below).

Single word belief updating

Given visual information and linguistic expectations, we may thus compute a posterior distribution over possible identities of the word. Since visual information arrives over time, this is a Bayesian belief updating process, where beliefs are updated as each new piece of visual information arrives. In the single word domain we study here, this Bayesian belief updating process turns out to be relatively computationally simple, and can be implemented as sampling from a multidimensional Gaussian distribution. Say we have a vocabulary of size v, where each word has dimensionality d (here $d = 52\times$ number of characters in the word), and we denote $\mathbf{y}_1$, $\mathbf{y}_2$, ..., $\mathbf{y}_v$ as the vector representations of all the words in the vocabulary. We can represent the current posterior over words at time step t by a $(v-1)$-dimensional log-odds vector $\mathbf{x}^{(t)}$, where each element $\mathbf{x}_i^{(t)}$ represents the log-odds of $\mathbf{y}_i$ relative to the final word $\mathbf{y}_v$. Working with beliefs in this format means that Bayesian inference is just additive in log-odds (no renormalization):

$$
\begin{aligned}
\mathbf{x}_i^{(t)} &= \log \frac{p(w_i|\mathcal{I}^{(0,\ldots,t)})}{p(w_v|\mathcal{I}^{(0,\ldots,t)})} \\
&= \log \frac{p(\mathcal{I}^{(t)}|w_i)p(w_i|\mathcal{I}^{(0,\ldots,t-1)})}{p(\mathcal{I}^{(t)}|w_v)p(w_v|\mathcal{I}^{(0,\ldots,t-1)})} \\
&= \log \frac{p(\mathcal{I}^{(t)}|w_i)}{p(\mathcal{I}^{(t)}|w_v)} + \log \frac{p(w_i|\mathcal{I}^{(0,\ldots,t-1)})}{p(w_v|\mathcal{I}^{(0,\ldots,t-1)})} \\
&= \Delta\mathbf{x}_i^{(t)} + \mathbf{x}_i^{(t-1)}
\end{aligned} \tag{3}
$$

That is, the log-odds posterior at time step t equals the log-odds posterior at time step $t-1$ (which serves as the prior at time step t) plus the log-odds likelihood. Thus, in an iterative belief-updating context, the log-odds vector begins at a value set by the prior, here the language model, $\mathbf{x}_i^{(0)} = \log p(w_i) - \log p(w_v)$. Then, as each piece of visual information $\mathcal{I}^{(t)}$ arrives, updating beliefs is as simple as adding to $\mathbf{x}^{(t-1)}$ the likelihood log-odds vector for this new piece of information $\Delta\mathbf{x}^{(t)}$, where each element $\Delta\mathbf{x}_i^{(t)}$ gives the likelihood log-odds for that word relative to the final word w_v. For a given true word, vocabulary, and eccentricity, the density function for the likelihood log-odds vector $\Delta\mathbf{x}^{(t)}$ is a $(v-1)$-dimensional multivariate normal distribution, as each element $\Delta\mathbf{x}_i$ is an affine transformation of $\mathcal{I}$, which is itself a multivariate Gaussian.

Experiment

To test whether readers display signatures of optimal integration across these contexts, we build a computational implementation of an ideal-integration model predicting identification confidence for each skipping decision. We show that these model predictions explain significant variance in human skipping rates when added to a strong baseline model.

Baseline model

Data The English part of the Dundee corpus contains eye movement records from 10 native English-speaking participants as they read through newspaper editorials (see Kennedy & Pynte, 2005, for further details.) We included 122,230 observations from the Dundee corpus if they were: 1) a word skipped on first pass (coded as a 1) or a word fixated on first pass (coded as a 0); 2) not adjacent to any blink; and 3) not the first or last fixation on a line. Further, the fixated/skipped word should not 1) contain any non-alphabetical character or be adjacent to punctuation, or 2) follow a word that was skipped or refixated. We excluded observations with far launch sites and long word lengths to ensure enough observations on every level of variations. In the final data, launch sites ranged between [-10, -1], with more than 1000 observations from each launch site, and word length ranged between [1, 8], with the skipping rate being higher than 9% for each word length. The overall skipping rate was 53.9%, resulting from the generally high skipping rate of Dundee corpus, which was over 40% (Demberg & Keller, 2008), and our criterion of requiring the previous word to be fixated, leading to a skipping rate even higher.

Table 1: Generalized additive mixed-effects regression model results of baseline model (note that random slopes for these fixed effects were not included in the model; the model included a random intercept over participants). The GAMM was fitted by REML, and p-values were reported using *summary.gam* function in *mgcv* package (Wood, 2011).

	χ^2	p-value
word length	6026.25	$< 2 \times 10^{-16***}$
launch site	9123.73	$< 2 \times 10^{-16***}$
frequency	527.94	$< 2 \times 10^{-16***}$
surprisal (5-gram)	38.40	$1.01 \times 10^{-6***}$
context entropy	71.16	$8.28 \times 10^{-11***}$
word length $\times$ frequency	89.06	$7.73 \times 10^{-16***}$
launch $\times$ frequency	36.09	$2.85 \times 10^{-5***}$
launch $\times$ surprisal	29.39	$1.13 \times 10^{-4***}$
launch $\times$ entropy	66.82	$2.24 \times 10^{-11***}$
word length (word N-1)	828.66	$< 2 \times 10^{-16***}$
frequency (word N-1)	54.11	$1.62 \times 10^{-9***}$
5-gram (word N-1)	127.22	$< 2 \times 10^{-16***}$
context entropy (word N-1)	31.68	$5.05 \times 10^{-5***}$
word length $\times$ frequency (word N-1)	84.69	$1.73 \times 10^{-14***}$

Model We analyzed first-pass skipping in the Dundee corpus with a generalized additive mixed-effects regression model (GAMM) predicting skipping from a wide range of variables previously shown to influence skipping, including word length, launch site, word frequency, surprisal, and contextual constraint. We estimated word frequency (log unigram probability) and 5-gram surprisal (log 5-gram probability) with n-gram models (Goodkind & Bicknell, 2018) trained on Google One Billion Word Benchmark (Chelba et al., 2013), and we measured contextual constraint as the entropy of the 5-gram probability distribution of words in a vocabulary of 20,001 words. We defined the vocabulary to include all words that were in both the Dundee corpus and our language modeling corpus, plus words with frequencies above a cutoff chosen such that the resulting total vocabulary would have about 20,000 words. We also controlled for the previous word's properties such as word length and frequency, and included a random intercept over participants. Crucially, this GAMM allowed for non-linear effects of each of these variables, providing a strong baseline. Table 1 shows all the fixed effects in the baseline model.

Rational model

Simulation For each observation in the dataset, we simulated 50 trials using the rational model of skipping for each parametrization of the model. In each trial, a piece of visual information from the launch site is sampled and combined with the linguistic information to generate a posterior distribution of possible identities of the word. As described above, the visual information in this model has two param-

Table 2: Significance of averaged entropy of a rational model's posterior distribution when added to the baseline model.

eters: overall visual input quality Λ and the width of acuity function σ. We used fifteen sets of parameter pairs for the models; these parameters were chosen to be values that spanned a wide part of the parameter space while also respecting the trade-off between width of the acuity function and its overall quality.[1] The linguistic information (prior) in this model is given by either the word frequency (unigram) or 5-gram language models, as used in our baseline model.

Analysis From each trial, we extract the entropy of the posterior distribution (postH) and then calculate the average of postH from the 50 trials for each observation (for each model parametrization). For each parametrization, we add this average postH to our baseline model as a linear predictor. If human readers extract visual and linguistic information in a rational manner, we predict postH to show a significant effect predicting human skipping, even in a strong baseline model, such that skipping is more likely when the posterior entropy is low.

Results

Baseline model

GAMM results of the baseline model are summarized in Table 1. The results confirm previous findings that word length, launch site, frequency, surprisal, and contextual constraint significantly influenced human skipping. Moreover, this baseline model captures non-linear interactions among these predictors, indicating that different sources of information interactively guide skipping at an aggregated level.

[1]If the function is very wide and high quality, the model has too much information about the whole word, whereas if narrow and low quality, the model has almost no information.

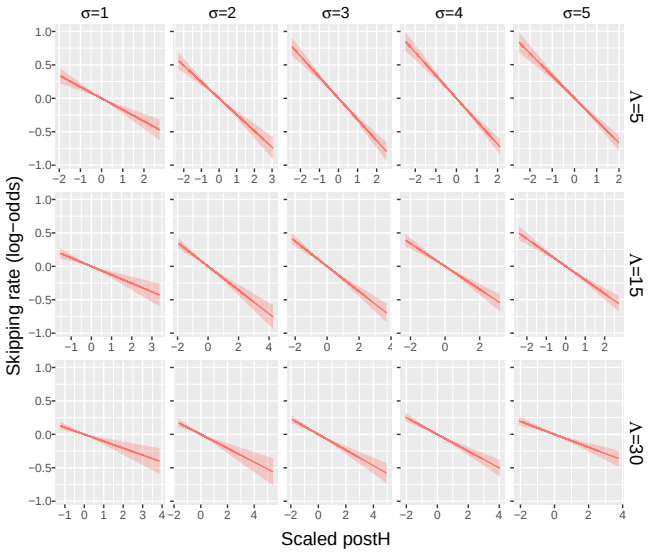

Figure 1: Partial effect of postH with a frequency prior in predicting skipping rate.

Rational model

The partial effects of postH computed from the GAMMs are visualized in Figure 1 (frequency prior) and Figure 2 (5-gram prior), after controlling for all variables in the baseline model and additionally a random slope of postH over participants. The significance of postH when added to the baseline model is reported in Table 2. For postH from rational models with a frequency prior, the effects are significant in the predicted direction: high postH indicates high uncertainty about the word's identification and is associated with lower skipping rates; these effects are robust to parameter choice and are significant for all parametrizations tested. For postH from rational models with a 5-gram prior, the effects are generally not significant, though they do all trend in the same direction and show the pattern that skipping rates increase as the uncertainty over the word's identity increases, opposite to the predicted direction.

Discussion

In this paper, we implemented a computational model of skipping that used Bayesian inference to combine visual and linguistic information. We then extracted the entropy of the posterior distribution as a measure of readers' confidence about word identification, and tested whether this measure improved the predictive power of a strong baseline model incorporating aggregate visual and linguistic factors known to influence skipping. Results showed that this postH measure had significant additional effect predicting skipping when extracted from rational models with a frequency prior, but generally not when extracted from rational models with a 5-gram prior. The direction of the effect of postH from models with a frequency prior is consistent with the prediction that low confidence about word identification leads to decreased skipping

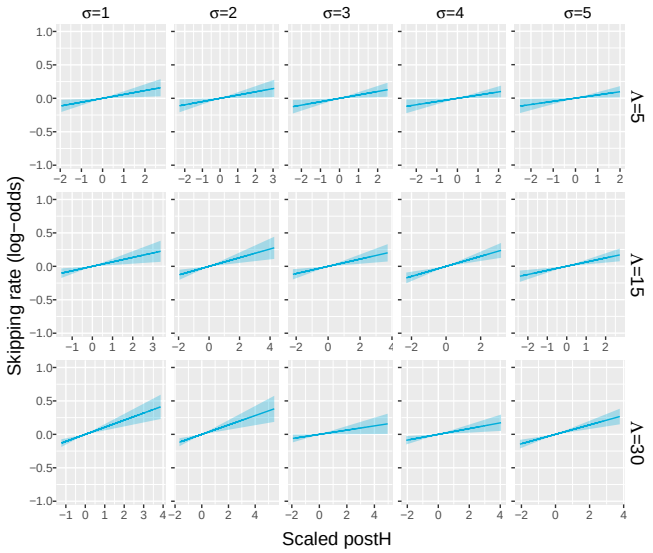

Figure 2: Partial effect of postH with a 5-gram prior in predicting skipping rate.

rate, while the trend of the effect of postH from models with a 5-gram prior is in an opposite direction.

These findings generally provide positive evidence for the rational model's prediction that readers' likelihood of skipping vary depending on the *particular* visual information obtained, and whether that information distinguishes it strongly from its (likely) visual neighbors as in linguistic knowledge. The predictor, postH, is computed from the posterior distribution of a Bayesian inference model with partial visual information about the word, and therefore captures how likely the word is differentiated from its neighbors in the vocabulary. If the true word is much more likely than its visually-similar neighbors, the postH should be low, while if the true word and its neighbors have similar probabilities, the postH should be high. Such a measure of reader's confidence about word identification is dynamic, innate, and hard to capture in factorial experiments, but can be approached through computational simulation. Its significant effect is not predicted by the heuristic model in principle, as postH is assumed to utilize information about how particular words relate to their neighbors regarding the specific visual information obtained about parts of the word.

The observation that postH from a frequency prior better predicts skipping than the 5-gram prior is potentially problematic for a fully rational model of skipping, though: a reader that maximize usage of all the information available should be better predicted by a model with 5-gram prior than one with frequency prior. Rather, this pattern lines up with previous findings on the skipping of *the*, which relies on visual and frequency information more than structural information (Angele et al., 2014). This pattern is also consistent with the finding that frequency effect but not predictability effect on skipping survives bad parafoveal visual input, which may be explained by different time course of frequency and contextual information in making eye movement decisions (Staub & Goddard, 2019). A possible reason of our finding is that skipping decisions may be made without full knowledge of the context, leading to the absence of effect from our measure (i.e. 5-gram) of contextual information. Specifically, since saccade programming takes a relatively long time and identification/processing of the fixated word continues during this lag, skipping decisions may be made before the previous word is fully identified and integrated into the context. In spite of this issue to be further examined, we find that the entropy of a posterior distribution from a frequency prior improves prediction of skipping with average variables, suggesting a complex combination of information sources as predicted by rational models of reading.

Abstract

Curiosity is considered essential for learning and sustained engagement, yet stimulating curiosity in educational contexts remains a challenge. Can people's curiosity about a topic be stimulated by evidence that the topic has potential value? In two experiments we show that increasing people's perceptions about the usefulness of a scientific topic also influences their curiosity and subsequent information search. Our results also show that simply presenting interesting facts is not enough to influence curiosity, and that people are more likely to be curious about a topic if they perceive it to be directly valuable to them. Given the link between curiosity and learning, these results have important implications for science communication and education more broadly.

Keywords: curiosity; intervention; education

Introduction

> *"Sometimes these dollars go to projects that have little or nothing to do with the public good. Things like fruit fly research. I kid you not."*
>
> – Sarah Palin, former Alaska Governor

In one of her first policy speeches, former Alaska Governor and Vice Presidential nominee Sarah Palin made the above remark to alert people to the alleged misuse of federal funds. Her comments were met with disappointment and dismay within the scientific community, and for good reason – fruit flies have been an essential part of biological research, and research on them has shed light on basic aspects of biology and prompted medical advance (Siegel, 2009).

Unfortunately, Palin's attack on fruit flies is not the first example of a politician deriding specific kinds of research (Kempner, 2008). While such statements could be motivated by various political or economic considerations, they also seem to reflect a lack of curiosity about the scientific topics in question. This highlights an important aspect of curiosity in that the *same* topic can elicit quite *different* levels of curiosity in different people. What accounts for this difference, and how might greater curiosity be induced?

Psychological accounts of curiosity posit that curiosity is piqued whenever people observe discrepancies (Berlyne, 1950, 1960), or perceive a "moderate" gap between their actual and desired knowledge state (Loewenstein, 1994). Based on these theories, many people's low curiosity for scientific topics (such as fruit flies) could be explained by a lack of (perceived) discrepancy and/or by inadequate prior knowledge, such that the information gap is too large. However, Palin's comments suggest an additional possibility: perhaps people simply fail to see any *value* in pursuing topics that seem to lack theoretical or practical implications. Indeed, a recent account of curiosity suggests that people's curiosity should be higher for information if they perceive that information to be important to them (Dubey & Griffiths, 2017). Furthermore, various studies from the education literature have shown that students' perceived utility value i.e., how valuable they think a task would be for future goals, correlates with their task enjoyment and engagement (Eccles & Wigfield, 1995; Hulleman et al., 2008). In line with these findings, education researchers have successfully used utility-value interventions to increase student's motivation and performance in various learning settings (Hulleman et al., 2010; Harackiewicz et al., 2012; Brown et al., 2015). However, this work has not investigated whether utility-value interventions can successfully induce *curiosity*.

The current work explores a novel way to stimulate curiosity – by manipulating the perceived value of a topic. More specifically, we explore whether changing the perceived value of a scientific topic can also affect people's curiosity about that topic. If such a value manipulation indeed affects curiosity, then interventions on value could not only have important implications for curiosity researchers, but also for science communicators and educators of all kinds.

The importance of perceived value

Motivation and value

A classic model of motivation is the expectancy-value theory (Atkinson, 1964; Wigfield & Eccles, 2000), which posits that motivation in educational contexts is determined by an individual's expected success (i.e., belief that one can succeed at an activity) and subjective task value. Studies based on this theory have primarily developed interventions that focus on the 'expected success' component – that is, on improving students' perceived ability to master tasks to improve their motivation and performance (Eccles & Wigfield, 1995; Wigfield & Eccles, 1994). More recently, a number of researchers have also developed interventions that focus on the 'subjective value' component. These interventions show that an increase in students' perception about the usefulness of a subject leads to enhanced motivation and improved performance in various learning settings (Hulleman et al., 2010;

Harackiewicz et al., 2012, 2014; Brown et al., 2015). Although curiosity is usually considered distinct from motivation, and possibly involves different computational and neural mechanisms, these findings provide a useful starting point for developing interventions on curiosity, and for considering why perceived value might play a role.

Curiosity and value

Although curiosity has long been recognized as an important aspect of cognition, there is no single, agreed-upon theory of curiosity (Kidd & Hayden, 2015). Instead, a number of theories have been proposed to explain curiosity (Berlyne, 1950, 1960; Schmidhuber, 1991; Loewenstein, 1994; Oudeyer et al., 2007). These theories link curiosity with various psychological factors, but none of them explicitly consider the potential role that value can play in influencing curiosity.

Dubey and Griffiths (2017) recently proposed an account that links curiosity to 'value of knowledge', which is a function of people's current understanding of a topic and the perceived usefulness of that topic. According to the theory, people's curiosity is evoked whenever they perceive an opportunity to increase the value of their knowledge (i.e., topics that either increase understanding or perceived usefulness). In essence, this model can be interpreted as providing a quantitative articulation of the expectancy-value theory. If people's curiosity is indeed driven by the perceived opportunity to increase the value of their knowledge, then this suggests that curiosity can be driven towards topics that seem initially unimportant if people come to perceive them as useful or otherwise valuable.[1]

Overview of experiments

In the current paper we ask whether manipulating perceived value can influence curiosity. Answering this question provides an opportunity to empirically evaluate theoretical claims related to the link between value and curiosity while also extending the rich literature in educational psychology on motivation.

To address this question, we report two experiments in which we present scientific topics to participants and have them indicate their curiosity about those topics. We then manipulate the perceived usefulness of those topics and record participants' change in curiosity. In Experiment 1, we manipulate how 'valuable' it would be for medical research to study fruit flies and rats, and we measure how participants' curiosity and information search is affected by this manipulation. In Experiment 2, we go one step further by considering what *kind* of value most effectively drives curiosity.

Experiment 1: Does value influence curiosity?

In Experiment 1, we investigated whether people's curiosity towards a scientific topic can be influenced by manipulating the perceived value of that topic, and whether this boost in curiosity affects subsequent information search. Participants read two short articles about two different scientific topics (one article for each topic). One of the two articles was 'high-value', and the other was 'low-value'. Participants' curiosity for the two scientific topics was recorded before and after they read the articles. Subsequently, participants had the choice to read some facts about the two scientific topics.

The experiment tested the following predictions: (1) Reading a high-value article will increase curiosity, and it will do so to a greater extent than reading a low-value article, (2) Participants will be more likely to read facts corresponding to the topic of the high-value article than those corresponding to the topic of the low-value article, and (3) The effect of the value manipulation on curiosity will be mediated by perceived value.

Participants

We recruited 240 participants from Amazon Mechanical Turk. They earned $1.00 for participating in a study that took approximately 7-8 minutes to complete.

Note that for both Experiments 1 and 2, sample sizes were determined prior to data collection; based on pilot data, we aimed to recruit at least 60 participants per condition (which required 240 in experiment 1, given two conditions with counterbalanced order).

Stimuli

The stimuli used in the experiment were two short articles describing the biology of fruit flies and two short articles describing the biology of rats. For each of the two topics (i.e., fruit fly and rat), one article was a 'high-value' article and the other was a 'low-value' article. The high-value article emphasized how research about that animal could be highly beneficial to medicine, while the low-value article raised questions about whether research concerning that animal could generate any medical benefits for humans. All four articles were otherwise matched in terms of length and, as much as possible, for general content and style (stimuli available at - `https://goo.gl/BNpHzU`).

Procedure

At the start of the experiment, participants were randomly assigned to one of two conditions. In condition 1, participants were assigned to the high-value article for fruit flies and to the low-value article for rats. In condition 2, participants were assigned to the low-value article for fruit flies and to the high-value article for rats.

Phase 1 At the beginning of the first phase, participants were presented with one of the two scientific topics, either 'biology of fruit flies' or 'biology of rats' (counter-balanced). After seeing the topic, participants were asked to respond to each of the following on a scale from 1-7:

1. *Usefulness:* "To what extent would knowing about this phenomenon be useful to you in the future?"

[1] Additionally, we note that although Loewenstein's theory of curiosity (Loewenstein, 1994) does not explictly consider value in its formal account, it does hypothesize that people will be more curious about topics that are important to them.

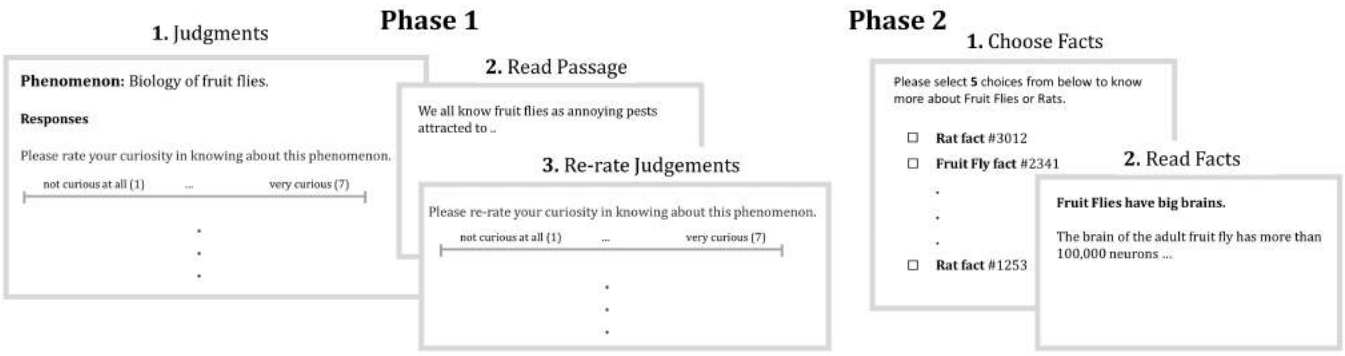

Figure 1: **Design of Experiment 1.** The experiment was divided into two phases. In Phase 1, participants were first presented with one of the two topics from our stimuli and asked to provide ratings for curiosity, understanding, and usefulness. They then read an article about that topic and once again rated curiosity, understanding, and usefulness. This procedure was then repeated for the second topic. In Phase 2, participants had the choice to reveal five out of eight facts presented to them (four facts from each topic). The chosen facts were then presented one by one. Note that instructions were provided before each phase

2. *Understanding:* "Please rate how well you feel you understand this phenomenon."

3. *Curiosity:* "Please rate your curiosity in knowing about this phenomenon."

The first question was to ensure that our manipulation of value was successful, and the second question was to ensure that the effect of value on curiosity couldn't be reduced to understanding. The third question i.e. participants' rating of their curiosity was the key variable of interest in Phase 1. After providing the ratings, participants were presented with the assigned article for that topic and they were instructed to read it as carefully as possible. After they finished reading the article, participants were asked to re-rate their understanding, perceived usefulness, and curiosity about that topic. Following this, the above procedure was repeated for the other topic (also refer to Figure 1).

Phase 2 In the second phase, participants were instructed that they would be presented with some facts about the two topics (four for each topic, eight in total), but that they only needed to read five of those facts. The eight fact choices were then presented (e.g., "Rat Fact 3201"), and participants indicated their five choices. The corresponding facts were shown to participants after they indicated their choices.

Results

For all analyses that follow, we compare participants' ratings for the low-value stimuli relative to the high-value stimuli across the two conditions.

Phase 1 We first investigated the change in participants' understanding ratings after reading the low- and high- stimuli. As shown in Figure 2(a), the mean understanding rating increased by 0.63 for the low-value stimuli and by 1.16 for the high-value stimuli. A mixed ANOVA revealed a significant interaction between time (pre and post ratings) and stimulus (low-value or high-value) on understanding, $F(1,239) = 29.1, MSE = 16.8, p < 0.001$. We next confirmed that our manipulation of value successfully manipulated perceived usefulness. As shown in Figure 2(b), the mean rating of value increased by 0.40 for the low-value stimuli and by 1.16 for the high-value stimuli. A mixed ANOVA again revealed a significant interaction between time (pre and post ratings) and item (low-value or high-value) on perceived value, $F(1,239) = 47.692, MSE = 35.3, p < 0.001$, indicating that our manipulation of value was effective. Finally, we tested whether our value manipulation influenced participants' curiosity. As shown in Figure 3(a), the mean curiosity rating increased by 0.44 for low-value stimuli and by 1.04 for high-value stimuli i.e. the increase for the high-value stimuli was 0.60 points higher than the increase for the low-value stimuli. A mixed ANOVA revealed a significant interaction between time (pre and post ratings) and item (low-value or high-value) on curiosity ,$F(1,239) = 32.69, MSE = 21.6, p < 0.001$, indicating that the manipulation of value had a significant effect on curiosity. A follow-up paired-samples t-test showed that the increase of curiosity was greater for the 'high-value' stimuli compared to the 'low-value' stimuli, $t(478) = -4.71, p < 0.001$.

We next considered whether understanding or perceived value mediated the effect of our value manipulation on curiosity. We first ran a linear regression to predict curiosity based on value manipulation (i.e. 'low-value' or 'high-value'); this yielded a significant and positive coefficient of 0.60, $t = 4.7, p < 0.001, 95\%$ CI$[0.35, 0.85]$. We then considered a regression predicting curiosity based on perceived value; yielding a significant and positive coefficient of 0.47, $t = 12.1, p < 0.001, 95\%$ CI$[0.39, 0.54]$. We also considered a regression predicting curiosity based on understanding; again yielding a significant and positive coefficient of 0.37, $t = 8.7, p < 0.001, 95\%$ CI$[0.28, 0.45]$. We then fit a multiple regression with both value manipulation and perceived value as predictors; this yielded coefficients of 0.26 and 0.44 respectively ($t = 2.21, p < 0.05, 95\%$ CI$[0.03, 0.49]$ and $t = 11.2, p < 0.001, 95\%$ CI$[0.37, 0.52]$),

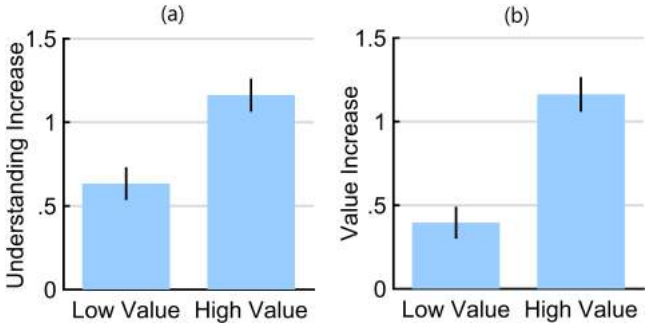

Figure 2: **Effect of value manipulation on understanding and perceived value (Experiment 1).** (a) Change in understanding ratings for participants who received the low-value and high-value stimuli before and after they read the corresponding articles. (b) Change in value ratings for participants before and after they read the corresponding articles.

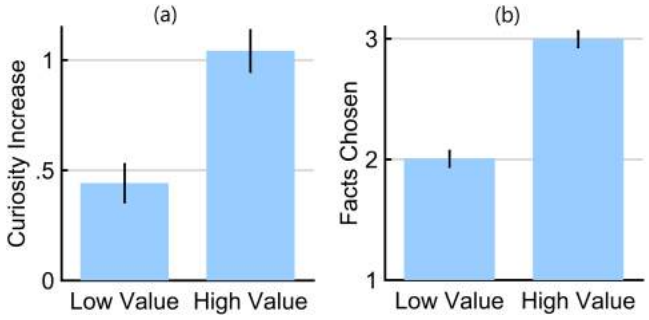

Figure 3: **Value influences curiosity (Experiment 1).** (a) Mean increase in participants' curiosity about a topic after reading a 'low-' or 'high-value' article. (b) Mean facts chosen after reading a 'low-' or 'high-value' article about that topic.

suggesting partial mediation. Finally, we fit a multiple regression with both value manipulation and understanding as predictors which yielded coefficients of 0.42 and 0.34 respectively ($t = 3.46, p < 0.001, 95\%$ CI$[0.18, 0.66]$ and $t = 7.98, p < 0.001, 95\%$ CI$[0.25, 0.42]$), again suggesting partial mediation.

Phase 2 We next investigated whether participants were more likely to reveal facts about the high-value stimuli compared to the low-value stimuli. As shown in Figure 3(b), participants indeed revealed more facts about the high-value stimuli (3 vs. 2). A paired-samples t-test found that this difference was significant, $t(478) = -10.6, p < 0.001$.

Discussion

Experiment 1 tested and found support for two of our three predictions about the effects of value on curiosity. First, results from phase 1 showed that participants became more curious about stimuli after reading information that suggested the topic was of high (vs. low) value. Second, results from phase 2 demonstrated that participants were more likely to reveal additional information about a topic after reading information suggesting it was of high value. We also found that our stimuli successfully manipulated perceived value, and that perceived value partially mediated the effect of our value manipulation on curiosity. However, the effect of our value manipulation on curiosity was also partially mediated by understanding. This raises the concern that perceived value is confounded with understanding, and that changes in understanding drove the effects of our manipulation on curiosity. We address this concern in Experiment 2.

Experiment 2: What influences value most?

Experiment 2 had two aims. First, the experiment aimed to test the influence of perceived value on curiosity while controlling for understanding. Second, the experiment aimed to investigate the effect of different kinds of information on people's perceived value and subsequently on curiosity. Participants were randomly assigned to three conditions in which they read a short article about the 'biology of fruit flies' and provided ratings before and after they read the article. In condition 1, the article presented interesting facts about *fruit fly reproduction*. In condition 2, the article showed how fruit flies are *valuable to the environment*. In condition 3, the article provided evidence that fruit flies are *valuable to medical research*. We hypothesized that participants' increase in understanding would be similar across the three conditions, but that perceived value would not be. Moreover, the contrast between conditions 2 and 3 allows us to test the hypothesis that perceived value would be especially sensitive to value with potential personal relevance.

More specifically, the experiment tested these predictions: (1) Participants' curiosity about fruit flies will increase most strongly in condition 3 (compared to conditions 1 and 2), and (2) the effect of perceived value on curiosity will not be reducible to other factors, such as understanding or surprise.

Participants

We recruited 203 participants from Amazon Mechanical Turk ($n = 67, 72$, and 64 for condition 1, 2, and 3 respectively). They earned \$0.35 for participating in a study that took approximately 2-3 minutes to complete.

Stimuli

The stimuli used in the experiment were three short articles describing the biology of fruit flies. The three articles varied in terms of their value to humans – the first article simply presented interesting facts about the reproductive cycle of fruit flies, the second article had facts about the importance of fruit flies for the ecosystem, and the third article provided facts about the importance of fruit flies for medical research. All three articles were matched for length and as much as possible for general content and style (stimuli available at - `https://goo.gl/BNpHzU`).

Procedure

At the start of the experiment, participants were randomly assigned to one of the three conditions. The three conditions followed the same procedure and differed only with respect to

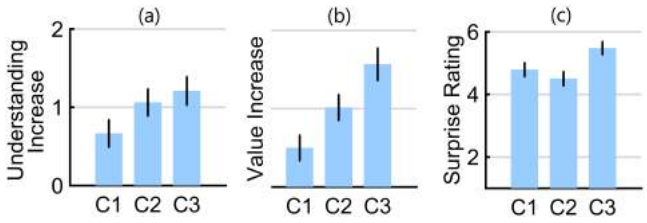

Figure 4: **Effect of value manipulation on understanding, value, and surprise (Experiment 2).** (a) Mean change in understanding ratings. (b) Mean change in value ratings. (c) Mean surprise ratings of participants in each condition.

which of the three articles the participants read. Participants were first presented with the scientific topic, 'biology of fruit flies', and were asked to rate their understanding, perceived value, and curiosity as in Experiment 1. After providing these ratings, participants were presented with the assigned article and they were instructed to read it as carefully as possible. After they finished reading the article, participants were asked to re-rate understanding, perceived usefulness, and curiosity about that topic. In addition to these ratings, after the participants read the article, they were also asked to respond to the following on a scale of 1-7 – "Please rate how surprising you found the previously shown information on fruit flies to be." This question on surprise was added as an additional control to ensure that any potential increase in curiosity was not caused simply by surprise.

Results

We first investigated how participants' understanding changed after they read the corresponding articles across the three conditions. As shown in Figure 4(a), participants' understanding ratings increased significantly after they read the article for all three conditions, $t(142) = -2.34, p < 0.05$ for condition 1, $t(126) = -3.57, p < 0.001$ for condition 2, and $t(132) = -3.88, p < 0.001$ for condition 3. Moreover, a one-way ANOVA revealed that these three groups were not significantly different from each other, $F(2,200) = 2.64, MSE = 5.5, p = 0.07$, indicating that understanding ratings increased the same across all three conditions. We next evaluated how participants' perceived value changed across the three conditions. Although participants' value ratings increased numerically for all three conditions (refer to Figure 4(b)), this increase was not significant for condition 1, $t(142) = -1.52, p = 0.13$. This suggests that simply presenting interesting facts about a topic was not enough to influence perceived value. Furthermore, a one-way ANOVA showed that the three groups differed significantly from each other, $F(2,200) = 9.25, MSE = 19.8, p < 0.001$, with condition 3 significantly higher than condition 2, $t(129) = 2.1, p < 0.05$, and condition 2 significantly higher than condition 1, $t(134) = 2.2, p < 0.05$. We next analyzed how much surprise each article evoked (refer to Figure 4(c)) and found that there was a significant difference for the surprise ratings across the three conditions, $F(2,200) = 5.12, MSE = 16.7, p < 0.01$. Specifically, condition 3 was significantly

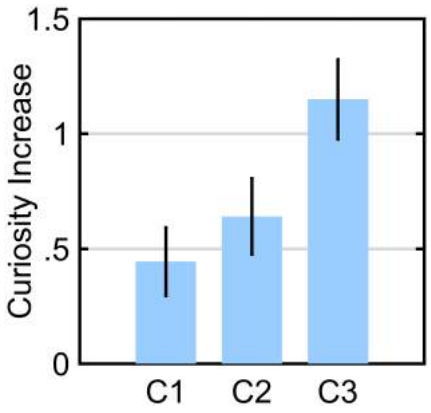

Figure 5: **People's curiosity is highest when they perceive something to be of direct value to them (Experiment 2).** Mean change in curiosity ratings for the three different conditions. Participants' curiosity increased the most in condition 3, in which they read an article that provided evidence that fruit flies are highly beneficial to medicine.

different than condition 2, $t(129) = 3.19, p < 0.05$, but condition 2 was not significantly different compared to condition 1, $t(134) = 0.92, p = 0.36$.

We next evaluated the change in participants' curiosity ratings and found that as per our hypothesis, curiosity ratings increased the most in condition 3 (by 1.15 points, also refer to Figure 5). Furthermore, similar to perceived value ratings, although participants' curiosity ratings increased for all three conditions, that increase was not significant for condition 1, $t(142) = 1.45, p = 0.15$. We also conducted a one-way ANOVA analysis and found that the three groups were significantly different from each other, $F(2,200) = 5.14, MSE = 9.1, p < 0.01$. Follow-up paired-samples t-tests showed that condition 3 was significantly different than condition 2 ,$t(129) = 2.13, p < 0.05$, but condition 2 was not significantly different compared to condition 1, $t(134) = 0.89, p = 0.38$. These results suggest that if people perceive stimuli to be less valuable to them, then they are less likely to become curious about them.

As in Experiment 1, we tested whether the effect of our value manipulation on curiosity was mediated by perceived value. First, a linear regression predicting curiosity from value manipulation (i.e. condition 1, condition 2, or condition 3) revealed a significant positive coefficient of 0.35,

Source	Effect Size	t	p-value	95% CI
condition 1	-0.30	-1.38	0.17	$[-0.73, 0.13]$
condition 2	-0.22	-1.01	0.31	$[-0.65, 0.21]$
understanding*	0.13	2.12	< 0.05	$[0.01, 0.25]$
value*	0.21	3.35	< 0.001	$[0.09, 0.34]$
surprise*	0.15	3.10	< 0.01	$[0.06, 0.25]$

Table 1: **Regression results (Experiment 2).** Regression results of the increase of curiosity ratings with condition 1, condition 2, understanding ratings increase, value ratings increase, and surprise; significant differences are starred.

$t = 3.1, p < 0.005, 95\%$ CI$[0.13, 0.57]$. A similar regression with perceived value as the predictor produced a coefficient of $0.33, t = 5.64, p < 0.001, 95\%$ CI$[0.21, 0.45]$. Next, a multiple regression with both value manipulation and perceived value resulted in a non-significant coefficient of 0.19 for value manipulation, $t = 1.72, p = 0.09, 95\%$ CI$[-0.03, 0.41]$, while perceived value remained significant at 0.3, $t = 4.91, p < 0.001, 95\%$ CI$[0.18, 0.42]$. This suggests that the effect of value manipulation on curiosity was fully mediated by perceived value. Finally, to confirm that the effect of perceived value on curiosity is not reducible to condition, understanding, or surprise, we conducted a linear regression to predict the increase of curiosity ratings with condition 1, condition 2, increase of understanding ratings, increase of value ratings, and surprise. We found a significant regression equation, $F(5, 197) = 10.61, p < 0.001$, with an R^2 of 0.192 and a significant effect of value on curiosity, greater than any of the other factors (refer to Table 1).

Discussion

The findings from Experiment 2 support both of our predictions. First, we found that not all kinds of value are equal: participants were more likely to become curious about a scientific topic if they learned of its direct value to them (condition 3 vs. 2). Second, we succeeded in identifying an effect of value that could not be explained by differences in understanding or surprise. Our results suggest that simply presenting interesting facts that have no direct value is not enough to induce curiosity (condition 1), even if those facts boost understanding and induce surprise.

General Discussion

The primary purpose of this research was to test whether curiosity can be influenced by manipulating people's perceptions of value. Across two experiments, we find that manipulating the perceived value of a topic influenced curiosity (Experiment 1 and 2), and this also influenced subsequent information search (Experiment 1). Results from Experiment 2 further demonstrated that the effects of our manipulation on curiosity were fully mediated by perceived value and cannot be reduced to understanding or surprise, which are both known to influence curiosity.

Our results have considerable theoretical implications as they demonstrate a link between value and curiosity. In doing so, our findings lend support to Dubey and Griffiths's (2017) theory of curiosity. They also challenge previous accounts of curiosity, such as the incongruity theory (Berlyne, 1960) and the information-gap theory (Loewenstein, 1994), insofar as those theories fail to incorporate an *explicit* role for value.

Despite the promise of our results, the significance of our study is limited by the nature of our stimuli, task, and our focus on short-term consequences of value on curiosity. Furthermore, several key theoretical questions about curiosity remain. For example, previous studies have shown that people become curious about completely irrelevant and sometimes even potentially harmful stimuli (Hsee & Ruan, 2016). Conversely, people are sometimes averse to information, even when that information is potentially useful to them (Sweeny et al., 2010). Understanding how curiosity interacts with value in these contexts is an important research question for future work.

Another limitation of our experimental manipulation is that the importance of the information is clearly spelled out to the participants especially in the high-value articles. Therefore, it is possible that the participants rate that information to be important even though they may not necessarily believe that to be the case (perhaps due to a social desirability bias). Future work will consist of conducting further experiments to rule out this possibility.

We also note that some theories stipulate that curiosity is an intrinsic drive and is not instrumental, thereby making our results seem counter-intuitive. On the other hand, even if the experience of curiosity is a drive for knowledge for its own sake, it is still possible that curiosity can be modulated by instrumental factors. Prior work has similarly pointed to the challenge of delineating extrinsic and intrinsic factors in various cases (Kidd & Hayden, 2015). For instance, what is intrinsic for one individual could be extrinsic for another.

Regardless of this debate, our work shows that self-reported curiosity (and information-seeking behavior) can be influenced by value and it sheds light on effective strategies to do so. The results from Experiment 2 suggest that simply presenting information that seems interesting is not effective in influencing value or curiosity (condition 1). Instead, a more effective way to stimulate curiosity is to present information in a way that allows people to directly see its value and relevance (condition 3). Perhaps fruit flies will never be welcome in our homes, but maybe people will become more curious about them – and more welcoming of basic research on them – once they find out how valuable they are to us.

Abstract

A consistent finding in research on conditional reasoning is that individuals are more likely to endorse the valid modus ponens (MP) inference than the equally valid modus tollens (MT) inference. This pattern holds for both abstract task and probabilistic task. The existing explanation for this phenomenon within a Bayesian framework (e.g., Oaksford & Chater, 2008) accounts for this asymmetry by assuming separate probability distributions for both MP and MT. We propose a novel explanation within a computational-level Bayesian account of reasoning according to which "argumentation is learning". We show that the asymmetry must appear for certain prior probability distributions, under the assumption that the conditional inference provides the agent with new information that is integrated into the existing knowledge by minimizing the Kullback-Leibler divergence between the posterior and prior probability distribution. We also show under which conditions we would expect the opposite pattern, an MT-MP asymmetry.

Keywords: conditional reasoning; probabilistic reasoning; Bayesian model; computational-level account

Introduction

Conditionals of the form "If A, then C" – for example, "If global warming continues, then London will be flooded" – are ubiquitous in everyday language and scientific discourse. One research question that has attracted a lot of attention is how individuals reason with conditionals. Usually four conditional inferences are studied, each consisting of the conditional as the major premise, a categorical minor premise, and a putative conclusion:

- *Modus Ponens* (MP): If A then C. A. Therefore, B.
- *Affirmation of the Consequent* (AC): If A then C. C. Therefore, A.
- *Denial of the Antecedent* (DA): If A then C. Not A. Therefore, not B.
- *Modus Tollens* (MT): If A then C. Not C. Therefore, not A.

According to classical logic MP and MT are valid (i.e., truth preserving) inferences and AC and DA are not valid. Early research with conditional inferences has emulated the inference process of classical logic; in the *abstract task*, inferences are presented with abstract content, participants are asked to treat the premises as true, and are asked to only accept necessary conclusions. Results generally showed that even untrained participants are able to distinguish valid from invalid inferences (i.e., they accept more valid than invalid inferences). However, their behavior is clearly not in line with the norms of classical logic. Whereas participants tend to unanimously accept the valid MP, the acceptance rates for the equally valid MT inference scheme is considerably lower. In a meta-analysis of the abstract task, Schroyens, Schaeken, and d'Ydewalle (2001) found acceptance rates of .97 for MP compared to acceptance rates of .74 for MT. This *MP-MT asymmetry* will be the main focus of the present manuscript.[1]

Research in recent years has moved away from the abstract task and its focus on logical validity towards tasks more akin to real-life reasoning within a *probabilistic framework* (Oaksford & Chater, 2007; Over, 2009). In the *probabilistic task*, inferences employ everyday content for which participant posses relevant background knowledge and they are usually asked for their subjective degree of belief in the putative conclusions. The degree of belief in the conclusion of course depends on the actual content (i.e., the probabilistic relationships among premises and conclusion), but there is still ample evidence for an MP-MT asymmetry that goes beyond what would be expected from existing probabilistic accounts. For example, Oaksford, Chater, and Larkin (2000) created materials for which their Bayesian model of conditional reasoning predicted participants to posses similar beliefs in MP and MT. Their results showed that, whereas this reduced the asymmetry, there were still differences such that participants expressed stronger beliefs in MP than MT. Similarly, Singmann, Klauer, and Over (2014) asked participants for their subjective degrees of belief, first in both premises, and then in the conclusion and showed that those only formed a coherent probability distribution "above chance" for MP, but not for MT. Essentially the same results were obtained by Evans, Thompson, and Over (2015). Together, these findings suggest a clear limit for simple probabilistic accounts of conditional reasoning.

Existing Accounts

To describe existing accounts and our new explanation, let us formalize the probabilistic structure of the reasoning problem. We consider an agent who entertains the propositions A (the antecedent) and C (the consequent) of a conditional

[1] Participants also tend to erroneously accept the invalid inferences AC and DA. Schroyens et al. (2001) report acceptance rates of .64 for AC and .56 for DA.

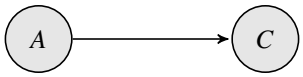

Figure 1: The Bayesian Network representation of the relation between A and C.

"If A, then C". To proceed, we introduce binary propositional variables A and C (in italic script) which have the values A and ¬A, and C and ¬C (in roman script), respectively. A prior probability distribution P is defined over these variables. It is represented by the Bayesian Network in Figure 1. For now, the exact parameterization of P is not yet relevant, however there exist several with three free parameters. In addition, we define the (absolute) *endorsement* of MP as $E_1 := P'(\mathrm{C})$. Similarly, we define the (absolute) endorsement of DA as $E_2 := P'(\neg\mathrm{C})$, the (absolute) endorsement of AC as $E_3 := P'(\mathrm{A})$, and the (absolute) endorsement of MT as $E_4 := P'(\neg\mathrm{A})$.

The original Oaksford et al. (2000) model makes two assumptions. First, it assumes that belief in the conclusion reflects the conditional probability of the conclusion given the minor premise. For example, $E_1 = P(\mathrm{C}|\mathrm{A})$ and $E_4 = P(\neg\mathrm{A}|\neg\mathrm{C})$. Second, it assumes that P is fixed throughout the reasoning process; that is, P is the same for responses to the four conditional inferences (Oaksford and Chater call this the "invariance assumption"). In other words, this model assumes that reasoning amounts to consulting ones fixed probability distribution and responding in line with it (e.g., by sampling from memory; Costello & Watts, 2014) . As shown by Oaksford and Chater (2007, ch.5) this model does a good job in accounting for many of the existing data from the abstract task, but underestimates the MP-MT asymmetry.

To account for the MP-MT asymmetry, the solution first proposed in Oaksford and Chater (2007, ch.5) and subsequently defended in (Oaksford & Chater, 2008, 2013) is to give up on the second of their assumptions, that P is fixed for responses to all four inferences. Specifically, they argue (e.g., Oaksford & Chater, 2013) that MP represents a special case that does not require changing P as it basically reflects the probabilistic information already present in the conditional (i.e., $P(\mathrm{C}|\mathrm{A})$). Thus, presenting MP does not allow the agent to learn new information about P. However, the other three inferences, MT, AC, and DA, present new information and thus require an updated probability distribution P', which individuals "learn". Practically, they did not specify many restriction of P', other than that $P(\mathrm{C}|\mathrm{A}) > P'(\mathrm{C}|\mathrm{A})$, which was primarily motivated by fitting their model to the extant data. From a statistical point of view, it not too surprising that a model that then essentially has one free parameter for fitting E_1 and three free parameters for fitting the remaining three observations (i.e., responses to the other three inferences, E_2, E_3, and E_4) does a relatively good job in accounting for the existing data.

Therefore, there are two main theoretical shortcomings in Oakford and Chater's approach. First, their revised model assumes that the endorsement for MP, E_1, comes from one probability distribution, P, whereas the endorsement for the other inferences, E_2 to E_4, comes from the updated probability distribution P'. This seems somewhat unsatisfactory from a rational Bayesian perspective and more of an ad-hoc solution than a principled argument. Second, the actual processes in which the agent updates P to arrive at P' are not specified well enough. What does it entail for the agent to learn the new information presented in MT? How can we characterize the cognitive processes involved in making a probabilistic MP or MT inference?

Our answer to these questions is based on Eva and Hartmann's (2018) recent Bayesian account of reasoning according to which "argumentation is learning". In line with Oaksford and Chater (2013), learning is specified as updating an agent's prior belief state, represented by P, in light of new information resulting in the posterior belief state P'. Specifically, the premises of an inference will affect specific parts of P (e.g., for MP, the agent learns the new values of both $P(\mathrm{C}|\mathrm{A})$ and $P(\mathrm{A})$). The novel assumption is that as a consequence, the agent needs to incorporate this new information into their existing beliefs which requires her to update potentially all parts of P. According to Eva and Hartmann (2018), this updating follows a well-defined Bayesian rule which generalizes conditonalization and Jeffrey conditionalization and requires that a suitably defined distance (or divergence) between P' and P is minimized. Eva and Hartmann (2018) argue that these divergencies should be members of the family of f-divergences. One important member of this family is the Kullback-Leibler (KL) divergence (Diaconis & Zabell, 1982), which we will use in the remainder. In this way, updating satisfies the constraints provided by the new information and is conservative (i.e., the changes are as minimal as possible). We will show that from this assumption, the typically found MP-MT asymmetry must appear for certain P. However, in some situations the opposite pattern (i.e., $E_4 > E_1$) should also be observed.

The Model

Our new explanation for the MP-MT asymmetry is based on the Bayesian Network in Figure 1 representing the prior probability distribution P. In addition, we assign

$$P(\mathrm{A}) = a, \tag{1}$$

for the prior probability of the antecedent and the conditional probabilities of the consequent C, given the values of its parent:

$$P(\mathrm{C}|\mathrm{A}) = p \quad , \quad P(\mathrm{C}|\neg\mathrm{A}) = q \tag{2}$$

With this, the joint prior probability distribution P over the variables A and C is given by

$$\begin{aligned} P(\mathrm{A},\mathrm{C}) &= a\,p \quad , \quad P(\mathrm{A},\neg\mathrm{C}) = a\,\overline{p} \\ P(\neg\mathrm{A},\mathrm{C}) &= \overline{a}\,q \quad , \quad P(\neg\mathrm{A},\neg\mathrm{C}) = \overline{a}\,\overline{q}, \end{aligned} \tag{3}$$

where we have used the shorthand notation $P(\mathrm{A},\mathrm{C})$ for $P(\mathrm{A}\wedge\mathrm{C})$ which we will use throughout this paper. We also use the shorthand $\overline{x}$ for $1-x$ and assume that $a,p,q\in(0,1)$.

Following the slogan "argumentation is learning", the agent then learns the premises of the argument. More specifically, she learns the major premise "If A, then C" and sets the new probability of $P'(\mathrm{C}|\mathrm{A})=p'=1$ in turn. This is the first constraint on P'. She also learns a minor premise: A in the case of MP, and ¬C in the case of MT. For completeness, we also consider AC and DA. In the case of AC, she additionally learns C, and in the case of DA she additionally learns ¬A. Following Eva and Hartmann (2018), we model this by assuming that the probability of the minor premise increases. This is the second constraint on P'. More specifically, we assume that the agent changes the probabilities of the minor premise in the following way:

$$\begin{aligned} P'_{MP}(\mathrm{A}) &= \lambda+\overline{\lambda}P(\mathrm{A}) \quad , \quad P'_{DA}(\mathrm{A}) = \overline{\lambda}P(\mathrm{A}) \\ P'_{AC}(\mathrm{C}) &= \lambda+\overline{\lambda}P(\mathrm{C}) \quad , \quad P'_{MT}(\mathrm{C}) = \overline{\lambda}P(\mathrm{C}) \end{aligned} \tag{4}$$

Here $\lambda\in(0,1]$ measures to what extent the agent changes the probability of the minor premise. For $\lambda\to 0$, the new probability of the minor premise does not change at all, and for $\lambda=1$ it goes to its maximal value, i.e. to 1.

To find the full new probability distribution P', we then minimize the KL-divergence between P' and P. This allows us to compute the new probability of the conclusion of the corresponding argument. For example, in the case of MP ($\mathrm{A},\mathrm{A}\to\mathrm{C}$, therefore C) the conclusion is C and the new probability of C, i.e. $P'(\mathrm{C})$ measures to what extent the agent endorses the corresponding inference pattern. More specifically, we define the (absolute) *endorsement* of MP as $E_1 := P'(\mathrm{C})$. As described above, we define the (absolute) endorsement of DA as $E_2 := P'(\neg\mathrm{C})$, the (absolute) endorsement of AC as $E_3 := P'(\mathrm{A})$, and the (absolute) endorsement of MT as $E_4 := P'(\neg\mathrm{A})$. Furthermore, we define the relative endorsement of inferences i and j as $\Delta_{ij} := E_i - E_j$ with $i<j$. These quantities will be calculated in the next section.

It is worth pausing here to note that these endorsement quantities should be conceptually distinguished from the corresponding acceptance rates discussed in the introduction. While the former are interpreted as representations of the extent to which a single idealised Bayesian agent will endorse an inference in a probabilistic reasoning task, the latter represent the relative frequency with which those inferences are accepted at the population level. There is no a-priori reason to expect a close correspondence between these two different quantities. In what follows, we try to explain the MP-MT asymmetry in terms of individual endorsement rates.

The Results

Our formal results can be summarized in the following two propositions (all proofs are in the Appendix):

Proposition 1 *An agent considers the binary propositional variables A and C with a probability distribution P defined over them. She then learns (i) the major premise of an argument and sets $P'(\mathrm{C}|\mathrm{A})=1$ and (ii) the minor premise and sets its new probability to a value according to eqs. (4) with $\lambda\in(0,1]$. To find the full new probability distribution P', we minimize the KL-divergence between P' and P. The (absolute) endorsements are then given by $E_1=\lambda+\overline{\lambda}P(\mathrm{A}\vee\mathrm{C})$, $E_2=\lambda P(\neg\mathrm{C}|\neg\mathrm{A})+\overline{\lambda}P(\neg\mathrm{A},\neg\mathrm{C})$, $E_3=\lambda P(\mathrm{A}|\mathrm{C})+\overline{\lambda}P(\mathrm{A},\mathrm{C})$ and $E_4=\lambda+\overline{\lambda}P(\neg\mathrm{A}\vee\neg\mathrm{C})$.*

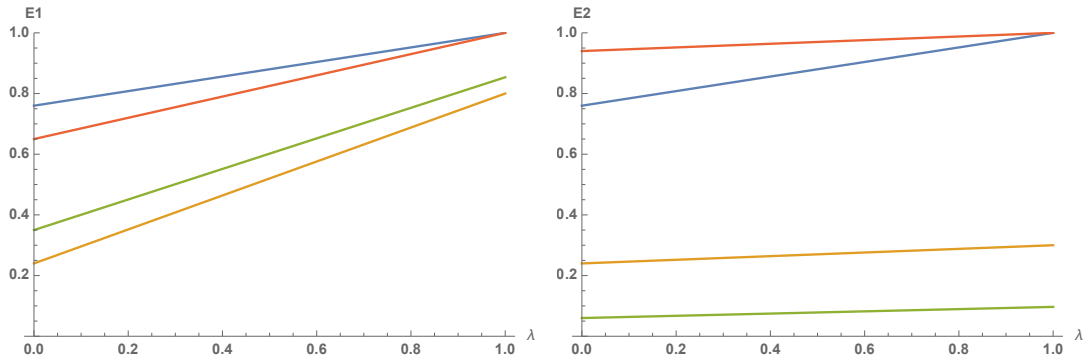
Proposition 2 *Proposition 1 implies the following statements: (i)* MP > AC. *(ii)* MT > DA. *(iii) If $P(\mathrm{A})\geq 1/2$, then* MP > DA *(iv) If $P(\mathrm{A},\mathrm{C})\geq P(\neg\mathrm{A},\neg\mathrm{C})$, then* MP > MT, AC > DA *and $E_1+E_2<E_3+E_4$. (v) If $P(\mathrm{A},\mathrm{C})\leq 1/2$, then* MT > AC. *(vi)* MP > MT *iff* AC > DA. *(vii) If $P(\mathrm{A}\vee\mathrm{C})\geq 1/2$, then* MP > DA.

Here we have used the notation MP > AC for $\Delta_{13}>0$ etc. Note that the assumptions stated in the various if-sentences in Proposition 2 are only sufficient conditions. It turns out that the respective consequents also hold in a large range of other contexts. These depend, however, on the value of both P and λ as shown in Figure 2.

The two left panels of Figure 2, panels (a) and (c), show a situation in which the probability of the antecedent is relatively high (i.e., large a), the conditional expresses a relationship with reasonable confidence (i.e., the conditional probability of the consequent given the antecedent, p, is at least .5), and exceptions are somewhat uncommon (i.e., relatively low conditional probability of the consequent given that the antecedent, q, does not hold). In this situation we see the typical MP-MT asymmetry pattern (as long as $\lambda<1$), when comparing the blue (MP) and red (MT) line. We also see that the degree of the MP-MT asymmetry crucially depends on λ and increases with decreasing λ. Furthermore, the degree of the MP-MT asymmetry also depends on the specific parameters of P. If the conditional expresses a more certain relationship, as in panel (c), the MP-MT asymmetry is larger than if the relationship expressed by the conditional is more uncertain, as in panel (a).

An interesting pattern is observed if the prior probability of the antecedent is low (i.e., $a<.5$), as shown in panels (b) and (d). We can see that in this case the sign of the MP-MT asymmetry flips. Now, we expect stronger endorsement to MT than to MP. However, as for the case in which the prior probability of the antecedent is relatively large, we see that the extent of this reversed asymmetry also depends on λ and the other parameters of P.

Figure 2 also shows the predicted endorsement for the other two inferences, AC and DA. Their ordering (i.e., whether endorsement is expected to be larger for AC or DA) follows the same general pattern also observed for MP and MT. For panels (a) and (c) we expect larger endorsement for AC and DA (as is commonly observed in the literature). However, if the prior probability of the antecedent is low, we expect the same flip; larger endorsement for DA than for AC. In addition, the figure shows another interesting empirical prediction. For certain values of P, see panel (c), we expect either AC > MT or MT > AC, depending on the value of λ



(a) $a = .7, p = .5$, and $q = .2$

(b) $a = .2, p = .3$, and $q = .7$

(c) $a = .8, p = .7$, and $q = .3$

(d) $a = .2, p = .7$, and $q = .3$

Figure 2: The absolute endorsements E_1 (MP, blue), E_2 (DA, orange), E_3 (AC, green) and E_4 (MT, red) as a function of λ for different prior probability distributions P.

(the qualitatively similar also holds between MP and DA, see panel (d)).

Discussion

These results show that the MP-MT asymmetry is predicted by the behavior of a rational agent who updates her belief after encountering new information that is part of the premises of a conditional inference under certain conditions. In contrast to previous probabilistic accounts (Oaksford & Chater, 2008, 2013), we do not need to assume two different probability distributions for MP and the other inferences. Instead, we describe a rational account of how agents update their beliefs in light of new information and use this updated probability distribution as the basis for her endorsement to the four conditional inferences. With this model, we can also make specific predictions when we would expect the opposite pattern, a MT-MP asymmetry.

Disabling Conditions

So far we have assumed that the agent only considers two propositions, i.e. A and C. In many cases, however, there are other relevant propositions and learning new information might affect them. This might have implications for the endorsement of the various inference patterns we have discussed. Consider the following case (Oaksford & Chater, 2008): Let A be the proposition "you turn the key of your car" and let C be the proposition "the car starts". You then learn the premises of a MT inference, i.e. $\mathrm{A} \rightarrow \mathrm{C}$ and $\neg\mathrm{C}$. In that case it seems reasonable to not infer $\neg\mathrm{C}$, but rather that the car is broken or, more generally, that a disabler is present (D). To model this situation, we consider the Bayesian Network in Figure 3 and assume that

$$P(\mathrm{A}) = a \quad , \quad P(\mathrm{D}) = d, \tag{5}$$

where a is large (you will be pretty certain that you turned the key of your car if you did so) and d is somewhat smaller, but it seems reasonable to take the possibility that the car might be broken into account before actually turning the key of the car.

Furthermore, we have to specify the likelihoods

$$\begin{aligned} P(\mathrm{C}|\mathrm{A},\mathrm{D}) &= \alpha \quad , \quad P(\mathrm{C}|\mathrm{A},\neg\mathrm{D}) = \beta \\ P(\mathrm{C}|\neg\mathrm{A},\mathrm{D}) &= 0 \quad , \quad P(\mathrm{C}|\neg\mathrm{A},\neg\mathrm{D}) = 0. \end{aligned} \tag{6}$$

Here we have assumed that the car does not start if the key is not turned. Note that the context suggests that $\beta > \alpha \approx 0$ although we will not need the left inequality. All we will need is that α is fairly small.

The agent then learns the conditional $\mathrm{A} \rightarrow \mathrm{C}$ which imposes the constraint $\beta' > \beta$ on P'.[2] The agent furthermore

[2] β' could be 1, but we will see that this does not matter. All we need is that $\beta, \beta' > 0$.

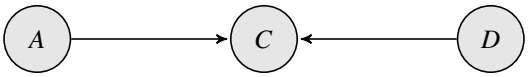


Figure 3: The Bayesian Network representation of the relation between A, C and D.

learns that $P'(\mathrm{C}) = 0$. (We set this value to 0 as it will be hard to doubt that the car did not start if in fact it did not start.) We then note that

$$P'(\mathrm{C}) = a'\,(d'\,\alpha' + \overline{d'}\,\beta') = 0, \tag{7}$$

where we have assumed that P' can be parameterized analogously to P. Given that $\beta' > \beta > 0$, eq. (7) has two solutions: (i) $a' = 0$ and (ii) $\alpha' = 0$ and $d' = 1$. Obviously, solution (i) corresponds to the proper MT inference. However, this inference is implausible in the present case. To explore this issue further, let us consider the KL-divergence between P' and P:

$$KL = \Phi_a + \Phi_d + a'\,d'\,\Phi_\alpha + a'\,\overline{d'}\,\Phi_\beta \tag{8}$$

We have to minimize KL with the constraint (7). Let us consider solution (i) first. Then $KL_1 = -\log\overline{a} + \Phi_d$. This expression minimizes for $d' = d$ and therefore $KL_1^{min} = -\log\overline{a}$. Next, consider (ii). Here $KL_2 = \Phi_a - a'\log\overline{\alpha} - \log d$. Minimizing this expression with respect to a' yields $a' = a\,\overline{\alpha}/(a\,\overline{\alpha} + \overline{a})$ and $KL_2^{min} = -\log((a\,\overline{\alpha} + \overline{a})\,d)$. Hence, $KL_2^{min} < KL_1^{min}$ iff $(a\,\overline{\alpha} + \overline{a})\,d > \overline{a}$ or $a\,\overline{\alpha} > \overline{a}\,\overline{d}$. This condition is fulfilled in the present case as $\alpha \approx 0$ and $a \approx 1$. (Note that the value of d does not matter too much here, but it should not be too low. If it is very low and the inequality is violated, then the agent should make a MT inference and infer $\neg$A.)

Conclusions

Our main goal was to provide a novel probabilistic explanation for the MP-MT asymmetry found in both the traditional abstract task as well as in probabilistic tasks with conditional inferences. In contrast to previous explanations within a probabilistic framework (Oaksford & Chater, 2007, 2013, 2008), our explanation is based on a principled approach of how agents update a probability distribution P in light of new information provided by the premises of a conditional inference resulting in a updated probability distribution P'. Following the idea that "argumentation is learning" (Eva & Hartmann, 2018), we propose that agents update their probability distributions in light of new information by minimizing the KL-divergence between the posterior and prior probability distribution. In this conceptualization, reasoning does not only amount to a read-out from memory, but requires the agent to actively integrate the new knowledge with the existing one. The exact cognitive processes how this is achieved (e.g., by creating new memory traces or overwriting existing ones), is an open question for future work. Our work provides a full *computational-level account* (in the sense of Marr, 1982) of conditional reasoning.

The theoretical results presented here provide evidence that the MP-MT asymmetry is a direct consequence from this Bayesian conceptualization of conditional reasoning. Specifically, it occurs if the prior probability of the conditional probability of C given A (i.e., the relationship expressed in the conditional) and the the prior probability of the antecedent is at least .5. In the case that these conditions do not hold, we expect the opposite pattern, an inverted MP-MT asymmetry.

Minimizing the KL-divergence, as proposed here, is one rational way for an agent to update her prior probability distribution in light of new information which implies Jeffrey conditionalization (Diaconis & Zabell, 1982). Importantly, the results shown here do not only apply to updating via minimizing the KL-divergence, but for updating based on minimizing the distance between P' and P for any divergence measure that is a member of the family of f-divergences. All these divergence metrics are rational in the same sense and also predict the MP-MT asymmetry under the same circumstances. This is an important aspect of our results in light of the findings of Singmann, Klauer, and Beller (2016). They have investigated the empirical adequacy of conditional reasoning based on KL-minimization between P' and P in a two-step conditional reasoning task – which allowed to obtain estimates of both P and P' in an independent manner – and found that it did not provide a very adequate account. However, as soon one is willing to give up the assumption that $P'(\mathrm{C}|\mathrm{A}) = p' = 1$ and assumes that $P'(\mathrm{C}|\mathrm{A}) < 1$ (as done in Singmann et al.'s study), different members of the family of f-divergences make different predictions. Preliminary work suggests that a more empirically adequate account of conditional reasoning is provided if we assume reasoners update their probability distribution by minimizing the inverse-KL divergence between prior and posterior distribution.

Proof of Proposition 1

We use the parameterization of the prior probability distribution P according to eqs. (1) and (2) and begin with MP and DA. Here we set the new value of the probability of the antecedent to a'. Disregarding constant terms, the KL-divergence is then given by $KL = \overline{a'}\,\Phi_q$ with

$$\Phi_x := x' \log\frac{x'}{x} + \overline{x'}\log\frac{\overline{x'}}{\overline{x}}\,. \tag{9}$$

Differentiating KL with respect to q' and setting the resulting expression equal to zero yields $q' = q$. Hence, $P'(\mathrm{C}) = a' + \overline{a'}\,q$. We now insert the appropriate values of c' from eqs. (4) and use the definition of the respective (absolute) endorsements to obtain

$$\begin{aligned} E_1 &:= P'(\mathrm{C}) \\ &= \lambda + \overline{\lambda}(a + \overline{a}\,q) \\ &= \lambda + \overline{\lambda}P(\mathrm{A} \vee \mathrm{C}) \\ E_2 &:= P'(\neg\mathrm{C}) \\ &= \lambda\,\overline{q} + \overline{\lambda}\,\overline{a}\,\overline{q} \\ &= \lambda P(\neg\mathrm{C}|\neg\mathrm{A}) + \overline{\lambda}P(\neg\mathrm{A}, \neg\mathrm{C}). \end{aligned}$$

Let us now consider AC and MT. In this case, learning the minor premise amounts to the constraint

$$a' + \overline{a'}\, q' = c', \tag{10}$$

with c' specified in eqs. (4). We therefore have to minimize the function

$$L = \Phi_a + a' \log \frac{1}{p} + \overline{a'}\, \Phi_q + \mu(a' + \overline{a'}\, q' - c'),$$

with the Lagrange multiplier μ.

Differentiating L with respect to q' and setting the resulting expression equal to zero yields

$$q' = \frac{1}{q + \overline{q}x}, \tag{11}$$

with $x := \exp(\lambda)$. Hence,

$$L = \Phi_a + a' \log \frac{1}{p} + \overline{a'} \log \frac{1}{q + \overline{q}x} + \mu \overline{c'}.$$

Differentiating this expression with respect to a' and setting the resulting expression equal to zero yields

$$a' = \frac{a\,p}{a\,p + \overline{a}\,(q + \overline{q}x)}. \tag{12}$$

From eqs. (10), (11) and (12), we then obtain

$$a' = \frac{a\,p\,c'}{a\,p + \overline{a}\,q}. \tag{13}$$

We now insert the appropriate values of c' from eqs. (4) in eq. (13) and use the definitions of the respective (absolute) endorsements to obtain

$$\begin{aligned}
E_3 &:= P'(\mathrm{A}) \\
&= \lambda \frac{a\,p}{a\,p + \overline{a}\,q} + \overline{\lambda}\, a\,p \\
&= \lambda P(\mathrm{A}|\mathrm{C}) + \overline{\lambda} P(\mathrm{A},\mathrm{C}) \\
E_4 &:= P'(\neg \mathrm{A}) \\
&= \lambda + \overline{\lambda}(1 - a\,p) \\
&= \lambda + \overline{\lambda} P(\neg \mathrm{A} \vee \neg \mathrm{C}).
\end{aligned}$$

This completes the proof of Proposition 1. ∎

Proof of Proposition 2

We use Proposition 1 to compute the relative endorsements:

$$\begin{aligned}
\Delta_{12} &= \lambda q + \overline{\lambda}\,[2(a + \overline{a}\,q) - 1] \\
\Delta_{13} &= \lambda \frac{\overline{a}\,q}{a\,p + \overline{a}\,q} + \overline{\lambda}(a\,\overline{p} + \overline{a}\,q) \\
\Delta_{14} &= \overline{\lambda}(a\,p - \overline{a}\,\overline{q}) \\
\Delta_{23} &= -(a\,p - \overline{a}\,\overline{q}) \cdot \left[\lambda \frac{q}{a\,p + \overline{a}\,q} + \overline{\lambda}\right] \\
\Delta_{24} &= -\lambda q - \overline{\lambda}(a\,\overline{p} + \overline{a}\,q) \\
\Delta_{34} &= -\lambda \frac{\overline{a}\,q}{a\,p + \overline{a}\,q} + \overline{\lambda}(2a\,p - 1)
\end{aligned}$$

From these results, the statements made in the proposition follow. For example, the third statement in (iv) follows by noting that $\Delta_{14} + \Delta_{23} < 0$. ∎

Children's overextension as communication by multimodal chaining

Abstract

Young children often stretch terms to novel objects when they lack the proper adult words—a phenomenon known as overextension. Psychologists have proposed that overextension relies on the formation of a chain complex, such that new objects may be linked to existing referents of a word based on a diverse set of relations including taxonomic, analogical, and predicate-based knowledge. We build on these ideas by proposing a computational framework that creates chain complexes by multimodal fusion of resources from linguistics, deep learning networks, and psychological experiments. We test our models in a communicative scenario that simulates linguistic production and comprehension between a child and a caretaker. Our results show that the multimodal semantic space accounts for substantial variation in children's overextension in the literature, and our framework predicts overextension strategies. This work provides a formal approach to characterizing linguistic creativity of word sense extension in early childhood.

Keywords: language acquisition; linguistic creativity; overextension; word sense extension; multimodality; chaining; communication

Young children often stretch terms to describe novel objects when they lack the proper adult words, a phenomenon known as overextension (Clark, 1978). Overextension is a communicative strategy that draws on knowledge of diverse relations in the world. For instance, a child may use "dog" to refer to a *squirrel*, "ball" to refer to a *balloon*, or "key" to refer to a *door*. This creative use of words toward novel meanings, or *word sense extension*, is not only attested in child language acquisition, but it is also reflected in historical meaning change, e.g., we extended the meaning of "mouse" from a rodent to a computer device. We explore the origin of word sense extension by asking how the cognitive capacity of overextension in childhood can be characterized formally.

Early work by Vygotsky (1962) suggests that overextension relies on "chain complex", a critical element of concept formation in childhood. He demonstrated chain complex by a series of overextension cases from a child who extended the meanings of "quah" to wide-ranging things including a duck, water in a pond, liquids in general, an eagle on a coin, and any coin-like objects. Vygotsky's account resonates with work from philosophy and cognitive linguistics that suggest the complex structure of word meanings (e.g. Wittgenstein, 1953) is formed possibly due to a process of chaining (Lakoff, 1987), where one referent is linked to another forming a chain-like structure. More recent work has shown that chaining predicts word sense extension in the history of English (Ramiro, Srinivasan, Malt, & Xu, 2018) and other languages (Xu, Regier, & Malt, 2016). However, these works did not offer a formal account of how one might represent the rich knowledge in a chain complex.

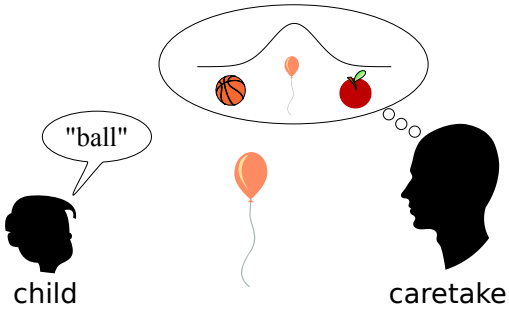

Figure 1: Overextension in child-caretaker communication.

Empirical work from Rescorla (1980) provided clues to the knowledge underlying children's overextension. Specifically, she identified three main types of relations between core and overextended meanings of a word, summarized as 1) *categorical* relation: overextension by linking objects within a taxonomy, e.g., "dog"→*squirrel*, 2) *analogy* or visual analogy: overextension by linking objects with shared perceptual properties, e.g., "ball"→*balloon*, and 3) *predicate-based* relation: overextension by linking objects that co-occur frequently in the environment, e.g., "key"→*door*. An open question we address in this work is how to combine these types of relations to predict overextension strategies in early childhood.

We propose a computational framework that considers overextension as a communicative game between a child and a caretaker, illustrated in Figure 1. The game involves a child and a caretaker in a situation where the child needs to refer to an out-of-vocabulary novel object. In this context, the child faces a *production problem*, where the goal is to extend a word from the existing vocabulary (e.g., "ball") to the novel object (e.g., a balloon). The caretaker instead faces a *comprehension problem*, where the goal is to guess the intended referent based on the child's utterance. Since "ball" does not typically map to balloons, we wish to reconstruct the cognitive processes that could have given rise to successful communication between the child and the caretaker in common cases of overextension. As such, our framework should support both strategic word choices for the child and prediction of intended referents for the caretaker.

Our communication-based framework relates to earlier work in overextension from the developmental literature. For example, Bloom (1973) argued that overextension is a performance error caused by vocabulary limitations, whereby a child may consciously use an incorrect word (from the adult perspective) as a strategy to convey the desired referent meaning. A related hypothesis poses overextension as a retrieval error (Fremgen & Fay, 1980; Gershkoff-Stowe, 2001; Huttenlocher, 1974; Thomson & Chapman, 1977), suggesting that children may overextend an earlier acquired word even if the correct adult word has been partially acquired (e.g., understood in comprehension), because the latter may be more difficult to produce. We explore evidence for a retrieval error hypothesis by evaluating whether children may favour words with higher usage frequencies in their overextended word choices. Another extensive line of research suggests that overextension arises from children's incomplete conceptual knowledge of the semantic features underlying different categories (Clark, 1973; Kay & Anglin, 1982; Mervis, 1987). While we do not directly test claims about children's conceptual space in this work, we show that a combination of semantic relations helps to explain overextension strategies, and may play an integral role in characterizing the mechanisms that subserve children's early word learning.

Our framework also draws on a multimodal space of semantic relations (cf. Rescorla, 1980) that serves as the knowledge engine for creating chain complexes in overextension. The notion of multimodality is motivated in part by work on visually-grounded word learning (e.g. Lazaridou, Chrupała, Fernández, & Baroni, 2016; Roy & Pentland, 2002; Yu, 2005), which shows that perceptual features play an important role in children's acquistion of core (or conventional) word meanings. Our focus is on investigating how by integrating diverse semantic relations one might account for word usage beyond the core meanings that children normally acquire. Our work thus differs from the extensive literature on cross-situational word learning (Fazly, Alishahi, & Stevenson, 2010; Frank, Goodman, & Tenenbaum, 2009; Kachergis, Yu, & Shiffrin, 2017; Siskind, 1996), where the emphasis has been typically on modeling children's behaviour in learning conventional word meanings, but not on how they extend existing terms to describe novel objects. Our work also extends existing computational studies that explore overextension in specific domains such as color terms (Beekhuizen & Stevenson, 2016) to more general cases of overextension that involve mappings across domain boundaries, e.g., "ball"→*balloon*.

Computational framework

We present our computational framework for overextension following two steps: 1) Specification of a probabilistic model that simulates child's word choices (production) and caretaker's inference of intended referents (comprehension); 2) Construction of a semantic space that supports multimodal chaining of word meanings, encapsulated in the same model.

For this work, we focus on overextension of nouns, but the general framework that we present can be used to explore other types of overextension (e.g., in verbs and adjectives).

Probabilistic formulation

We formulate overextension as communication between a child and a caretaker. In particular, the child wishes to refer to a novel object c in an environment E. The child does so by choosing (and stretching) a word w from her vocabulary V. We assume that the correct term for the novel object is not yet acquired by the child, hence $c \neq w$ and $c \notin V$. Based on the child's utterance w, the caretaker wishes to infer the referent c among possible referents in E. We then model the child's behaviour by a *production model* and pair it with a *comprehension model* for the caretaker's behaviour.

Production. We cast the production problem as probabilistic inference over existing words in the child's vocabulary given the probe novel object c, via Bayes' rule:

$$p_{\text{prod}}(w|c) \propto p_{\text{prod}}(c|w)p(w) \tag{1}$$

We define the prior $p(w)$ proportional to the logarithmic usage frequency of a word with add-one smoothing $p(w) \propto \log(1+\text{freq}(w))$. This formulation is consistent with the frequency effect found in the study of overextension in color terms (Beekhuizen & Stevenson, 2016). It captures the intuition that all things being equal, the child is more likely to choose a common word versus a rare word for overextension. We define the likelihood function $p_{\text{prod}}(c|w)$ by a meta similarity measure that encapsulates the three types of semantic relations reported by Rescorla (1980) which the novel referent c can bear with the existing referent c_w of word w:

$$\begin{aligned} p_{\text{prod}}(c|w) &\propto \text{sim}(c, c_w) \\ &= \exp\left(-\frac{d_c(c,c_w)+d_v(c,c_w)+d_p(c,c_w)}{h}\right) \end{aligned} \tag{2}$$

We take the exponential-decay form from the generalized context model (GCM) or exemplar model of categorization (Nosofsky, 1986), where the influence of each relational type is proportional to how similar c and c_w are under that relation. We represent similarity by inverse distance, where d_c, d_v, and d_p represent distances measured according to categorical relation, visual analogy, and predicate-based relation, respectively. We describe the construction of each of these relational features in the next section. To control for model sensitivity to these distance functions, we use a single parameter h that we estimate empirically from data. The magnitude of h determines how slowly the meta similarity or the likelihood function decreases with respect to the distance measured in the multimodal relations.

Comprehension. We pair the child's production model with a comprehension model for the caretaker. Specifically, the caretaker solves the inverse inference problem as the child by a probability distribution over the space of intended referents based on the child's utterance w:

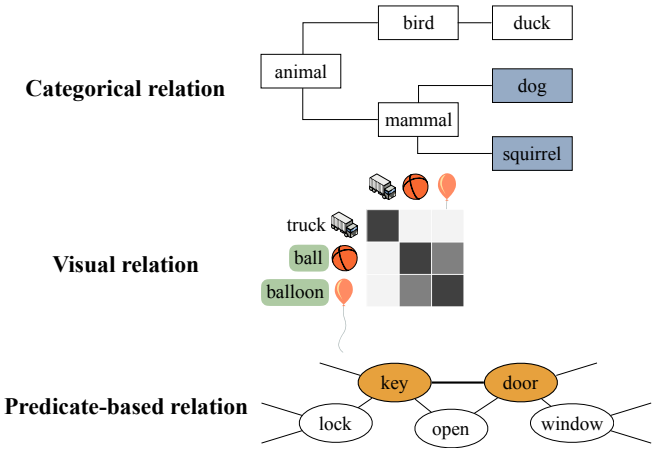

Figure 2: Types of semantic relations in multimodal space.

$$p_{\text{comp}}(c|w) \propto p_{\text{comp}}(w|c)p(c) \tag{3}$$

We consider the space of c to be all referents that appear in the communicative environment E where the child and the caretaker are situated in. We also assume a uniform prior $p(c)$ on possible referents in this environment, although it may be possible to enrich this prior by considering perceptual salience, eye gaze, pointing, and other pragmatic cues, which we do not model or have explicit access to in this work.

We define the likelihood function identical to the formulation used in the production model, under the assumption that both the child and the caretaker have knowledge of the multimodal relations:

$$p_{\text{comp}}(w|c) \propto \text{sim}(c_w, c) = \text{sim}(c, c_w) \tag{4}$$

Although it is possible to model perspective taking in a recursive way $p_{\text{comp}}(w|c) = p_{\text{prod}}(w|c) = p_{\text{prod}}(c|w)p(w)$ under the assumption that the caretaker takes into account the child's word choice in guessing the intended referent, e.g., similar to the rational speech act model (Goodman & Frank, 2016), we choose to work with the simplest version of this model that does not make any recursive assumption in the caretaker. We show in *Results* that our framework accounts for data well even without this assumption.

Multimodal semantic space

We define a multimodal semantic space that captures the three types of relational features in Rescorla (1980): categorical relation, visual analogy, and predicate-based relation. We construct these relational features using a fusion of resources drawn from linguistics, deep learning networks, and psychological experiments, as illustrated in Figure 2.

Categorical relation. We define categorical relation between two referents via a standard distance measure d_c in natural language processing by Wu and Palmer (1994), based on taxonomic similarity. Concretely, for two concepts c_1 and c_2 under a taxonomy T (i.e., a tree), the distance is:

$$d_c(c_1, c_2) = 1 - \frac{2N_{\text{LCS}}}{N_1 + N_2} \tag{5}$$

N_{LCS} denotes the number of shared parent nodes of the two concepts in the taxonomy. N_1 and N_2 denote the depths of the two concepts in the taxonomy. This distance measure is effectively the negated taxonomic similarity between c_1 and c_2, and is bounded between 0 and 1. Under this measure, concepts from the same semantic domain (such as *dog* and *squirrel*) should yield a lower distance than those from across domains (such as *ball* and *balloon*). To derive the categorical features, we took the taxonomy from WordNet (Miller, 1995) and annotated words by their corresponding *synset*'s in the database. We used the *NLTK* package (Bird & Loper, 2004) to calculate similarities between referents for this feature.

Visual analogical relation. We define visual analogical relation by cosine distance between vector representations of referents in visual embedding space. In particular, we extracted the visual embeddings from convolutional neural networks—VGG-19 (Simonyan & Zisserman, 2015), a state-of-the-art convolutional image classifier pre-trained on the ImageNet database (Deng et al., 2009)—following procedures from work on visually-grounded word learning (Lazaridou et al., 2016). Under this measure, concepts that share visual features (such as *ball* and *balloon*, both of which are round objects) should yield a relatively low distance even if they are remotely related in the taxonomy. To obtain a robust visual representation for each concept c, we sampled a collection of images $I_1, \ldots, I_k$ up to a maximum of 512 images from ImageNet. With each image I_j processed by the neural network, we extracted the corresponding visual feature vector from the first fully-connected layer after all convolutions: v_j^c. We then averaged the sampled k feature vectors to obtain an expected vector v^c for the visual vector representation of c.

Predicate-based relation. We define predicate-based relation by leveraging the psychological measure of word association. We assume that two referents that frequently co-occur together should also be highly associable, e.g., *key* and *door*. Specifically, we followed the procedures in De Deyne, Navarro, Perfors, Brysbaert, and Storms (2018) and took the "random walk" approach to derive vector representations of referents in a word association probability matrix. This procedure generates word vectors based on the positive pointwise mutual information from word association probabilities propagated over multiple leaps in the associative network. As a result, concepts that share a common neighbourhood of associates are more likely to end up closer together in the vector space. De Deyne et al. (2018) showed that this measure yields superior correlations with human semantic similarity judgements in comparison to other measures of association. We used word association data from the English portion of the Small World of Words project (De Deyne et al., 2018). The data is stored as a matrix of cue-target association probabilities for a total of 12292 cue words. We used the implementation provided by the authors (`https://github.com/SimonDeDeyne/SWOWEN-2018`)

to compute vector representations from the association probability matrix. We used cosine distance to compute predicate-based distances between pairs of referent vectors.

To ensure that the three types of relational features provide complementary information, we calculated their intercorrelations based on 66 concept pairs that we used for our analyses. Although correlations were significant ($p < .001$), all coefficients were low (category & visual: 0.179; category & predicate: 0.186; visual & predicate: 0.274).

Data

We collected linguistic data from three sources: 1) Metadata of child overextension from the literature; 2) Vocabulary of early childhood; 3) Text corpora of child-caretaker speech.

Metadata of child overextension. We performed a meta survey of 12 representative studies from developmental psychology and collected a total of 86 overextension example word-referent pairs. Each pair consists of an overextended word and the novel referent that word has been extended to. We kept word-referent pairs that overlapped with the available data from the three features we described, resulting in a total of 66 word-referent pairs. Table 1 shows examples from this meta dataset and their sources from the literature.

While the data we used for analysis may not constitute an unbiased sample of child overextension, two factors help to alleviate this concern. First, we followed a systematic approach in data collection by recording every utterance-referent pair in which both constituents could be denoted by one noun. Second, the diversity of the sources that we examined reduces the possibility of biasing our sample from any individual study.

Table 1: Examples of overextension data.

Uttered word → *Referent*	Source
"banana" → *moon*	Behrend, D. A. (1988)
"car" → *truck*	Fremgen, A., & Fay, D. (1980)
"apple" → *orange juice*	Rescorla, L. A. (1981)
"ball" → *bead*	Barrett, M. D. (1978)
"fly" → *toad*	Clark, E. V. (1973)
"cow" → *horse*	Gruendel, J. M. (1977)
"apple" → *egg*	Rescorla, L. A. (1980)

Vocabulary from early childhood. To approximate children's vocabulary in early childhood, we collected nouns reported to be produced by children of up to 30 months of age from the American English subset of the Wordbank database (Frank, Braginsky, Yurovsky, & Marchman, 2017). Because overextension has been typically reported to occur between 1;1 and 2;6 years (Clark, 1973) (that covers the range in Wordbank), we constructed a vocabulary V using all the nouns from Wordbank for which we could obtain the required semantic features. The resulting vocabulary includes 316 out of the 322 nouns from the database.

Corpora of child-caretaker speech. To evaluate our models in a realistic communicative context, we collected a large set of child-caretaker speech transcripts from the CHILDES database (MacWhinney, 2014), for child Eve (age 1;6 to 2;3) from the Brown corpus (Brown, 1973), Peter (1;9 to 3;1) from the Bloom70 corpus (Bloom, Hood, & Lightbown, 1974), and Nina (1;11 to 3;3) from the Suppes corpus (Suppes, 1974). We chose these children's data because their ages closely match the typical overextension period reported in child development. We considered each transcript as forming a communicative environment, and from each environment, we collected the set of all nouns uttered by the child and the caretaker for the analyses detailed in the next section. In total, we obtained 1586 communicative environments with a median of 139 distinct nouns per context.

Results

We assess our proposed framework in three aspects: 1) model accuracy in reconstructing child and caretaker strategies in overextension; 2) evidence for multimodal chaining in overextension; 3) model generation of chain complex.

Model reconstruction of overextension strategies

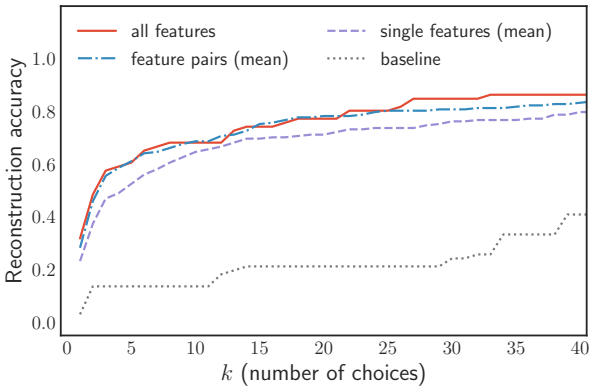
Production. We evaluated the child production model against the curated set of overextension word-referent pairs, $O = \{(w_i, c_i)\}$, with respect to all words in the child vocabulary V. For each pair, the model chooses the target word based on the given overextended sense c_i by assigning a probability distribution over words w in V. We assessed the model by finding the maximum *a posteriori* probability (MAP) of all the overextension pairs under the single sensitivity parameter h, which we optimized to the MAP objective function via standard stochastic gradient descent:

$$\max_h \prod_i p_{\text{prod}}(w_i|c_i;h,V) = \max_h \prod_i \frac{p_{\text{prod}}(c_i|w_i;h)p(w_i)}{\sum_{w\in V} p_{\text{prod}}(c_i|w;h)p(w)} \tag{6}$$

To assess the contribution of the three relational features, we tested this production model under single features and all possible combinations of features in pairs and triplets. We also compared these models under the frequency-based prior versus those under a uniform prior, along with a baseline model that chooses words only based on the prior distribution. We evaluated all models under two metrics: the Bayesian information criterion (BIC), which is a standard measure for probabilistic models that considers both degree of fit to data (i.e., likelihood) and model complexity (i.e., number of free parameters); a performance curve that measures model accuracy at different values of k, similar to the standard receiver-operating curve (ROC), where we assessed the predictive accuracy of each model from its choice of top k words for different levels of k, or the proportion of overextension pairs (w_i, c_i) for which the model ranks the correct production w_i among its top k predictions for referent c_i.

The left two columns of Table 2 summarize the BIC scores of the family of production models. We made three observations. First, models that incorporate features performed

(a) Production model



(b) Comprehension model

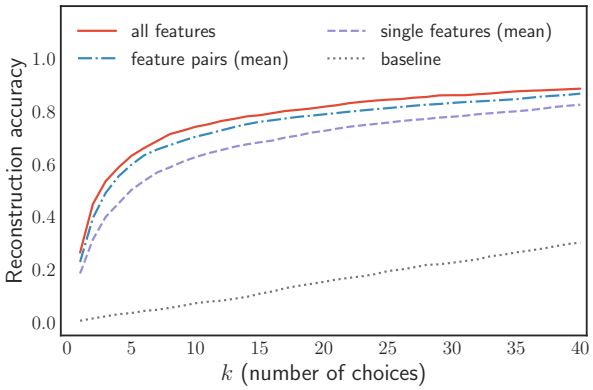


Figure 3: Performance curves for production and comprehension models.

Table 2: Bayesian Information Criterion (BIC) scores for production and comprehension (comp.) models.

	Production		**Comp.**
Model likelihood	freq. prior	unif. prior	unif. prior
Baseline	695	760	13268
category (cat.)	502	583	9663
visual (vis.)	496	574	10344
predicate (pred.)	499	582	9890
cat. + vis.	454	537	8949
cat. + pred.	457	544	8885
vis. + pred.	461	546	9261
all features	**439**	**526**	**8594**

better than the baseline (i.e., lower in BIC scores), suggesting that children overextend words by making explicit use of the semantic relations we considered. Second, models with the frequency-based prior performed dominantly better than those with the uniform prior, suggesting that children jointly consider word usage frequency (or effort) and semantic relations in overextension. Third, models with featural integration performed better than those with isolated features (i.e., all features<features pairs<single features in BIC score), suggesting that children rely on multiple kinds of semantic relations in overextensional word choices. Figure 3a further confirms these findings in performance curves that show the average predictive performance under the full range of k in top k modelled word choices: all features>features pairs>single features>baseline in the area under curves.

Comprehension. We next assessed the caretaker comprehension model by asking whether the model can retreive the intended referent from an uttered overextended word. Because we do not have the actual records of caretakers' inferences, we simulated a dataset for model evaluation by 1) identifying child-caretaker speech scripts that contain the overextended referents $\{c_i\}$ from our curated data; 2) replacing the correct word for a referent c_i (in the script) with the overextended word w_i reported in the literature. We then examined if the model is able to retrieve the correct referent c_i based on w_i among all other competing nouns in the communicative context of a script. As an example, knowing that "ball" has been reported to be overextended to *balloon*, we would identify child speech scripts that contain the word "balloon" and replace that word with "ball". We would then run our comprehension model and check if the top referents recovered by the model contain "balloon" among other nouns that appeared as context in that given script.

Similar to the case of production, we assessed the model by maximizing the posterior comprehension probability over all curated referents based on their appearances in the CHILDES transcripts. We optimized the MAP objective function under the sensitivity parameter h using stochastic gradient descent:

$$\max_h \prod_i p_{\text{comp}}(c_i|w_i;h,E_i) = \max_h \prod_i \frac{p_{\text{comp}}(w_i|c_i;h)p(c_i)}{\sum_{c\in E_i} p_{\text{comp}}(w_i|c;h)p(c)} \quad (7)$$

We used the same two metrics to evaluate the family of comprehension models and summarized the BIC-based results in the third column of Table 2 and ROC-based results in Figure 3b. We observed that results are qualitatively similar to those obtained in the production model: the rank order of performance among baseline model, models with single features, feature pairs, and all features, remains unchanged.

Evidence for multimodal chaining

To examine directly how the multimodal semantic space we constructed accounts for variation in the overextension data, we performed a logistic regression analysis. In particular, we considered two sets of data: the *attested set* overextension word-referent pairs, and a *control set* that shuffles the word-referent mappings from the attested set. We then performed a binary classification task via logistic regression to assess whether the attested pairs can be detected from the control pairs, given the same three relational features that we used for our previous analyses. The logistic model achieved 83% accuracy, compared to 50% chance. We also trained models on subsets of the feature space, achieving best feature pair performance of 82% and best single feature performance of 80%. This suggests that semantic relations provide significant predictability of concepts that might undergo overextension.

Figure 4 shows the distribution of dominant features across the 66 overextension pairs (we labelled each pair according to the top-scoring feature in the logistic regression model), along with a few examples that are best explained by each relational type. We observed that the contributions of these features are roughly even, providing support for the view that children rely on a combination of modalities in overextension.

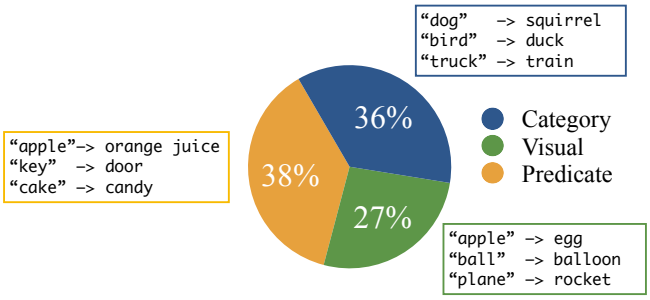

Figure 4: Percentage shares and examples explained by the three types of features from the curated overextension dataset.

Model simulation of chain complex

To illustrate how our model might simulate a chain complex, we applied an iterative scheme to sample a chain of concepts from the multimodal semantic space. Specifically, we began the chaining process with a seed word w_0 and initial chain $C^0 = \{w_0\}$. In the j-th iteration, we sampled word w uniformly from C^{j-1}, and word w' from children's vocabulary V according to probability distribution $p(w'|w) \propto \text{sim}(c_{w'}, c_w)$, where the similarity function is defined in Equation 2. We then added w' to the chain complex by linking it to w, hence extending the chain to $C^j = C^{j-1} \cup \{w'\}$. Figure 5 shows a chain complex sampled from seed concept "door". Similar to Vygotsky's "quah" example, it features referent-to-referent extensions that involve different types of relations, illustrating the thought processes that could have given rise to the diverse overextension patterns attested in young children.

While exploratory in nature, our simulation demonstrates the potential of a multimodal approach to capture the formation of chain complexes in child overextension. Future work should explore this generative aspect of the framework in more rigorous terms.

Discussion

We have presented a formal framework for characterizing children's overextension. We have shown that this framework yields good accuracies in reconstructing child-caretaker communication based on a relatively large set of overextension examples we curated from the developmental literature. Our results indicate that the diverse range of overextension patterns can be explained by our framework that encapsulates a multimodal representation of semantic relations with categorical, visual, and predicate-based features.

With respect to earlier work from developmental psychology, our results support the view that children's overextended

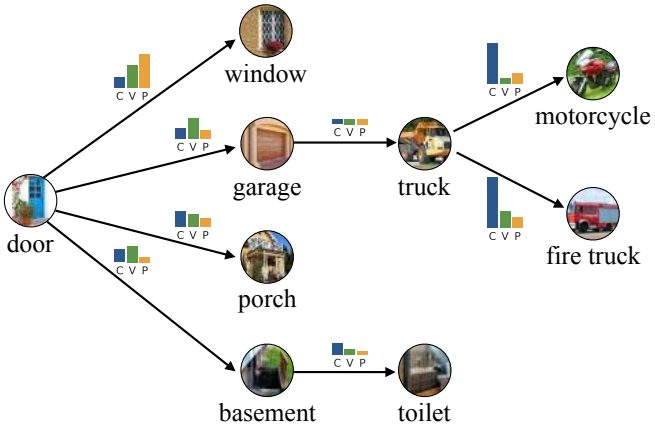

Figure 5: Chain complex sampled from the multimodal semantic space, and contributions of categorical (C), visual (V), and predicate-based (P) relations to chaining probabilities.

word choices reflect a communicative strategy under a limited vocabulary. Moreover, we have shown that children tend to favour high-frequency words in overextension, which provides evidence for the retrieval-error view of overextension. Future work should explore whether the current framework can explain overextension in children's language comprehension, as well as account for the later convergence to adult word usage.

We have shown the initial promise of a multimodal representational scheme toward a better characterization of the generative capacity for word sense extension in early childhood. Future work could explore the generality of this framework in accounting for overextension beyond nouns, as well as historical changes of word meaning.

Acknowledgements

We would like to thank Yu B Xia for helping with collection of child overextension data, Charles Kemp for reference to Vygotsky's work, and Suzanne Stevenson for constructive comments on the draft. We are also thankful to the members of the Computational Linguistics group at the University of Toronto for comments on an early version of this work. Abstract

Investigating folk conceptions of choice and constraints have been problematic given that human actions are rarely considered constrained. In this paper, we utilize humanoid robots (more clearly influenced by determined programming) to empirically test children's developing concepts of choice and action. Using a series of agency attribution and choice prediction tasks, we examined whether children differentiate free will abilities between robots and humans. Results indicated that 5–7-year-old children similarly attributed the ability to choose to both a robot and human child. However, for moral scenarios, participants considered the robot's actions to be more constrained than the human. These findings demonstrate that children appear to hold a nuanced understanding of choice across agents and across context.

Keywords: choice attribution; human–robot interaction; free will; cognitive development

Introduction

Attributing another entity with the ability to make choices lies at the foundation of treating that individual as having moral responsibility and as being deserving of rights. As such it is critically important to understand when and why people attribute choice to others. Because it is difficult to imagine typical human actions being constrained or devoid of choice (Nichols, 2011), research on free will has been limited by participants' inabilities to conceive of a deterministic world (Sommers, 2010). In other words, since it is difficult for us to imagine our own actions as being constrained, it is similarly challenging to conceive of others' actions as being constrained. Investigating ideas of free will in non-human entities, such as robots, shows promise in terms of releasing participants from anecdotal notions of choice and constraint.

Modern technology has resulted in a growing presence of interactive robots (e.g., Siri, Alexa, Roombas), particularly in the environments of younger generations (Wei et al., 2011). Robots present an increasingly important category for which to investigate choice attribution, as they are known to be largely programmed by their designers. Previous research has indicated that adults are ambivalent about robots' capacities to make choices (Weisman, Dweck, & Markman, 2017). However, nothing is known about children's tendencies to attribute robots with the freedom to choose, despite children now growing up in technologically rich environments.

From early in life, children understand the possibility of completing "alternative" actions, denoting a basic grasp of free will. For example, 10-month-old infants expect human agents to use different actions to obtain an object depending on whether there are physical constraints present or absent (Brandone & Wellman, 2009), and toddlers use this understanding to differentially respond to agents who could have acted one way, but chose another (Behne et al., 2005; Dunfield & Kuhlmeier, 2010; Hamlin, Wynn, & Bloom, 2008). By the preschool years, children not only anticipate and react to alternative actions (e.g., Nichols, 2004), but are able to verbally generate alternative options when the main goal of an agent is constrained (Sobel, 2004). Thus, early in life, children show a relatively sophisticated understanding that human agents can choose to act in certain ways, and that these actions may be constrained by internal or external barriers.

This ability to entertain alternative actions suggests that children understand that agents can "choose to do otherwise", a hallmark for a mature understanding of free will (see Kushnir, 2018). However, a reliance on experiments involving human agents as targets of judgment means that the boundaries of children's free will ascriptions have not been fully charted. Though some work has shown that children assign more freedom of choice to human agents than inanimate objects (Nichols, 2004), none have explicitly examined attribution of free will to humanoid robots.

As in adults (e.g., Kahn et al., 2012b), research has shown that children ascribe a mixture of animate and inanimate characteristics to humanoid robots, suggesting an ontological category that is functionally separate from either (Kahn et al., 2012a; Severson & Carlson, 2010). For example, children may assume that robots hold a certain level of intelligence and some sensory abilities (e.g., can think, can see, can be tickled), but not emotions or biological capabilities (e.g., can feel happiness, needs sleep, can grow), though these ascriptions vary with both participant age and robot type (e.g., Bernstein & Crowley, 2008; Jipson & Gelman, 2007; Saylor, Somanader, Levin, & Kawamura, 2010). Furthermore, children often require prior information or experience with robots before they consider them as agentive

beings. For example, 18-month-old infants only follow the gaze of a robot they previously saw acting contingently with an adult (Meltzoff et al., 2010), 4- to 7-year-old children are more likely to assume a robot has intelligence if they have more exposure to robots (Bernstein & Crowley, 2008), and 5- to 7-year-old children are more likely to attribute emotional and physical characteristics to a robot that was previously framed as autonomous (Chernyak & Gary, 2016). This work highlights the ways in which robots straddle the animate and inanimate worlds, making them particularly interesting as a test case for children's ascriptions of free will.

Importantly, it appears that children's understanding of free will, even for human agents, is not monolithic, as children seem to struggle with understanding how alternatives can be applied in certain circumstances. For example, 4- to 5-year-old children seem to believe that it is not possible to act against desires even without physical constraints (e.g., wanting to eat a tasty cracker but choosing not to; Kushnir et al., 2015), and often choose to act in accordance with their desires at the expense of reaching a salient goal (Yang & Frye, 2018). Relatedly, 3- to 5-year-old children are likely to say that a choice is more moral if it is consistent with an agent's desires (e.g., cleaning up toys because they wanted to) versus conflicting with an agent's desires (e.g., cleaning up toys even if they wanted to go play outside), a pattern that is reversed in older children and adults (Starmans & Bloom, 2016). As such, there are certain scenarios, particularly those relating to internal desires or moral decisions, that appear to muddle children's understanding of free will for human actors.

In the current study, we asked whether 5- to 7-year-old children's predictions of action and choice varied across target agent (human child or robot) and constraint scenario (No Constraint, Moral Constraint, Rational Constraint). Children in this age range undergo relevant changes in their free will beliefs and their perceptions of robots (Bernstein & Crowley, 2008; Kushnir et al., 2015). During testing, both the human and robot agents were introduced as being similarly likely to make a particular choice when no constraints were present (i.e., was either 'programmed to' or 'born to" play a certain game). Within each scenario, we explored whether children predicted that the agent would follow the typical, default object choice or would respond to the constraints and pick an alternate object.

Based on previous work exploring children's trait attributions to robots and humans (Chernyak & Gary, 2016; Kahn et al., 2012), along with children's differential reactions to context and constraint (Kushnir et al., 2015; Nichols, 2011), we hypothesized the following: Without constraints, participants would predict the default action for both the robot and the human agent, and each would be significantly above chance in this choice. With rational constraints (the default action being impossible to completely fulfill), participants would predict the default action significantly more for the robot than the human agent. In the robot condition, participants would predict the default action above or at chance, and in the human condition, participants would predict the default action significantly below chance. With moral constraints (the default action causing harm), participants would predict the default action significantly more for the robot than the human agent. In the robot condition, participants would predict the default action above or at chance, and in the human condition, participants would predict the default action significantly below chance.

Method

Participants

The final sample consisted of 32 children, aged 5–7 years old (M_{age} = 5.72, SD_{age} = 0.68, 15 females, 26 White), who were recruited from a participant database and tested in a laboratory in a small city in the northeastern region of the United States. One additional child participated but was excluded due to a developmental disability.

Materials & Procedure

Participants were randomly assigned to one of two conditions (robot or human). In the robot condition, children were asked to watch and respond to the actions of a robot figure named Robovie. The robot was a black and white humanoid toy, approximately 35 cm tall. It was preprogrammed to complete a number of actions. In the human condition, participants watched and responded to the actions of a human child. The actor was a boy approximately the same age as participants, named Billy. All stimuli were pre-recorded and presented via video on a Dell laptop so that the agent's actions and perceived agency could be matched across conditions.

Regardless of condition, all participants proceeded through the same paradigm to assess their understanding of free will across ontological kinds. Children watched the video of either the robot or human, during and after which all participants were asked to predict the agent's actions (default or alternative object choice) and asked to attribute choice to the agent (did they "choose to" do the action or not, adapted from Kushnir et al., 2015). Answers to these questions indicated whether children believed the agent could act against its default choice and respond to constraints in a way that indicated free will.

Video Paradigm

Introduction Phase During the introduction phase of the video, participants watched a short clip (60 seconds long) that introduced the agent (robot or human) and showed the agent performing simple actions. The purpose of this introduction was to demonstrate that the agent was autonomous, intentional, and had some basic intelligence, as this has been found necessary for children to attribute agency (Chernyak & Gary, 2016; Meltzoff et al., 2010). The video consisted of a narrator first describing the agent ("This is Robovie, Robovie is a robot."/ "This is Billy. Billy is a kid") paired with a still picture of the agent in a children's room (see Figure 1). Then the agent performed two simple actions: dancing and

throwing a bucket. The next video clip presented the agent's actions as determined, stating that the agent was either programmed (robot condition, "Robovie is programmed to know a lot about science and can play science games") or born (human, "Billy's parents are scientists, so Billy knows a lot about science and plays science games") to play a certain type of game (science games). Following this presentation, it was reiterated that the agent *only* plays the science game, even if there are other games present. This conveyed to participants that the science game, given no other constraints, was the default choice for both agents. This also indicated that a choice to play an alternative game (e.g. a history game), given constraints, would require the agent to "override" their entrenched pattern of playing the default games.

Action Prediction After the introduction video, participants watched three further video segments that presented each of the constraint scenarios (No Constraint, Moral Constraint, Rational Constraint). These segments described the objects in the room (a science game and a history game), presented the relevant constraints on the agent's ability to play these games, and asked the participant to predict which game the agent would play within each of these scenarios. As explained in the introduction video segment, the science game should be the default game if no other constraints are present. The history game is the alternative game choice.

In the first video (No Constraint scenario), participants were asked to pick which of two games (default or alternative) the agent would play without any limitation. Since participants had previously been told that agent only plays the default game, we hypothesized that this question would elicit a default response without the need for inferring choice or free will. The second video (Moral Constraint scenario) was identical to the first, but with the limitation that the agent will be playing with another person and playing the default game would result in hurting that person's feelings. In this video, it would be wrong for the agent to play the default game, thus requiring them to play the alternative game if they wanted to stay within moral bounds. The third video (Rational Constraint scenario) asked the child to predict the game the agent would play if the default game was broken. In this video, it would be irrational to play the broken (unplayable) game, requiring them to play the alternative game in order to act rationally.

Figure 1: Screenshots of video stimuli used in the robot condition. Participants watched a short introduction video and then proceeded to view three Constraint scenario videos. Videos in the human condition were identical, with the exception of a child in place of the robot.

Choice Attribution After each video, the experimenter asked two follow-up questions to explore choice attribution, adapted from Kushnir et al. (2015). Specifically, participants were asked whether the agent "chose to" or "had to" play the default/alternative game, along with an open-ended prompt asking them why.

Coding

Children's action predictions were coded for each of the video constraints. In the No Constraint scenario, picking the alternative game (rather than the default game) clearly indicated choice, as it went against the default pattern of behavior. However, as there was no obvious reason to select the alternative game, the alternative game was not expected in either the human or the robot condition. In the Moral Constraint scenario, picking the alternative game indicated a choice that was driven by a consideration of others' feelings, whereas picking the default game indicated a disregard for others' feelings. Thus, we expected participants would predict the agent to play the alternative game in the human condition, but not in the robot condition. In the Rational Constraint scenario, picking the alternative game indicated a choice that was driven by a rational consideration of which game was possible to play, whereas picking the alternative game indicated a disregard for rational considerations. Therefore, in this scenario we expected participants would predict the agent to play the alternative game in the human condition, but not in the robot condition.

Children's responses to the choice question were coded for whether or not they responded that they agent "had to" or "chose to" play a certain game. The ability to choose was indicated by a response that the agent "chose to" play the game, regardless of which game the agent chose.

Results

Action Prediction Results

Across all three constraint scenarios, action predictions were explored by running an omnibus binomial test to determine whether the percentage of game prediction (default and alternative) differed from chance (50%). The percentage of the default game predicted was marginally lower than chance in the human condition ($p = .059$) and at chance in the robot condition ($p = .665$). A Mann-Whitney test indicated that the default game prediction did not differ by agent condition ($U = 1032$, $p = .301$, $r = .182$). Within each of the three constraint scenarios, action predictions were explored by running binomial tests to determine whether the percentage of game prediction (default and alternative) differed from chance (50%). Further, Mann-Whitney U tests were run to test for

differences between agents (human and robot) in the predicted percentage of default game prediction in each of the constraint scenarios. Frequencies are presented in Figure 2.

Action Prediction: No Constraint We ran binomial tests on participants' prediction of the game that would be played (default or alternative), for both the human and robot agents. Participants overwhelmingly tended to predict that both the human and the robot would play the default game (*ps* < .001). This demonstrates that participants predicted the agent to act in accordance with the ways that it had always acted in the past (i.e., playing the default game that it was programmed or born to play), indicating that participants understood that there was a strong likelihood for both the human and the robot to select the default game and confirming that the participants understood the introduction video. A Mann-Whitney test indicated that the default game prediction did not differ by agent condition ($U = 120$, $p = .317$, $r = .18$).

Action Prediction: Moral Constraint A binomial test indicated that the percentage of the default game predicted in the human condition was significantly lower than chance ($p < .001$). Thus, participants believed the human would go against his desires in order to act morally. In contrast, the percentage of the default game predicted in the robot condition was not significantly different from chance ($p = .804$). This demonstrates that participants were unsure if a robot would go against its programming in order to act morally. A Mann-Whitney test indicated that the prediction of the default game was significantly higher for the robot condition than the human condition ($U = 80$, $p < .05$, $r = .42$).

Action Prediction: Rational Constraint Binomial tests indicated that the percentage of the default game predicted in both the human condition and the robot condition was significantly lower than chance (*ps* < .001). This demonstrates that participants believed that both agents would go against their programming or desires in order to act rationally. A Mann-Whitney test indicated that action prediction did not differ by condition ($U = 120$, $p = .317$, $r = .18$).

Choice Attribution Results

In each scenario, participants were asked whether the agent "chose to" or "had to" play the predicted game, regardless of game type (default or alternative). Across all three constraint scenarios, choice attributions were explored by running an omnibus binomial test to determine whether the percentage of choice attribution ("choose to" and "have to") differed from chance (50%). The percentage of "choose to" responses did not differ from chance in either the human condition or the robot condition (human: $p = .312$; robot: $p = .193$). A Mann-Whitney test indicated that the choice attribution did not differ by agent condition ($U = 1128$, $p = .836$, $r = .037$). Within each of the three constraint scenarios, choice attributions were explored by running binomial tests to determine whether the percentage of choice attribution ("choose to" and "have to") differed from chance (50%). Further, Mann-Whitney U tests were run to test for differences between agents (human and robot) in the predicted percentage of default game prediction in each of the constraint scenarios. Frequencies are presented in Figure 3.

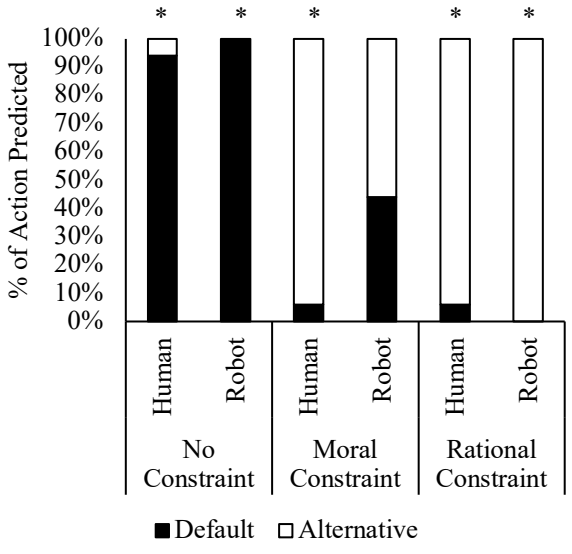

Figure 2: Percentage of the participants' action prediction across conditions for each constraint. Asterisks signify predictions that are significantly different than chance.

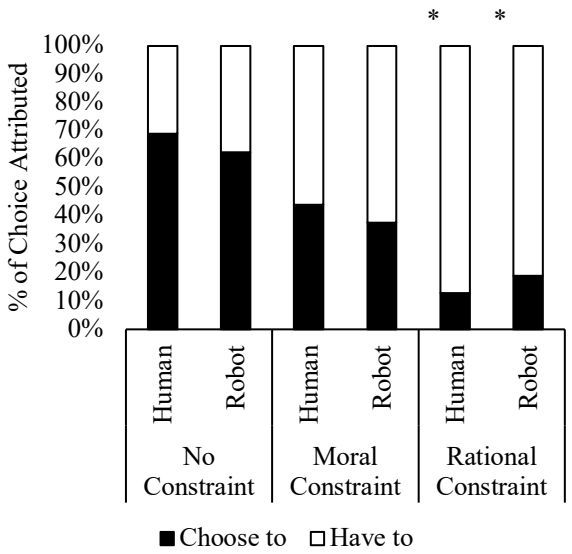

Figure 3: Percentage of participants' attribution of choice across conditions for each constraint. Asterisks signify attributions that are significantly different than chance.

Choice Attribution: No Constraint Binomial tests indicated that the percentage of "choose to" responses in both the human condition and the robot condition did not differ from chance (human: $p = .210$; robot: $p = .454$). A Mann-Whitney test indicated that choice attribution did not differ by condition ($U = 120$, $p = .714$, $r = .065$).

Choice Attribution: Moral Constraint Binomial tests indicated that the percentage of "choose to" responses in both the human condition and the robot condition did not differ from chance (human: $p = .804$; robot: $p = .454$). Mann-Whitney test indicated that choice attribution did not differ by condition ($U = 120$, $p = .723$, $r = .063$).

Choice Attribution: Rational Constraint Binomial tests indicated that the percentage of "have to" responses in both the human condition and the robot condition was significantly higher than chance ($ps < .05$). Mann-Whitney test indicated that choice attribution did not differ by condition ($U = 120$, $p = .632$, $r = .111$). These findings indicate that the participants believed acting in accordance with physical limitations was a constraint on choice regardless of the agent acting, such that free will was significantly limited by this rational constraint.

Discussion

This research investigated children's predictions and choice attributions about the actions of a robot or a human child. Results indicated that, overall, children tended to judge a humanoid robot as having a similar amount of freedom of choice as a human child. For example, without any constraints, or with a rational constraint (such as the default game being broken), participants predicted similar actions for both the human and the robot. However, when the robot had an opportunity to change its actions in order to avoid making another child sad, children judged the robot as less likely to act in this way as compared to the human.

Action Prediction

In the No Constraint scenario, participants significantly predicted the agent to play the default game, in both the human and robot condition. This demonstrates that children's basic understanding of the introduction video, where it was made clear that the agent only plays the science game. In the Rational Constraint scenario, results demonstrated that participants believed that both the robot and the human could act against its programming in order to act rationally (i.e., to play the alternative game). This may be an indication of choice attribution, as children believe a robot can be responsive to reasons and is not entirely constrained by its programming (Fischer, 2006). In the Moral Constraint, however, participants believed the human would be responsive to reasons and act morally (i.e., play the alternative game), but they were at chance in the robot condition. This demonstrates that in moral situations, children were unsure if the robot could go against its programming. This could be explained in a number of ways. Children may have thought that the robot did not "care" about moral reasons or they may have thought that the robot did not have the capacity to recognize moral reasons. The latter explanation could be due to the fact that children did not interact with the robot in this study, making the robot's social capacities were ambiguous. Future research could include various interaction components between the participant and the robot, which might unveil the types of social capacities that are required for a robot to appear responsive to moral reasons.

Choice Attribution

Overall, our results indicate that children's attribution of choice is not unitary across situations. Similar to previous work (Kushnir et al., 2015), it appears that children are sensitive to both the agent type and the context that an agent is presented in when attributing free will. Furthermore, these results suggest that robot programming is not *always* a constraint on freedom of choice for young children. Most importantly, these results demonstrate that children are sensitive to constraints, such that some constraints (e.g. physical impossibility) are more restrictive to an agent's choice than other constraints (e.g. desires, morals), and finding consistent for both the robot and the human agent.

In the No Constraint scenario, we were surprised to see that participants did not attribute choice above chance to the human agent. This may have been due to the presentation in the introduction video. For example, similar to the robot, we presented the human as having an entrenched disposition to play the default game. However, unlike the robot, who was programmed by scientists to choose this game, the human's "programming" was that his parents were scientists and that he played science games every day. Previous research has shown that child participants attribute this type of consistent (non-random) choice as denoting not just 'programming', but desires (Kushnir, Xu, & Wellman, 2010). Since participants were at chance in attributing choice to the human agent, this could mean that children varied in believing whether or not having a strong desire is a constraint on actions.

In contrast to the human condition, we did not anticipate that participants would attribute so *much* choice to the humanoid robot in the No Constraint scenario. Here, the percentage of children that said the robot "chose to" select the default game was not significantly different from chance, suggesting that approximately half of our participants gave some semblance of free choice to the robot agent. This could be due to the varied exposure children have to robots, which research has shown is correlated with children's propensity to attribute agency (Bernstein & Crowley, 2008). Alternatively, this could also be an indication of children's general understanding of choice under minimal constraints. Specifically, children varied in the amount of choice they thought an agent had if the agent was constrained to perform a certain action based on how the agent was programmed or raised. Future research should investigate what underlies this individual difference; for example, do children who have

more interactions with robots also attribute them more choice in unconstrained scenarios?

In the Moral Constraint scenario, children were at chance in attributing choice in both the human condition and robot condition. This demonstrates that participants were almost equally likely to say that a moral action was a constraint or a choice. These results dovetail with previous research that has shown that children under 7-years-old are less likely to say that people have a choice in moral actions in comparison to older children (Chernyak et al., 2013). For the Rational Constraint, results also followed previous research, such that children assumed the agent "had to" make a certain choice when there were physical constraints (Kushnir et al., 2015), regardless of agent type. While these results support previous work, they also extend previous findings to other agents. Since results were similar for the human condition and the robot condition, this demonstrates that children extend their existing beliefs of choice and constraint to a fundamentally different type of agent. Future research should investigate other agents, such as plants or animals, to see if choice attribution in light of moral and rational constraints is a general or agent specific attribution.

It is important to note that we don't fully understand the way children were interpreting some of our events, particularly those relating to programming ("Robovie is programmed to know a lot about science") or genetic inheritance ("Billy's parents are scientists so he knows a lot about science"). However, previous research has shown that, starting at 5-years-old, children display knowledge of biological inheritance (Gimenez & Harris, 2002) and children understand a robot is programmed (Bernstein & Crowley, 2008). Furthermore, all participants were told multiple times that the agent (whether robot or human) only played the default game. Future research should explicitly measure children's understanding of programming and inheritance in relation to their action prediction and choice attribution to an agent.

In sum, this research indicates that children are able to attribute choice to actions that are programmed or hard-wired. This suggests that "compatibilist" theories of free will – in which choice can be said to exist even in a fully determined universe (e.g., Fischer, 2006) – may be an intuitive aspect of folk psychology. This dovetails with previous studies that have advanced this claim, but which have based their conclusions on adults' assessments of complicated thought experiments (e.g., Nahmias et al., 2005). The present research has shown this to be true in children and for an everyday case of pre-determinism. New advances in technology, which have introduced robots into children's everyday environments, have not only improved quality of living but have also allowed for improvements in testing for folk attributions of choice to agents that straightforwardly exist in a constrained environment.

Children, more than adults, rely on similarity to access multiple meanings of words

Abstract

Past research has shown that adults can access multiple meanings for a word, but little work has examined how children process multiple meanings. We tested 48 4- to 7-year-old children and 48 adults in a touchscreen picture recognition task. Two meanings of the same word were displayed on successive trials, which varied according to whether the 2 meanings were unrelated (homonyms), related (polysemes), or repeated (same-meaning). Adults identified the second meaning more quickly than the first in all conditions and to the same extent. Children, however, identified the second meaning more quickly only on polysemy and same-meaning trials. This difference suggests that children are less capable of co-activating unrelated meanings, which raises the possibility that children must *learn* to do so over development. Despite the ubiquity of polysemy in language, our work is the first to show that children's processing of word representations is organized by similarity.

Keywords: polysemy, lexical processing, development, cognitive development, ambiguity

Introduction

Upon hearing a word like *bat,* which can refer to a flying mammal or a wooden stick, adults unconsciously activate both meanings, at least for a brief period when there is no biasing context and both meanings are equally frequent (Brocher, Koenig, Mauner, & Foraker, 2017; Onifer & Swinney, 1981; Swinney, 1979; Zwitserlood, 1989). This intriguing finding was initially used to argue for "exhaustive" lexical access during an early modular stage of processing (Fodor, 1985; Swinney, Plather, & Love 2000; but cf. Armstrong & Plaut, 2016). At the same time, a large and growing body of evidence indicates that people take advantage of communicative contexts to predict interpretation from the earliest stages of comprehension (Kintsch, 1988; Rubio-Fernandez, Mollica & Jara-Ettinger, 2018; Tanenhaus, Spivey-Knowlton, Eberhard, & Sedivy, 1995; Yip & Zhai, 2018).

Due to the tension between evidence for exhaustive lexical access, on the one hand, and early contextual influences on the other, much work has varied task demands, relative frequencies of the two meanings, interstimulus intervals and degrees of contextual bias in order to predict the conditions under which multiple meanings of a word are accessed or recognized. Selective, rather than exhaustive, activation has been found to occur when the context is strongly biased toward a more frequent meaning (Meyer & Federmeier 2007; Sereno, Brewer, & O'Donnell 2003; Sereno, Pacht, & Rayner 1992; Simpson, 1981; Marslen-Wilson & Welsh, 1978).

Another factor that plays a role in lexical access and recognition is the degree of relatedness among a word's meanings. That is, there is a gradient distinction between meanings that are **homonymous** or unrelated to one another (e.g., a flying bat vs. baseball bat), and **polysemous** meanings, which are semantically related to varying degrees (Tuggy, 1993). For instance, the word *network* can be used to refer to a TV channel, a group of colleagues, or a graph (Lau, Cook, McCarthy, Gella, & Baldwin, 2014). While these meanings are distinct, they are to some extent related.

Relationships among meanings are relevant to the so-called "ambiguity advantage": Adults have been found to respond faster in lexical decision tasks to a meaning for an ambiguous word compared to a word with a single meaning (Jastrzembski, 1981; Rubenstein, Garfield, & Millikan, 1970). This effect has sometimes been found to be stronger for words with multiple *related* senses (Klepousniotou & Baum, 2007; Rodd, Gaskell, & Marslen-Wilson, 2002). In fact, Armstrong & Plaut (2008) and Rodd, Gaskell & Marslen-Wilson (2002) found that homonymous senses can *slow down* lexical access due to competition under higher of levels task difficulty (see also Brocher et al. 2016). Other evidence that ambiguous words compete in a way that polysemous meanings may not comes from an ERP study by Klepousniotou et al. (2012), who found a greater N400 was evoked by a less dominant meaning of homonymous words in a lexical-decision task, but no increase in the N400 for the less dominant meaning of polysemous words. On the other hand, Brocher et al.

(2017) found that both homonymous and polysemous meanings compete when words were equally biased toward both meanings. Thus, the work on access and recognition of ambiguous words has revealed a complicated picture, indicating that frequency, degree of contextual bias, timing, task demands, and semantic relatedness each influence lexical activation (Tabossi & Sbisá, 2001).

In order to clarify key influences on lexical access, the current work compares the behavior of children and adults on an identical task. A word repetition paradigm is used to detect whether witnessing one meaning of a word primes a second meaning of the word. Specifically, in a 2-alternative forced-choice picture identification task, adults and 4- to 7-year-old children were exposed to a word on each trial, and had to select which of two images corresponded to that word's meaning. On the immediately following trial, the same word was presented again. Across these key trials, the degree of relatedness between the first and second target meanings of words was systematically varied.

Of interest was whether reaction times decreased between the identification of the first and second meanings of words. If we do see priming effects for both homonymous and polysemous word meanings, it would be evidence that the two meanings are linked as is required for exhaustive access. This is expected in adults, at least if the time between trials is sufficiently brief. At longer inter-stimulus intervals (ISIs), we might expect the first meaning to interfere with the second meaning, which would predict an increase in reaction times to the second meaning.

If both children and adults display the same increase or decrease in reaction time when identifying the second meanings of ambiguous words, it would suggest that key aspects of lexical access are a developmentally stable. We know that children, like adults, comprehend language incrementally (Swingley, Pinto, and Fernald 1999; Fernald, Swingley, & Pinto 2001). Also, children, like adults, are subject to priming and plausibility effects when they need to disambiguate an intended meaning (Rabagliati, Pylkkänen & Marcus 2013). But we don't yet know whether children and adults will behave alike or differently under the identical task demands that require them to identify two familiar meanings of words in succession.

A significant difference between children and adults' behavior could shed light on the mechanisms involved in lexical access or on the way that lexical representations develop. If children show *stronger* evidence of exhaustive lexical access for ambiguous and polysemous words, it would be consistent with proposals that view selective access as requiring cognitive control (Balota, Cortese, & Wenke, 2001), since children's cognitive control is less well developed than adults (Bunge, et al. 2002). On the other hand, if children show *weaker* evidence of accessing multiple familiar meanings of words, it would suggest that they represent individual meanings more independently than adults do. This would suggest that word learning involves both acquisition of item-specific knowledge for each meaning *and* a protracted trajectory for linking among each word's meanings. This would indicate that children have to *learn* to co-activate multiple meanings based on experience, with potentially different trajectories for related versus unrelated meanings.

Some past work has investigated how children over the age of 8 activate the intended meaning of homonymous words, by focusing on cases of homonymy in which one meaning was dominant over others (Marmurek & Rossi, 1993; Simpson & Forster, 1986; Simpson et al. 1994). This research found relatively consistent results: older children are better at using contextual cues to activate less frequent homonymous meanings than younger children. Booth, Harasaki & Burman (2006) extended this work by comparing effects of sentence-level primes vs. lexical primes and found a more complex picture. Younger children or less skilled readers were less likely than older children to use a preceding lexeme to facilitate activation of a less-frequent homonymous meaning, while older children/high skilled readers facilitated and inhibited homonymous meanings using sentence-level information (Booth, Harasaki & Burman 2006).

The present work uses participants' reaction times to investigate how words with multiple meanings are processed in children and adults, when both meanings need to be identified in succession. By comparing performance on homonymous and polysemous meanings with a baseline condition, we can determine whether greater semantic similarity supports the co-activation of lexical representations. This would be evident if participants are faster to recognize the second meanings of polysemous words than homonymous words.

In the experiments reported below, we children and adults were presented with each of 18 target words twice in immediate succession: 6 words were paired with 2 unrelated meanings (homonymy condition); 6 words with 2 related meanings (polysemy condition); and 6 words were presented with different images which represented the same meaning (same-meaning trials). We also included 12 singleton filler trials to reduce the extent to which participants could rely on a repetition expectation to predict what they might hear and see next. For homonymous and polysemous trials, each word was presented with one target meaning on first exposure and a different target meaning on the second

Trial type	Word
6 same-sense repeated	*bowl, treehouse, ring, key, lantern, shelf, trunk*
6 polysemous senses	*cap, buttons, cone, glasses, shower, step*
6 homonymous meanings	*bow, ruler, pitcher, bat, calf, nail*
12 singletons	*basket*, *cake, crayon, feather, hood*, *lemon*, *ivy, log, playground, punch, wagon, bark*

Table 1: Items

exposure, with the order of target meanings counterbalanced across participants and sides of presentation randomized. Repeat same-meaning trials served as a window into baseline priming effects. The main prediction was that, if children's word representations are organized by similarity, they may be able to activate a second, distinct meaning quickly in the case of polysemy. In the case of homonymy, however, where semantic similarity is not available to help co-activate other meanings which share the same label, accessing both meanings should be slower. In the same paradigm, we also predict that adults should be able to activate multiple meanings equally well in both polysemy and homonymy, consistent both with prior findings and with the idea that we learn to access unrelated meanings, at least in certain contexts, through experience. Finally, adult participation allows us to verify that it is, in fact, possible for our paradigm and chosen items to elicit priming of unrelated meanings.

Method

Participants

48 adult participants [recruited online] and 48 children ages 4.5-7 (M=5.89; SD= 0.62). Children were given a book of their choosing and a small prize as thank-you gifts.

Procedure

Two initial training trials provided feedback if participants answered incorrectly, or took longer than 4500ms, ensuring that they understood the goal of the task was to answer accurately and quickly (see Figure 1). Between each trial (including between training trials), a pulsing blue dot appeared that participants had to press to advance to the next trial. This was to ensure that participants' hand positions were centered. Each participant responded to 48 trials including 6 homonym pairs (12 trials), 6 polysemy pairs (12 trials), 6 same-sense pairs (12 trials) and 12 singleton filler trials.

The design was 3 (condition) x 2 (1^{st} or 2^{nd} encountered meaning), within-subjects. We tested two groups (adults and children). Before each trial began, participants had to place their pointer finger on a dot in the middle of the screen. Overall order of stimuli (or stimuli pairs) from each of the four trial types (polysemy, homonymy, same-sense pairs, and fillers) was randomized across participants. The experiment was conducted on an iPad that recordedd participants' accuracy and reaction times to target. The key dependent measure was the difference in reaction time from the identification of first and second senses of words in the three experimental conditions.

On each trial, participants heard a word and had to choose the target image representing its meaning from a distractor image presented on the opposite side of the screen (screen side counterbalanced). For homonymous, polysemous and same-sense trials, the same word was repeated twice in succession with images corresponding to a second unrelated, related, or same sense, respectively.

The order of presentation within each word's pair of meanings as well as the order of trials in the experiment was counterbalanced across participants to avoid possible confounds of meaning familiarity or distractor salience. Moreover, since participants witnessed both ambiguous and polysemous trials, any significant difference in familiarity between the ambiguous items and the polysemous items should be evident in a comparison of response times to the first presentations across these conditions, which we also include as part of our analyses.

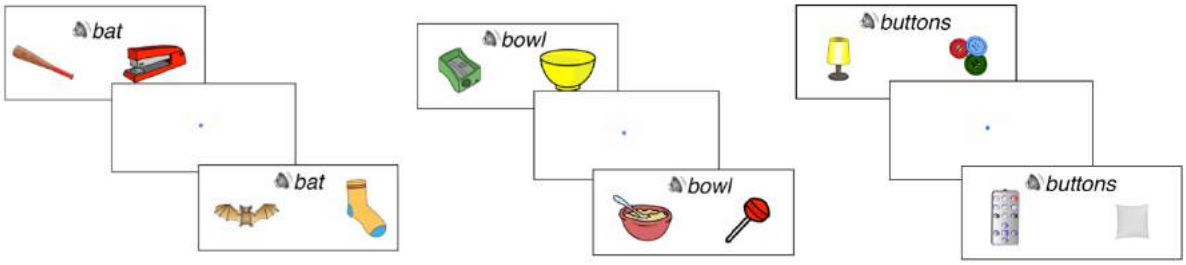

Figure 1: Representation of the experimental stimuli in the homonymy (*bat*), repeat (*bowl*) and polysemy (*buttons*) conditions.

Results

The data were log-transformed and analyzed using a multilevel linear model with condition (homonymy vs. polysemy vs. same meaning) and first vs. second meaning of each pair as fixed effects, and maximal converging random effect structure: here, random intercepts and slopes for subjects, presentation order, and items: Reaction Time ~ FirstOrSecond * Condition + (1 + FirstOrSecond | subject) + (1 + Condition | order) + (1 + FirstOrSecond | item).

Adults recognized the second sense of words more quickly after the initial exposure to that word, and facilitation was equally strong for unrelated (homonymy), related (polysemy), and same senses: (main effect of secondary sense response, β = -0.15515, p = 0.00129, with no significant interactions by condition (Figure 2).

Children, on the other hand, did not show significant facilitation when selecting the second sense of homonymous words, but did for polysemous words (β = -0.12798, p = 0.0333) and repeated meanings (β = -0.200424, p = 0.0122) (Figure 2). The difference between facilitation for polysemous and same-sense trials was not significantly different (β = -0.08638, p = 0.2189), suggesting that related senses were primed by one another to almost the same degree as a second instance of the same sense. Unlike results for adults, there was not even a numerical decrease in reaction time when the second presentation of a word was paired with an unrelated (homonymous) sense.

A concern worth addressing is whether children were less familiar with the meanings of the homonymous words. Indeed, we cannot expect facilitation for a second meaning if only one meaning was familiar to children. To ensure this did not account for our results, we excluded any trials in which children or adults had answered incorrectly on either trial for all analyses reported thus far. This issue can be further addressed by a comparison of accuracy in the polysemy vs. homonymy condition. We found that their accuracy was not significantly lower in homonymy than polysemy in a linear model with maximal converging random slopes and intercepts for subject and order (β -0.03, t= -1.410, p= 0.172), and neither were their reaction times slower to the first exposure in homonymy as compared to polysemy (β= 0.075, t= 0.844, p= 0.405). Since the order of presentation of the two meanings was counterbalanced across participants for each word, we can conclude that children were equally familiar with the senses of the homonymous, polysemous, and same-sense meanings, as intended.

Limitations

In our task, answers appeared on either side of the screen. In order to control for hand/mouse position effects, intervals between each trial required participants to press a central fixation, and the experiment did not advance to the next trial until participants did so. Because of this, inter-stimulus intervals (ISIs) were not controlled, and instead were determined by how long the participant took to press the central fixation. Importantly, prior work has shown that second senses of homonymous words become suppressed as quickly as a few syllables downstream, and early work in semantic priming did not reveal effects for priming across more than one intervening trial (Joordens & Besner, 1992), suggesting that we should not expect to see priming in the case of longer inter-stimulus intervals. Therefore, the ISIs observed in our experiment warrant further investigation.

To address this concern, we report average ISIs for the two groups, as well as a comparison of the two (adults: M = 1961ms, SD = 5196ms, children: M = 1147ms, SD = 701ms). We then entered log-transformed ISI lengths into a mixed effect model with age group (child vs. adult) as the fixed effect and maximal converging random structure including a random intercept and slope for subject and intercept for trial number (order), revealing no effect of the age group (child): β =-0.09643, p = 0.4). So, while average ISIs were longer than those used in traditional priming experiments, it is unlikely that the difference between

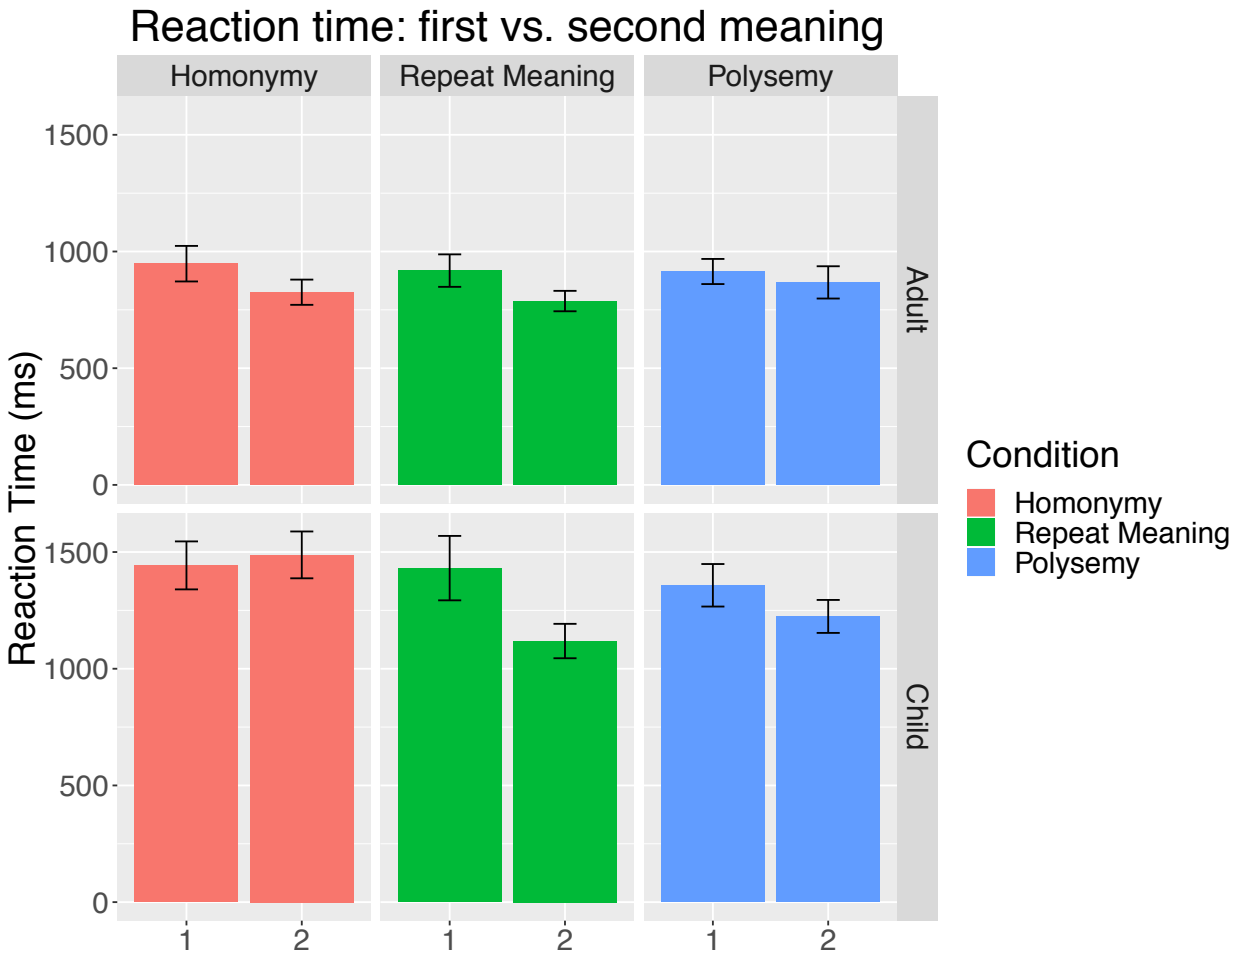

Figure 2: Raw reaction time data (analyses were done on log-transformed data). Error bars represent bootstrapped 95% confidence intervals.

ISIs is what drove our children to perform differently than adults. Past work with children has also used longer ISIs with children, such as 1,000ms (Booth, Harasaki & Burman, 2006), as compared to ISIs in adult lexical decision tasks.

Consistent with our results, Armstrong & Plaut (2016) emphasize that the timing of adult participants' suppression of irrelevant senses varies by task difficulty as well as latencies. Later work on semantic priming has in fact shown evidence for longer-term priming, across as many as 8 intervening items (Joordens & Becker, 1997). The implication of this work on our predictions instead suggests that participants may be expected to benefit from priming over longer periods of time.

Discussion and Conclusion

This investigation is the first, to our knowledge, to compare children's and adults' co-activation of related word meanings. Prior work has found that under certain conditions, adults access more than one meaning of a word, at least for a short period of time, unless one meaning is both more frequent and anticipated within the context. In the current study, the facilitation evident in adults' response times to second meanings demonstrates that, regardless of relatedness, adults are capable of accessing two meanings simultaneously or are at least able to anticipate a second meaning. To emphasize, adults displayed faster reaction times to a second meaning even when that meaning was entirely unrelated to the first (e.g., baseball *bat* following mammal *bat*).

Children, on the other hand, showed facilitation only when the second meaning was related or identical to the first. They showed no evidence that the recognition of one sense of a word facilitated the recognition of an unrelated meaning of that word. We addressed the possibility that children were less familiar with the meanings of the homonyms by observing that their

accuracy and response times on the first exposure of each word-type were not different. The current findings thus indicate that children's representations of a word's two unrelated meanings may not be linked together in the same way that adults' are. Instead, while children showed a facilitation effect in the recognition of a second *related* meaning, unrelated meanings were recognized as slowly as completely new words.

Given this, it may be that children must *learn* to activate multiple homonymous meanings across time. Intuitively, this makes sense: a spreading of activation between the mental representation of "bottle cap" and of "pen cap" may be a natural consequence of shared or similar features, while the representations of "baseball bat" and "flying bat" are likely to overlap very little, if at all. Yet again, ultimately speakers do eventually learn to access both meanings, at least or a brief period under certain task demands, as demonstrated by evidence co-activation both in our task and in previous work with adults (Brocher, Koenig, Mauner, & Foraker, 2017; Onifer & Swinney, 1981; Swinney, 1979; Zwitserlood, 1989). This raises the question as to *why* and *how* the ability to access unrelated meanings of a word develops.

Insofar as listeners cannot reliably predict which meaning of a word is intended, a degree of flexibility is advantageous in language processing to avoid being essentially garden-pathed by an unintended meaning. Indeed this type of flexibility may be advantageous in language learning as well, insofar as a more efficient ability to update predictions has been found to correlate with larger vocabulary size (Reuter, Emberson, Romberg, & Lew-Williams, 2018).

We can only speculate as to exactly *how* this ability to access secondary unrelated meanings of words increases after the age of 7. But presumably either links between two distinct representations are created or the representations of homonymous meanings come to share greater overlap. Stronger links between unrelated senses of homonymous words may be formed as a result of repeated misinterpretations that require learners to access an alternative sense as quickly as possible for the sake of comprehension. Alternatively, it is possible that links between meanings of homonymous words are formed on the basis of more explicit, metalinguistic knowledge. It is possible that co-activation is facilitated simply by an awareness that labels can refer to multiple meanings. On this interpretation, the information that the word *bat* as two unrelated meanings would be similar to learning that the word, *aunt* can be pronounced in two distinct ways.

A non-mutually exclusive possibility is that co-activation may be encouraged by learning to read. Specifically, a shared written form in combination with a shared auditory label can be expected lead to an increase in representational overlap between two meanings of a homonymous word. This would support the idea that representational overlap is required for co-activation. Future work can test this by comparing words that vary in whether they are spelled alike compared to words that are not (*bat vs. bat; flower vs. flour*). If the link between unrelated meanings is mediated via a shared visual form, we expect facilitation for homonyms that share the same spelling but not for homonyms that are spelled distinctly.

Abstract

People frequently use metaphors to communicate and reason about complex topics. However, many studies of metaphorical reasoning exclusively rely on researcher intuitions about different metaphors and their associated entailments. Here we describe a more principled method for mapping the structure of metaphorical lay theories, focusing on metaphors for teaching. Across two studies, we identified four common, apt metaphors for the teacher-student relationship and used factor analysis to explore whether these metaphors reflect systematically different intuitions about the qualities of college teachers. Our findings demonstrate that (1) people endorse a variety of different teaching metaphors, and (2) these metaphors bring to mind distinct, coherent clusters of teacher attributes. This work demonstrates a novel method for systematically mapping the structure of metaphorical lay theories and sets the stage for future research on metaphorical reasoning as well as innovative educational interventions centered on shifting lay theories of teaching.

Keywords: metaphors, lay theories, concepts, teaching

Introduction

According to a popular cognitive science metaphor, people are amateur scientists who actively explore the environment and develop intuitive theories for how the world works (Furnham, 1988; Gopnik, Meltzoff, & Kuhl, 1999). In turn, these intuitive, lay theories help people make sense of and respond to new experiences, guiding thought and action. For example, research over the last two decades suggests that students' lay theories about the malleability of intelligence (also known as *mindsets*) drive educational achievement (Yeager & Dweck, 2012). Students who think of intelligence as something that can improve through hard work—the *brain-as-muscle* metaphor—react better to performance setbacks, resulting in superior long-term learning outcomes (but see Sisk et al., 2018).

As we have just illustrated, one way that intuitive beliefs are conveyed is via metaphor. To take another example, when we describe a teacher as "*molding impressionable* students," we imply that the teacher is like a *sculptor* and students are like *clay*. Metaphors allow people to draw on familiar, common knowledge of a basic source domain (*building muscles; sculpting clay*) to communicate about a more complex or abstract target domain (*how brains learn; teaching*; Lakoff & Johnson, 1980). A large body of research finds that the metaphors people use to talk about complex issues both reflect and shape how they think about those topics (for review, see Thibodeau, Hendricks, & Boroditsky, 2017). The *teacher-as-sculptor* metaphor, for example, may reflect the intuitive belief that learning is passive and that the teacher (not the student) largely determines the learning outcomes.

How can we best understand the structure of these metaphorical lay theories and the extent to which they influence thought and action? An important first step is to map out the *entailments* of the metaphors; that is, the associated ideas and inferences licensed by the metaphorical comparison. For example, one potential entailment of the *brain-as-muscle* metaphor described earlier is that, while hard work may increase someone's intelligence or abilities, working too long on any one task may be cognitively exhausting (much like continuous physical exertion tires out muscles). These sorts of entailments, it is argued, provide critical insight into the mental model people use to represent the target domain and allow for empirically-informed predictions about how metaphors reflect and shape thinking.

The most common approach to mapping entailments is to examine the figurative language people use in everyday speech and apply a commonsense understanding of the observed source domains (as we have demonstrated in the preceding paragraph). Cognitive linguists have used this approach to isolate the structural schemas that underlie many fundamental concepts, from emotion to politics to time, across a variety of languages and cultures (Kövecses, 2005; Lakoff and Johnson, 1980).

However, there are several theoretical problems with relying on intuition and patterns of language alone to make inferences about underlying conceptual representations (Keysar & Bly, 1995; Casasanto, 2009; Murphy, 1996). For example, the meaning of common metaphorical expressions might seem obvious and intuitive but could also reflect a post-hoc rationalization based on one's preexisting understanding of the expression (Keysar & Bly, 1995). Indeed, some (non-linguistic) experiments have shown that metaphors in language do not always reflect how people mentally represent a given topic (see Casasanto, 2009). How, then, can researchers more reliably map the structural entailments of metaphorical concepts?

Another approach is to ask a set of naïve participants to freely generate the structural entailments of a source domain in order to derive a set of conceptually coherent metaphorical

entailments for the target domain. For example, for the metaphor "crime is a *virus,"* participants might be asked how they would solve a *literal* virus problem in their city. The responses would then be used to predict which solutions to a city's crime problem would be conceptually congruent with the *crime-as-virus* metaphor (Thibodeau & Boroditsky, 2011). To validate these experimenter intuitions, another set of participants might be asked to match specific solutions to a crime problem to specific metaphors (i.e., match a solution to a city's crime problem to either a *crime-as-virus* or *crime-as-beast* metaphor; Thibodeau & Boroditsky, 2013).

In this paper, we build on this approach and offer a systematic method for mapping the structural entailments of a complex metaphor, focusing specifically on metaphors for teaching. Our approach was inspired in part by traditional psychometric methods that have been used to uncover the dimensional structure of personality traits and other psychological constructs.

In Study 1, we first identified six common metaphors for the college teacher-student relationship, drawing on the literature in teacher education (e.g., Patchen & Crawford, 2011; Shaw, Berry, & Mahlios, 2008). We assessed the relative aptness of these metaphors by asking participants to rate their agreement with each metaphor, select the one they liked best, and explain their choice. In Study 2, we presented a new set of participants with one of the four most popular metaphors from Study 1. With this one metaphor in mind, participants rated the degree to which a wide range of statements describing the attributes of college teachers fit with the metaphor (as well as rating each metaphor on a few additional features). We used exploratory factor analysis to identify a smaller set of latent factors underlying the larger collection of teacher attributes. This allowed us to identify a distinct, coherent cluster of teacher attributes associated with each metaphor, providing a principled way of mapping the structure of metaphorical lay theories.

Study 1

Methods

Participants We recruited 119 participants to complete the survey through Amazon's Mechanical Turk. We required that participants be a current or former college student living in the U.S. or Canada, with an approval rating greater than 95% on at least 100 prior Turk tasks. We excluded data from nine participants: two that came from duplicate IP addresses, four that provided duplicated (i.e., copy and paste) responses to all free response items, and two who reported that they had never attended college.

Of the 110 participants included in the final data set, 54% were male, 83% identified solely as White, 7% as Black, 2% as Asian, 3% as Hispanic/Latino, and the remaining 4% as multiracial. About 71% had graduated from college, 15% were currently enrolled students, and 15% had attended college at one point but were not currently enrolled. About 43% had attended college less than 4 years ago, and 57% had been out of college for more than 4 years. Mean age was 35 (SD = 11) with a range of 20-74.

Materials & Procedure We designed a survey using Qualtrics online survey software in which participants considered six possible metaphors for the teacher-student relationship (see Table 1). We derived these metaphors based on qualitative findings of the metaphors that teachers use to describe their roles (e.g., Patchen & Crawford, 2011; Shaw, Berry, & Mahlios, 2008). Each metaphor described both the teacher and the student and suggested a relationship between them (e.g. "*A teacher is like a sculptor and students are like clay*").

Participants viewed all six metaphors in a random order and each was described as a metaphor for college teaching. Participants first rated their agreement with the metaphor on a 6-point scale (strongly disagree to strongly agree, with no neutral midpoint) and then freely explained their response by typing in a text box. After considering all six metaphors, participants considered the entire collection of metaphors and selected their favorite. They explained why they preferred this metaphor and, specifically, how it fit their experiences and views of college teaching. Finally, participants answered a series of basic demographic questions.

Results

What are the most popular metaphors? As shown in Table 1, participants leaned toward agreement (M > 3.5) for all the metaphors except the *app store* metaphor, but they agreed the most with the *gardener* metaphor, followed closely by the *coach*, *tour guide*, and *sculptor* metaphors. Participants' selection of their preferred metaphors showed a similar pattern of popularity. Of the six metaphors, the most popular was the *gardener* metaphor (32.7%), followed by the *tour guide* (19.1%) and *coach* metaphors (18.2%). The *sculptor* (10.9%), app store (9.1%) and ship captain metaphors (8.2%) were less favored.

An initial examination of participants' justifications for the metaphors shows that they frequently extended the metaphors in their free response descriptions. For example, the *gardener* metaphor prompted descriptions of teachers as "sowing information," "planting seeds of knowledge," and "cultivating students." The *coach* metaphor elicited descriptions of teachers working with students "toward the same goal," helping students "win and succeed," giving students "exercises," and creating "a plan of attack." The *tour guide* metaphor led to descriptions of teachers "showing students around", taking them into "the unknown," "showing the way," helping students "navigate" and taking them along "the path of learning." The *sculptor* metaphor prompted descriptions of teaching as "molding," "shaping," and being "hands-on," and described students as "impressionable," "raw material," and "undefined" but becoming "polished." This suggests that participants were actively using the metaphor to reason about the qualities of a teacher associated with a given metaphor (Thibodeau, Crow, & Flusberg, 2017).

Table 1. Rank-ordered ratings of agreement with each of the teaching metaphors on a 6-point scale. Higher numbers indicate higher levels of agreement.

Metaphor	*M*	*SD*
*"A teacher is like a **gardener** and students are like plants"*	4.36	1.29
*"A teacher is like a **coach** and students are like athletes"*	4.28	1.21
*"A teacher is like a **tour guide** and students are like tourists"*	4.19	1.31
*"A teacher is like a **sculptor** and students are like clay"*	4.15	1.25
*"A teacher is like the **captain** of a ship and students are like sailors"*	3.79	1.40
*"A teacher is like an **app store** and students are like smartphone users"*	2.95	1.56

Discussion

The findings from this initial study suggest that people with college experience endorse a variety of metaphors for the teacher-student relationship, but the most apt are the *gardener*, *coach*, *tour guide*, and *sculptor* metaphors. That participants spontaneously extended these metaphors in articulating their personal preferences provides some evidence that they were *thinking* about the nature of college teaching in terms of the metaphorical lay theory.

The primary goal of Study 2 was to identify and map out the conceptual entailments associated with each of the four most popular metaphors for the teacher-student relationship; that is, the associated beliefs and expectations that logically follow from the metaphor. Identifying the entailments of various metaphors is critical for making informed predictions about how metaphors may shape beliefs, attitudes, and behaviors. As a starting point, we examined entailments that focused on the characteristics of *teachers* (as opposed to students). Our key question was whether different metaphors would be reliably associated with distinct clusters of teacher attributes, and whether this can be measured in a systematic, principled way.

Study 2

Methods

Participants We recruited 201 participants to complete the survey through Amazon's Mechanical Turk using the same exclusion criteria as in Study 1. We excluded data from two participants who provided duplicated (i.e., copy and paste) responses to all free response items.

Of the 199 participants included in the final data set, 54% were male, 75.6% identified solely as White, 9% as Black, .5% as American Indian or Alaskan Native, 5% as Asian, 2.5% as Hispanic/Latino, and the remaining 7% as multiracial. About 70% had graduated from college, 13.4% were currently enrolled students, and 17% had attended college at one point but were not currently enrolled. Only 39% were recent college students who had attended college less than 4 years ago, and 61% had been out of college for more than 4 years. Mean age was 36 (*SD* = 11.6) with a range of 18-76.

Materials & Procedure Participants were randomly assigned to view one of the four most popular metaphors from Study 1: the *gardener*, *coach*, *tour guide*, and *sculptor* metaphors. Participants then viewed a list of 43 statements describing college teachers (e.g., "*Teachers transfer their knowledge to students*") and rated how well each item fit the metaphor that they were given (see Table 2). The statements were generated by consulting measures of teacher behavior (e.g., teacher behavior checklist, Keeley, Smith, & Buskist, 2006), examining free response data from Study 1, and the personal experience of the researchers). Participants were specifically instructed to rate how well each item agreed with the metaphor they received, not whether they personally believed each item was true.

Next, participants viewed all four of the metaphors and selected their personal favorite. Finally, participants answered four questions aimed whether the metaphors captured beliefs about teacher responsibility and power: They rated, according to the metaphor, (a) how much responsibility college teachers have for students' learning, (b) how much responsibility students have for their own learning in college, (c) how much power college teachers have to influence what students learn, and (d) how much power college teachers have to influence how students to develop as people. Each item was rated on a scale of 0 to 100, with 0 meaning "none at all" and 100 meaning "a great deal."

Results

Factor structure of teacher characteristic. To begin, we performed a principal axes factor analysis on the 43 different teacher attributes (oblimin rotation) to identify the latent variables underlying the attributes. Based on the eigenvalues, as well as the ability to meaningfully interpret the clustered attributes, a 7-factor solution provided the best fit for the data. The eigenvalues for the first seven factors were: 21.81, 3.02, 2.59, 1.63, 1.25, 1.00, and .82, with the eighth being .75. The rotated pattern matrix is shown in the Appendix. Based on the highest-loading items, we interpreted the factors as:

(1) **Community-building** (e.g., "Teachers encourage a sense of community")
(2) **Knowledgeable** (e.g., "Teachers are knowledgeable about their subject matter)
(3) **Authoritative** (e.g., "Teachers establish classroom rules")
(4) **Influencing** (e.g., "Teachers powerfully influence their students")
(5) **Philosophical** (e.g., "Teachers are abstract thinkers" and "Teachers provoke debate")
(6) **Informing** (e.g., "Teachers present information")
(7) **Nurturing** (e.g., "Teachers are sensitive to their students' needs")

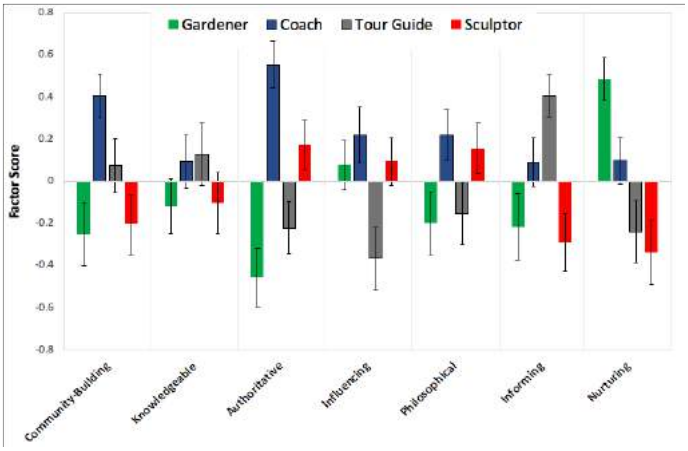

Figure 1: Mean factor scores for each of the seven factors, as a function of the conceptual metaphor that participants considered. The factor scores for the authoritative and nurturing factors are reversed for ease of interpretation.

Figure 1 shows the pattern of differences across the metaphors for each factor. Visual examination of the figure shows some striking differences in teacher characteristics across metaphors. The *gardener* metaphor entails that teachers are nurturing but low on other characteristics, especially authoritative traits. The *coach* metaphor entails that teachers build community, are authoritative, influencing, and even philosophical, in the sense of stimulating new knowledge and provoking debate. The *tour guide* metaphor entails that teachers are informing, but low on other characteristics, especially their ability to influence students. The *sculptor* metaphor entails that teachers are neither nurturing nor informing, but are somewhat authoritative, influencing, and philosophical.

How do teacher characteristics vary across metaphors? Once a 7-factor solution was applied, we saved the factor scores using the regression method. A multivariate ANOVA was performed on the seven factor scores with metaphor (gardener, coach, tour guide, or sculptor) as a between-subjects variable. Overall, metaphor condition showed a significant effect on the set of factors, $F(21, 552) = 6.98$, $p < .001$, $\eta^2 = .21$. Univariate analyses of variance revealed a significant effect of metaphor on the *community-building* ($F(3,188) = 5.01$, $p < .01$) *authoritative* ($F(3,188) = 12.72$, $p < .001$), *influencing* ($F(3,188) = 4.02$, $p < .01$), *informing* ($F(3,188) = 6.20$, $p < .001$), and *nurturing* factors ($F(3,188) = 8.23$, $p < .001$). There was only a marginal effect of metaphor on the *philosophical* factor ($F(3,188) = 2.43$, $p = .07$) and no effect on the *knowledgeable* factor ($F(3,188) < 1$).

Are different metaphors associated with different beliefs about responsibility? Metaphor had a small but reliable effect on ratings of how much responsibility college teachers had for students' learning, $F(3, 197) = 2.93$, $p < .05$, $\eta^2 = .04$. No pairwise comparisons across the conditions (using a Bonferroni adjustment) were significant. As shown in Figure 2, the *sculptor* metaphor promoted the highest rating of teacher responsibility, and the *coach* metaphor the least. Metaphor had a more dramatic effect on ratings of how much responsibility students had for their own learning, $F(3, 197) = 11.42$, $p < .001$, $\eta^2 = .15$. Pairwise comparisons indicated that the *coach* metaphor promoted the highest ratings of student responsibility, significantly more than the *gardener* or *sculptor* metaphors. As shown in Figure 2, the *sculptor* and *gardener* metaphors promoted the lowest ratings, significantly lower than the *coach* and *tour guide* metaphors, but not different from one another.

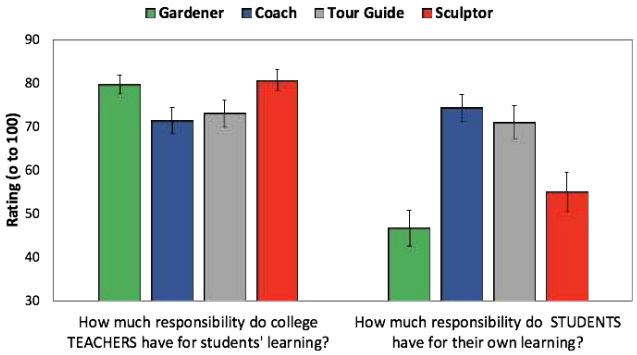

Figure 2. Effects of metaphor on ratings of how much responsibility teachers and students have for learning.

Are different metaphors associated with different beliefs about teacher's power? Metaphor condition had a small but reliable effect on ratings of how much power college teachers had to influence what students learn, $F(3, 197) = 3.02$, $p < .05$, $\eta^2 = .04$. No pairwise comparisons across the conditions were significant, however (all pairwise comparisons used a Bonferroni adjustment). As shown in Figure 3, the sculptor metaphor promoted the highest rating of teacher power over student learning, and the tour guide the least. Metaphor had a more dramatic effect on ratings of how much power college teachers had to influence how students develop as people, $F(3, 197) = 7.44$, $p < .001$, $\eta^2 = .10$. Pairwise comparisons indicated that the *sculptor* metaphor prompted the highest ratings of power to influence development, significantly more than either the *coach* or *tour guide* metaphor. The *gardener* metaphor did not significantly differ from the others.

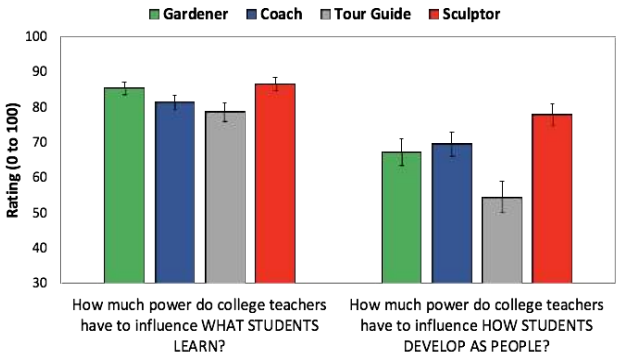

Figure 3. Effects of metaphor on ratings of how much power teachers have to influence what students learn and how they develop as people.

What are the most popular metaphors? Participants most preferred metaphors replicated the pattern found in Study 1. Of the four metaphors, the most popular was the *gardener* metaphor (26.9%), followed by the *coach* (25.9%) and *tour guide* metaphors (25.4%). The *sculptor* metaphor was the least favored (20.4%). Participants' preferred metaphor was not influenced by condition. That is, participants did not select a favorite metaphor that simply matched what they had been presented with in earlier questions. This suggests that people have stable preferred metaphors for thinking about the teacher-student relationship.

Discussion

The findings from this study suggest that different metaphors for teaching are associated with distinct entailments, specifically with respect to the characteristics of teachers. Different metaphors imply that teachers have different "profiles" or clusters of characteristics that can differ dramatically from one another. Notably, the metaphors differ in their implications for students' responsibility for their own learning. The *coach* and *tour guide* metaphors hold students more responsible for their own learning than do the *gardener* and *sculptor* metaphors. The metaphors also differ in how much power the teacher has to influence a student's general development. The *gardener* metaphor entails the most power to influence students' development, and the *tour guide* metaphor the least.

General Discussion

People use metaphors to express their lay beliefs about everything from the nature of intelligence to how the economy works. Though it seems quite natural to identify the conceptual entailments of such metaphors based on common sense knowledge, there are issues with theorizing about the structure of people's metaphorical lay theories based on patterns in language alone. In this paper, we aimed to provide a more principled method for mapping the structure of metaphorical lay theories, using metaphors for teaching as a case study. Our approach was inspired in part by psychometric methods used to uncover the latent structure of other theoretical psychological constructs.

In our first study, we used participant ratings to identify four common, apt metaphors for the college teacher-student relationship (*gardener*, *coach*, *sculptor*, and *tour guide*). In Study 2, participants were provided with one of these metaphors and rated the extent to which a large set of teacher attributes conceptually cohered with the metaphor. We then used exploratory factor analysis to uncover a small subset of meaningful dimensions underlying the larger set of teacher attributes. This revealed that our four teaching metaphors reflect systematically different intuitions about the qualities of college teachers, which can be captured by distinct, coherent clusters of teacher attributes. We contend that this method offers a useful, principled way for researchers interested in metaphorical reasoning to empirically derive the conceptual entailments of different metaphors.

In ongoing and future work, we are continuing to validate this approach by (1) replicating our findings in more representative samples of current college students, (2) applying the same factor analysis method to ratings of *student*, rather than teacher, attributes and (3) mapping the structure of these metaphors in the context of other types of teaching settings (e.g., high school or elementary school teaching). We also plan to measure the explanatory power of lay theories of teaching by examining whether the particular metaphor a student holds for the teacher-student relationship predicts their own attitudes and behaviors in the classroom. Based on the results of Study 2, for example, we would hypothesize that students who hold a *coach* metaphor should expect teachers to be more demanding and assertive than students who hold a *gardener* metaphor, and thus may expect higher and stricter standards in the classroom. Similarly, because the *gardener* and *sculptor* metaphors imply less responsibility on the part of the student, students who endorse these metaphors may hold a more passive view of the learning process and be less likely to engage in active-learning strategies (e.g., self-quizzing) than students who endorse the *coach* and *tour guide* metaphors.

Ultimately, this work could lay the foundation for novel educational interventions based around metaphor framing. Some studies have found that metaphors can shape student mindsets (Blackwell et al., 2007) and attitudes (Landau et al., 2014), but this work has not examined metaphors for teaching specifically. In addition, interventions aimed at changing intuitive lay theories of intelligence to improve student performance have generated inconsistent results (Sisk et al., 2018). One reason for this inconsistency may be that academic performance is shaped by *numerous* intuitive beliefs, not just about intelligence. It is possible that, because learning occurs in a social context that includes teachers and the broader classroom environment, the intuitive beliefs students hold about the nature of *teaching* will also influence academic behaviors and outcomes. As our current work offers a principled way to understand the structure of people's intuitive beliefs about teaching, it provides an important first step in developing such interventions.

Phoneme learning is influenced by the taxonomic organization of the semantic referents

Abstract

Word learning relies on the ability to master the sound contrasts that are phonemic (i.e., signal meaning difference) in a given language. Though the timeline of phoneme development has been studied extensively over the past few decades, the mechanism of this development is poorly understood. Previous work has shown that human learners rely on referential information to differentiate similar sounds, but largely ignored the problem of taxonomic ambiguity at the semantic level (two different objects may be described by one or two words depending on how abstract the meaning intended by the speaker is). In this study, we varied the taxonomic distance of pairs of objects and tested how adult learners judged the phonemic status of the sound contrast associated with each of these pairs. We found that judgments were sensitive to gradients in the taxonomic structure, suggesting that learners use probabilistic information at the semantic level to optimize the accuracy of their judgements at the phonological level. The findings provide evidence for an interaction between phonological learning and meaning generalization, raising important questions about how these two important processes of language acquisition are related.

Keywords: language acquisition; phonological development; word learning; speech perception.

A crucial part of language acquisition is the mastery of the sound inventory, i.e., the set of atomic sounds of which words are made. The sound inventory is language-specific. English speakers, for instance, have to learn the distinction between the sounds /l/ and /r/ to differentiate minimal pairs such as *glass* and *grass*. In contrast, Japanese learners need not differentiate these sounds, which do not bring about difference in word meaning in their language. Crucially, even within the same language, learners have to distinguish the sounds that contrast word meaning (phonemic contrasts) from the sounds that do not (non-phonemic contrasts). For example, the aspirated and unaspirated versions of /p/ (which occur, respectively, in the first segment of the word *pin*, and the second segment of the word *spin*) belong to the same phonemic category. Another example, is the *cot-caught* merger whereby the vowels [ɑ]-[ɔ] have come to be treated by some English speakers as non-phonemic variations of the same sounds (Labov, 1991).

How do people learn when a sound contrast is phonemic and when it is a phonetic variation of the same sound category? Children start to show sensitivity to their native sounds at a very early age (e.g., Werker & Tees, 1984). Throughout development, they also learn to distinguish the subset of the native sounds that cue meaning (Dietrich, Swingley, & Werker, 2007; Seidl, Cristi, Onishi, & Bernard, 2009; Kazanina, Phillips, & Idsardi, 2006). These developmental facts have been documented in detail over the past few decades, but the mechanism of this learning is still poorly understood.

Most research has focused on exploring mechanisms which operate on the speech signal without any referential input (Peperkamp, Le Calvez, Nadal, & Dupoux, 2006; Maye, Werker, & Gerken, 2002; Vallabha, McClelland, Pons, Werker, & Amano, 2007; Swingley, 2009; Martin, Peperkamp, & Dupoux, 2013; Feldman, Myers, White, Griffiths, & Morgan, 2013; Dillon, Dunbar, & Idsardi, 2013). These mechanisms have been tested successfully with simplified input. However, they were not as successful when tested on more realistic acoustic data which is highly variable and noisy (e.g., Varadarajan, Khudanpur, & Dupoux, 2008; Fourtassi, Schatz, Varadarajan, & Dupoux, 2014; Jansen et al., 2013). Thus, though these mechanisms may play an important role, they are unlikely to account for the entire process of learning and refinement.

Learners are exposed to more than the speech signal. In particular, they usually have access to multimodal input which co-occur with speech. For example, the words *glass* and *grass* in English are typically associated with different visual input. Experimental data has shown that both children and adults can leverage such semantic/visual information to discriminate ambiguous sounds (Teinonen, Aslin, Alku, & Csibra, 2008; Yeung & Werker, 2009; Hayes-Harb, 2007).

Nevertheless, previous research has generally assumed–whether implicitly or explicitly–that learners have access, not only to the immediate visual input, but also to the entire meaning category intended by the speaker, e.g., the meaning of the word 'cow' is not limited to one specific cow–it includes cows of all shapes and colors, and it excludes instances of another category such as deer. Knowing the meaning's extension and boundary of a given word is crucial to the task of phoneme learning: If an ambiguous sound contrast is associated with two different objects (e.g., a cow and a deer), then in order to decide whether or not this contrast is phonemic, the learner has to determine first if the speakers' target meanings are two specific categories (cow and deer) or one broad category (e.g., animal). The contrast is phonemic in the former case, and non-phonemic in the latter.

Often, however, learners in the early stages of acquiring their first or second language, do not yet know the full mean-

ing extensions of the words they hear around them. Work in the word learning literature suggests that humans spontaneously restrict the set of possible extensions to taxonomic classes (Markman, 1989). For example, upon hearing the word 'cow' with an instance of, say, a brown cow, humans are unlikely to consider an extension that includes 'milk' or 'brown rice'. Though the taxonomic assumption simplifies the task, it still leaves a great deal of ambiguity regarding the level of generalization intended by the speaker. For example, the word 'cow' could have meant more abstract categories such as "mammal" or "animal".

The current work aims at studying how learners behave in a situation where there is uncertainty at both the phonological and semantic levels. We associate minimally different non-sense words (along the ambiguous sound contrast ɑ-ɔ) with pairs of objects that vary in their taxonomic proximity (Figure 1). Crucially, mere exposure to instances of the sound-object pairings is not enough to determine the exact meaning extension, leaving the participants in a situation of uncertainty similar to that faced by learners in the early stages of language acquisition. We are interested in the participants' subsequent judgment about the phonemic status of the pair of sounds.

There are several possible scenarios. For instance, participants may not be sensitive to the degree of taxonomic distance, treating all visual differences as equally indicative of a phonemic status. It is also possible that participants treat degrees of taxonomic distance in a categorical way, i.e., they may treat pairs of objects up to a certain taxonomic level as equally indicative of non-phonemicity, whereas they treat pairs of object beyond that level as equally indicative of phonemicity. Finally, participants may be sensitive to each gradient of taxonomic distance in their phonemic learning, in which case their judgements should be graded as well.

In what follows, we test these predictions with adults learning an alien language. In Experiment 1, we parametrize a subset of the semantic space, creating an evenly-spaced taxonomic scale, and we use this scale to explore the effect of different gradients of taxonomic distance on the phonemic status of the ɑ-ɔ contrast. In Experiment 2, we test whether results of Experiment 1 are due to interference from existing lexicalized categories in the first language. Finally, we discuss the implication of the findings on phoneme learning in the context of early language acquisition.

Experiment 1

The goal of this first experiment is to use a parameterized subset of the semantic space to test the effect of each gradient of taxonomic distance on learning the phonemic status of an ambiguous sound contrast. We use a between-subject design to avoid carry-over effects in the sound judgements.

Participants

152 Participants in total were recruited online through Amazon Mechanical Turk, restricting the pool to the United States residents. At the end of the experiment, participants were asked to rate the overall quality of the audio-visual stimuli on their local software/hardware. We excluded participants who judged this quality as medium or bad (N=26), keeping only those who rated the quality as good, that is, those for whom the experiment functioned correctly. We also excluded participants who took the experiment more than once (N=3), and participants who obtained less than 50% correct answers on the obvious filler questions (e.g., are the words "komi" and "pibu" different?) (N=5). We ended up with a sample size of 115 participants split across 5 groups.

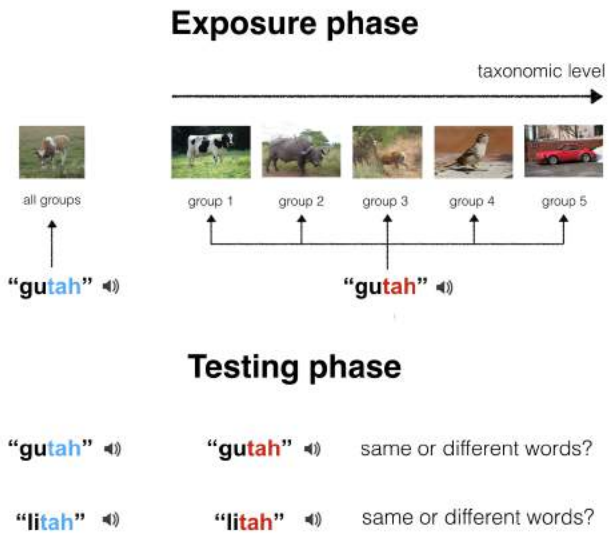

Figure 1: Overview of the task.

Stimuli

Objects The stimuli consist of a reference object (a cow), and five other objects which varied in their similarity to this reference. These objects were, in this order, another cow (with a different color), a buffalo, a deer, a bird and a car (Figure 2). To parmaterize the object stimuli in the taxonomic space, we recruited an additional N=30 participants online (through Amazon Mechanical Turk), and we asked them to rate the similarity of a series of pairs of objects in a 9 point-scale, 1 being "very similar" and 9 being "very different". The pairs of objects were formed by the pairwise combination of all six items described above. The order of trials was randomized across participants. We computed the average rating for each pair, which gave us a distance matrix.

Figure 2 (left) shows the taxonomic organization of the object stimuli, which we obtained via hierarchical clustering (using average linking) applied to participants' similarity data. Height indicates the average similarity within clusters at each hierarchical/taxonomic level. Figure 2 (right) shows a different visualization of the same data using bi-dimensional scaling. Both representations show that the way objects are organized around the reference (i.e. cow) corresponds to graded differences in the semantic space, and that these gra-

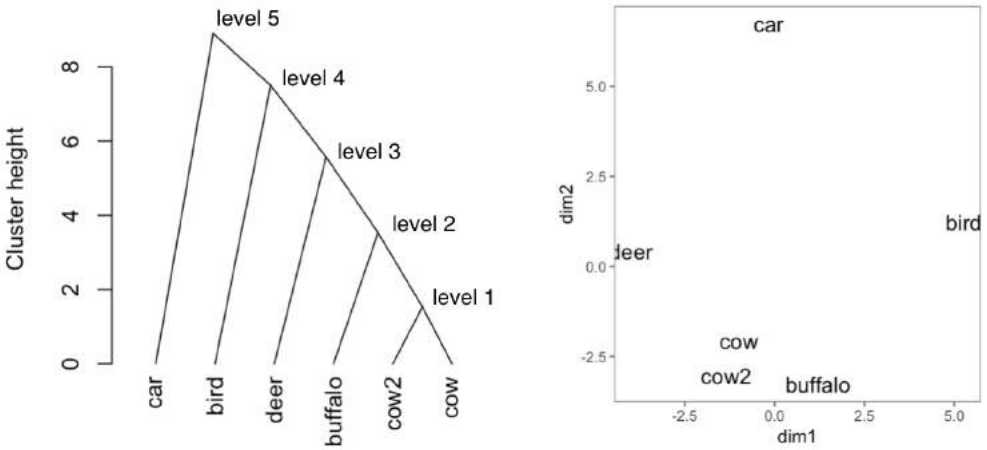

Figure 2: The graph on the left shows the taxonomic organization of the object stimuli obtained via hierarchical clustering of the participants' similarity ratings. The graph on the right shows another way of visualizing the same data via bi-dimensional scaling. Both representations show that the object stimuli lead to a graded and evenly-spaced semantic scale.

dients are quite evenly-spaced.

Sounds We followed Feldman et al. (2013) in using minimal pairs that vary along the vowel contrast [ɑ]-[ɔ]. This contrast is neither too acoustically similar, nor too different. In fact, depending on the dialect, these two vowels can be treated by English speakers as belonging to one or two categories (Labov, 1991). We chose such an ambiguous contrast in order to put the participants in a rather flexible situation where they can switch between phonological interpretations depending on the context. Two minimal pairs were constructed by concatenating two context syllables ([gu] and [li]) produced by a female native speaker of American English, with a target syllable contrast ([tɑ]-[tɔ]) produced by the same speaker. The resulting minimal pairs were [gutɑ]-[gutɔ] and [litɑ]-[litɔ]. For ease of presentation, we will refer to these minimal pairs by *gutah*/*gutaw* and *litah*/*litaw*. In addition, we used two artificial filler words [pibu], [komi] which we obtained by concatenating four vowels produced separately by the same speaker.[1]

Procedure

In order to avoid any carry-over effect on sound judgements, we used a between-subject design, i.e., each group of participants were exposed to only one degree of taxonomic distance. The minimal pair was paired with two objects whose similarity varied across five groups of participants (Figure 1). In all these groups, one member of the minimal pair (e.g., *gutah*) was paired with picture of a cow. The second member (i.e., *gutaw*) was paired with a referent whose similarity with the first referent varied on the five-step taxonomic scale.

The experiment had an exposure and a testing phase. In the exposure phase, participants heard a novel word in an alien language and saw the corresponding object simultaneously. In this phase subjects did not have to perform any specific task, but they were encouraged to listen carefully and try to learn the words. They were exposed to 3 series composed each of a randomized presentation of 4 word-object pairings: 2 target words (*gutah*/*gutaw*) whose referents similarity varied across groups of participants (Figure 2), and 2 filler words (*pibu* and *komi*) mapped invariably to two different objects. There were 12 trials in total, with each presentation lasting around 850 ms (i.e., the time it took the bi-syllabic word audio to complete).

In the testing phase, participants heard a series of trials composed of two word tokens, and were asked to judge if these tokens corresponded to different words in this artificial language, or if they represented a mere phonetic variation of the same word. We used a wording similar to the one used by Feldman et al. (2013)[2]. In this testing phase, subjects were encouraged to follow their intuition and think carefully before answering.

Half of the testing trials contained identical sounds ('same trials'), and the other half contained different sounds ('diff. trials') and were presented in a random order. The diff. trials were composed of the minimal pair used during the exposure phase (*gutah*/*gutaw*) plus a novel minimal pair containing the same syllable contrast (*litah*/*litaw*), and which we used only in the testing phase to investigate the ability of participants to generalize across the lexicon. There were 12 test trials in total: 4 for for the exposure word (2 same and 2 different), 4 for the generalization word (idem), and 4 for the fillers komi/pibu (idem). Participants were tested twice, once before exposure to referential data and once after the exposure.

[1] The audio stimuli were graciously provided by Naomi Feldman.

[2] "You will listen to pairs of words from an artificial language. You should decide if they are same or different. The words can be different in the language even if they are similar. Conversely, they can be same even if they are pronounced slightly differently."

Results

Figure 3 shows the proportion of times participants judged the minimal pairs as phonologically different as a function of group (i.e., taxonomic level), and as a function of the testing session, i.e., before or after exposure to referential data.[3] We show results for both diff. trials (e.g., "gutah"/"gutaw") and same trials ("gutah"/"gutah").

Note, first, that the proportion of 'different' answers for same trials was close to zero across groups, showing that participants were almost perfect in detecting same pairs. However, the proportion of 'different' on the diff. trials varied across groups, and this proportion was 50% in the 'before' session. These initial observations confirm our choice of the sound contrast, which was supposed to be perceptually distinguishable, but ambiguous in terms of its phonemic status, allowing participants to adjust their phonological interpretation depending on the referential context.

	Estimate	Std. Error	z value	Pr(>|z|)
(Intercept)	-1.07	0.41	-2.59	0.01
group	0.32	0.12	2.65	0.01
session	-0.86	0.35	-2.46	0.01
trial	-3.59	0.19	-18.55	<0.01
group:session	0.28	0.10	2.85	<0.01

Table 1: A mixed-effects logistic regression predicting participants' responses in a same-different task.

After exposure to referential data, we observed a graded effect of the objects' taxonomic distance on phonological judgment: Participants were more likely to judge the phonologically ambiguous contrast as different when this contrast corresponded to higher taxonomic levels (Figure 3). We fit a mixed-effect logistic regression which predicted the participants' response by the group (i.e., taxonomic distance), the session (before or after exposure the referential data), and the trial (same or diff. pairs). The model was specified as follows: `response` ∼ `group * session + trial + (1|Subj) + (1|item)`. The estimates are summarized in Table 1. Confirming our qualitative observations, the model shows that the type of the trial predicted the participants' responses (i.e., answering more 'same' on same pairs). Crucially, we also found an interaction between group and session, indicating that exposure to referential data influenced the participants' responses.

To further examine the influence of exposure on learning and generalization, we fit two simple mixed-effects logistic models to the diff. trials after exposure predicting responses as a function of group. We found an effect of object semantic distance on phonological judgment in both the exposure word ($\beta = 4.55$, $SE = 1.13$, $p < 0.01$) and the generalization item ($\beta = 2.58$, $SE = 1.00$, $p < 0.01$).

[3]Since answers do not vary across groups prior to the exposure phase, in the 'before' session we only show the average results where data were collapsed across groups.

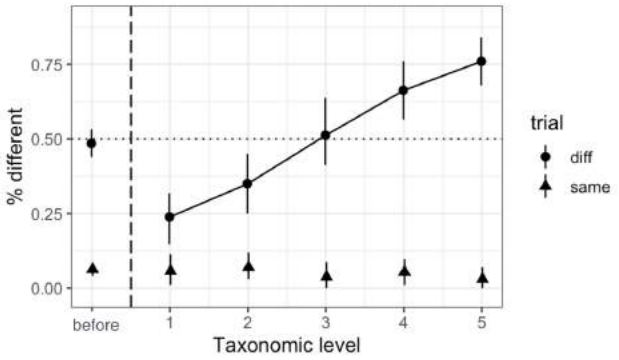

Figure 3: The points are the proportion of times participants judged the pair of sounds as 'different'. The triangles represent the judgments for exactly same pairs (e.g., gutah-gutah). The circles represent the judgments for different pairs (e.g., gutah-gutaw). Data on the left side of the vertical dashed line show the average responses before exposure to the referential data. The horizontal dotted line represents chance. Error bars represent 95% confidence intervals.

Discussion

Experiment 1 tested how gradients in the semantic space influence judgments about the phonemic status. It is possible, however, that participants relied, not on the taxonomic distance in the semantic space, but on available lexicalized concepts in their first language. Indeed, one could imagine that the more a common label is easily accessible for a pair of objects, the more participants answer "same" in the phonemic task. For example, if it is easier to access a common label in the case of *cow* and *deer* (e.g., "mammals"), than it is in the case of *cow* and *car* (e.g., "things"), then this difference may explain why participants judged the sound contrast more as phonemic in the latter. In Experiment 2 we explore whether such an account could explain the findings.

Experiment 2

We asked participants to provide common labels in English for each of the objects pairs used in Experiment 1, and we quantified the difficulty they had in generating these labels. If the phonemic judgements are driven by common labels in the first language, then the difficulty in accessing these labels should mimic closely the phonemic judgments (Figure 3).

Participants

40 participants were recruited online through Amazon Mechanical Turk, restricting the pool to the United States residents.

Stimuli

The same object stimuli used in Experiment 1.

Procedure

Participants were presented with pairs of objects, and were asked to type in, as fast as they could, the most specific la-

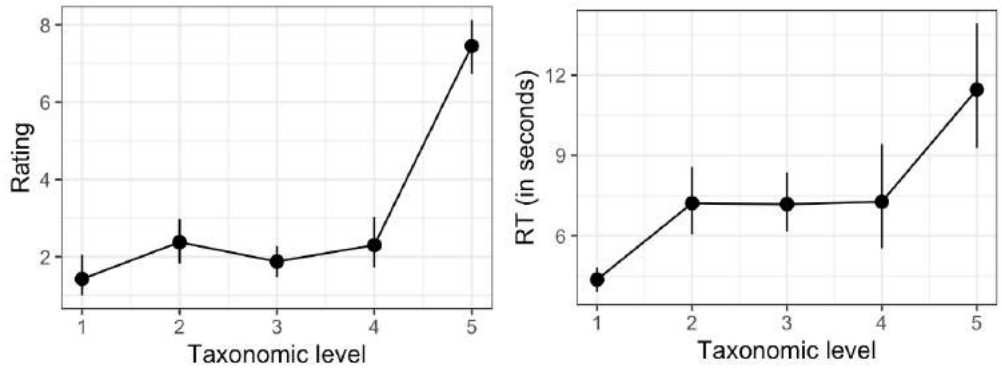

Figure 4: The graph on the left shows the average self-reported difficulty in generating a common English label for pairs of objects at different taxonomic levels (on a scale from 1 to 9). The graph on the right shows the average time it took participants to generate these labels.

bel in English that describes both objects (or "none" in the case they could not find a common label). We obtained both the labels and the reaction times, i.e., the time it took them from seeing the object to confirming their answer. Besides, participants were asked to evaluate the difficulty they had in generating the label on a scale from 1 to 9. The pairs were randomized across participants. To avoid carry-over effects, each participants saw the pairs only once.

Results

Results are shown in Figure 4. Overall, participants were faster and found it easier to generate a common labels when both objects were cows (the most frequent response was 'cow'). They were slower and found it difficult to generate a common labels when the pair was cow/car (most participants did not find a common label and typed 'none'). That said, they did not show any noticeable difference (neither in reaction times nor in subjective evaluation) for the intermediate cases. For all these cases, the most frequent response was 'animal'. Thus, though common labels in the first language may explain limit cases, it does not account for the entire pattern of graded responses obtained in Experiment 1.

General discussion

Previous research has suggested that semantic information can help with phoneme acquisition (Yeung & Werker, 2009; Hayes-Harb, 2007; Werker & Curtin, 2005). Nevertheless, learners often have to learn the phonemic status of the sounds they hear around them before they have determined the exact extension of the meaning intended by the speaker (e.g., a cow and a deer can be described by one or two words depending on the speaker's target level of taxonomy). The current work studied how the process of phoneme learning is influenced by such uncertainty at the semantic level.

More precisely, this study explored the effect of taxonomic distance on phonemic judgments. We associated minimally different word-forms with two semantic referents whose taxonomic distance varied across groups, and we asked participants in each group to judge the phonemic status of the corresponding sound contrast. We found that increasing the taxonomic distance induced graded judgments on the phonemic status, suggesting that learners are sensitive to the taxonomy of the referents when acquiring phonemes.

According to work in the word learning literature, humans have a bias towards extending the meaning of novel words to objects of similar kinds (Markman, 1989; Xu & Tenenbaum, 2007). In our case, this bias may have prompted participants to treat objects that were taxonomically similar (i.e., two cows with different colors, or cow/buffalo) as instances of the same meaning category, thus judging the sound variation as non-phonemic. In contrast, they may have treated objects of different kinds (cow/bird, or cow/car) as instances of different meaning categories, thus judging the corresponding sound variation as phonemic. Besides, the fact that participants provided graded–rather than stepwise–pattern of judgments mirroring the graded taxonomic distance suggests that they make use of probabilistic information at the semantic level to optimize the accuracy of their inference at the phonological level (see also Fourtassi & Frank, 2017).

How could the obtained relationship between taxonomic distance and phonemic judgements inform our understanding of development? First, this relationship may allow learners to collapse non-phonemic but perceivable sounds into the same phonemic category. This is crucial since the majority of sound contrasts in natural input consists of different pronunciations of the same word, rather than words that differ minimally (see Martin et al., 2013). Instances of the same words are likely to be associated with similar semantic information (i.e., at a similar taxonomic level), thus inducing a non-phonemic judgment for the corresponding contrasts.

As for true phonemic contrasts (e.g., *glass* vs. *grass*), sensitivity to the taxonomic structure will favor differentiation to the extent that minimal pairs have distant taxonomic distance in natural languages. Some research suggests that words that are similar phonologically tend to be similar semantically as well (Dautriche, Mahowald, Gibson, & Piantadosi, 2017).

However this research measured semantic similarity using a distributional model which relies on co-occurrence in a large corpus of text. It is possible that the type of semantic relationship that the model derived was thematic, rather than taxonomic. In fact, thematically related words can be taxonomically different (e.g., *cow* and *milk*). It has been shown that the nature of the semantic relationship depends on the model's parameter setting (Lenci, 2018). Further work on the semantic organization of minimal pairs is needed to elucidate this point.

The current study has some limitations. First, we only used the taxonomy of a subset of the conceptual space. To test the generality of the findings, future work will use different scales spanning several conceptual domains. Second, we only used familiar stimuli (real world objects and a native sound contrast). To completely rule out interference from categories in the native language, future work will seek to replicate the findings with non-native contrasts and with novel object stimuli.

To conclude, the current work showed that different degrees of taxonomic distance in the semantic space influence the acquisition of the phonemic status of sound contrasts. The findings show that learners make use of probabilistic information at the semantic level to optimize the accuracy of their phonemic judgments. More generally, this work suggests there to be an interaction between sound learning (phonemic judgment) and word learning (meaning generalization). Further work should aim at characterizing precisely this interaction and exploring its implications for both phonological and semantic development, two aspects of language development which have largely been studied separately.

Abstract

How do you make sense of an unconventional graph? Building on research demonstrating that prior knowledge of graphical conventions is difficult to overcome, we reconstrue graph reading as an insight problem. We hypothesize that imposing a *mental impasse* during a particular type of graph reading task will improve comprehension by inducing a sense of puzzlement, prompting learners to reconsider their interpretation. We find support for this proposal in a between-subjects experiment in which participants presented with an impasse-formulated version of graph reading questions are significantly more likely to correctly interpret a graph featuring an unconventional coordinate system. We characterize the differential patterns of mouse movements for learners between conditions and discuss implications for the use of novel graphical forms in science communication.

Keywords: graph comprehension; diagrammatic reasoning; insight; problem solving; representation; external representation; information visualization; mouse tracking

Introduction

The adage, "a picture is worth ten thousand words," surely applies to graphs. But what about a graph you don't know how to read? As Larkin and Simon note, "a representation is useful only if one has the productions that can use it," (1987, pg. 71). If we lack the ability to draw inferences from a graph, it is rendered useless. How is it then, that we develop such productions for new graphical forms?

Techniques for supporting graph comprehension have been a focus of research in the learning, cognitive and computer sciences for the past two decades. The most minimal interventions involve "graphical cues": visual elements that guide attention, akin to gesture and pointing. Acartürk (2014) investigated the influence of lines, arrows and point markers, finding that—used appropriately—such cues can help readers interpret the emphasis and temporal scope of a graph in alignment with a designer's intention. Kong and Agrawala (2012) surveyed the use of "graphical overlays" finding that reference structures (e.g. added gridlines), redundant encodings (e.g. data value labels), highlights, summary statistics, and annotations, are all commonly used to reduce cognitive load for particular graph reading tasks. Drawing inspiration from the literature in reading comprehension, Mautone & Mayer (2007) successfully demonstrated that animations, diagrams and drawings could help geology students connect the features of graphs to their geological referents. Each of these techniques serves to reinforce the semiotic connection between a graph, the world, and the reader's understanding, or to guide attention to information designers wish to emphasize. Importantly however, the techniques explored in this literature do not support learners in discerning *how* to read the graphs: the "rules" for their representational systems. Rather, it is assumed that the reader already has some familiarity with the type of graph being read (e.g. scatterplot, line graph, bar chart). In this way, the literature fails to differentiate between two types of prior knowledge brought to bear on a graph reading problem: knowledge of the domain, and knowledge of the graphical formalism.

In recent work (Fox & Hollan, 2018) we have taken up this challenge by investigating self-directed comprehension of an unconventional graph. In our paradigm, learners answer simple graph reading problems about a familiar domain—events in time—using an obscure graphical formalism. In an observational study, we found that readers struggled to make sense of the graph, misinterpreting the coordinate system as Cartesian. In a subsequent experiment, we evaluated four sets of instructional scaffolds aimed at overcoming the Cartesian misconception. We found that only an interactive version of the graph was effective for most learners. It seems that learners' expectations for the graphical formalism were so strong, even explicit text or image instructions failed to alert them to erroneous interpretations.

We argue this can be viewed as a sort of "graphical fixedness." Akin to Duncker's classic candle problem (1945), the learners in our previous studies were fixated on the conventional functions of the tools at their disposal: the marks on the page, and their assumptions about how axes and gridlines are meant to function. In the present work, we

reconceptualize our graph reading task as an insight problem. We test the hypothesis that intentionally inducing a state of puzzlement in learners—posing a *mental impasse*—will improve their ability to extract information from a simple unconventional graph.

Background

Graph Comprehension

Process models of graph comprehension describe an integration of top-down and bottom-up processing (Shah, Freedman, & Vekiri, 2005). Following the information processing tradition, these models invoke the concept of a *schema*: a structured representation of knowledge in long term memory that guides processing of new information in a "top- down" fashion (*see* Alba & Hasher, 1983; Anderson & Pearson, 1984). A number of theories describing graph comprehension have posited the existence of a graph schema that guides an individual's interpretation on the basis of their prior knowledge of similar external representations (Freedman & Shah, 2002; Pinker, 1990; Tabachneck-Schijf, Leonardo, & Simon, 1997).

Unsurprisingly, there is no consensus on the format or content of graph schemata. One important question that has been addressed is what features of a stimulus trigger activation of a particular graph schema. According to the "invariant structure view" certain general characteristics are shared across a number of graph types that then rely on a shared schema (Peebles & Cheng, 2003). Ratwani & Trafton (2008) proposed that the structural components of a graph that represent basic concepts and operations for extraction—the *graphical framework*—may be that invariant structure. In a scatterplot, for example, the graphical framework includes the x and y axes. From this formulation, one can predict that bar, line and scatterplot graphs (all relying on a Cartesian coordinate system) might invoke a single graph schema, while pie charts (relying on a polar coordinate system) might invoke a different schema. It is unclear what (if any) schema might be activated in order to comprehend a novel representation. Pinker (1990, p. 105) theorizes that upon encountering a novel graph, a reader will instantiate a "general graph schema", likely based on a combination of the graph's coordinate system and most predominate graphical forms (e.g. points, lines, bars, etc.) The exact mechanism of construction for this general schema is unknown, but Pinker suggests it may be related to the cognitive processes that represent abstract concepts like space and the movement of objects within it.

Prior Knowledge and Graphical Sensemaking

While the marks on a page invoke our prior knowledge of graphical formalisms, the context of the marks activate our knowledge of the domain (Shah & Hoeffner, 2002). We argue that scarcity of each type of prior knowledge impedes comprehension in different ways.

Limited prior knowledge. If presented with an unfamiliar graph depicting information in an unfamiliar domain, you will be unable to use knowledge of one to bootstrap inferences for the other. Imagine you are a novice physics student reading a Feynman diagram: without some understanding of particle physics, you cannot reverse-engineer the formalisms of the diagram. Without these formalisms, you cannot draw inferences about particle physics.

Limited prior *domain* knowledge. Alternatively, if presented with a familiar graph depicting data in an unfamiliar domain, you might draw on your knowledge of that graph type to learn something new about the content. If you know that a straight line represents a linear relationship, you can infer this relationship between unfamiliar variables connected by a straight line. It is this situation that we aim to optimize in STEM education. To this end, Mautone & Mayer (2007) demonstrated that animations, arrows, diagrams and photographs can all help students connect their prior knowledge of graphs to represented variables, improving their ability to draw inferences about related scientific concepts.

Limited prior *graphical* knowledge. Here, we are interested in the reciprocal case: an unfamiliar representation depicting information about a familiar domain; perhaps that strange-looking graph you saw in your favorite academic journal. Importantly, by "graphical knowledge", we are not referring to knowledge of graphs in general (graphicacy), but rather knowledge of the rules governing a *particular* graphic form. Can you figure out how to read the graph, if you know enough about the domain? (Test yourself! See Figure 1)

Reverse Engineering Formalisms. If the typical function of graphs is to use their formalisms as vehicles to learn something about the data (i.e. the domain) they represent, is the reverse also true? With sufficient domain knowledge, can readers reverse-engineer the formalisms governing a graph? Our data suggest this reciprocity of does not exist (Fox & Hollan, 2018). Despite extensive domain knowledge and personal experience with time, learners failed to correctly interpret the formalism of our graph with an unconventional coordinate system. Explicit instructions (text and images) were ineffective in supporting this reverse engineering, suggesting the need for a different scaffolding approach.

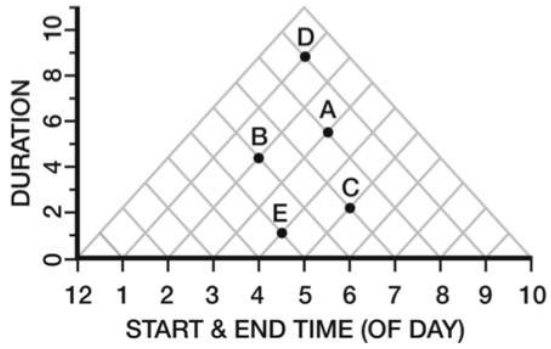
Problem Solving & Insight

In our earliest observational study with the Triangular Model graph (Figure 1), the vast majority of participants made the "Cartesian mistake": misinterpreting the graph as a Cartesian scatterplot (Fox & Hollan, 2018). However, for the few successful outliers, their production of the correct interpretation was accompanied by a protracted struggle, a

sudden clap of their hands and ecstatic exclamation, "Oh! *That's* how it works!"

What we observed were moments of *insight.* This insight came during the study debrief when we gave the learner feedback that their answers were incorrect. In some cases, this feedback alone was sufficient to produce a moment of insight. According to Ohlsson (1992), insight results when one breaks free from an impasse*:* "a mental state in which problem-solving has come to a halt; all possibilities have been exhausted and the problem-solver cannot think of any way to proceed" (pg. 4). But unlike traditional problems in the insight literature, the state of impasse in graph comprehension is not readily apparent. We must therefore craft the state of impasse to intentionally draw a learner's attention to their own misconception. The function of our feedback in the verbal debrief was to alert the learner to the fact they had made a mistake. While we cannot provide verbal feedback as a passive scaffold, we *can* indicate to learners that they've made a mistake by anticipating their mistaken response, and designing the graph reading question to exploit this error: relying on the convention that a multiple-choice question should have at least one response.

An Unconventional Graph: The Triangular Model of Interval of Relations



This graph depicts a schedule of events (A through E)
At what time does event B begin? [non-impasse]
What event(s) begin at 3? [impasse]
**see answers in acknowledgements*

Figure 1. A Triangular Model Graph (TM)

This line of research requires a very special stimulus: one that represents information about a familiar domain but is sufficiently obscure to be unrecognizable by most learners. We selected the Triangular Model graph (Figure 1) to depict information about schedules of events using a novel coordinate system. It has an informationally equivalent analogue, the Linear Model which, as the conventional external representation for intervals of time, is the basis for many scheduling artifacts including Gantt Charts. Both models indicate the start and end time, duration, and relations between intervals, which we present to participants as "events in time."

Based on work by Kulpa (2006) extended by (Qiang, Delafontaine, Versichele, De Maeyer, & Van de Weghe, 2012) the Triangular Model (*hereafter* TM) represents intervals as points in 2D metric space (Figure 1). Each point represents an interval of time. In the vertical dimension, the height of the point indicates its duration. The intersection of the point's triangular projections (using diagonally oriented grid lines) onto the *x*-axis indicate the start (leftmost) and end (rightmost) times. In this way, every interval is represented as a unique point in the 2D graph space, and each of its elementary properties are explicitly encoded by the location of the point. Although the graph's computational efficiency is best realized with a large number of data points, and tasks that require judgement about the relation between intervals (e.g. "starts-with", or "during" relations), first order readings (i.e. reading the start, end or duration) are readily available and directly reveal the reader's interpretation of the coordinate system. (See Qiang et. al (2012) for a thorough review of the computational efficiency of the Triangular Model, and elaboration of use cases for which it is preferable to more conventional interval graphics.)

A brief inspection of the TM by even the most experienced graph reader demonstrates its relative obscurity. However, while the coordinate system is unconventional, the graph depicts information about a domain in which we all share substantial prior knowledge: events in time.

The Present Study

Results of two prior studies (Fox & Hollan, 2018) give us reason to suspect that conventional graph knowledge may hinder comprehension of unconventional representations. In the case of the TM graph, Cartesian expectations for the structure of the coordinate system interfere with our ability to follow perceptual cues provided by the graph's diagonal gridlines. In the present study, we test the hypothesis that constructing a mental impasse will improve comprehension of this unconventional graph.

Methods

Participants and Design. Sixty (55% female) undergraduate STEM majors at a public American University participated in exchange for course credit (age: 18 - 33 years). We utilized a between-subjects design with two groups and one independent variable (scaffold: none [control] vs. impasse). Participants were randomly assigned to an experimental group, yielding 30 students per condition. Prior to analysis, data from six participants were excluded based on their failure to correctly answer an attention check question.

Procedure. Participants completed the study in person, seated at a desktop computer. After a brief introduction, they were randomly assigned to an experimental condition and

completed the Graph Reading Task, after which they received a short debrief. The session lasted approximately 30 minutes.

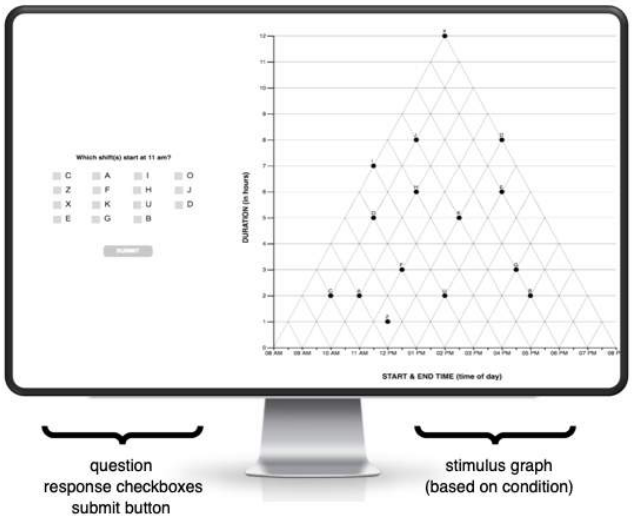


Figure 2. Sample stimulus

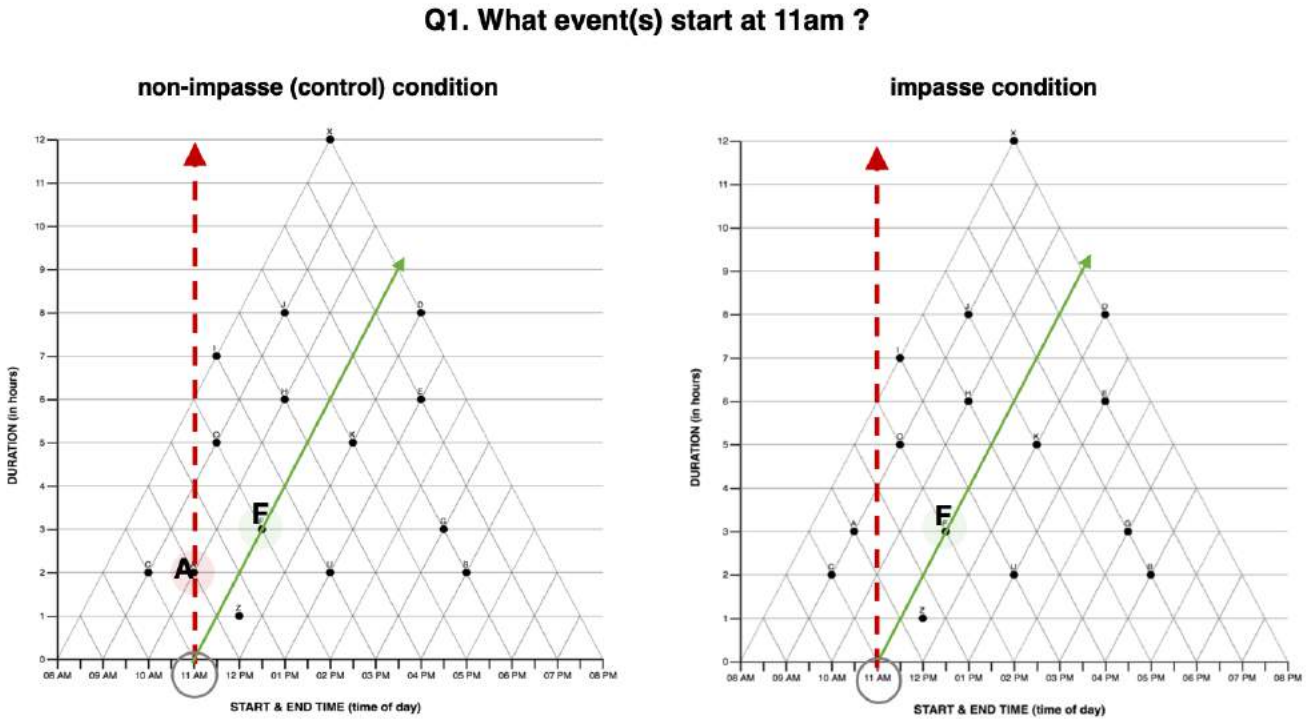
Materials. The Graph Reading Task consisted of a sequence of fifteen trials, each featuring a TM graph and multiple-choice question (Figure 2) about the temporal relationship between data points in the graph (i.e. "*Which event(s) start at 11am? At what time does event B end?*) Learners responded by clicking a checkbox corresponding to the data point(s) they wished to select. Trials were presented one at a time without feedback, in the same order for both conditions. Learners could not skip ahead nor return to previous questions. To assess the stability of student strategies over time, the first five trials included the assigned scaffold condition (none-control or impasse), while the following ten trials were identical (none-control). Questions were identical for both experimental conditions; however, the data sets rendered in the graph were slightly different for the first five trials. This allowed us to construct impasse problems with minimal differences between conditions. For each question in the non-impasse (control) condition, there was always a data point in the position where the participant would search if they interpreted the graph as Cartesian (Figure 3—*left*). Alternatively, in the impasse condition, the learner would find no data point in the expected position (Figure 3—*right*). For the final ten trials learners saw the same graph and questions. *See Figure 3 inset for a detailed description of the impasse structure.*



In both conditions, event F (solid green) is the single correct answer. In the non-impasse (control) condition at left, data point A crosses the Cartesian projection (dashed red line) from 11am, the most likely strategy taken by a learner misinterpreting the coordinate system. In this case, we expect the learner to select answer A. In the impasse condition (right) there is no data point intersecting the Cartesian projection. We expect this to pose a mental impasse. *note: extra lines and labels added for clarity, actual stimuli contain no such cues*

Figure 3. Experimental Conditions for Graph Reading Task Question #1

Data and Analysis. For each participant, we calculated a cumulative comprehension score [0-15], which served as the dependent variable. For further exploration of learner strategies, we integrated a JavaScript-based service (Mouseflow) to record all mouse-movements made by participants during the experiment session. Comprehension data were analyzed via inferential statistics, while mouse data were subject to exploratory qualitative analysis.

Results

Performance Accuracy. The mean comprehension score across the sample (n = 54) was approximately 6 points with a standard deviation of 0.68, and values ranging from 1 to 15 (max) points. On average, participants in the *impasse* group had higher scores (M = 7.6, SD = 5.2) than those in the non-impasse control group (M = 3.9, SD = 4.2), yielding a statistically significant difference $t(49.7) = -2.8$, $p = 0.006$; a moderate-sized effect $r = 0.37$.

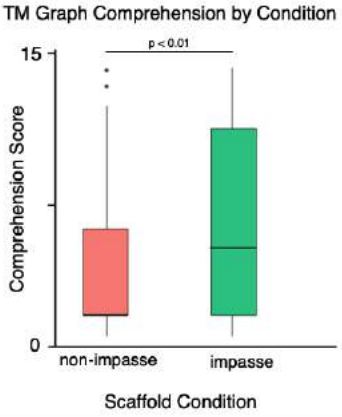


Figure 4. Results for graph reading task, by condition

Mouse Tracing Behavior. While raw comprehension scores can indicate whether learners correctly interpret the graph, they cannot reveal the strategies employed to answer the questions. To explore the mechanisms behind our results, we captured mouse tracing data. Similar to eye tracking data, mouse tracing provides an imperfect proxy for visual attention of the learner during the problem-solving session. This is a particularly rich source of insight for our graph reading problems as learners frequently used the mouse to navigate across the graph, the mouse acting like fingers tracing down or across gridlines. Of course, not all learners utilize the mouse to the same extent, and so we limit the present analysis to qualitative observation of gestalt patterns of graph traversal.

Figure 5 contains a set of heatmaps generated from raw path and dwell time data depicting the mouse movements of all participants on the *first* question of the Graph Reading Task. In the left column, we see data for learners in the control condition, and on the right, the impasse condition. The top row of heatmaps were generated from only those participants who correctly answered the question, while the bottom row from participants with a variety of incorrect answers. Visual inspection of these heatmaps reveal that across both conditions (top row), learners who correctly interpreted the coordinate system traversed the graph in a similar fashion, with the most prominent patterns following the relevant diagonal gridlines. Inspecting those with incorrect answers (bottom row), we see dramatically different patterns of tracing across conditions. While those in the control condition (bottom left) follow the expected Cartesian projection, learners in the impasse condition (bottom right) exhibit no single discernible pattern. While these learners did not arrive at the correct answer, their tracing behavior may be an indication of puzzlement.

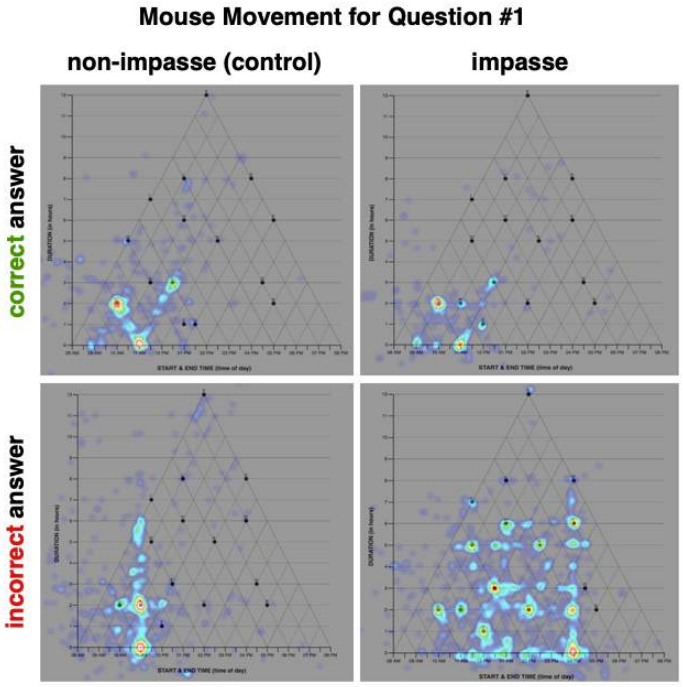

Figure 5. Mouse movement as heatmap for all participants, question #1

Discussion

The essence of functional fixedness, according to Ohlsson (1992), is that the experience of using an object in a particular way lowers the probability of finding a solution in which one uses the object in a different way. The strength of our association of the function to the object sets the strength of fixedness. In this light, we can see how substantial experience with common graphical forms serve to fix our expectations of axes, and coordinate systems in general, toward a Cartesian interpretation. The results of this study support our hypothesis that constructing a problem to present a learner with a mental impasse yields significantly better performance

on the unconventional graph reading task. Of course, not all graph reading tasks need be construed as insight problems. Most often the challenge we face concerns second-order readings—the inferences to be drawn from available information— and there is a close relationship between the nature of a graph-reading task and the suitability of the graph design (Shah & Hoeffner, 2002). However, we argue that these readings of trends and relationships between data points are unlikely to be made if the reader does not understand the nature of the graphical formalism itself, and this is where insight comes into play.

Lockhart, Lamon & Gick (1988) characterize difficulties in problem solving as a failure to *access* available information. This certainly seems applicable to the difficulties we observe with the Triangular Model graph where the reader need only perceive and recognize the importance of the diagonal gridlines to extract information from the graph (first-order readings). Lockhart et. al. propose that learners must often reconceptualize a problem in order to solve it, and simply giving students information may not be enough to achieve this effect. Presenting information in a form that induces puzzlement is significantly more effective in facilitating conceptual transfer and subsequent problem solving. We argue that the puzzlement induced by finding 'no available answer' in our impasse condition worked by leaving learners with no recourse but to reconsider their strategy (or give up). This conclusion is further supported by learners' failure to interpret this graph when provided with explicit information. While the text and image scaffolds in (Fox & Hollan, 2018) did not improve performance with the TM graph, a simple manipulation of the availability of answers to the first problems in a scenario for this study did.

We expect this technique should generalize to other representations with unconventional coordinate systems, though it is unclear whether the same attention-directing mechanisms would be appropriate for forms utilizing alternative markings. This is one of several open questions we are presently pursing. In ongoing analysis of mouse tracing data, we are exploring the strategies employed by learners in the impasse state and how they may reflect learner's graphical intuitions. In particular, we're interested in the strategies employed by learners in the impasse condition that provide non-Cartesian, but nonetheless incorrect responses. How are these learners reasoning about the graph elements, and does their behavior remain consistent after the scaffold phase (first 5 questions) when the remaining 10 questions have possible Cartesian answers? Based on ongoing analysis of the time course of response accuracy, we suspect that for impasse to be effective, the learner must confront the impasse in the initial phase of graph interpretation—when the graph schema is instantiated. In ongoing work, we address this question by varying the timing of impasse vs. non-impasse questions with analysis of the time course of correct and incorrect responses. We are also investigating which components of the design and layout of the graph are most influential in triggering a Cartesian interpretation, by manipulating the layout and saliency of axes, gridlines, and rotation of the figure in graph space.

While we hope this line of research will shed light on the elusive graph schema and how we develop graphical knowledge, the most immediate implications of our findings address the presentation of graphics in publications like this one. As communicators of science, we face an inevitable tension between communicating in what we believe to be the most revealing or expository fashion, and the way a community has come to expect. This makes innovation difficult. Nonetheless, the popularity of information visualization as a research area means that novel graphical forms are ever more present in our discourse. If you choose to utilize an unconventional representation in a traditional publication format, posing a carefully designed question (in perhaps, the figure caption) may aid the motivated reader to persevere in correctly reading the new graphic, and discovering your insights.

Abstract

Recurrent neural network (RNN) models of sentence processing have recently displayed a remarkable ability to learn aspects of structure comprehension, as evidenced by their ability to account for reading times on sentences with local syntactic ambiguities (i.e., garden-path effects). Here, we investigate if these models can also simulate the effect of semantic appropriateness of the ambiguity's readings. RNN-based estimates of surprisal of the disambiguating verb of sentences with an NP/S-coordination ambiguity (as in 'The wizard guards the king and the princess *protects* ...') show identical patters to human reading times on the same sentences: Surprisal is higher on ambiguous structures than on their disambiguated counterparts and this effect is weaker, but not absent, in cases of poor thematic fit between the verb and its potential object ('The teacher baked the cake and the baker *made* ...'). These results show that an RNN is able to simultaneously learn about structural and semantic relations between words and suggest that garden-path phenomena may be more closely related to word predictability than traditionally assumed.

Keywords: garden-path sentences; self-paced reading; reading time; thematic fit; recurrent neural network; LSTM; surprisal

Introduction

Garden-path phenomena, in which a local structural ambiguity results in comprehension difficulty upon disambiguation, have been studied extensively in psycholinguistics. Traditionally, the garden-path effect has been explained in terms of syntactic structure building: When the ambiguity is encountered, the parser chooses the structure that later turns out to be incorrect, triggering a process of syntactic reanalysis (e.g., Frazier & Rayner, 1982). Nowadays, this process is often expressed in probabilistic terms: The syntactic interpretation of the sentence-so-far takes the form of a probability distribution over (all) possible structures, and processing a word comes down to redistributing the probability mass in light of the incoming linguistic information. In case of a garden-path sentence, the incorrect reading of the ambiguity receives a (much) higher probability than the correct one, which means that a lot of probability mass needs to be redistributed upon encountering the disambiguating word (Brouwer, Fitz, & Hoeks, 2010; Hale, 2001; Levy, 2008). This corresponds to high cognitive processing load.

In the probabilistic account of sentence processing sketched above, the amount of update in the probability distribution due to processing a word can be shown to equal the word's *surprisal*, which has therefore been proposed as relevant measure of cognitive processing difficulty during incremental language comprehension (Hale, 2001; Levy, 2008). Indeed, word surprisal correlates with word reading time in general, as long as it is estimated by an accurate-enough probabilistic language model. The model's underlying architecture does not appear to matter much: It can be a probabilistic grammar (Boston, Hale, Patil, Kliegl, & Vasishth, 2008; Demberg & Keller, 2008), a recurrent neural network (Goodkind & Bicknell, 2018; Monsalve, Frank, & Vigliocco, 2012), or even a simple *n*-gram model (Frank, 2017; Smith & Levy, 2013). However, it stands to reason that surprisal must be estimated by a model that builds syntactic structure (like a probabilistic grammar does) if it is to account for the garden-path phenomenon. After all, the garden-path effect is (allegedly) caused by structural reanalysis. Hence, a model that does not engage in structure building should not be able to explain the effect.

Recent results from Long Short-Term Memory models (LSTM; Hochreiter & Schmidhuber, 1997) cast doubt on this assumption. An LSTM is a recurrent neural network in which the flow of activation is controlled by gates with learned weights, making it better at learning long-distance dependencies than Elman's (1990) well-known Simple Recurrent Network. LSTMs have shown remarkable capability to deal with long-term structure (Gulordava, Bojanowski, Grave, Linzen, & Baroni, 2018), including correct predictions of reading-time effects in garden-path sentences. Van Schijndel and Linzen (2018) had an LSTM estimate surprisal on the disambiguating verb phrase in sentences such as 'The employee understood [that] the contract *would be* ...' (NP/S ambiguity; critical word in italics) and 'Even though the girl phoned[,] the instructor *was* ...' (NP/Z ambiguity). They found higher surprisal in the locally ambiguous sentences than in their unambiguous counterparts.[1] Futrell, Wilcox, Morita, and Levy (2018) show that an LSTM model can account for the garden-path effect in sentence pairs such as 'The witness [that was] examined *by the lawyer*' (RR/MV ambiguity). Moreover, the model correctly predicts the absence of a garden-path effect when the subject noun is inanimate, as in 'The evidence [that

[1] Futrell et al. (2019), however, report that LSTMs predict a weaker NP/Z garden-path effect when the ambiguous region is longer, contrary to what has been observed in human readers (Tabor & Hutchins, 2004).

was] examined *by the lawyer*'. This suggests that the LSTM learned not only the relative frequencies of the different structures but also how these frequencies interact with a lexical semantic property.

The current study goes beyond this work by looking at a different local structural ambiguity and, more importantly, its interaction with the thematic fit between an action (i.e., verb) and its potential patient (i.e., syntactic object). That is, we investigate the sensitivity of LSTMs to a semantic *relation* as opposed to a single word's semantic property.

Garden paths and thematic fit

Sentence (1a) is structurally ambiguous when the third noun phrase ('the princess') in encountered: It can be understood as part of the larger NP 'the king and the princess' or as the beginning of a new sentence clause. This is known as the NP/S-coordination ambiguity. The upcoming verb ('protects') disambiguates towards the S-coordination structure, which causes comprehension difficulty compared to the unambiguous variant (1b). In other words, (1a) is a garden-path sentence because readers initially prefer the NP-coordination reading (Frazier, 1987).

(1a) The wizard guards the king and the princess *protects* the prince with her life.

(1b) The wizard guards the king, and the princess *protects* the prince with her life.

Sentence pairs (2a) and (2b) are structurally identical to (1a) and (1b) but differ in an important respect: The NP-coordination reading, in which the teacher bakes both the cake and the baker, is semantically anomalous: Bakers are not usually baked objects. Would such poor thematic fit lead to an immediate S-coordination interpretation and, consequently, remove any comprehension difficulty in (2a) compared to (2b)?

(2a) The teacher baked the cake and the baker *made* twelve breads for the coming holidays.

(2b) The teacher baked the cake, and the baker *made* twelve breads for the coming holidays.

In an eye-tracking experiment, Hoeks, Hendriks, Vonk, Brown, and Hagoort (2006) investigated the processing of sentences with NP/S coordination ambiguities in Dutch, which is structurally identical to English in this respect. They found the expected garden-path effect in the Good Fit condition: Reading times were longer on sentences such as (1a) than on (1b). When thematic fit was poor (sentence pair 2a/b) the picture was less clear, but the authors concluded that there is also a garden-path effect in this condition, albeit weaker than that for the sentences with good thematic fit.

However, the reliability of this result is questionable because the garden-path effect on Poor Fit sentences never reached statistical significance on any of the investigated reading time measures; it was at best marginally significant for total reading time. Hoeks et al.'s conclusion was based on the presence of a main effect of Ambiguity (i.e., whether or not the sentence had a comma) in combination with the *absence* of a significant interaction with Thematic Fit. Hence, the claim that the garden-path effect also occurred in the Poor Fit sentences is in fact based on accepting the null hypothesis that there is no interaction.

The current study

We trained LSTM models on Dutch text corpora after which they estimated surprisal of the critical words in the experimental sentences of the Hoeks et al. (2006) study. In addition, we analysed unpublished self-paced reading data on these same sentences. Bayesian mixed-effects regression analyses revealed similar patterns for the surprisal values and reading times (RTs): They are larger in the locally ambiguous than unambiguous sentences and this difference is smaller (but not zero) in case of poor thematic fit than for sentence with good thematic fit. These findings demonstrate that poor thematic fit indeed reduces, but not completely removes, the garden-path effect caused by the NP/S-coordination ambiguity; and that these effects can be explained by the statistical word-order patterns that recurrent neural networks are able to learn from text corpora.[2]

Method

Self-paced reading experiment

Stimuli The stimulus set was identical to that of Hoeks et al. (2006). It consisted of 120 experimental sentences with a local NP/S coordination ambiguity. In 60 of the 120 sentences, the two nouns of the (potential) NP coordination were animates, making them semantically plausible objects of the verb. These were the Good Thematic Fit sentences (Example 1a, translated from Dutch). In the 60 Poor Fit sentences, in contrast, the verb had a strong selectional preference for an inanimate object and only the first noun of the potential NP coordination was inanimate (see 2a). Items were not matched between the Good Fit and Poor Fit conditions.

The sentence's critical word was the second verb (italicized in Examples 1 and 2), which always disambiguated towards the S-coordination reading. Unambiguous versions of the sentences were constructed by simply introducing a comma after the second noun (Examples 1b and 2b).

In addition to the experimental sentences, there were 200 filler sentences, 80 of which had unambiguous conjoined object NPs. In half of these fillers sentences, both object nouns were animate; in the other half the first object noun was inanimate and the second one animate, mimicking the order of inanimate/animate nouns in the Poor Fit condition. The other 120 fillers contained relative clauses.

Forty items were paired with a simple comprehension question in the form of a statement about the sentence. These were intended to ensure participants would read for comprehension.

[2]The LSTM models, self-paced reading data, and analysis code are available from `https://osf.io/npzc7`.

Participants One hundred and three native Dutch speaking undergraduate students from Radboud University participated in the experiment. The data from seven participants were excluded from analysis because they answered more than 20% of the comprehension questions incorrectly.[3] This left 96 participants with analysed data.

Procedure Each participant read 120 experimental sentences, 30 in each of the 2×2 (Ambiguity × Thematic Fit) conditions. Stimuli were presented using word-by-word, non-cumulative, moving window self-paced reading. The sentence appeared when the participant pressed a button, but only the first word was visible initially. All other characters (including the comma but excluding spaces and the end-of-sentence period) were replaced by hyphens. On each subsequent button press, the next word would be revealed and the previous word changed back to hyphens. If, after completing the sentence, a comprehension question appeared, the participant had to indicate by button press whether or not the statement was correct.

Neural network models

Training corpus Training sentences were selected from the NLCOW2014 corpus (Schäfer, 2015) which contains individual Dutch sentences crawled from the web. It is divided into seven slices with approximately 37 million sentences each. NLCOW14 treats punctuation marks as individual tokens, meaning that they are separated from the preceding and the following word. Because this is incorrect in case of the apostrophe, we preprocessed the corpus, reattaching apostrophes to the word to which they belong.[4]

For each slice, we extracted the 20,000 most frequent words without distinguishing between upper- and lower-case and ignoring any string containing a non-letter other than the hyphen or apostrophe. Next, this frequent-word list was joined with the set of word types in the Hoeks et al. (2006) stimuli. We then selected only and all corpus sentences that contain only words from the combined word list.[5] These sentences form the training data from that slice. The seven training sets comprised between 8.57 and 9.00 million sentences (108 to 115 million tokens) each.

Model architecture We trained one LSTM network on each of the seven training data sets for two epochs. All networks had a 300-dimensional input embedding layer, a 600-unit recurrent layer, a 300-unit non-recurrent layer between the recurrent and output layers, and softmax output layer with one unit for each word type in the training set. No attempt was made to optimize this architecture. The seven networks differed only in their output layer sizes and random initial connection weights.

After processing the first $t-1$ words of a sentence, the network's output activation for word unit w is its estimate of $P(w_t|w_{1\ldots t-1})$: the probability that word w will occur at position t given the word sequence (sentence context) w_1 to w_{t-1}. The surprisal of the actually occurring next word is defined as the negative logarithm of its occurrence probability: $\text{surprisal}(w_t) = -\log P(w_t|w_{1\ldots t-1})$.

Test sentences All seven networks estimated surprisal on all experimental sentences in both the Ambiguous (comma absent) and Unambiguous (comma present) condition. However, in spite of the training sentence selection method described above, 22 of the 120 experimental stimuli sentences contained one or more words not present in all seven training data sets. We replaced these words by semantically congruent words from the same syntactic category that did occur in all training sets. For example, in *De politie traceerde de dief* ('The police traced the thief') the verb *traceerde* was changed to *achtervolgde* ('chased').

Data analysis

We analysed the effect of Ambiguity on surprisal and RT by fitting Bayesian mixed-effects regression models using the R package `brms` (Bürkner, 2018). A positive regression coefficient for Ambiguity (i.e., $\beta_{\text{ambiguity}} > 0$) indicates higher surprisal or RT on Ambiguous than Unambiguous sentences, that is, a (predicted) garden-path effect.

The prior for $\beta_{\text{ambiguity}}$ was an improper flat distribution over the real numbers, as is the default in `brms`. For the RT analysis, it would have been justified to have the prior be informed by the Hoeks et al. (2006) results. However, we opted for a flat prior so that exactly the same analysis could be run for surprisal as for RT. The dependent variable was normalized so the intercept of the regression line is guaranteed to be 0. Hence, we set the strong prior of $\mathcal{N}(0, 0.1)$ over the intercept. We chose the Exponentially modified Gaussian family because of the positive skew in the dependent variables' distributions. The regression model included as random effects by-network and by-item random intercepts and random slopes of Ambiguity. Random-effect priors were the `brms` defaults.

Separate analyses were run for the Good and Poor Fit conditions, in addition to analyses including the factors Ambiguity, Fit, and their interaction. Both the Ambiguity and Fit factors were effect coded (± 0.5) with positive values for the Ambiguous and Good Fit conditions. Priors on the Fit and interaction coefficients were the default improper flat distribution.

Because self-paced reading often leads to so-called spillover effects, where comprehension difficulty on a word results in reading slowdown at a later word, we analysed RT on both the critical word and the immediately following word.

[3] There were in fact two versions of the experiment, which differed only in whether or not the comprehension questions were presented. Fifty-five of the the 103 participants took part in the version that included the questions. The data from the two experiment versions are combined in our analysis.

[4] In Dutch orthography, apostrophes can occur in the plural suffix *-'s* and in unstressed forms of pronouns (e.g., *m'n*, 'my') and determiners (e.g., *'n*, 'a').

[5] Single-word sentences and sentences containing over 50 words were excluded, as were sentences containing a punctuation token other than the period, comma, exclamation point, and question mark.

For completeness, we did the same for the surprisal analysis even though there is no reason why surprisal effects would spill over to the next word.

RTs below 50ms or over 4000ms were considered outliers and removed from analysis, but there were only four such data points (three on the critical word, one on the post-critical word).

Results

Effects of ambiguity and thematic fit

The two upper panels of Figure 1 show the posterior probability densities for the effect of Ambiguity on RT, in the Good and Poor Fit conditions. The reading time pattern is consistent with the conclusions Hoeks et al. (2006) draw from eye-tracking data on the same items: The ambiguity leads to a garden-path effect that is stronger in the Good than Poor Fit condition. The latter is apparent from the fact that, in Poor Fit sentences, the effect of Ambiguity occurs only on the critical word whereas it spills over to (and is even stronger on) the following word of Good Fit sentences. Table 1 presents the probability that there is indeed a garden-path effect in each of the Thematic Fit conditions, as well as the probability of an interaction such that the Ambiguity effect is larger in the Good Fit than Poor Fit condition.

This RT pattern is correctly predicted by the LSTM, as can be seen in the lower panels of Figure 1 as well as in Table 1. There is a clear effect of Ambiguity on surprisal in both the Good and Poor Fit conditions, and the evidence for an interaction between Ambiguity and Fit is very strong. Surprisal effects appear on the critical word rather than the post-critical word, which supports the claim that the post-critical RT effects are due to spillover of comprehension difficulty that arises at the critical word.

Effect of network training

As shown in Figure 2, it takes about 1 to 3 million training sentences for the garden-path effect and its interaction with thematic fit to appear. These effects continue to grow in size with additional training.

Table 1: Posterior probabilities of positive coefficients (i.e., $P(\beta > 0)$) of Ambiguity and its interaction with Thematic Fit.

			Word position	
Coefficient	Fit	Dep. Var.	Critical	Post-crit.
$\beta_{\text{ambiguity}}$	Good	RT	.98	$> .99$
		surprisal	$> .99$	.18
	Poor	RT	.93	.69
		surprisal	$> .99$	.32
$\beta_{\text{ambiguity}\times\text{fit}}$		RT	.78	$> .99$
		surprisal	$> .99$	.36

Item-level analysis

To investigate whether LSTM surprisal accounts for garden-path effects at the item level, surprisal was averaged per sentence over the seven fully trained networks, and log-transformed RTs were averaged per sentence over participants as well as over the critical and post-critical words. Figure 3 shows a scatter plot of average surprisal against average log-RT, excluding the 22 sentences that were adapted for LSTM processing. Clearly, the surprisal estimates are unable to explain garden-path effects at the level of individual sentences.

Discussion

Surprisal and reading time

Patterns of surprisal on the critical word matched the self-paced-reading results (as well as Hoeks et al.'s, 2006, eye-tracking data) albeit not at the individual item level. When comparing between experimental conditions, surprisal was higher when the sentence contained a local ambiguity (e.g., the LSTMs predict a garden-path effect) and this effect of Ambiguity was reduced (but not absent) when poor thematic fit between the verb and a following noun made the correct S-coordination reading more semantically appropriate before the disambiguating word. These results again demonstrate the power of RNNs to learn fairly subtle structural and semantic aspects of language, and thereby account for human processing behaviour.

The absence of effects on surprisal at the post-critical word supports the interpretation that the effect on RT here is caused by spillover from the critical word, as Hoeks et al. (2006) also conclude on the basis of their eye-tracking data. In that study, the authors found the garden-path effect to be more short-lived on Poor compared to Good Thematic Fit sentences. Our analysis of self-paced RTs shows the same pattern, in that the effect has disappeared on the post-critical word in the Poor Fit but not in the Good Fit condition. This suggests there may be a qualitative difference in the garden-path effects between the Thematic Fit conditions, that is not captured by the unidimensional surprisal measure.

Structural processing in RNNs

As explained in the Introduction, garden-path effects have been explained in terms of syntactic reanalysis, or probabilistically in terms of the redistribution of probability mass over syntactic structures. However, RNNs do not encode syntactic structure, at least not explicitly, so why did our networks correctly predict the garden-path effect?

One possibility is that the correspondence between surprisal and reading time is just an artefact of the experimental items. Possibly, the mere presence of a comma speeds up reading at the critical word, but less so in the Poor Fit Sentences, without any relation to the garden-path phenomenon. However, even if this is the case, it leaves unexplained why at least three other garden-path effects have been explained by

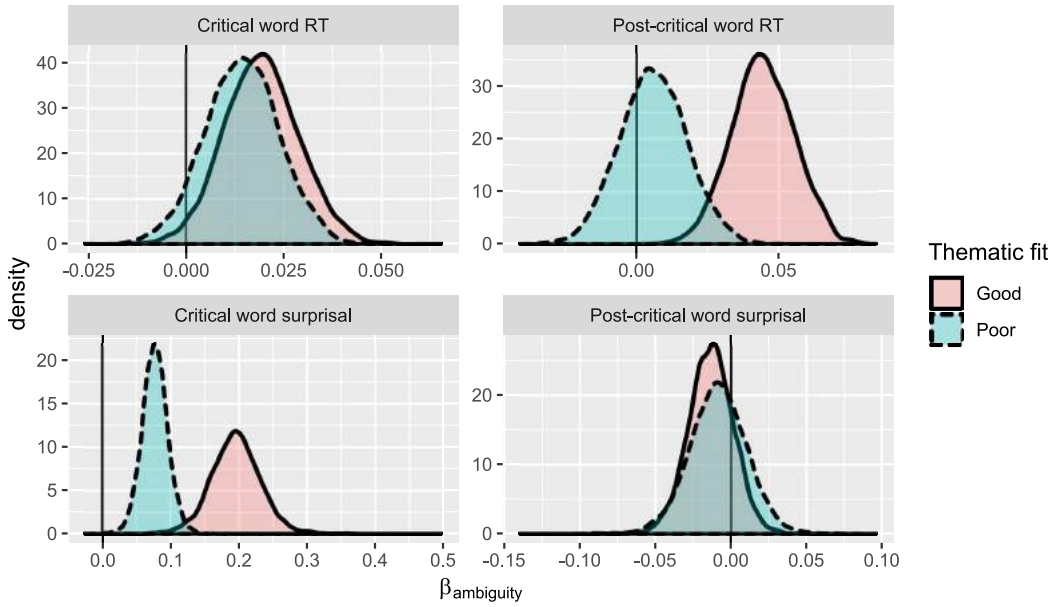

Figure 1: Posterior probability densities of the Ambiguity coefficient. Top: effect on RT; bottom: effect on word surprisal. Left: effect at critical word; right: effect at post-critical word.

Figure 2: Estimated coefficient of Ambiguity at the critical verb in the surprisal analysis, as a function of number of training sentences and thematic fit. Shaded areas represent 95% Credible Intervals.

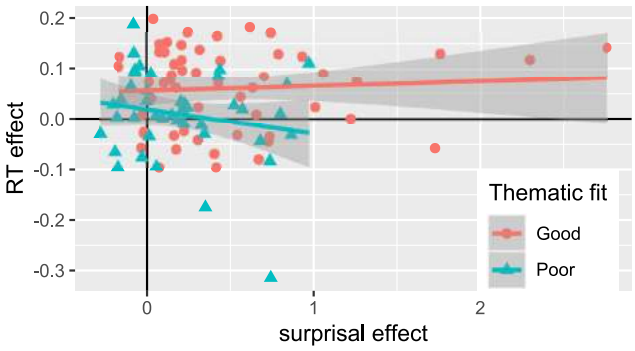

Figure 3: Garden-path effects in surprisal estimates and log-transformed RT, with regression line per Thematic Fit condition.

LSTM surprisal (Futrell et al., 2018; Van Schijndel & Linzen, 2018).

Alternatively, garden-path effects could be merely due to incorrect next-word prediction, as reflected in high surprisal on the disambiguating word. This would imply that there is no qualitative difference between comprehension difficulty due to a garden-path and due to an unlikely word co-occurrence. However, this seems implausible considering that ERP studies have shown that garden-pathing leads to a P600 effect (Osterhout & Holcomb, 1992; Osterhout, Holcomb, & Swinney, 1994) while higher surprisal in non-garden-path sentences corresponds to a stronger N400 component (Delaney-Busch, Morgan, Lau, & Kuperberg, 2019; Frank, Otten, Galli, & Vigliocco, 2015). Moreover, the initially preferred, but incorrect, reading of the ambiguity in a garden-path sentence can 'linger' (Christianson, Hollingworth, Halliwell, & Ferreira, 2001; Patson, Darowski, Moon, & Ferreira, 2009) which shows that such an interpretation was indeed entertained.

Possibly, being led up the garden path *also* results in incorrect next-word prediction and the *reading time effect* that comes with garden pathing actually reflects the resulting surprisal increase rather than the update of a structure or interpretation. However, this is not a particularly satisfying explanation as it would mean that the cognitive work of reanalysis

is itself not reflected in longer reading time.

Hence, we tentatively conclude that the LSTMs learn representations that capture relevant aspects of sentence structures/interpretations. As words come in, the network performs probabilistic, incremental reinterpretation, and generates word surprisal values that reflect the amount of representation update required to incorporate the word into the sentence representation under construction.

Conclusion

Word surprisal values estimated by LSTM models mirrored human reading times on garden-path sentences, predicting both the garden-path effect itself and its interaction with the manipulation of thematic fit between a verb and its potential object noun. This finding yet again demonstrates LSTMs' ability to extract structural aspects of language by learning to do next-word prediction in flat, unannotated text. Investigations of the neural networks' internal state are needed to substantiate this claim. If such an investigation fails to reveal evidence of structure representations in the networks, this would raise doubt about the necessity for structure building and revision in an explanation of garden-path phenomena.

Subjectivity-based adjective ordering maximizes communicative success

Abstract

Adjective ordering preferences (e.g., *big brown bag* vs. *brown big bag*) are robustly attested in English and many unrelated languages (Dixon, 1982). Scontras, Degen, and Goodman (2017) showed that adjective subjectivity is a robust predictor of ordering preferences in English: less subjective adjectives are preferred closer to the modified noun. In a follow-up to this empirical finding, Simonič (2018) and Scontras, Degen, and Goodman (to appear) claim that pressures from successful reference resolution and the hierarchical structure of modification explain subjectivity-based ordering preferences. We provide further support for this claim using large-scale simulations of reference scenarios, together with an empirically-motivated adjective semantics. In the vast majority of cases, subjectivity-based adjective orderings yield a higher probability of successful reference resolution.

Keywords: adjective ordering, subjectivity, reference resolution, hierarchical modification

Introduction

When speakers use two or more adjectives to modify a noun, they exhibit robust preferences in the relative order of the adjectives (e.g., *big brown bag* vs. *brown big bag*). Using a series of behavioral and corpus experiments, Scontras et al. (2017) demonstrated that adjective order in multi-adjective strings is reliably predicted by the subjectivity of the adjectives involved: less subjective adjectives are preferred closer to the modified noun, and the strength of the preference is modulated by the subjectivity differential between the adjectives. Thus, speakers strongly prefer *big brown bag* over *brown big bag*, as *brown* is much less subjective than *big*.

The question that immediately arises is why subjectivity should play the role it does in adjective ordering preferences. The current work follows Simonič (2018) and Scontras et al. (to appear) in advancing the claim that pressures from successful reference resolution deliver subjectivity-based ordering preferences. In certain cases of restrictive modification which proceed incrementally based on syntax-driven meaning composition, adjectives that compose with the nominal later will classify a smaller set of potential referents (e.g., the set of bags vs. the set of brown boxs). We demonstrate that, in order to avoid alignment errors where a listener might mischaracterize the intended referent, it is, when averaging over many contexts of use, a better strategy to introduce the more error-prone (i.e., more subjective) adjectives later in the hierarchical meaning composition; the structure linearizes such that subjectivity decreases the closer you get to the modified noun. We build on the work that precedes ours by making minimal assumptions about online processing (cf. Scontras et al., to appear) and by assuming a more principled implementation of adjective subjectivity within an empirically-motivated semantics (cf. Simonič, 2018).

The paper is structured as follows. First, we review the empirical generalization concerning subjectivity-based preferences, together with the proposals offered to account for this generalization. Then, we consider empirical work on adjective semantics, which serves as inspiration for our own proposal. We demonstrate, using Monte Carlo simulation, how a minimal set of independently-motivated assumptions leads to a ready explanation for subjectivity-based ordering preferences: ordering adjectives with respect to decreasing subjectivity has a higher probability of successful reference resolution, when averaging across many contexts of use.

Background

Given the robustness of adjective ordering preferences within and across languages, there has been no shortage of proposals meant to account for the regularities in adjective ordering. Some have offered grammatical proposals that attend to semantic composition or articulated syntactic hierarchies (e.g., Cinque, 1994; Scott, 2002; McNally & Boleda, 2004; Truswell, 2009). Others have advanced more psychological proposals built around notions like inherentness or accessibility (e.g, Whorf, 1945; Ziff, 1960; Martin, 1969). Recently, Scontras et al. (2017) synthesized several proposals that preceded them and advanced the hypothesis that adjective subjectivity predicts ordering preferences (see also Quirk, Greenbaum, Leech, & Svartvik, 1985; Hetzron, 1978; Dixon, 1982; Tucker, 1998; Hill, 2012).

In order to test the subjectivity hypothesis, Scontras et al. (2017) first had to determine what the ordering preferences were. They established a behavioral measure of the preferences whereby experimental participants indicated the preferred ordering of multi-adjective strings that differed only in the relative order of the adjectives involved (e.g., *the big brown bag* vs. *the brown big bag*). Scontras et al. (2017) then validated their behavioral measure by comparing it with naturalistic productions from corpora. They found a high correlation between the behavioral and corpus measures ($r^2 = .83, 95\%$ CI $[.63, .90]$), suggesting that the behavioral measure was successful in capturing the preferences speakers use

when forming multi-adjective strings.

Next, Scontras et al. (2017) measured adjective subjectivity. They started by simply asking participants how "subjective" a given adjective was (e.g., "How subjective is *brown*?"). Wary of how naive participants might interpret the word "subjective," the authors validated their subjectivity measure by comparing it with faultless disagreement scores (Kölbel, 2004; Barker, 2013; Kennedy, 2013; MacFarlane, 2014). In a faultless disagreement task, participants observe a disagreement between two speakers about whether an adjective applies to some object (e.g., whether or not a table is brown). The task is to decide whether the two speakers can both be right while disagreeing, or whether one of them must be wrong; to the extent that both speakers can be right, the adjective admits that degree of faultless disagreement. Scontras et al. (2017) found an extremely high correlation between the raw "subjectivity" scores and the faultless disagreement measure ($r^2 = .91, 95\%$ CI $[.86, .94]$), suggesting that they had a reliable measure of adjective subjectivity.

Comparing the ordering preferences with adjective subjectivity, Scontras et al. (2017) found that subjectivity accounts for 85% of the variance in the ordering preferences ($r^2 = .85, 95\%$ CI $[.75, .90]$) for 26 different adjectives from seven semantic classes. The authors then looked at every multi-adjective string in the Switchboard corpus of English, finding that subjectivity accounts for 61% of the variance in ordering preferences ($r^2 = .61, 95\%$ CI $[.47, .71]$) for 74 unique adjectives from 13 semantic classes. In other words, the authors found strong support for their hypothesis that subjectivity predicts adjective ordering preferences. The question that immediately presents itself, however, is why subjectivity should matter in adjective ordering. Scontras et al. (2017) gesture toward an answer to this question—less subjective adjectives are more useful for establishing reference—but their suggestion is purely speculative.

Using a model of probabilistic utterance choice (e.g., *big brown bag* vs. *brown big bag*), Simonič (2018) systematically explored the idea that subjectivity-based ordering preferences arise under pressure from successful reference resolution. The utterance choice model was formulated within the Rational Speech Act modeling framework (e.g., Franke & Jäger, 2016; Goodman & Frank, 2016; Scontras, Tessler, & Franke, n.d.).[1] To model adjective subjectivity, the speaker is taken to assumes that the listener might have a different lexical meaning for each adjective. If $L^{S,C}_{adj}$ is the speaker's lexical entry for adjective adj in context C, the speaker believes that the listener has lexical entry $L^{L,C}_{adj}$ with probability:

$$P(L^{L,C}_{adj} \mid L^{S,C}_{adj}) \propto \begin{cases} 1 & if L^{S,C}_{adj} = L^{L,C}_{adj} \\ \varepsilon_{adj} & \text{otherwise} \end{cases} \quad (1)$$

[1] See Hahn, Degen, Goodman, Jurafsky, and Futrell (2018) for a different approach to modeling adjective ordering within the Rational Speech Act framework. Their model defines speaker utility not in terms of referential success, but rather in terms of communicating subjective opinions about objects.

The more subjective the adjective, the higher the error probability ε_{adj}. With these beliefs about lexical divergence, Simonič shows that the subjectivity-based ordering *big brown bag* is a more rational choice for the speaker than *brown big bag* in a wide range of randomly-generated contexts. However, Simonič did not explicitly quantify the extent to which one ordering of adjectives is better than another, when averaging over many contexts.

Scontras et al. (to appear) pursue a similar explanation. They treat adjective subjectivity as potential noise in the semantics of an adjective, similar to Simonič, but they assume that, based on a ground-truth of objective adjective meaning, each agent (speaker or hearer) will incorrectly classify each potential referent in the current context C with an error rate ε_{adj}, which, again, indexes adjective subjectivity:

$$[\![\text{ADJ}]\!]^C = \lambda x \in C.\ \text{if } \texttt{ADJ}(x) \text{ then } \texttt{flip}(1-\varepsilon_{adj}), \quad (2)$$
$$\text{else } \texttt{flip}(\varepsilon_{adj})$$

This move allows Scontras et al. to treat deviations from the ground truth as gradient: greater deviation is increasingly less likely. Scontras et al. further assume that each object classification requires some processing cost. As a result, the error probability ε_{adj} is assumed to increase with the size of context C. Based on these assumptions, Scontras et al. demonstrate how subjectivity-based ordering preferences can maximize the probability of correctly classifying the intended referent. The authors explored 103,740 cases of multi-adjective modification and found that subjectivity-based ordering behaved as expected in 93% of those cases.

In sum, both Simonič (2018) and Scontras et al. (to appear) demonstrate how subjectivity-based adjective ordering serves successful referential communication. However, both accounts involve non-trivial and potentially controversial assumptions. Simonič's definition in (1) of the speaker's beliefs about the listener's lexicon are not very intuitive: why would the speaker believe that a small deviation from his own lexicon is equally likely as a massive deviation? Scontras et al. (to appear) likewise merely stipulate that error of classification ε_{adj} in (2) is a function of context size C. It would be much more desirable to derive divergences between the speaker's and listener's semantic classifications from more fundamental assumptions, first and foremost by a more explicit view of what the underlying semantics of adjectives is. Consequently, our aim here is to build on these previous accounts by showing how subjectivity-based ordering serves successful referential communication. However, rather than making what are now rather stipulative assumptions about the misalignment of semantic representations, we will show how these misalignments can arise from a generally plausible context-dependent semantics. It is to one such semantics that we turn next.

Semantic assumptions

Schmidt, Goodman, Barner, and Tenenbaum (2009) built their study of adjective meaning on the observation that gradable adjectives mean different things depending on the nouns

they modify: what counts as big for a mouse diverges drastically from what counts as big for an elephant. The question is what serves as the core meaning of a gradable adjective, such that speakers can determine its contextual extension?

To answer this question, Schmidt et al. collected human judgments about what counts as "tall" for different sets of objects. They then compared these judgments with the predictions from a number of semantic models that use various strategies to determine tallness in context. The strategies considered fell into one of two classes. The first class computed the tallness threshold directly, using various parametric and non-parametric procedures to compute a height cutoff above which objects count as tall. The second class inferred the tallness threshold on the basis of category membership, first performing a clustering analysis on the set of objects and then identifying as tall those objects that belonged to the cluster with the tallest object.

Two models outperformed the rest. The simplest was a threshold-computing model that sets the threshold on the basis of relative height by range: any object that fell within the top $k\%$ of the range of heights in context C counts as tall in C. Formally, the set $[\![\text{tall}]\!]^C$ of objects in C that count as tall in C is (where $\texttt{tall}(o)$ is the tallness of object o, $\texttt{max}$ is the tallness of the tallest object in C, and $\texttt{min}$ that of the smallest):

$$[\![\text{tall}]\!]^C = \{o \in C \mid \texttt{tall}(o) \geq \texttt{max} - \theta \cdot (\texttt{max} - \texttt{min})\}, \quad (3)$$
$$\text{where } \theta = k/100.$$

So, if the maximum object height is 10 on the relevant scale and the minimum height is 2, a k of 50% would set the tallness threshold at 6; that is, an object with a height of at least 6 would count as tall in that context. Notably, the more complex clustering model performed no better than this threshold model when it came to predicting human judgments. We will therefore use this simple but empirically-motivated threshold semantics in the reasoning that follows, treating the threshold θ as a free model variable.

Following Simonič (2018) and Scontras et al. (to appear), we assume that iterated adjectival modification triggers *sequentially intersective context updates*. Later adjectives (syntactically farther from the modified noun) are interpreted relative to contexts that are already restricted by previous adjectives. For example, the denotation of the phrase "$[\text{adj}_\text{i}\ [\text{adj}_\text{j}\ N]]$" given a shared context C of potential referents is:

$$[\![[\text{adj}_\text{i}\ [\text{adj}_\text{j}\ N]]]\!]^C = [\![\text{adj}_i]\!]^{[\![\text{adj}_j]\!]^{C \cap [\![N]\!]}} \quad (4)$$

In words, a string like "big brown bag" characterizes the set of all bags in context C that count as brown (in the set of bags in C) and that count as big (in the set of bags that count as brown in the set of bags in C). Each adjective is therefore interpreted relative to its local context of incremental compositional semantic interpretation, so to speak. The effect is that adjectives closer to the noun will operate over a larger context (i.e., one that is less restricted); paired with a context-dependent semantics as in (3), it is conceivable that the ordering of adjectives matters for referential success.

Figure 1: Illustration of subjective agent representations.

Motivating example

For the discussion that follows, we use "brown" and "big" as mnemonic labels for any two adjectives that are, respectively, less and more subjective. Our goal is to demonstrate why an utterance of "big brown X"—that is, a multi-adjective string ordered with respect to decreasing subjectivity—is communicatively more efficient on average than an utterance of "brown big X"—an utterance not ordered with respect to decreasing subjectivity. An utterance's average communicative success is spelled out here as the *expected utility* in a situation where the speaker wants to refer to an object; this value is specified as the average probability of the listener choosing the intended referent on the basis of that utterance.

We first need to make some assumptions about the effects of adjective subjectivity on our mental representations—representations that will be relevant to referential communication. Figure 1 gives a concrete example to illustrate the main idea. Suppose that the speaker and listener share access to a context of four bags that differ only with respect to color and size. Depending on their different perceptual angles, different background knowledge, or differences in previous experiences, the speaker and listener might represent the context differently: their impressions of object size and object color could deviate from the ground truth.

Here is where subjectivity comes in: we assume that more subjective properties are more likely to lead to deviation between the ground truth (i.e., the true context) and an agent's representation of the property. Crucially, by deviating from the ground truth, these more subjective properties are also more likely to lead to deviations between two agent representations (e.g., between the speaker's and listener's representations in Figure 1); these deviations *and our awareness of their potential* are what lead to perceived subjectivity as measured by a faultless disagreement task. Language users are aware that their representations might deviate from each other's, and the potential for deviation is different for different properties. We illustrate this tendency in Figure 1, where the agent representations of size deviate more from the ground truth than their representations of color.

We now ask: if the speaker wants to describe a bag that is both big and brown according to her subjective representation

of the context, would it be better, on average, to describe it as "big brown bag" or "brown big bag", if the listener would interpret either phrase from his own subjective perspective? Concretely, suppose the speaker wants to refer to bag 4 in Figure 1, which is both brown and big from her subjective point of view. If the listener hears "big brown bag", he tries to find the speaker-intended referent by incrementally restricting the set of possible referents according to the interpretation rule in (4), applying the context-dependent semantics in (3) to his own subjective representation of the objects in question. For the example from Figure 1 and assuming that $\theta = 0.5$ in (3), the phrase "brown bag" would make the listener consider only bags 2 and 4. Of these, only bag 4 is in the top 50% along the range of size in this context set. So, the interpretation of "big brown bag" is successful; the listener recovers the speaker-intended referent uniquely. In contrast, for the expression "brown big bag", the listener first looks at the bags that count as big, which rules out only bag 2, since it is the only bag whose size is in the lower 50% of the range of sizes. Among the remaining bags (1, 3 and 4), bag 3 is clearly not brown. For the sake of this informal example, assume that the listener therefore considers both bags 1 and 4 as possible referents when hearing "brown big bag". The chance of referential success (i.e., choosing bag 4)—neglecting salience or other factors—would be $1/2$, which is lower than the certain communicative success when interpreting "big brown bag".

Computing average communicative success

We use a Monte Carlo simulation to estimate the difference in expected referential success between phrases "big brown bag" and "brown big bag"; we calculate this value by averaging over many different contexts with different numbers of objects and varying degrees of subjectivity for the properties involved. In this way, we are not assuming that agents themselves necessarily reason actively about the stochastic misalignment of semantic judgements, or that they always choose expressions that are optimal with respect to these calculations in each context. (We will come back to this issue in the final discussion.) We merely compute the average communicative success of, say, a fictitious community of agents who would use "big brown bag" (i.e., subjectivity-based ordering) and compare their average communicative success to that of a different community that uses "brown big bag" instead.

A single run of the Monte Carlo simulation proceeds as follows:[2]

1. We first sample a number n of bags in the current context uniformly at random from 4 to 20.
2. We then sample the degree to which each object is brown and the degree to which it is big. Samples are independent draws from a standard normal distribution. This yields a representation of the *actual context* C as an $n \times 2$ matrix of feature values for the n objects. The probability of sampling context C for fixed n is
$$P(C \mid n) = \prod_{i=1}^{n} \prod_{j=1}^{2} \mathcal{N}(C_{ij} \mid \mu = 0, \sigma = 1)\,.$$
3. Agent X's (speaker's or listener's) subjective representation C^X of C is derived from C by assuming normally distributed noise around the property degrees in C, with a fixed standard deviation for each adjective. The probability of obtaining a subjective representation C^X from true C is
$$P(C^X \mid C) = \prod_{i=1}^{n} \prod_{j=1}^{2} \mathcal{N}(C^X_{ij} \mid \mu = C_{ij}, \sigma = \sigma_j)\,.$$
The standard deviations $\sigma_{1,2}$ are obtained by sampling two numbers uniformly from the interval $[0; 0.5]$ and assigning the higher number to the more subjective ("tall") and the lower to the less subjective adjective ("brown").
4. A *semantic threshold* θ is sampled uniformly at random from the unit interval. We apply the context-dependent threshold semantics in (3) from Schmidt et al. (2009) with the incrementally intersective context update in (4), using each agent's context representation, to yield each agent's subjective interpretation of each referential phrase.
5. We then sample the *speaker-intended referent object* i^* randomly from the set $[\![\text{adj}_1]\!]^{C^S} \cap [\![\text{adj}_2]\!]^{C^S}$ (i.e., an object that is both brown and big from the point of view of the speaker). If there is no such object, the run is discarded.
6. If the listener's interpretation of the phrase "[adj_i [adj_j]]" from his subjective point of view is $I = [\![[\text{adj}_\text{i}\ [\text{adj}_\text{j}]]]\!]^{C^L}$, the probability of recovering the intended referent is $|I|^{-1}$ if $i^* \in I$ and 0 otherwise. We record the probability of recovery for both adjective orders and evaluate their distribution over all samples obtained in this way.

Results

Based on 10^6 Monte Carlo samples from the process outlined above, we estimate the expected probability of recovering the speaker's intended referent with the subjectivity-based ordering "big brown bag" as 0.54, compared to 0.49 for the reverse ordering "brown big bag". The obtained samples of expected utilities for each ordering appear to indeed be different (paired t-test, $t \approx 19.261$, $p < 10e^{80}$). The direction of this difference lends credence to the general idea that, on average, ordering adjectives by subjectivity does affect average referential success, and that using the less subjective adjective early in sequential interpretation is communicatively beneficial. In other words, ordering adjectives with respect to decreasing subjectivity increases the probability of communicative success.

To understand these results better, Figure 2 shows results from Monte Carlo simulations for a small selection of the parameter values we investigated. We limit our focus to values for standard deviations $\sigma_{\text{brown}} \in \{0.1, 0.2\}$ and $\sigma_{\text{big}} \in$

[2] Code to reproduce this simulation can be found at `https://github.com/michael-franke/adjective_order`.

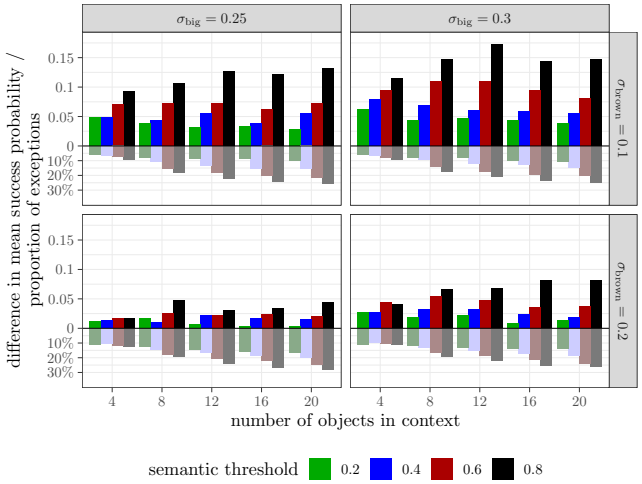

Figure 2: Results from Monte Carlo simulation with fixed values of σ_{brown}, σ_{tall} and θ. Above the 0-mark, the vertical axis shows the mean expected success of "big brown bag" minus that of "brown big bag". Below the 0-mark it shows the percentage of simulation runs where the latter ordering had a higher (however small) expected success.

$\{0.25, 0.3\}$ for the subjective agent representations; we consider semantic threshold values $\theta \in \{0.2, 0.4, 0.6, 0.8\}$. For each combination of these values, we ran 10,000 simulations following the procedure outlined above. The vertical axis in Figure 2 plots two measures. Upward from the 0-mark is the difference in mean communicative success between "big brown bag" and "brown big bag". We see that all mean values are positive, which signals that for all parameter constellations picked out here, the phrase "big brown bag" was indeed estimated to be communicatively more successful in each case. Below the 0-mark in Figure 2, we see the percentage of simulation runs in which the reverse ordering "brown big bag" had a higher expected utility. This shows that the communicative advantage of one adjective ordering over another is not absolute: there are exceptions. However, when averaging over all cases, there is nonetheless a clear communicative benefit of "big brown bag" over "brown big bag".

Discussion

The results of our simulation suggest that a simple, empirically-motivated adjective semantics can lead to increased communicative success when multi-adjective strings are ordered with respect to decreasing subjectivity. We thus have an answer for the question of why subjectivity should matter in adjective ordering: subjectivity matters because ordering adjectives by decreasing subjectivity increases communicative success. Importantly, we arrive at this conclusion without the potentially controversial assumptions from previous work (cf. Simonič, 2018; Scontras et al., to appear). However, our model is not without its own assumptions. In what follows, we revisit the critical assumptions that led to our findings.

From a theoretical standpoint, there are three important assumptions implemented by our model. While each of these assumptions may be challenged, they serve to deliver an articulated hypothesis concerning the interpretation of multi-adjective strings—a hypothesis that offers a plausible explanation for the role of subjectivity.

First, we here operationalize the subjectivity of property *A* as the degree to which, on average, listeners and speakers will have diverging (meaning-relevant) representations of the same object's property *A*. It bears noting that the subjective property representations we assume are not (necessarily) the same as the formal linguist's notion of degree. For us, these representations serve as an abstract way of implementing divergences in truth-value assignments. As modeled here, stochastic misalignments can arise from the particulars of perception in context, but these misalignments could also arise from differing general dispositions toward classifying an object as having the property *A* when paired with random other objects.

Second, we assume that adjectival modification is, at least sometimes (see below), incrementally intersective. Moreover, we assume that meaning composition follows the hierarchical syntactic structure, rather than the linear order of the relevant string. We share this assumption with both Simonič (2018) and Scontras et al. (to appear). This assumption—that the construction of a multi-adjective nominal proceeds outward from the modified noun—ostensibly stands at odds with findings concerning the linear uptake of information in adjectival modification (e.g., Eberhard, Spivey-Knowlton, Sedivy, & Tanenhaus, 1995; Sedivy, Tanenhaus, Chambers, & Carlson, 1999). However, this assumption is common to semantic analyses of modification and necessary in many cases of multi-adjective modification (e.g., "Minnesotan wild rice" or "angry bad apple"; McNally & Boleda, 2004).

The final critical assumption we make is that adjectives have, at least sometimes (see below), a meaning that is determined at least in part by the local context that they modify. In other words, we assume that it is possible to interpret the meaning of "big" in the phrase "big brown bag" as "big for the brown bags". This assumption is the primary driver of the increased communicative success for subjectivity-based orderings: placing more subjective adjectives farther from the modified noun means that they modify a smaller context, which means that there are fewer opportunities for the listener's subjective representation to deviate from the speaker's. While some adjectives are surely less likely to have variable meanings of this sort (e.g., "cardboard", "four-legged"), the presence of any such adjectives in a multi-adjective string will lead to the pressures summarized above, which means that they will lead to pressure toward subjectivity-based orderings.

When we combine these three assumptions, which appear necessary for the obtained results, we can see more clearly what the sources of assumed inter-subjectively divergent representations of objects might (not) be. For example, it is a nat-

ural idea to conceive of inter-subjective differences in judgements of whether a given object has property *A* as the result of inter-subjectively different beliefs about the comparison class against which *A*-hood of the object is evaluated. Concretely, agents might interpret "big" as "big for boxes from country *X*" where *X* is their, say, home country. Differences in the statistical distribution of sizes of boxes in different countries would then lead to inter-subjective disagreement about whether a given box might be "big" or not (Qing & Franke, 2014; Lassiter & Goodman, 2015). While we do not deny that this kind of inter-subjective divergences in comparison-class relative evaluations may exist, they are not, at least not straightforwardly, the kind of inter-subjective difference that drives the results of the present simulation study. This is because, as stressed above in connection with the third and final assumption, the presented setup requires inter-subjective differences that are affected by the current local context. This is compatible with the idea of differential beliefs about the comparison class. But if we wanted to say that diverging beliefs about the relevant comparison class are the main or sole factor that explains adjective ordering preferences based on the mechanism proposed here, we would have to spell out precisely how local contexts affect truth-value judgements in interaction with beliefs about the comparison class. — An interesting challenge for future work.

We conclude by considering the implications of our findings for our understanding of how adjective ordering preferences might develop over time. First, a note on the limitations of our findings. Our simulations, while extensive and systematic, have looked at a narrow sample of properties and scale types. We have begun to explore the predictions for other scale types (i.e., closed scales for adjectives like "full" or "safe"); however, a systematic investigation awaits future research. Still, we have demonstrated a clear communicative benefit of subjectivity-based orderings. Perhaps more importantly, we have demonstrated that this benefit does not apply universally to every possible multi-adjective string. Some parameter settings lead to exceptions where the reverse of subjectivity-based ordering yields a higher probability of communicative success.

The presence of exceptions suggests that speakers' robust, subjectivity-based adjective ordering preferences arise not out of active rational deliberation about the optimal ordering in context, but rather evolved gradually as speakers increasingly took notice of the communicative successes and failures associated with their utterances. In this way, the communicative pressures that favor subjectivity-based orderings in the majority of cases could have strengthened into the robust preferences we observe today. This sort of reasoning calls into question the nature of our knowledge of these preferences. It seems less likely that speakers represent this knowledge as a subjectivity-based heuristic that gets applied in the construction of multi-adjective strings, and more likely that the knowledge is a reflection of the statistical regularities of our linguistic experience.

Other potential explanations for subjectivity-based ordering preferences are conceivable. A prominent example is the recent explanation put forward by Hahn et al. (2018) who, unlike here, focus on non-restrictive uses of multi-adjective strings and communicative benefit related to exchanging subjective opinions about objects, which they show can be related to surface order and its impact on memory. We believe that this approach is perfectly compatible with our approach here. Both factors can play a role in supporting subjectivity-based adjective orderings. Even more usage-types of adjectival modification can and should be considered. Seen in this light, the present contribution is but a first step. It highlights that under one specific kind of use—albeit arguably the most fundamental information conveying mode of language: referential communication—a general benefit accrues for ordering adjectives by subjectivity in the way widely observed in many of the world's languages.

Abstract

Understanding the cognitive structure of explanations— and the cognitive processes that assemble them— is a milestone for understanding how people learn and communicate. Recent research on *explanatory coexistence* suggests that people's causal beliefs are less globally coherent than previously thought: people use seemingly-competing supernatural and biological causes to explain different aspects of the same phenomenon, or they assemble supernatural and biological causes into single, coherent explanations (Legare & Gelman, 2008; Legare & Shtulman, 2018; Shtulman & Lombrozo, 2016). This coexistence— and unexpected coherence— of diverse causal mechanisms poses interesting questions about the role of coherence and fragmentation in people's mental models and explanations. This paper presents a computational model of explanatory coherence in the well-characterized domain of disease transmission, extending a previous cognitive model of explanation-based conceptual change (Friedman, Forbus, & Sherin, 2018). Our approach (1) retrieves diverse causal model fragments based on the phenomenon to explain, (2) assembles coherent causal models using relevance-directed abductive reasoning, and (3) selects explanatory paths that support within-explanation and within-scenario coherence. Our model simulates the three different types of explanatory coexistence detailed in the literature.

Keywords: cognitive modeling; explanatory coexistence; AI; abductive reasoning; explanation

Introduction

The cognitive process of explanation has been a central focus of cognitive science since its inception, and it has broad implications for communication, instruction, and conceptual change (Chi, De Leeuw, Chiu, & LaVancher, 1994; Vosniadou, 1994; diSessa & Sherin, 1998; Shtulman & Lombrozo, 2016; Friedman et al., 2018). The more recent focus on *explanatory coexistence*, whereby people utilize diverse— and seemingly incompatible— causal mechanisms in their explanations (Legare & Shtulman, 2018), poses additional questions about how people construct and consider explanations, how explanations are structured, and how explanations cohere with other beliefs.

This paper presents a computational cognitive model of explanation, building on previous cognitive models of conceptual change (Friedman et al., 2018). We apply our cognitive model to simulate human subjects' explanatory coexistence in the domain of disease, as characterized by Legare and Gelman (2008) and later by Legare and Shtulman (2018).

Our cognitive model assembles situation-specific causal models from smaller, generic *model fragments* (i.e., causal knowledge units). Given a new situation to explain, the model explains the situation by:

1. Retrieving causal model fragments based on the situation.
2. Traversing backwards recursively, instantiating model fragments within the situation in an relevance-directed beam search, assuming entities and relations as necessary.
3. Identifying the causal path(s) that maximize an objective coherence function with respect to global assumptions, coverage over the situation, and *presupposition* beliefs.

This model assumes that intuitive and culturally-acquired knowledge coexists, and that the process of assembling explanations is biased principally by coherence. This means that scientific and supernatural causal mechanisms can coexist in the same explanation, e.g., so that supernatural events might cause a biological event that leads to a viral infection, assuming the causal knowledge is primed and applicable.

Our simulation results demonstrate that that our model (1) simulates the three categories of explanatory coexistence in the literature and (2) varies its choice of explanation according to priming in a manner similar to human subjects.

We continue with an overview of explanatory coexistence and computational methods used in our cognitive model. We then describe our approach, present our simulation results, and conclude with a discussion of our results, key psychological assumptions, and directions for future work.

Background

We describe psychology research on explanatory coexistence, and then we review computational modeling techniques relevant to our simulation.

Explanatory Coexistence

There are scientific and religious or supernatural explanations for the same natural phenomena (e.g., creation of the universe, death, disease transmission). It is intuitive that learning scientific explanations for natural phenomena would replace previously learned supernatural explanations; however, evidence over the past decade suggests the opposite: scientific explanations replacing supernatural explanations is the

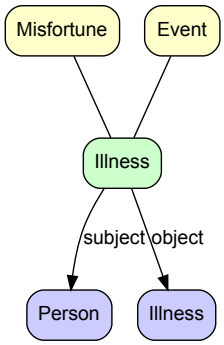

Figure 1: Model fragment for *Illness*.

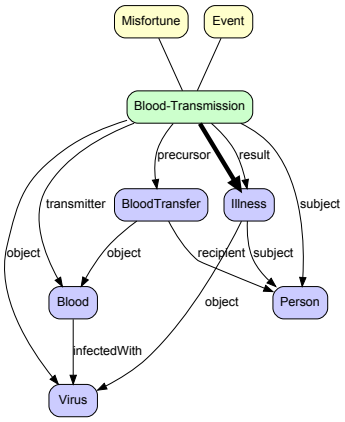

Figure 2: Model fragment for *Blood-Transmission* of disease via *BloodTransfer*.

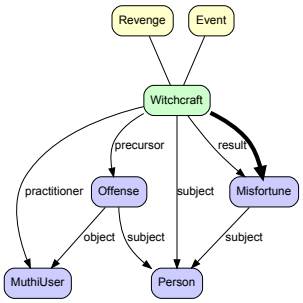

Figure 3: Model fragment for *Witchcraft* causing misfortune after an offense.

exceptional case. More frequently, people utilize both explanations (Shtulman & Lombrozo, 2016).

Legare and Gelman (2008) examined the specific case of explaining HIV transmission in South Africa. Before educational interventions focusing on the biological transmission of HIV, AIDS symptoms were explained as the result of witchcraft. Legare and Gelman (2008) showed that the educational interventions did not replace the bewitchment explanations; instead, both biological and bewitchment explanations coexist. For example, a man may have contracted HIV from sexual intercourse, but was attracted to a woman with HIV because of witchcraft.

Legare and Shtulman (2018) acknowledge the following categories of explanatory coexistence, all of which we simulate in this work:

1. **Integrated** reasoning combines seemingly-incompatible causal mechanisms into a coherent causal structure. For instance, bewitchment could cause somebody to choose a sexual partner who has AIDS, and intercourse with that partner causes disease transmission.
2. **Synthetic** reasoning invokes multiple causal mechanisms without articulating hierarchical or temporal precedence to any, possibly due to competing explanations.
3. **Target-dependent** reasoning applies different mechanisms to distinct aspects of a situation, in a highly-contextualized fashion. The various mechanisms do not participate in the *same* explanation.

Compositional Modeling

Simulating people's causal mental models requires expressive knowledge representation and reasoning (KR&R). An approach using only atomic logical propositions is not expressive enough to suit the mental model literature (Vosniadou, 1994; Chi et al., 1994; diSessa & Sherin, 1998; Gentner & Stevens, 1983) or the analogy literature (Friedman, Barbella, & Forbus, 2012), and an approach using only neural networks does not support sufficient interpretability.

Previous KR&R research on *compositional modeling* (Falkenhainer & Forbus, 1991) provides (1) representations for modeling the structure and continuous processes of dynamic systems, and (2) algorithms for composing these models on-the-fly for novel situations. Structure-behavior-function models (Goel, Rugaber, & Vattam, 2009) expand on this formalism to capture teleology, and have been used to simulate people's mental models.

Following recent cognitive modeling work (see the **Assembled Coherence** subsection), we simulate people's mental models using compositional modeling semantics extended with more expressive event structure (Pustejovsky, 2013). We represent each causal mechanism as a generic *model fragment* that can compose with others into large situation-specific explanations. Each model fragment describes:

- **Categories** that it instantiates, from general (e.g., *Misfortune*) to specific (e.g., *Sexual Transmission* [of a virus]).
- **Participants** are the entities or events that interact within the described mechanism. Each participant has one or more categories of its own. Model fragments with the same binding of participants are semantically equivalent.
- **Constraints** are *existence* conditions specified over the participants. If the constraints hold over participants in a situation, the model fragment may be *instantiated*.
- **Consequences** are functional or behavioral representations specified over the participants. They are asserted into the situation when the model fragment is instantiated.[1]

We include diagrams of three of the ten model fragments used in this simulation domain: Figure 1 shows a simple fragment describing an *Illness* state: a *subject* participant of type *Person*; a *object* participant of type *Disease*; and super-categories of *Event* and *Misfortune*.

Figure 2 shows the more complex fragment *Blood Transmission* [of disease], including sub-events of *Blood Transfer*

[1] A consequence may have *conditions* that must hold in the situation for them to be asserted, but in this paper each conclusion is a causal relationship without conditions.

and *Illness*, as well as a conclusion stating that, if instantiated, the *Blood Transmission* is a cause of the *Illness*. Importantly, this model fragment constrains its own participants: its subject (the *Person* at lower-right) is the subject of the *Illness* and the *Blood Transfer*. These constraints are required for the fragment— and its causal structure— to be realized.

Finally, Figure 3 illustrates a simple *Witchcraft* fragment, with a conclusion stating that an instantiated *Witchcraft* can cause a *Misfortune* of its subject. Per Figures 1 and 2, both *Illness* and *Blood Transmission* are types of *Misfortune*, so they can be directly caused by *Witchcraft*. This allows assembly of larger causal models, provided the situation (or explicit assumptions) satisfies the fragments' constraints. We describe assumptions below, and their affect on explanation quality.

Scalability of compositional modeling is a key consideration as the number of fragments grows, since the deductive closure of possible models can grow geometrically. We later describe a relevance-based heuristic in our approach that jointly (1) reduces the compositional modeling search space drastically and (2) helps model priming effects.

Abductive Reasoning

Abductive reasoning generates multiple explanations for observations— potentially generating assumptions along the way— and then selects the *"best"* explanation and its constituent assumptions as inferences or rationale for the observations. Previous computational approaches have modeled explanation quality as numerical cost (Charniak & Shimony, 1994) or as likelihood maximization with Bayesian approaches (Raghavan & Mooney, 2010). Our approach uses cost-based abductive reasoning to select explanations built from model fragments, and could be extended to use Bayesian approaches if we had estimates of subjects' beliefs of prior probability distributions. To improve scalability over previous abduction approaches— since the search space can grow geometrically (Poole, 1993)— our approach uses a relevance-based heuristic to guide its search for explanations.

Assembled Coherence

This paper extends recent work on the *assembled coherence (AC) theory* (Friedman et al., 2018) of mental models and conceptual change.

AC theory proposes that fragmented knowledge is assembled into larger, coherent mental models through the process of *abductive reasoning* (i.e., reasoning to the best explanation). Once assembled, these mental models are evaluated against a network of *presupposition* beliefs and then reused in novel situations by partial reformulation or by analogy (Friedman et al., 2012). This incorporates ideas from both the knowledge-in-pieces (diSessa & Sherin, 1998) and framework theory (Vosniadou, 1994) perspectives of mental models, and postulates that the two perspectives are compatible and complementary.

AC theory has been implemented in computational cognitive models to simulate explanation-based conceptual change in the domains of force dynamics (Friedman & Forbus, 2010), the day-night cycle (Friedman et al., 2012), the human circulatory system (Friedman & Forbus, 2011), and seasonal change (Friedman et al., 2018).

Approach

Our computational model generates a causal explanation by (1) retrieving model fragments based on the scenario to explain, (2) instantiating causal model fragments in an effect-to-cause beam search prioritized by relevance, (3) scoring coherent explanatory paths for coherence, and (4) selecting the most optimal explanatory path. We describe each of these processes below.

Retrieving causal knowledge. Given a new situation to explain, the system retrieves its model fragments (i.e., causal mechanisms) based on the categorical and relational overlap of the situation with those of its model fragments.

Specifically, given a situation s and a model fragment m, we compute relevance $Rel(m,s)$ with respect to the model fragment's participant categories C_m and constraint relations R_m and the situation's categories C_s and relations R_s. We use a simple Jaccard distance as a relevance function:

$$Rel(m,s) = \frac{|C_m \cap C_s| + |R_m \cap R_s|}{|C_m \cup C_s| + |R_m \cup R_s|} \quad (1)$$

This relevance function is a very coarse estimate of a model fragment's applicability to a situation, and we use it for simplicity: a model fragment's relevance strictly increases with situation-shared categories (e.g., *Person*, *Blood*, *SexualIntercourse*) and relations (e.g., *infectedWith*, *knows*, *motherOf*), and its relevance decreases monotonically relative to its total number of categories and relations. This approach is similar to performing spreading activation (Crestani, 1997) from categories and relations to relevant model fragments but allows indexing for scalability.

We discuss other plausible retrieval and salience factors in the conclusion of this paper.

Relevance-directed beam search. Given its relevance over causal model components, the system performs an incremental backward search through the space of possible causal models. This process is given an *explanandum* (i.e., event or assertion to explain), such as the illness of an individual, and then performs the following recursive operations for its explanation queue.

For each item x in its queue, it finds *applicable* model fragments that have x's type as a habitat consequence, e.g., if x is an *Illness*, then *BloodTransmission* (Figure 2) and *Witchcraft* (Figure 3) both apply. It selects applicable model fragments within the top 10% relevance window and attempts to compose the retrieved model fragment(s), constraining them by binding x as the consequent participant. The composition algorithm may assume any participants necessary to compose at least one instance, provided it obeys the input binding(s). The system then adds these new instances (e.g., *BloodTransmission* or *Witchcraft*) to the queue and will focus on those next, repeating.

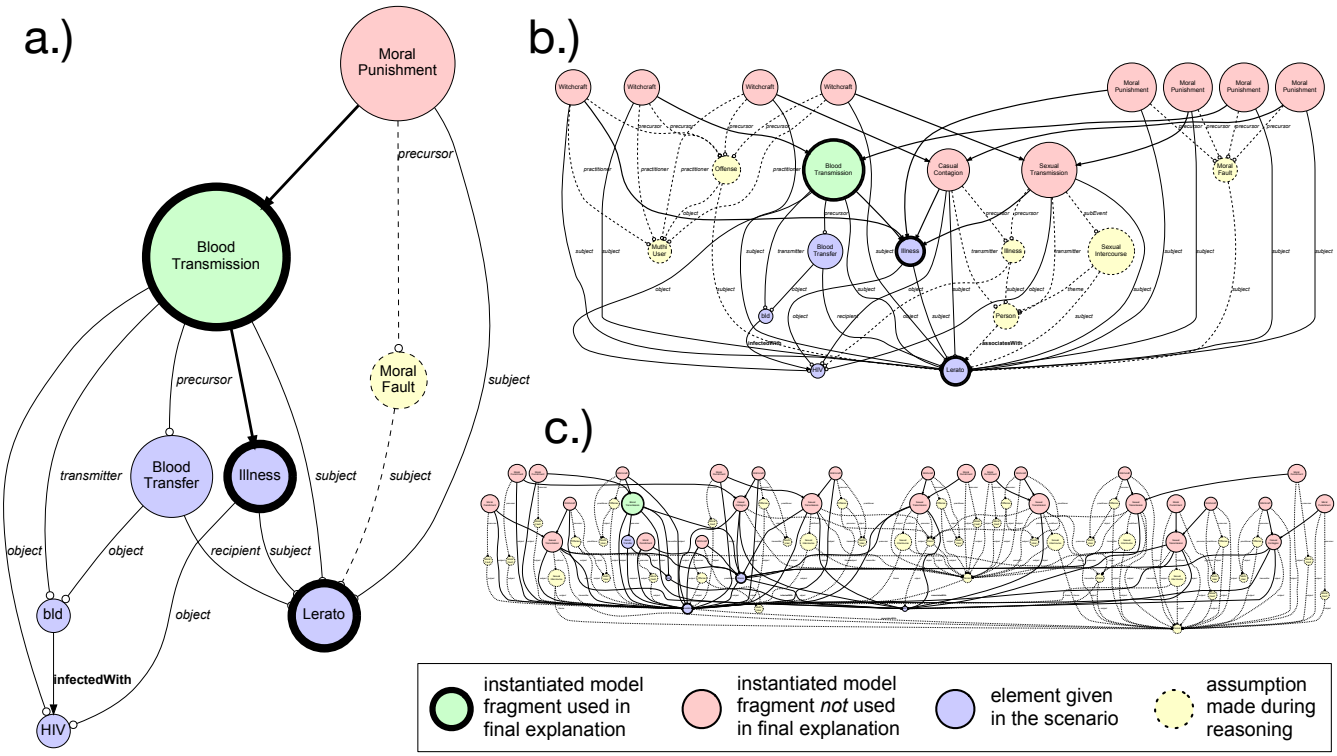

Figure 4: Explanations generated and selected for the same prompt of Lerato's AIDS after a blood transfer: (a) with relevance-directed causal search; (b) with undirected causal search; and (c) with exhaustive forward-chaining. All approaches utilize the same causal knowledge and result in the same final explanation, but with orders of magnitude difference in computation.

Explanation structure. Relevance-directed beam search produces a network of model fragment instances, as illustrated in Figure 4(a). In Figure 4(a), we provided the system the situation plotted in blue: Lerato has HIV and was the recipient of a blood transfer. Lerato and her *Illness* instance are outlined in bold for clarity. As with the human subjects of Legare and Gelman (2008), Lerato's illness is the explanandum in every simulation in this paper, but we vary the details of the situation to model priming effects.

The green (e.g., *Blood Transmission*) and red (e.g., *Moral Punishment*) elements in Figure 4(a) are instances of model fragments that were retrieved and assembled by this algorithm. The difference is that the green instances were chosen as part of the *best explanation* (described below), and the red instances were assembled and considered by the system, but were not ultimately included in the best explanation.

The yellow elements (e.g., *Moral Fault*) were *assumed* during the course of instantiation in order to satisfy model fragment participants and constraints.

In summary, Figure 4(a) shows that the system assembled a *Blood Transmission* event as a cause of Lerato's HIV, given that Lerato was the recipient of a blood transfer that was infected with HIV. It explained the *Blood Transmission* with a possible *Moral Punishment*, and assumed that Lerato committed some *Moral Fault* in the course of instantiating the *Moral Punishment*. The *Moral Punishment* (in red) was not included in the best explanation due to the additional assumption, since this reduces the coherence score (described below). All of our simulation results use this color-coding.

For reference, we contrast the Figure 4(a) explanation structure resulting from relevance-directed beam search with two other (less efficient) explanation-assembly algorithms to characterize the strength of our approach:

- Figure 4(b) illustrates the same situation and explanandum (i.e., blue nodes) using a backward search *without* relevance as a heuristic: it regresses from effects to causes, but tries *all* causes rather than those primed by the situation.
- Figure 4(c) illustrates the same situation and explanandum using exhaustive forward search. This instantiates all applicable events and then repeats.

Neither of these graphs' structure are legible, but we include them to visualize the difference in computation across approaches. Both of these alternative approaches select the exact same final explanation (in green) as the more efficient relevance-directed beam search in Figure 4(a). This suggests that relevance from the situation is a useful heuristic for approximating coherence while assembling explanations in a large space of possible explanatory paths.

These plots also demonstrate that our qualitative models are capable of expressing a wide range of explanations, many of which are incoherent and not employed by people.

This means we have not trivially *"baked in"* the explanation within the knowledge representation; rather, it is the product of assembly and assumption (described above) and coherence assessment, which we describe next.

Scoring explanations for coherence. After assembling explanation structure from model fragments— and potentially making assumptions in the process— the system traverses the explanation structure to select a *best explanation*. This is the culmination of *abductive reasoning* (i.e., inference to the best explanation), which has been formulated as likelihood maximization (Raghavan & Mooney, 2010), simplicity, and other measures of explanation quality (Lombrozo, 2007).

Our system scores explanations by (1) identifying connected causal subgraphs of at least one cause (i.e., of Lerato's *Illness*), (2) scoring those subgraphs for coherence, where larger scores indicate greater coherence, and (3) selecting the highest-scoring subgraph as the best explanation.

The coherence score is the sum of epistemic *features* of a causal graph, where features positively or negatively contribute to coherence. Each feature is scored once for each causal graph, so many model fragment instances can rely on one assumption and incur the cost once. We employ a simple order-of-magnitude scoring technique over these features:

- *Model Fragments* (-1) penalize for increasing complexity.
- *Assumptions* (-10) penalize for increasing complexity.
- *Situation premises* (10) are situation events and entities that participate in model fragments, increasing explanatory inclusion (i.e., coherence) over the stated situation.
- *Causal associations* (100) are presuppositions that associate categories of causes and effects, e.g., *witchcraft* causally contributes to *illness*.
- *Causal dissociations* (-100) are presuppositions that dissociate categories of causes and effects, e.g., *witchcraft* does not cause *physical effects*.

These features coarsely quantify coherence: within-explanation coherence, explanation-to-situation coherence, and explanation-to-presupposition coherence. Following Vosniadou (1994), we model presuppositions as overarching belief-level constraints on people's explanations acquired culturally or via observation. We do not believe our list of is complete, since factors like analogical structure, narrative structure, likelihood, and other factors all contribute to people's explanatory preferences (Lombrozo, 2007).

Simulation

Our simulation setup is a variation of a human experiment by Legare and Gelman (2008): as exemplified in the previous section, we prompt the system to explain how Lerato contracted HIV. We use priming conditions from their study— *biological* priming, *bewitchment* priming, *neither* priming, and *both* types of priming— by varying the information we provide about Lerato. We provide two alternative types of biological priming: sexual intercourse and blood transfer. We also provide a "moral" priming condition, since other results from Legare and Gelman (2008) suggests that some subjects believe immoral behavior can cause illness.

Legare and Gelman (2008) report that 60% to 70% of their subjects exhibited some case of explanatory coexistence, where both supernatural and biological mechanisms (a) explained aspects of the scenario (*target-dependent*); (b) were juxtaposed (*synthetic*); or (c) coexisted in a causal chain (*integrated*). Subjects were sensitive to priming effects: biological and bewitchment priming was associated with more of those mechanisms appearing in explanations. We next review our simulation results for seven priming conditions, shown in the Figure 5 explanation graphs.

Target-dependent reasoning. Graphs (a-e) are all evidence of target-dependent reasoning. Graph (a) is *no priming*, where the system assumes immoral behavior as a simple cause for the disease. Graph (b) is immoral priming, which removes the need for the assumption of immorality. Graph (c) is bewitchment priming, mentioning a practitioner who knows Lerato, which results in assuming an offense, and also considering *Moral Punishment*, but ultimately choosing *Witchcraft* as an explanation. Graph (d) is biological priming with mention of receiving infected blood, resulting in a *Blood Transmission* explanation. Graph (e) is biological priming with mention of sexual intercourse with an HIV-infected partner, resulting in a *Sexual Transmission* explanation, but considering that the illness or the sexual transmission might have been caused by immoral behavior.

Synthetic reasoning. Graph (g) demonstrates one possible example of synthetic reasoning, where a presupposition causally associates *Witchcraft* with *Illness*, and we prime both biological and witchcraft causes. In this case, the *Sexual Transmission* fragment coheres with the situation (i.e., it requires no assumptions), and the *Witchcraft* fragment coheres with the presupposition (rendered in black), so the union of those causes of the illness is higher-scoring than either alone. Our system has no hard constraint to select single causes at causal junctions; however, selecting two causes— when either alone is sufficient— is counter-intuitive. The "synthetic reasoning" category of explanatory coexistence is not as well-specified as the other two, and could plausibly represent multiple sub-strategies, e.g., where subjects integrate causes in parallel, mention multiple salient or competing causes, or are vaguely verbalizing a more integrated causal chain (as below). This suggests further research with human subjects.

Integrated reasoning. Graphs (f) and (h) are evidence of integrated reasoning. Graph (f) is priming of both bewitchment and biology, resulting in an integrated explanation: witchcraft caused the sexual transmission of HIV during the sexual encounter. Graph (h) is priming of moral and biology, resulting in another integrated explanation: immoral behavior caused transmission of HIV during a transfer of blood. Legare and Gelman (2008) did not explicitly attempt the priming condition in Graph (h), but our model predicts that an integrated explanation is plausible for these mechanisms.

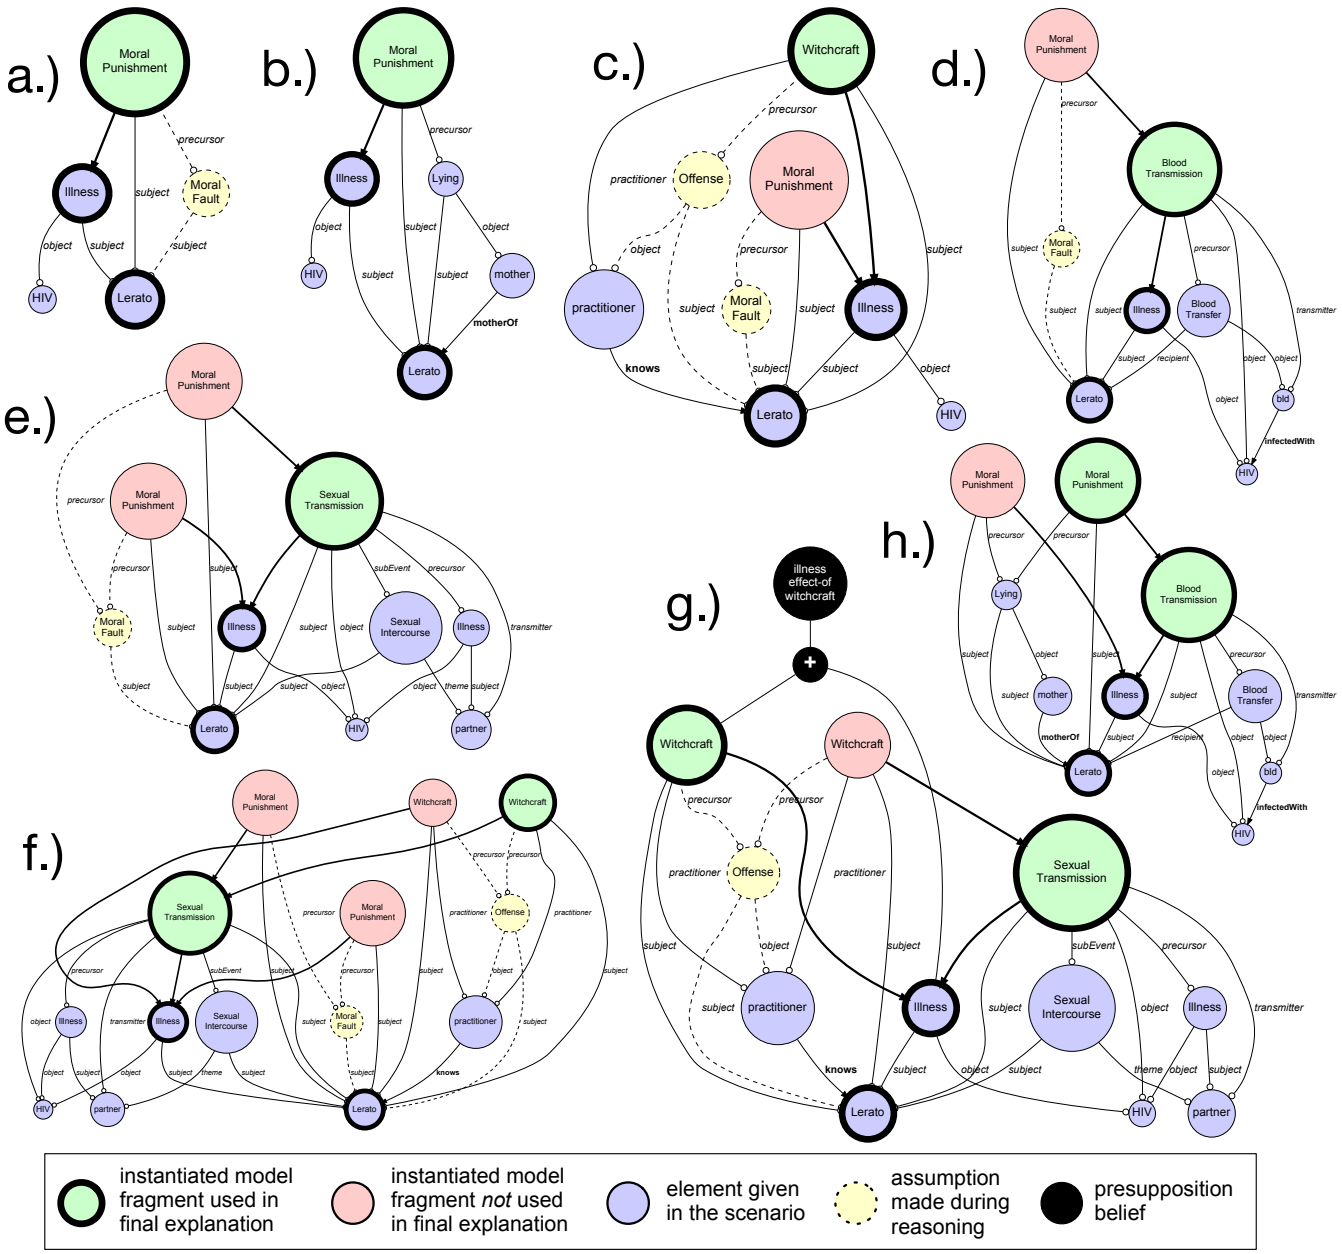

Figure 5: Simulation results with identical causal knowledge, by varying priming: (a) no priming; (b) priming immoral behavior; (c) priming with witchcraft practitioner; (d) priming with blood transfer; (e) priming with sexual encounters; (f) priming with *both* sexual encounters and witchcraft; (g) same priming but including a presupposition that illness is caused by witchcraft; and (h) priming with *both* immorality and blood transfer.

Conclusion

This paper presents a computational cognitive model that simulates all three categories of explanatory coexistence (Legare & Shtulman, 2018; Legare & Gelman, 2008), using the same psychological assumptions as previous models of conceptual change and self-explanation (Friedman et al., 2018). Our computational model retrieves diverse causal model fragments based on relevance to the scenario, and then assembles and evaluates explanations that may integrate both biological and supernatural causes.

We simulated different explanatory coexistence outcomes by varying high-level presuppositions and priming effects; we did *not* vary any causal models, likelihood values, or retrieval parameters across trials. The simulations demonstrate that the model's explanation-assembly is sensitive to priming effects, similar to people (Legare & Gelman, 2008). We showed that salient high-level beliefs— which have been termed *presuppositions* (Vosniadou, 1994)— bias the system to prefer explanations that cohere with their constraints.

Psychological claims and assumptions. This model and simulation support the claims that (1) explanatory coexistence may be the rule rather than the exception (Legare & Shtulman, 2018) and (2) explanatory coherence is a secondary property of assembling and assessing fragmentary, reusable causal knowledge (Friedman et al., 2018). These claims must be framed within the assumptions and limitations of our computational cognitive model.

Our model does not explicitly represent prior probabilities or joint probabilities across causal mechanisms. On the one hand, this allows it to flexibly assemble human-like causal explanations with diverse, seemingly-conflicting mechanisms; however, it could produce uncharacteristic explanations in other domains. This is an empirical question we will investigate in future work, described below. Although we did not encode likelihoods in this work, our model is compatible with Bayesian and statistical relational learning: its situation-specific explanation structure supports statistical inference (Raghavan & Mooney, 2010), and its coherence score could inform likelihood judgments in absence of prior probabilities.

Our model simplifies the psychological processes of knowledge activation and explanation assessment. Some activation and assessment factors *not* modeled here include structural similarity to previous situations, prior likelihood estimates for any given causal mechanism, and probability distributions over causal mechanisms conditionalized on the situation. Implementing these factors would increase the power of our model, but at the expense of interpretability: these factors make additional assumptions about the belief state of each simulated subject, such as their episodic knowledge and the likelihood they ascribe to each causal mechanism.

Future work. In addition to the domain of disease, people's explanatory coexistence has been characterized in the domains of death and human origins (Legare & Shtulman, 2018). Simulating these domains will provide additional empirical evidence of our model's generality.

In addition to other domains, running this model of explanation on other explanation tasks will help qualify its broader psychological plausibility. Also, applying this model of explanation within larger models of explanation-based learning and conceptual change will help us refine the model's parameters knowledge representations.

Finally, this paper's simulations utilized a purely qualitative comparison between human and machine explanations as a proof of concept, but we plan to model quantitative properties, such as subjects' reaction time, in future work.

Stereotypes of Transgender Categories: Attributes and Lay Theories

Natalie Gallagher
Northwestern University, Evanston, Illinois, United States

GALEN BODENHAUSEN
Northwestern University, Evanston, Illinois, United States

Abstract

What is the descriptive content and guiding lay theory of transgender stereotypes? The recent rise in public visibility and the numeric minority of this gender group make this an opportunity to understand not only the content of stereotypes applied to transgender individuals today, but also the ontology of gender guiding the content of these stereotypes. Using convergent methods, we measure the descriptive content of transgender stereotypes and assess the role of essentialist beliefs in guiding that content. We show that transgender categories are perceived less positively than cisgender categories, and that while perceptions of cisgender men and women differ sharply, those of transgender men and women show striking similarity. Essentialist beliefs about gender exaggerate these patterns.

Incorrect Guesses Boost Retention of Novel Words in Adults but not in Children

Abstract

What is the mechanism by which linguistic knowledge is updated over time? In six experiments, we asked whether error-driven learning can explain how adults and children add new words to their vocabulary. Participants were exposed to novel object labels that were more or less unexpected given participants linguistic knowledge. Two-to-four-year-olds were strongly affected by expectations based on contextual constraint when choosing the referent of a new label. However, while adults formed stronger memory traces for novel words that violated a stronger prior expectation, childrens memory was unaffected by the strength of their prior expectations. We conclude that the encoding of new words in memory follows the principles of error-driven learning in adults, but not in preschoolers.

Sleep Does not Help Relearning Declarative Memories in Older Adults

Abstract

How sleep affects memory in older adults is a critical topic, since age significantly impacts both sleep and memory. For declarative memory, previous research reports contradictory results, with some studies showing sleep-dependent memory consolidation and some other not. We hypothesize that this discrepancy may be due to the use of recall as the memory measure, a demanding task for older adults. The present paper focuses on the effect of sleep on relearning, a measure that proved useful to reveal subtle, implicit memory effects. Previous research in young adults showed that sleeping after learning was more beneficial to relearning the same Swahili-French word pairs 12 hours later, compared with the same interval spent awake. In particular, those words that could not be recalled were relearned faster when participants previously slept. The effect of sleep was also beneficial for retention after a one-week and a 6-month delay. The present study used the same experimental design in older adults aged 71 on average but showed no significant effect of sleep on consolidation, on relearning, or on long-term retention. Thus, even when using relearning speed as the memory measure, the consolidating effect of sleep in older adults was not demonstrated, in alignment with some previous findings.

Keywords: sleep-dependent memory consolidation; ageing; learning; relearning; repeated practice

Sleep, Memory, and Age

The importance of sleep in cognitive functioning is now well established. For instance, sleep has been shown to benefit the consolidation of declarative memories acquired during the day. It is usually observed that sleeping after a learning episode improves recall performance during a test compared to the same delay without sleep (see Rasch & Born, 2013, for a comprehensive review). Such memory consolidation is thought to originate from two complementary processes. First, the reactivation or "replay" of recent memory traces during slow-wave sleep (SWS) causes declarative memories that are initially hippocampal-dependent to become increasingly dependent on the prefrontal cortex (Takashima et al., 2009). In parallel, a downscaling process during sleep leads to the recalibration of synaptic connections that were modified during learning (Tononi & Cirelli, 2014). The overnight memory improvement has been clearly demonstrated in young adults but is more controversial in older adults (Harand et al., 2012).

Sleep undergoes both quantitative and qualitative changes over the course of ageing. The most obvious change in sleep in healthy older adults is a decrease in total sleep time (TST) induced by an increase in the time spent awake both after bedtime (i.e., sleep latency) and during the night (Carrier et al., 1997). As a result, sleep efficiency (i.e., ratio TST / time in bed) declines and reaches 79% or less at age 70 (Bliwise, et al., 2005) compared to about 90% in healthy adults. Sleep architecture is also modified, with a reduction in SWS (Lombardo et al., 1998), whereas time in lighter stages (non-Rapid Eye Movement nREM1 and nREM2) increases (Ohayon et al., 2004). However, the time spent in REM sleep remains relatively unchanged. Modifications in sleep microstructure are also observed. A reduced spectral EEG power is observed, in particular for slow-wave activity (SWA) during SWS, especially over the prefrontal cortex (Dubé et al., 2015). Spindle density, frequency, and duration are also diminished (Crowley et al., 2002; Guazzelli et al., 1986), as well as the density of phasic REM phases (Darchia, Campbell, & Feinberg, 2003). Thus, many sleep components underpinning sleep-related memory consolidation in young adults, such as SWA and spindle activity, are reduced with increasing age (Carrier et al., 2011; Martin et al., 2013).

Aging is also associated with declarative memory changes. Overall, older adults exhibit poorer memory recall while their recognition performance remains relatively spared (e.g. Danckert & Craik, 2013; see Grady & Craik, 2000 for review). They also exhibit an increasing difficulty to learn new material compared to the younger adults, because of poor encoding strategies (see Craik & Rose, 2012, for review). These effects might be mainly explained by an impairment in forming associations (Old & Naveh-Benjamin, 2008).

It has been proposed that changes in sleep may contribute to age-related memory impairments (Buckley & Schatzberg, 2005; Hornung, Danker-Hopfe, & Heuser, 2005; Mander et al., 2014; see Scullin & Bliwise, 2015). A proposed mechanism (Mander et al., 2013) is that reduction of gray matter volume associated with aging impedes the generation of SWA and spindles during sleep, thereby impairing memory consolidation.

Despite these age-related changes in sleep, some research reported the persistence of sleep-dependent memory consolidation in the older adult (Aly & Moscovitch, 2010; Sonni & Spencer, 2015; Wilson et al., 2012), whereas others failed to demonstrate it or demonstrated a lesser consolidation compared to young adults (Baran, Mantua, & Spencer, 2016; Cherdieu et al., 2014; Mander et al., 2013, 2014; Mary, Schreiner, & Peigneux, 2013; Scullin, 2013; Scullin et al., 2017). Other research described a more complex picture (Jones et al., 2016).

Most of these studies used free- or cued-recall performance as a measure of consolidation. Such measures may be suboptimal to reveal consolidation and may thus contribute to the contradictory findings, especially since recall is a demanding task specifically impaired in the older adult (e.g. Troyer, Graves, & Cullum, 1994; Danckert & Craik, 2013). In addition, these measures are binary (i.e., correct/incorrect) and are poorly informative as to the strength of a memory trace. It seems possible to assess memory retention in an alternative, more implicit manner by measuring how fast participants relearn the information (i.e., savings in relearning). In a recent study, Mazza et al. (2016) found that young adults significantly benefitted from sleep to improve their memory performance in both relearning and retention of word pairs. The Sleep group, who slept during the 12-hour interval between the learning and the relearning sessions, displayed a faster rate of relearning compared to the Wake group that did not sleep. This was true even after controlling the recall performance just before relearning. In other words, those words that could not be recalled before the relearning session were relearned faster. The present study consists of a close replication of the study by Mazza et al. (see Figure 1) with older adults and using the same type of material. We tested the hypothesis that sleep does still favor consolidation in older adults, as evidenced when relearning speed is measured instead of recall.

Method

Participants

Forty French healthy participants completed the study. They were aged between 65 and 80 and had normal sleep and cognitive abilities. Participants with sleep problems, as assessed by a score of 8 or above on the Pittsburgh Sleep Quality Index (PSQI; Buysse et al., 1989), or presenting altered cognition, as assessed by a score below 27 in the Mini-Mental State Examination (MMSE; Folstein, Folstein, & McHugh, 1975), were excluded. Health information was gathered from all participants during an interview about their medical history and medication. Participants with a medical history and/or taking medications with known sensory or neurological effects were also excluded. All participants in the study were native French-speaking and present normal or corrected-to-normal vision. The present study was in accordance with the ethical standards of the responsible committee on human experimentation of the Helsinki Declaration of 1975, as revised in 2000. Informed written consent was obtained from each participant.

Furthermore, all participants underwent a neuro-psychological and sleep assessment with sleep quality (PSQI), circadian topology (the Horne and Ostberg morning/evening questionnaire; Horne & Ostberg, 1976), level of sleepiness (Epworth Sleepiness Scale; Johns, 1991), basic long-term and short-term memory capacity (subtests from the Wechsler Adult Intelligence Scale IV, Wechsler, 2008, and from the Wechsler Memory Scale III; Wechsler, 1997), global cognitive ability (MMSE), and anxiety and depression levels (The Hospital Anxiety and Depression Scale; Zigmond & Snaith, 1983).

The participants were randomly assigned to the Sleep or the Wake group. Three participants did not pursue the experiment after having spent too much time completing the learning session. Eventually, the data from 19 participants in the Sleep and 18 in the Wake group were included for analysis. Their age ranged from 65 to 80 (mean age 71.6 +/- SE) with 20 women in total. The Sleep and Wake groups did not significantly differ on any of the following variables: gender, age, number of attended school years, sleep quality, circadian topology, level of sleepiness, basic long-term and short-term memory capacity, global cognitive ability, and anxiety and depression levels. An additional 6 participants started but did not complete the study for various reasons (e.g., not available for the upcoming session).

Material and Procedure

During the first session, participants were trained to learn the French translation of 12 Swahili words (e.g., nyanya-tomate), using repeated tests with feedback. The number of pairs was decreased from 16 in Mazza et al. (2016) to 12 here to adjust to the memory difficulties encountered by the older adult. A perfect learning criterion was adopted in which pairs were tested until they received a correct answer (Figure 1A). Twelve hours later, in the second (relearning) session, they

had to relearn the pairs to the criterion of correctly answering the 12 items in a row (Figure 1B). This equated the participants' performance at the end of the relearning session. Initial performance on the first trial for the 12 items and the number of trials necessary to attain the relearning criterion were measured.

The Wake group performed the learning session at 9:00 a.m. and the relearning session at 9:00 p.m. the same day (Figure 2). They did not sleep between the two sessions, as was instructed. The Sleep group performed the learning session at 9:00 p.m. and the relearning session at 9:00 a.m. the following day. They experienced a night of sleep between the two sessions, during which actimetry (Actiwatch system, CamNtech, Cambridge, UK) was used to quantify TST. One week and six months after the relearning session, the retention of the material was further assessed for each group using a cued-recall task without feedback.

Results

Based on the results obtained in the young adults in Mazza et al. (2016), it was expected that the Sleep group would start the relearning session with an advantage over the Wake group, would relearn faster, and would perform better after one week and six months. The overall results are presented in Figure 3.

Along with inferential frequentist statistics (two-tailed Student's *t-tests*) using a critical *p*-value of .05 and effect sizes reported using Cohen's *d*, dependent variables were also submitted to two-tailed Bayesian *t-tests* (Rouder, et al., 2009) comparing the Wake and the Sleep groups. Because we observed weak effects, we will present the BF_{01}, that is, the odds ratios in favor of the null hypothesis H_0 (i.e., no difference between the means) against the alternative hypothesis (i.e., a difference between the means). They were computed using JASP (JASP software, 2016) and will be considered according to the following scale: values inferior to 3 as anecdotal evidence, values ranging from 3 to 10 as substantial evidence, and values above 10 as strong evidence in favor of H_0, with higher values indicating gradually increasing confidence (Jarosz & Wiley, 2014; Jeffreys, 1961).

The learning session was performed similarly by the two groups with respect to the proportion of correct answers provided at the first trial ($M = 0.21$, $SE = 0.04$ in both groups). The estimated Bayes factor ($BF_{01} = 3.14$) suggested that the data were 3.14 times more likely in favor of H_0 than of the alternative hypothesis, i.e., indicative of anecdotal to substantial evidence in favor of the absence of a difference. The number of trials necessary to achieve the learning criterion was not significantly different (Sleep: $M = 5.79$, $SE = 0.41$; Wake: $M = 6.00$, $SE = 0.45$; $t(35) = 0.35$, $p = .73$), with an anecdotal evidence in favor of H_0 ($BF_{01} = 3$).

During the relearning session, the proportion of correct answers on the first trial did not differ in the Sleep ($M = 0.46$, $SE = 0.04$) and in the Wake group ($M = 0.40$, $SE = 0.05$; $t(35) = 0.93$, $p = .36$, Cohen's $d = 0.31$, $BF_{01} = 2.23$, anecdotal evidence in favor of H_0). Both groups needed an equivalent number of trials to achieve the relearning criterion (Sleep: $M = 7.63$, $SE = 0.76$; Wake: $M = 8.00$, $SE = 1.16$; $t(35) = 0.27$, $p = 0.79$; $d = 0.09$; $BF_{01} = 3$, anecdotal evidence in favor of H_0). The *relearning speed* was computed by dividing the number of unrecalled items at the first trial by the number of

trials necessary to complete the session. This was a way to control for the influence of initial performance on relearning speed. Indeed, the more the participants initially recalled, the fewer items remained to be relearned. The relearning speed did not differ between the Sleep (M = 0.96, SE = 0.09) and the Wake group (M = 1.06, SE = 0.08, $t(35) = 0.78$, p = .44; d = 0.26; BF_{01} = 2.5, anecdotal evidence in favor of H_0). Thus, contrary to our expectation, there was no clear-cut indication of a consolidating effect of sleep, since neither the initial retrieval performance nor the relearning speed varied between the two groups.

After one week, there was no significant difference between the performance in the Sleep (M = .75, SE = .04) and the Wake group (M = .64, SE = .06; $t(35) = 1.59$, p = .12; d = .52; BF_{01} = 1.19, anecdotal evidence in favor of H_0). In addition, these scores were overall relatively high, indicating that the specific relearning method used was quite efficient at inducing long-term retention. For the six-month delay, the data from 4 participants in the Sleep group and from 2 participants in the Wake group could not be obtained. There was no significant difference between the groups (Sleep: M = .42, SE = .08; Wake: M = .30, SE = .06; $t(29) = 1.22$, p =.23; d = .44; BF_{01} = 2.35, anecdotal evidence in favor of H_0).

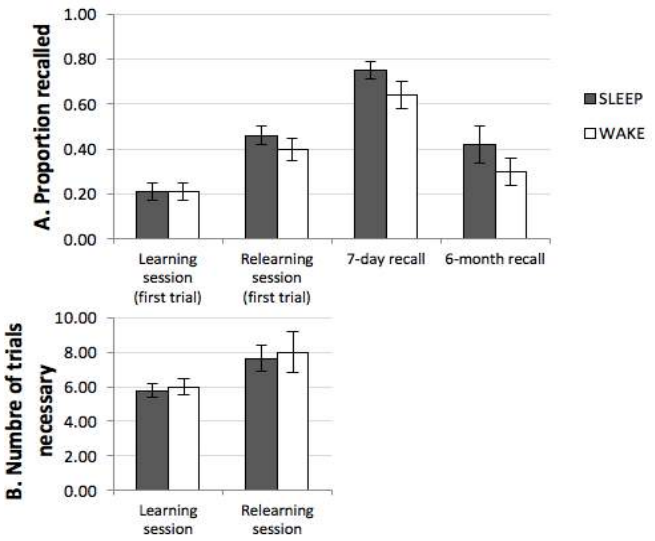

Figure 3: Upper part: Mean proportion correct in the first trial of the learning and relearning sessions, and in the 7-day and 6-month recall sessions.
Lower part: Number of trials necessary to achieve the criterion in the learning and the relearning session.
The error bars represent standard errors of the mean.

The actimetric data was lost for 4 participants in the Sleep group. The Sleep group (N = 15) exhibited a mean TST of 402 min (6 hours and 42 minutes; 308 - 469 min; SE = 12.1). The correlation between TST and initial performance on the relearning session was not significant (r = .40; df = 13; p = .14). The correlation between TST and the number of trials needed at the relearning session was surprisingly positive but not significant either (r = .45, p = .09). In addition, the correlation between TST and the relearning speed was significant and negative (r = -.74, p = .0015), indicating that the more the participants slept, the slower they were to relearn. Finally, there was no correlation between TST and the performance after one week (r = -.03, p = .92).

Discussion

The present results display major differences from those of the Mazza et al. study that used similar methods and sample sizes (n=20 in each group) with younger adults. In the present study with older adults, an episode of sleep did not significantly boost subsequent recall 12 hours after learning, compared to wakefulness, Thus, contrary to our hypotheses, even with more fine-grained and implicit measures of declarative memory, we did not show significant benefits of sleep on relearning in this population. The effect on the long term, however, is more ambiguous, with a potential weak benefit of interpolated sleep after 7 days and 6 months, which is not significant in the present study, most likely due to lack of power. In any case, the size of this benefit is far weaker in the older than in the younger adults.

Our hypothesis that the sleep-dependent processes that consolidate memories are subtle in the older population and therefore require more implicit measures to be shown was not validated. These results are however consistent with other studies that did not show any sleep-dependent benefit for declarative memory in the older adult (see Gui et al., 2017 for a review). Contrary to younger adults, recommendations such as "you should sleep between learning and relearning" does not seem as relevant for the aging population, although it does not seem detrimental either (especially for long-term retention).

One surprising finding is the negative correlation between TST and the relearning speed, indicating that the more the participants slept, the more trials they needed in order to reach the relearning criterion. This is in contradiction with results from Aly & Moscovitch (2010) but is consistent with that of Scullin (2013) and Tsapanou et al. (2017). A possibility is that people with poorly efficient sleep with respect to consolidation and maybe other functions tend to sleep more to compensate.

How to reconcile these results with those indicating clear sleep-dependent consolidating effects of sleep in the older adult (e.g., Aly & Moscovitch, 2010; Sonni & Spencer, 2015; Wilson et al., 2012)? A first limit might be that the task was too difficult and not well calibrated for the participants, therefore impeding the emergence of potential effects of sleep. However, the relatively high scores observed after one week go against this limitation. Another limit could be that the criteria of perfect-performance during learning and relearning did not leave enough possibility for sleep-dependent improvement. However, the relatively low performance at the beginning of relearning and the fact that the paradigm was identical to that in Mazza et al.'s study go against this limitation. Finally, the discrepancies could be linked to the material used. Our study consisted of learning

pseudowords which are verbal representations that do not yet exist in the mental lexicon and need to be integrated into it. This integration has been shown to require time (e.g., Dumay & Gaskell, 2007). Moreover, in the present study, in addition to creating such a novel verbal representation, participants needed to associate it to a known French word in order to succeed at the cued-recall task. Such associative learning is impaired in aging (e.g., Service & Craik, 1993). Therefore, it would be interesting to examine in future research whether the absence of sleep-induced benefits would also be observed when older adults learn and relearn word pairs instead of pseudoword-word pairs (see Kurdziel, Mantua, & Spencer, 2017 for an overall review of the effect of sleep on word learning in the older adult).

Quality of sleep and memory performance are critical issues in modern societies, especially for older people. Their functional relationship needs to be investigated further (Scullin & Bliwise, 2015). In particular, an intriguing issue is whether improving sleep quality could efficiently improve memory functioning. Such possibility could lead to potential practical applications for improving the aging population's quality of life.

Abstract

Drift diffusion (or evidence accumulation) models have found widespread use in the modelling of simple decision tasks. Extensions of these models, in which the model's instantaneous drift rate is not fixed but instead allowed to vary over time as a function of a stream of perceptual inputs, have allowed these models to account for more complex sensorimotor decision tasks. However, many real-world tasks seemingly rely on a myriad of even more complex underlying processes. One interesting example is the task of deciding whether to cross a road with an approaching vehicle. This action decision seemingly depends on sensory information both about own affordances (whether one can make it across before the vehicle) and action intention of others (whether the vehicle is yielding to oneself). Here, we compared three extensions of a standard drift diffusion model, with regards to their ability to capture timing of pedestrian crossing decisions in a virtual reality environment. We find that a single variable-drift diffusion model (S-VDDM) in which the varying drift rate is determined by visual quantities describing vehicle approach and deceleration, saturated at an upper and lower bound, can explain multimodal distributions of crossing times well across a broad range vehicle approach scenarios. More complex models, which attempt to partition the final crossing decision into constituent perceptual decisions, improve the fit to the human data but further work is needed before firm conclusions can be drawn from this finding.

Keywords: complex decision making; road crossing; variable-drift diffusion models

Introduction

Sensorimotor decision making, how people decide what motor actions to take and when, has been a key object of research over the past hundred years in the psychological sciences. One area of particular progress has been in the development of mathematical models which predict action choices and reaction times. In particular, drift diffusion models (DDMs) and various related models, which describe the decision making process as a noisy accumulation of sensory information to a bound, have been found to very successfully capture behavioral data across a plethora of experimental tasks (Bogacz, Brown, Moehlis, Holmes, & Cohen, 2006; Ratcliff, Smith, Brown, & McKoon, 2016) and have shown success in bridging the gap between neurophysiological and behavioral data (Purcell et al., 2010).

DDMs and related models have most commonly been applied to two alternative force choice (2-AFC) tasks, in which people make a decision between two alternative choices based on perceptual information. Quintessential among these is the kinematogram task in which people decide the direction of a random flow of dots (Ratcliff et al., 2016). DDMs have also been successfully applied to more complex sensorimotor tasks, such as determining the action intentions of other people (Koul, Soriano, Tversky, Becchio, & Cavallo, 2019). However, standard DDMs and related models of the evidence accumulation type typically assume that the drift rate (i.e., the rate at which evidence accumulates to a bound), is set to a fixed value. Yet many sensorimotor decisions take place in the context of a continuous stream of varying sensory information. Models with variable drift rate, which we will refer to here as variable-drift diffusion models (VDDMs), have been successful in the vehicle driving context, accounting well for driver brake responses to the time varying visual looming of an approaching vehicle (Xue, Markkula, Yan, & Merat, 2018) as well as for steering responses during lane-keeping (Markkula, Boer, Romano, & Merat, 2018).

However, further generalization to more complex real world decisions brings additional challenges. Firstly, more

complex decisions may depend on multiple types of sensory cues, raising the question of how different cues should contribute to the drift rate. In this paper, we will consider a pedestrian's decision of when to cross at a zebra crossing with an approaching vehicle, a decision relying on at least two types of cues (Rasouli, Kotseruba, & Tsotsos, 2017): (1) Cues regarding own affordances, for example in terms of the time to arrival (TTA) of the approaching vehicle, in relation to the width of road to be crossed. (2) Cues regarding the action intention of the vehicle driver, in the form of kinematic cues (e.g., vehicle deceleration) and/or communicative cues (e.g., flashing headlights).

Secondly, when the sensory inputs to the model vary over a large magnitude, this may result in undesirable model behavior. For example, when a vehicle decelerates to a stop, its perceptually estimated TTA will go to infinity. If this is used as a model input then the accumulator will be guaranteed to reach its threshold (and initiate a crossing) immediately when the vehicle stops, when in fact people show a probabilistic delay in crossing times.

Finally, it remains unclear how complex decisions, like the zebra crossing decisions, are structured in practice. Is the overt behavior the result of only a single action decision ("I am crossing now"), or is that action decision underpinned by separate, purely perceptual decisions about the affordances and action intentions mentioned above (e.g., "I can make it across before the car"; "The car is stopping for me")? There are many examples in the broader literature of psychological, cognitive, and robotics models where multiple parallel units of activation dynamics akin to evidence accumulators have been interconnected to produce more complex emergent behavior (e.g., Cooper & Shallice, 2000; Sandamirskaya, Richter, & Schöner, 2011), but DDM type decision models have seemingly not been previously generalized in this direction.

In the current study we wished to test three novel VDDMs, which aim to address the above three challenges. Firstly we wished to test a model recently proposed by Markkula, Romano, et al., (2018), which we refer to as the connected variable-drift diffusion model (C-VDDM). The C-VDDM models action decisions and perceptual decisions as separate but interconnected accumulator units as discussed above (see Figure 1, top), where the drift rate of each perceptual unit is a function of a time varying sensory input. In turn, the drift rate of the action unit is a function of the current activation levels of each of the two perceptual units. The activation of each perceptual unit is bounded to ± 1 which ensures that large perceptual inputs do not immediately lead to the action unit reaching threshold. Markkula, Romano, et al., (2018) showed that this model could qualitatively account for bimodal distributions of crossing decision times, as reported for human pedestrians, but did not formally test or fit the model with human data.

We also wished to test a simplification of the C-VDDM model, in which a single perceptual unit has a drift rate which varies as a function of a linear combination of multiple sensory cues (see Figure 1, middle), in turn

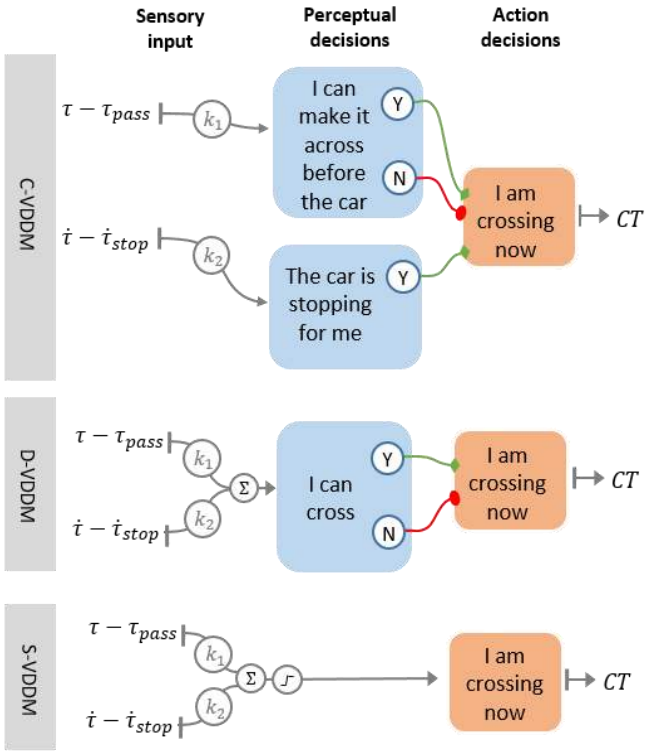

Figure 1: The three variable-drift diffusion models (VDDMs).

modulating the activation level of an action unit. We refer to this as the dual variable-drift diffusion model (D-VDDM). Like the C-VDDM, this model ensures that large sensory inputs do not result in the reaction time distribution collapsing to a spike. However, unlike the C-VDDM, this model does not independently represent different underlying decision processes.

Finally, we also wanted to test a model consisting of a single accumulator unit with a drift rate that varies as a function of a linear combination of sensory cues (see Figure 1, bottom). Instead of the D-VDDM's intermediate accumulator unit, to ensure that high input values did not result in rapid termination of the accumulation process, we limited the drift rate of this model by saturating the perceptual input, such that it could not have a magnitude greater than a certain value. We refer to this model as the S-VDDM.

To compare the three models we collected data on pedestrian crossing times, using a virtual reality (VR) headset. VR allowed us to carefully control the experimental stimulus (i.e., vehicle approach trajectories) and avoid confounding variables that may be present when observing crossing behavior in the real world (e.g., effects of other pedestrians or additional vehicles on crossing behavior). We used a large range of vehicle approach trajectories, which were specifically chosen with the aim of creating different types of situations with respect to pedestrian affordances and vehicle action intentions.

Virtual Reality Road Crossing Task

Participants

Twenty participants (age 24-60, average 27.9 years; 11 male) took part in the study and were recruited from a University participant pool. All participants provided informed consent, and the study was approved by the University Research Ethics committee.

Materials and Design

Participants wore an HTC Vive Virtual Reality headset while standing. All stimuli were created in Unity 2018. The stimuli consisted of a straight two lane road (width: 5.85 m) with a zebra crossing and pavements on either side. The trial started with the participant standing at the edge of the zebra crossing, looking directly across it. To start the trial the participant turned their head to the right, which (unbeknownst to the participants) instantiated the approaching car at its initial position and speed for the scenario in question. For increased experimental control and simplicity, the participants did not physically walk across the VR pedestrian crossing, but instead pressed a trigger button on an HTC Vive controller when they decided it was safe to cross, and the participant's view point in the virtual world then translated across the crossing at 1.31 $\mathrm{m\,s^{-1}}$. Once the participant had crossed the road in VR, the trial ended. The time at which the participant initiated the crossing, measured from the point at which the vehicle began moving, was the primary outcome measure.

Scenarios

To preserve as much as possible a natural road-crossing behavior, the number of trials per participant was limited to 16. Each of these trials used a different vehicle approach scenario, presented in a pseudo-randomized order to the participants. The scenarios were defined so as to elicit a broad range of different crossing situations, and were of three general types, with parameters as listed in Table 1:

"*Constant velocity*" (6 scenarios): The vehicle appeared at distance D_{init} from the pedestrian, and maintained a constant velocity v_{init}, i.e., it had an initial time to arrival TTA_{init}.

"*Decelerate to a stop*" (8 scenarios): The vehicle appeared at distance D_{init} from the pedestrian, with initial speed v_{init}, and immediately decelerated at a constant rate so as to reach zero speed at distance D_{stop}.

"*Decelerate without stopping*" (2 scenarios): The vehicle appeared at distance D_{init} at speed v_{init} and immediately decelerated at a constant rate until distance D_{stop}, where it continued to travel at a final speed of 5 km/h.

Table 1: Scenario parameters

Scenario type	v_{init} (km/h)	D_{init} (m)	TTA_{init} (s)	D_{stop} (m)
Constant velocity	25	15.90	2.29	N/A
	50	31.81	2.29	N/A
	25	31.81	4.58	N/A
	50	63.61	4.58	N/A
	25	47.71	6.87	N/A
	50	95.42	6.87	N/A
Decelerate to a stop	25	15.90	2.29	4
	50	31.81	2.29	4
	50	31.81	2.29	8
	25	31.81	4.58	4
	50	63.61	4.58	4
	50	63.61	4.58	8
	25	47.71	6.87	4
	50	95.42	6.87	4
Decelerate w/o stopping	50	27.78	2	8
	50	41.67	3	8

Variable-Drift Diffusion Models

We developed three models to capture the road crossing times (CT) of pedestrians in the VR study, as illustrated in Figure 1. All models received the same perceptual inputs. As in Markkula, Romano et al., (2018) the first input was based on the instantaneous apparent time to arrival (TTA) of the vehicle, disregarding any deceleration. This apparent TTA is visually available, as the relative rate of optical expansion τ (Lee, 1976). The model input was given by $\tau - \tau_{pass}$, where $\tau_{pass} = 2.46$ (the time it took to cross the VR road). Thus the model input was positive when it was possible to make it across the road before the vehicle (based on apparent TTA), and negative when it was not. The second model input was based on the derivative of the vehicle's apparent TTA, $\dot{\tau}$. The input was defined as $\dot{\tau} - \dot{\tau}_{pass}$, with $\dot{\tau}_{pass} = -0.5$, corresponding to the vehicle stopping to just exactly touch the participant (Lee, 1976). Thus, the input was positive when the vehicle was decelerating so as to stop before the participant, and negative when not.

For the C-VDDM model these inputs were fed into two separate "perceptual decision" units. For the D-VDDM and S-VDDM model these were linearly combined and fed into a single accumulator unit. For the S-VDDM this combined weighted input was also limited such that it could not exceed a certain magnitude.

Model Specification

The models were all specified on the same general form, following Markkula, Romano et al., (2018), of which a brief summary is provided here. At any point in time t, the activation level of each of the model's accumulator units is described by the vector, $\boldsymbol{A}_t = \left[A_{1,t}, A_{2,t}, \ldots, A_{U,t}\right]^T$, where U is the number of accumulator units, and each unit's activation is limited to $-1 \leq A_{i,t} \leq 1$, with 1 and -1 signifying "yes" and "no" decision states, respectively. At each simulation time step, the activation levels are updated according to,

$$\frac{d}{dt}\boldsymbol{A}_t = -\frac{1}{T}\boldsymbol{A}_t + f_c(\boldsymbol{W}_I D(\boldsymbol{K})\boldsymbol{I}_t, \eta) + \boldsymbol{W}_Y D(\boldsymbol{Y}) f_Y(\boldsymbol{A}_t) + \boldsymbol{W}_N D(\boldsymbol{N}) f_N(\boldsymbol{A}_t)$$

$$\boldsymbol{A}_{t+dt} \sim MultiNorm\left(\boldsymbol{A}_t + d\boldsymbol{A}_t, \boldsymbol{\Sigma}\sqrt{dt}\right),$$

where $\boldsymbol{I}_t = \left[\tau_t - \tau_{pass}, \dot{\tau}_t - \dot{\tau}_{stop}\right]^T$, is a vector of perceptual inputs. $\boldsymbol{K} = [k_1, k_2]^T$ is a vector of relative weights for these two perceptual inputs, $\boldsymbol{Y}$ and $\boldsymbol{N}$ are vectors of connection weights for the "yes" and "no" accumulator output connections respectively and $D(\boldsymbol{x})$ is a diagonal matrix with diagonal $\boldsymbol{x}$. $\boldsymbol{W}_I$, $\boldsymbol{W}_N$ and $\boldsymbol{W}_Y$ are design matrices which specify accumulator inputs and connections, with elements $\boldsymbol{W}_{[j,k]} \in \{0, 1\}$. The function $f_c(\boldsymbol{W}_I D(\boldsymbol{K})\boldsymbol{I}_t, \eta)$ limits the perceptual inputs to the accumulators between $\pm\eta$. In the C-VDDM and D-VDDM η was fixed at infinity (and so had no effect), while in the S-VDDM it was a free parameter. This allowed the S-VDDM's activation to gradually rise to 1, even when the inputs were at large values. The function $f_Y(x)$ limits the input between 0 and 1, thus returning $f_Y(A_{i,t}) = 1$ for an accumulator activation $A_{i,t} = 1$ (a "yes" state), while $f_N(x) = f_Y(-x)$, such that $f_N(A_{i,t}) = 1$ for $A_{i,t} = -1$ (a "no" state). $\boldsymbol{\Sigma}$ is a covariance matrix with all off diagonal elements set to 0, and all diagonal elements sharing the same value, σ^2, representing noise in the decision process.

When the activation of the action decision accumulator reaches a value of 1, a decision to cross the road is made, and the time at which this occurs is the crossing time, CT_m.

Model Fitting

To simplify notation, here we denote all the parameters of a given VDDM model as θ. Fitting to the VR dataset is made challenging as calculating the likelihood function, $P(CT|\theta)$, involves computing a high dimension integral.

Instead we estimated the likelihood function using a large number of data simulations, referred to as the pseudo-likelihood estimation, $\hat{P}(CT|\theta)$. For each trial scenario we generated 5000 simulated crossing times, CT_m, from the model being fitted. We then calculated a numerical probability distribution $\boldsymbol{b}$ over 80 bins equally spaced between 0 and 20 seconds, where $\boldsymbol{b}$ is a vector where each element, b_i, is the relative frequency of CT_m falling into the ith bin. $\hat{P}(CT|\theta)$ was then estimated as the value of $\boldsymbol{b}$ for the bin corresponding to CT.

Due to the finite number of model simulations, with this method it is possible that a bin is assigned zero probability (no values of CT_m fell within that bin), despite the model having support over this region. If CT falls within such a bin then $\hat{P}(CT|\theta) = 0$, which can cause issues for the model fitting. To avoid this, we ensured that all bins had a non-zero probability by adjusting $\boldsymbol{b}$ by a constant $\boldsymbol{z}$, to $\boldsymbol{b}\lambda + \boldsymbol{z}(1-\lambda)$, where $\lambda = .98$. $\boldsymbol{z}$ was set as the probability of drawing a value from any given bin when sampling from a uniform distribution with bounds 0 and 20. In practice this had almost no discernible effect on the estimate of $\hat{P}(CT|\theta)$, but ensured non-zero support over all values of CT. Finally we removed the first "decelerate without stopping" trial from the analysis. This was because many participants began crossing while the vehicle was still in front of them, which the models were not designed to capture.

We used PSO (Wahde, 2008) to fit the models using the pseudo-likelihood estimation method described above. A swarm of 50 particles was used and optimized for 50 iterations. In all cases the algorithm appeared to converge to some local optimum (pseudo log-likelihood estimates stopped increasing) before the 50th iteration.

Table 2: Log likelihood and Akaike information criterion (AIC) for each of the models. *indicates the model with highest log likelihood estimate

Model	$log\ P(CT\|\hat{\theta})$	N param	AIC
C-VDDM	-953.72	7	1921.4
D-VDDM*	-871.90	6	1755.8
S-VDDM	-882.04	5	1774.0

Table 3: Estimated parameter values for each model. Fixed parameters are shown in italics.

Param	C-VDDM	D-VDDM	S-VDDM
T	0.67	0.26	0.34
$\boldsymbol{K}$	[4.35, 0.46]	[0.66, 0.42]	[0.47, 0.19]
$\boldsymbol{Y}$	[*0*, 0.44, 1.83]	[*0*, 3.25]	N/A
$\boldsymbol{N}$	[*0*, 0.76, *0*]	[*0*, 10.0]	N/A
σ	0.87	1.03	1.05
η	N/A	N/A	2.5

Results

Table 2 shows the pseudo log-likelihood estimate and AIC of the VR crossing time data for each of the three models. We can see that the D-VDDM captured the data the best (highest log likelihood) and had the lowest AIC value. The S-VDDM performed slightly worse, while the C-VDDM performed poorer than both. The parameters returned by the PSO algorithm are shown in Table 3.

To explore the model fits in more detail we simulated 5000 crossing times (CT_m) for each vehicle approach scenario and each fitted models. The left panel of Figure 2 shows the real CT (top panel), and simulated CT_m (bottom panel) for one of the "constant velocity" scenarios. We also plot the model activations for the S-VDDM (black traces, bottom panel). In this trial the vehicle starts far enough away that the participant has time to successfully cross the road, if this decision is made relatively quickly. However, the vehicle soon comes too close for a successful crossing to take place. Some participants crossed early in the vehicle's trajectory, while some waited for the vehicle to pass. All of the models were able to capture this trend. However, it appears that the S-VDDM (blue line; bottom panel) and

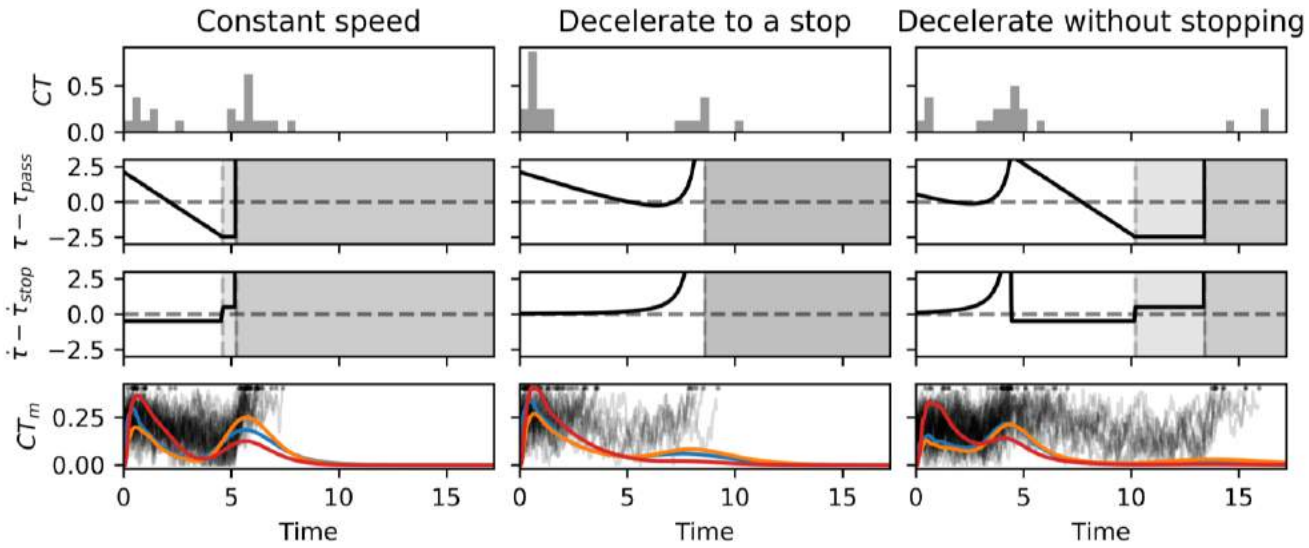

Figure 2: Human and model behavior in three example scenarios. Top panels show the observed human crossing times (CT) in the virtual reality experiment, and the second and third rows of panels show the sensory input cues to the models. Dark grey regions indicate that the vehicle has come to a stop or has passed the participant. Light grey regions indicate that the vehicle is passing the participant. The bottom panels show the simulated crossing time (CT_m) for the C-VDDM (red lines), D-VDDM (orange lines), and S-VDDM (blue lines). The black traces show example activations of the S-VDDM accumulator unit.

especially the C-VDDM (red line; bottom panel) showed a larger peak around the early crossings, while the D-VDDM (orange line; bottom panel) showed a larger peak after the vehicle had crossed, which better matched the participants' behavior.

The middle panels of Figure 2 shows the same plots for one of the "decelerate to a stop" scenarios. Again, we observed a bimodal distribution of crossing times (top panel), with some participants crossing early in the vehicle's trajectory, and others waiting until the vehicle had nearly or completely stopped. Here both the D-VDDM and S-VDDM captured this trend rather well, with a larger mode at the early crossing times and a smaller mode after the vehicle stopped. However, the C-VDDM was not able to capture the later crossing mode.

The right panels of Figure 2 show the same plots for one of the "decelerate without stopping" trials. Here, beyond the bimodal pattern already described for the "decelerate to a stop" scenario, a small number of participants also waited for the vehicle to completely pass before crossing. Thus the observed CT showed a tri-modal distribution. Both the D-VDDM and S-VDDM models reproduced these three modes well (the third mode is rather flat, but its presence can be seen from the black activation traces in bottom panel), while again the C-VDDM appeared to place too much weight over the initial mode, and predicted close to zero participants crossing after the vehicle had passed. Figure 3 shows the observed CT and model simulations, CT_m, for all scenarios.

However, we were concerned that the more complex C-VDDM's poor performance might be caused by the PSO algorithm getting stuck in a local optimum. Indeed, rerunning the fitting of the different VDDMs with new initial random seeds, and/or additional constraints on the parameter search range, we obtained slightly different parameterizations, but for the C-VDDM these never performed better than either the D-VDDM or S-VDDM.

Assuming that the C-VDDM's poor relative performance is not the result of challenges in finding the global optimum, we wondered whether one issue might be that the connected accumulator models all share a single σ parameter. Thus we refit the C-VDDM model with a separate σ parameter for each accumulator unit. This improved the model fit, achieving a log likelihood of -874.17 (AIC 1766.3), a better fit than for the S-VDDM and approaching the performance of the D-VDDM. For completeness, we also tested a version of the D-VDDM with separate σ parameters for its two accumulator units, achieving a log likelihood of -924.66 (AIC 1863.3), i.e., a worse fit than the single-σ D-VDDM. This is clearly a local optimum, since the better-performing single-σ D-VDDM is actually present in the parameter search space of the dual-σ VDDM (along the line where both σ are equal).

Discussion

Here we explored the ability of variable-drift diffusion models (VDDMs) to capture complex sensorimotor decisions based on a continuous stream of multiple sensory cues. Our initial hypothesis was that a complex model consisting of several parallel VDDM processes (the C-VDDM) would be needed to capture the multimodal decision time distributions exhibited by humans in the zebra crossing situation. Instead, we found that a relatively simple model with just a single VDDM unit (the S-VDDM) and five free parameters was able to reproduce multimodal probability distributions of human crossing times, across 15 separate scenarios with a diverse range of vehicle approach

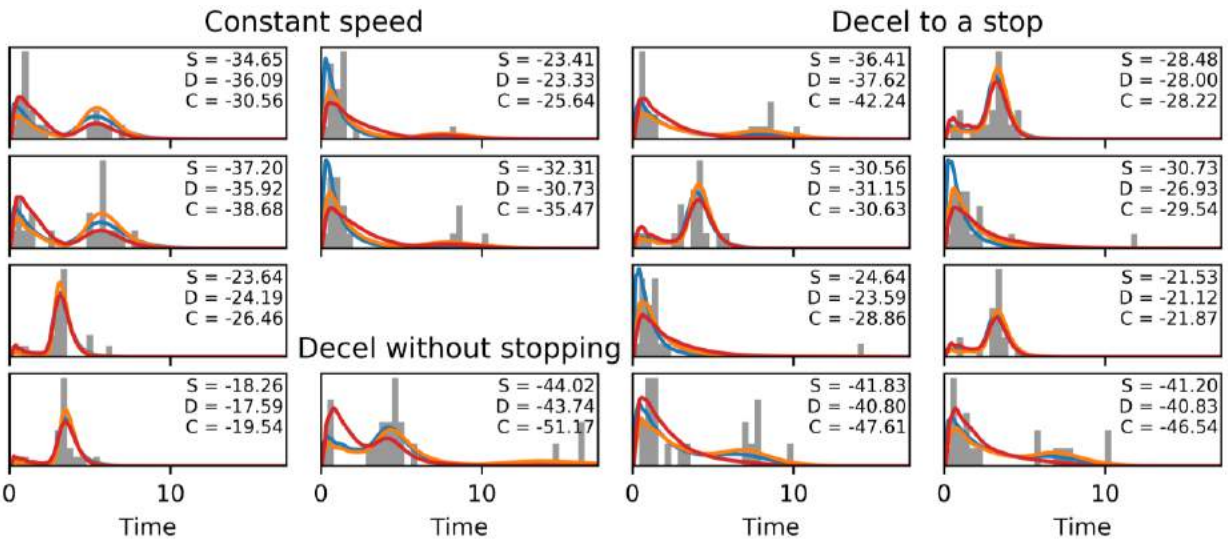

Figure 3: Observed crossing times versus predictions by the C-VDDM (red lines), D-VDDM (orange), and S-VDDM (blue) for all scenarios. Y-axis scale varies between panels. The text shows density estimate log-likelihoods for the three models.

trajectories. This is arguably the most striking finding from this work.

One important insight here, and seemingly a main reason behind the good performance of the S-VDDM, is that the τ variable (the apparent time to arrival; TTA), can in itself help explain the observed human behavior to a large extent. As seen in Figure 2, with more positive $\tau - \tau_{pass}$, participants became more likely to initiate crossing, and the non-trivial variation of τ over time during each scenario seemed to drive the number and location of peaks in the crossing time distribution. The VDDM provides a potential mechanistic explanation for how the observed crossing time distribution arises from this time-varying perceptual input.

Another critical aspect of the S-VDDM model was that while the drift rate was allowed to vary as a function of the perceptual inputs, we also limited its magnitude with a saturation threshold parameter. This ensured that large inputs, arising when the vehicle decelerated to a stop, did not result in the drift rate immediately trending to a very large value. This enabled the model to capture the distribution of crossing times that are observed after a vehicle comes to a stop or passes.

With respect to the more complex model variants, it is difficult to draw firm conclusions from the present results. If the C-VDDM model had been able to capture qualitative aspects of the human data that the S-VDDM was unable to, this could have been taken as tentative evidence for the C-VDDM's hypothesized partition of the decision process into constituent perceptual and action decisions. However, since the best version of the C-VDDM, with three separate σ parameters, simply improved the goodness of fit without changing the qualitative nature of the model behavior, it cannot be excluded that the added model complexity simply led to overfitting to the present data. To further investigate whether there is some merit to the hypotheses behind the C-VDDM, larger datasets with even more diverse scenarios would be useful, and more stringent methods than AIC for controlling for overfitting, such as hold-out validation on parts of the dataset.

Exactly the same argument applies to the D-VDDM, which was the model for which the overall best fit was obtained. The D-VDDM was adopted here as an intermediate-complexity model, in practice replacing the static input saturation step of the S-VDDM with a time-dynamic accumulator. Again, for the same reasons as mentioned above, further work is needed to shed light on whether the improved fits for this model over the S-VDDM have some theoretical relevance.

These difficulties in drawing conclusions from the fits of the more complex models are exacerbated by the apparent tendency of the PSO algorithm to get stuck in local optima. This was evidenced clearly when the PSO found a provably suboptimal parameterization for the two-σ D-VDDM, but may also be part of the reason for the somewhat surprising finding that the relatively complex single-σ C-VDDM yielded the poorest goodness of fit across all tested models. Existing methods for efficient DDM fitting are based on the conventional assumption of constant drift rate (e.g., Vandekerckhove, Tuerlinckx, & Lee, 2011); good methods for fitting also VDDMs would be a valuable future pursuit.

In summary, we demonstrate that already simple VDDMs are able to capture sensorimotor decision making behavior in a task that is more complex, and arguably of higher applied relevance, than the laboratory decision-making tasks typically modelled with DDMs. We suspect that VDDMs could be applied to a wide range of non-trivial real world sensorimotor decision making tasks, but methodological developments are needed to efficiently and reliably fit these models to data.

Evidence of error-driven cross-situational word learning

Abstract

One powerful way children can learn word meanings is via cross-situational learning, the ability to discern consistent word-referent mappings from a series of ambiguous scenes and utterances. Various computational accounts of word learning have been proposed, with mechanisms ranging from storing and testing a single hypothesized referent for each word, to tracking multiple graded associations and selectively strengthening some of them. Nearly all word learning models assume storage of some feasible word-referent mappings from each situation, resulting in a degree of learning proportional to the number of co-occurrences. While these accumulative models would generally predict that incorrect co-occurrences would slow learning, recent empirical work suggests these accounts are incomplete: paradoxically, giving learners incorrect mappings early in training was found to boost performance (Fitneva & Christiansen, 2015). We test this finding's generality in a new experiment with more items, consider system- and item-level explanations, and find that a model with error-driven learning best accounts for this benefit of initially-inaccurate pairings.

Keywords: cross-situational word learning; error-driven associative learning model; word learning;

Introduction

Among the many challenging aspects of learning a language is the problem of determining which words pick out which referents in our environment. When we encounter a new word, there is rarely an explicit explanation of its meaning, and the context it appears in may present any number of possible referents. While any given situation may present a high degree of ambiguity with many possible referents, if learners are able to roughly track words and referents that often co-occur, they may learn word meanings cross-situationally (Gleitman, 1990). Both infants and adults have been found capable of cross-situationally learning names for novel objects in the laboratory (Smith & Yu, 2008; Yu & Smith, 2007; Kachergis & Yu, 2013), and such learning may be one important means of acquiring the meanings of nouns (Smith, 2000).

It is generally assumed that learners accomplish cross-situational learning by tracking the co-occurrence of each uttered word with a subset of the visible referents in a scene. A variety of biases have been proposed that could enable the learner to restrict the number of word-referent mappings they must attend to and remember. For example, the learners have been shown to exhibit a mutual exclusivity bias, preferring to map each word to one referent–and vice-versa (Markman & Wachtel, 1988; Markman, Wasow, & Hansen, 2003; Ichinco, Frank, & Saxe, 2009). Despite a variety of proposed biases and constraints, considerable debate remains about the exact mechanisms underlying this ability.

Models of Cross-situational Word Learning

A variety of computational models have been proposed, ranging from models that store and test a single hypothesized referent per word (Trueswell, Medina, Hafri, & Gleitman, 2013), to Bayesian models, (Frank, Goodman, & Tenenbaum, 2009), to associative learning models (Kachergis, 2012; Fazly, Alishahi, & Stevenson, 2010). Typically, most models can match overall human learning performance in several experiments, and can be hard to distinguish on the basis of goodness of fit. However, detailed modeling of human learning trajectories (Kachergis & Yu, 2017) and performance in systematically varied conditions (e.g., repetitions and context diversity: (Kachergis, Yu, & Shiffrin, 2016); repetitions and number of distractors: (Yurovsky & Frank, 2015) have revealed interacting memory and attentional constraints that help differentiate models.

In many accounts of cross-situational learning, it is assumed that forming an association (or hypothesis) between a word and referent makes future exposures more valuable, as the familiar trace will draw more attention if confirmed. This advantage for prior knowledge (i.e., "rich-get-richer") is present both in hypothesis-testing accounts such as the propose-but-verify model (Trueswell et al., 2013), as well as in associative accounts that allocate more attention to pre-existing associations (Kachergis, 2012).

However, errors also play an important role in a variety of types of learning. For example, in motor control learning is thought to be based on a mismatch between predicted sensory outcomes of an action and the actual sensation (Seidler, Kwak, Fling, & Bernard, 2013). Similarly, models of animal and human conditioning experiments (Kamin, 1968; Rescorla & Wagner, 1972; Kruschke, 2011) adjust associations based on how surprising an outcome is when given particular cues. A classic example of a prediction error-based learning mechanism is the (Rescorla & Wagner, 1972) model in which the amount of learning on a trial is proportional to the amount of prediction error (i.e., surprise at an outcome). When there is a large difference between the actual outcome and predicted outcome, a large change in the predictive value of a stimulus results. Applied to cross-situational learning, surprise will be generated by the failure of a word and referent to appear together when they have been previously associated. This surprise, generated by the difference between the expectation of the word, given that object, and the actual outcome (failure of the word to appear), results in a higher learning rate for a new word to be associated with that object. Despite the widespread evidence of prediction error-based learning in the animal kingdom, empirical investigations of its role in

word learning have been limited (though see Ramscar, Dye, and McCauley, 2013). Most cross-situational word learning experiments do not facilitate continuing prediction errors: in most designs, each time a word is heard its intended referent is visible, and thus as learning proceeds, the surprise that is initially generated due to the discrepancy between the words a learner predicts and what they actually hear will only decrease.

Findings from two recent empirical studies investigating erroneous mappings early in learning suggest that greater prediction error may play an important role in cross-situational word learning (Fitneva & Christiansen, 2011, 2015). In Fitneva and Christiansen (2011), eye-tracking during cross-situational learning was used to investigate the performance of learners who by chance initially looked longer or shorter at the correct referent when a word was heard. Participants were trained on 24 word-referent pairs in four blocks, seeing two referents on each trial while hearing two sequential pseudowords. A post-hoc median split based on location of longest fixation when a word was first heard was used to place participants into High and Low Initial Accuracy conditions (HIA and LIA, respectively). Thus, participants in the HIA condition happened *by chance* to look at more of the intended referents upon each word's first occurrence than the LIA participants, who happened to look more at the incorrect referents. The accuracy of each trial in the first block (i.e., initial accuracy) was determined by the fixation time on each referent after each pseudoword was displayed. A subset of 12 of the words was used for 2-alternative forced choice (2AFC) test, in which a participant heard a word and selected the better of two referents. Participants in the LIA condition outperformed the HIA group at test. Additionally, eye tracking data provided implicit evidence for increased learning among LIA participants. In instances where the correct referent was the first location of fixation, the LIA group took longer to look away than the HIA group, and when the location of first fixation was inaccurate the LIA group was quicker to move their gaze. Proportion of time spent fixated on the accurate referent increased in LIA participants, past that of HIA participants.

A follow-up study used a "familiarization" phase before a similar cross situational learning task to induce differences in initial accuracy, and tested three age groups: 4 year-olds, 10 year-olds, and adults (Fitneva & Christiansen, 2015). In the familiarization phase, 10 unambiguous word-object pairs were serially presented to participants. However, four of these pairs would be switched in the subsequent cross-situational training for participants randomly assigned to the HIA condition (60% initial accuracy), while six of the 10 pairs would be switched in the LIA condition (40% initial accuracy). This exposure was meant to seed more (LIA) or fewer (HIA) inaccurate hypotheses/associations before the subsequent cross-situational training, which presented 15 2x2 trials (i.e., two word-referent pairs per trial). Adult participants in the LIA condition again showed higher performance than those in the HIA condition, in line with the prior results. Notably, the initial accuracy of an item within a given condition seemed to have no significant effect on performance. (Fitneva & Christiansen, 2015) interpreted this lack of an item-level effect as evidence of a 'system-level' effect, meaning that "the effect emerges from the cognitive resources recruited by initially inaccurate items affecting initially accurate items as well" (p. 5). Interestingly, four year-olds showed an opposite effect of condition, with HIA participants performing better, and 10 year-olds showed only an effect of item category, performing better on initially accurate items in both conditions.

Fitneva and Christiansen (2015) suggest that the lack of item-level effects of initial inaccuracy in adults (and in 4-year-olds) may be taken as evidence of system-driven learning: rather than individual initially-inaccurate items garnering extra attention (compared to IA items), more cognitive effort is expended overall by adults in the Low IA condition, triggered by the many inaccuracies. The present study again considers system-level vs. item-level effects of IA in adults by conducting an experiment with more to-be-learned items than Fitneva and Christiansen (2015) (18 vs. 10), and with a more sensitive 19-alternative forced choice (19AFC) test. A potential concern about finding item-level effects of IA in Fitneva and Christiansen (2015) is that adults had quite high performance in the task, which tested half of the 10 studied words using a 2AFC test. In addition, the difference between the HIA and LIA conditions was one of only two words (6 out of 10 and 4 out of 10 accurate, respectively).

The superior performance on initially inaccurate items in both experiments may be accounted for with a prediction error mechanism. An additional attentional account may be able to account for the overall difference in performance between the HIA and LIA conditions. Thus, the present design offers a stronger manipulation, more data per participant, and a more sensitive test, while addressing the same underlying issue of the effects of initial accuracy on learning. We then present modeling in an associative learning framework to determine if learning behavior is better accounted for by an attentional (system-level) mechanism, or by a prediction error-based (item-level) mechanism.

Experiment

To investigate the robustness of the effect of low initial accuracy observed in Fitneva and Christiansen (2015) in a setting with more to-be-learned items and a consequently longer training period, we use a similar 2x2 procedure with a "familiarization phase". However, in our design, we used studied 18 stimulus pairs (vs. 10), and a greater degree of difference between between high and low initial accuracy (12 vs. 6 of 18 pairs switched instead of 6 vs. 4 of 10 pairs switched). This presents a stronger manipulation of initial accuracy: 66.6% vs. 33.3% in the current study, compared to 60% vs. 40% in Fitneva and Christiansen (2015). In addition, at test we presented the full array of possible referents for each word (18 studied + 1 unstudied: 19AFC vs. 2AFC), and tested all 18 words (vs. 5 of 10).

Methods

Participants Participants were 45 people recruited online who completed the experiment in their web browser through Amazon Mechanical Turk. All participants completed the entire experiment, and were paid $1.50 for their participation. Participants were randomly assigned to either the High or Low Initial Accuracy condition (23 and 22 participants, respectively).

Stimuli Stimuli consisted of images of uncommon real-world objects and mono- and bisyllabic nonce words. Each participant was given a random selection of 18 images and 18 nonce words from a collection of 72 images and words.

Procedure The experiment consisted of three phases: familiarization, study, and test. The familiarization phase was one block of 18 trials. Participants were told they would be shown examples of the type of objects and words they would be learning. Each trial showed one object-pseudoword pair for 3 s with a 1 s interstimulus interval (ISI), with each of the 18 pairs being shown once, in a randomized order.

For participants in the Low Initial Accuracy (LIA) condition, 12 of the 18 pairs were switched (inaccurate) in the subsequent study phase, yielding 33.3% initial inaccuracy. In the High Initial Accuracy (HIA) condition, 6 of the 18 pairs were switched at study, yielding 66.6% initial accuracy. For each participant, the total number of objects was constant, such that when word-object pairs were switched at study, both the word and object had been seen in the familiarization phase.

On each trial during the study phase, two word-object pairs were shown simultaneously for 3 s, with a 1 s ISI. Objects were shown side by side, with words vertically arrayed in the center, below the object images. The location of objects and words was randomized to ensure participants could not reliably determine the pairing of stimuli by their location with respect to one another. Trial order, along with which word-object pairs were shown on a given trial, was randomized with the constraint that each word-object pair was presented once before being shown again. Thus, there were three (contiguous) blocks of 9 trials, for a total of three presentations per pair.

In the test phase, each trial displayed an array of all 18 studied objects along with one novel object (the same across all test trials) and a single pseudoword from the study. For each pseudoword, participants were instructed to click on the corresponding object. In addition to testing each of the 18 studied pseudowords, a trial with a novel pseudoword was added, to determine if participants were able to fast-map this novel word to the novel object in the array. The order of test trials was randomized for each participant.

A post-test questionnaire asked participants how many words they thought they mapped correctly (0-19), their rating of the engagement and difficulty of the task on scales of 1-7, and whether they used any external memory aids (Yes/No; indicating that they would still be paid, regardless).

Results

Participant's item-level accuracy data for each studied item were subjected to a logistic mixed-effects regression with condition (High Initial Accuracy (HIA) or Low Initial Accuracy (LIA)) as a between-subjects factor and item category (Initially Accurate or Initially Inaccurate) as a within-subject factor. Mixed-effects regression is more appropriate for forced-choice data than ANOVAs, especially for experiment designs with imbalanced cells such as this one (Jaeger, 2008). The analysis was conducted using the `afex` `R` package (Singmann, Bolker, Westfall, & Aust, 2018). This analysis indicated a significant main effect of item category (F(1,43.7)=42.19, $p < .001$), and no significant main effect of condition (F(1,43.7)=0.86, $p = .36$). Learners had higher performance for items that were initially accurate (M=.59, SD=.31) than for items that were initially inaccurate (M=.35, SD=.30). There was a marginal interaction of condition and item category (F(1,43.7) = 3.50, $p = 0.07$). Shown in Figure 1, accuracy on initially inaccurate items was higher in the LIA condition (M=.42, 95% CI=$[.30, .55]$) than in the HIA condition (M=.28, CI=$[.15, .40]$), but lower than initially accurate items, which were similarly high in both conditions (IA: LIA M=.60, CI=$[.46, .73]$; HIA M_{HIA}=.59, CI=$[.47, .72]$). Overall, in both conditions participants learned on average the same proportion of the 18 items (M_{HIA}=.49; M_{LIA}=.48). Finally, for the novel word presented at test, 47% of participants chose the unstudied test object.

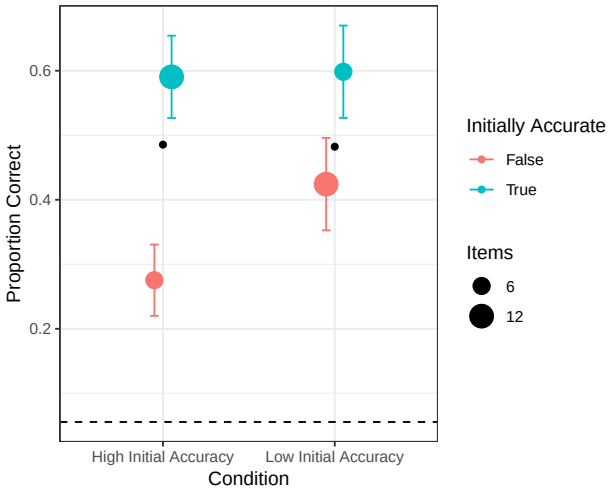

Figure 1: Participants' mean accuracy at test in each condition by item category, with dot size denoting the number of items that could be learned in that category. Black dots show mean performance per condition. Dotted line shows chance (1/18). Error bars represent ± 1 SE.

Post-test Questionnaire To investigate metacognitive awareness, individuals' performance was correlated with post-test questionnaire results. Participants in both conditions

were aware of their performance level, with significant correlations between their actual and estimated number of learned items they learned (HIA $r(20) = 0.67$, $p < .001$) and LIA ($r(18) = 0.60$, $p < .01$)). Rank-order tests were used to investigate the relationship of engagement and difficulty ratings with performance at test. Strong negative relationships between performance at test and difficulty ratings were found in both HIA ($r_s = -0.73$, $p < .001$) and LIA ($r_s = -0.77$, $p < .001$) conditions. A system-level account of benefits of initial inaccuracy might predict that difficulty would be higher in the LIA condition, but that engagement would be higher. However, there was no difference in participant's perceived level of difficulty in the two conditions ($t(42.7) = 0.56$, $p = .57$), and participants in the HIA condition trended toward being more engaged than LIA participants ($t(38.6) = 1.87$, $p = .07$)–the opposite of what might be predicted by a system-level account.

Discussion

Our results differ somewhat from those of Fitneva and Christiansen (2015) in that we do not find an overall advantage for the Low Initial Accuracy condition. Moreover, we find in both conditions that initially accurate items are learned more often than initially inaccurate items, in agreement with conventional assumptions. However, we do find that initially inaccurate items are learned at a greater rate when they are a greater proportion of the study items (i.e., in the LIA condition). Given that this experiment has a stronger manipulation of initial accuracy (66% vs. 33% instead of 60% vs. 40%), includes more studied items (18 instead of 10), and tests all 18 of them (instead of half) with a more sensitive test (19AFC instead of 2AFC), we contend that it makes a stronger case for the influence of varying initial inaccuracy on cross-situational learning. In the following, we explore what mechanisms account for these effects.

Models

To determine whether the effect of initial accuracy implies novel system-level or item-level learning mechanisms, we first test whether the biased associative model (Kachergis, Yu, & Shiffrin, 2012), with competing attentional biases for existing associations and for attending to stimuli with uncertain associates, is able to account for the effect of varying initial accuracy. This model, explained in detail below, has successfully captured human behavior in a variety of cross-situational learning experiments (Kachergis & Yu, 2017; Kachergis et al., 2016; Kachergis, 2012; Kachergis & Yu, 2013). We also test two modified versions of this model, representing the two theories of why forming initial inaccurate associations may improve overall learning. In the system-level variant, the learning rate on each trial was scaled by the model's relative uncertainty about the words for each presented referent, representing the theory proposed in (Fitneva & Christiansen, 2015) that learners may be more alert in the Low Initial Accuracy condition. In the item-level variant, we add a simple prediction error-based learning mechanism borrowed from Rescorla and Wagner (1972).

Biased Associative Model

The biased associative model (Kachergis et al., 2012) assumes that learners do not attend equally to all possible word-object pairings. Thus, although all co-occurrences are registered to some extent in associative memory (a word $\times$ object association matrix), greater attention and storage is directed to pairings that have previously co-occurred. Moreover, this bias for familiar pairings competes with a bias to attend to stimuli that have no strong associates (e.g., novel stimuli). In addition to familiar associations being reinforced, attention is also pulled individually to novel stimuli because of the high uncertainty of their associations (i.e., they have diffuse associations with several stimuli). Uncertainty is tracked by the entropy of a stimulus' association strengths, and attention is allocated to a stimulus in proportion to this entropy.

Formally, given n words and n objects to be learned over a series of trials, let M be an n word $\times$ n object association matrix that is built incrementally during training. Cell $M_{w,o}$ will be the strength of association between word w and object o. Strengths are augmented by viewing the particular stimuli. Before the first trial, M is empty. On each training trial t, a subset S of m word-object pairings appears. If there are any new words and objects are seen, new rows and columns are first added. The initial values for these new rows and columns are k, a small constant (here, 0.01).

Association strengths are allowed to decay, and on each new trial a fixed amount of associative weight, χ, is distributed among the associations between words and objects, and added to the strengths. The rule used to distribute χ (i.e., attention) balances a preference for attending to unknown stimuli with a preference for strengthening already-strong associations. When a word and referent are repeated, extra attention (i.e., χ) is given to this pair—a bias for prior knowledge. Pairs of stimuli with no or weak associates also attract attention, whereas pairings between uncertain objects and known words, or vice-versa, do not attract much attention. To capture stimulus uncertainty, strength is allocated using entropy (H), a measure of uncertainty that is 0 when the outcome of a variable is certain (e.g., a word appears with one object, and has never appeared with any other object), and maximal ($log_2 n$) when all of the n possible object (or word) associations are equally likely (e.g., when a stimulus has not been observed before, or if a stimulus were to appear with every other stimulus equally). In the model, on each trial the entropy of each word (and object) is calculated from the normalized row (column) vector of associations for that word (object), $p(M_w, \cdot)$, as follows:

$$H(w) = -\sum_{i=1}^{n} p(M_{w,i}) \cdot \log(p(M_{w,i})) \quad (1)$$

The update rule for adjusting the association between a given word w and object o on a given trial is:

$$M_{w,o} = \alpha M_{w,o} + \frac{\chi \cdot e^{\lambda \cdot (H(w)+H(o))} \cdot M_{w,o}}{\sum_{w \in W} \sum_{o \in O} e^{\lambda \cdot (H(w)+H(o))} \cdot M_{w,o}} \quad (2)$$

In Equation 2, α is a parameter governing forgetting, χ is the weight being distributed, and λ is a scaling parameter governing differential weighting of uncertainty ($H(\cdot)$; roughly novelty) and prior knowledge ($M_{w,o}$; familiarity). As λ increases, the weight of uncertainty (i.e., the exponentiated entropy term, which includes both the word and object's association entropies) increases relative to familiarity. The denominator normalizes the numerator so that exactly χ associative weight is distributed among the potential associations on the trial. For stimuli not on a trial, only forgetting operates. As each word w is tested, learners choose referent o from the m alternatives in proportion to associative strength $M_{w,o}$.

Biased Associative Model with Attention

To capture the theory proposed in (Fitneva & Christiansen, 2015) that learners may be more alert in the Low Initial Accuracy condition, we scale the learning rate used on each trial by the mean entropy of the objects on a given trial, relative to the overall entropy of all associations. Thus, trials with more uncertain items–as in the Low IA condition, and particularly for initially inaccurate items–will have a higher learning rate.

Predictive Biased Associative Model

This model differs from the original Biased Associative Model in two ways. First, for the cues (objects) on the trial, let the prediction of each outcome (word w) be

$$V_w = \sum_{o \in O} M_{w,o} \quad (3)$$

V_w was added to the update equation for on-trial word-object associations as a prediction error term

$$M_{w,o} = \alpha M_{w,o} + \chi \cdot e^{\lambda \cdot (H(w)+H(o))} \cdot M_{w,o} \cdot (\beta - V_w) \quad (4)$$

where β is the maximum association value (here, 1), and as before α is a memory fidelity parameter, χ is a learning rate, and λ is relative novelty/familiarity focus. The second difference is the removal of the denominator, which makes it possible for the predictive model to distribute different amounts of associative weight per trial. Thus, the amount of adjustment for a particular association $M_{w,o}$ is scaled not only by the current strength of that association and the uncertainty (entropy) of w and of o, but also proportional to the prediction error of w from the sum of all associations involving w and objects on that trial.

Model Fitting

All models were fit hierarchically: first, differential evolution optimization (Ardia, Mullen, Peterson, & Ulrich, 2015) was used to find best-fitting parameters for each individual, and then optimization was run again with a regularization term to penalize parameter values far from the medians of the group's parameter values.[1]

Model Results

The best-fitting performance achieved by each model, along with Mean Squared Error (MSE) are shown in Figure 2, as well as in Table 1. All variants of the Biased Associative Model (BAM) match performance well in the HIA condition, for both initially accurate and inaccurate items. However, in the LIA condition, both the original BAM and BAM + Attn underestimate human performance on initially inaccurate items and overestimate learning of initially accurate items, while the Predictive BAM fits well.

Condition	High IA		Low IA			
Initially Accurate	False	True	False	True	MSE	r^2
Human	.28	.59	.42	.60	–	–
Biased Assoc.	.26	.60	.30	.66	.026	.939
Biased Assoc. + Attn	.27	.60	.34	.67	.025	.941
Predictive Biased Assoc.	.27	.59	.40	.63	.008	.983

Table 1: Human performance vs. best-fitting models.

Model Discussion

All models match human performance well in the High Initial Accuracy (HIA) condition, and predict slightly higher than observed performance for initially accurate items in the Low IA condition. Both the original Biased Associative Model (Kachergis et al., 2012) and the variant with a learning rate scaled to the uncertainty (i.e., entropy) about items on the current trial are unable to match human performance for initially inaccurate items in the Low IA condition. However, the variant of the Predictive Biased Associative Model does match human performance, suggesting that learners allocate more attention to associations involving words from initially inaccurate items as a result of prediction error.

Discussion

Similar to earlier studies of the effects of initial accuracy on cross-situational word learning (Fitneva & Christiansen, 2011, 2015), our findings show that experiencing a single initial inaccurate mapping of more word-object pairs selectively benefits the later learning of those initially mismatched pairs. However, in contrast to prior research, which found overall higher learning in the Low Initial Accuracy condition, we found the benefit was not conferred on initially accurate items. Rather, performance on initially accurate items in our experiment was similarly high in both conditions–and higher than initially inaccurate items in either condition. As mentioned earlier, the present experiment presents a stronger test of the effects of initial accuracy due to the stronger manipulation, the larger number of studied and tested words, and the

[1] This approximates Gaussian L1-regularization.

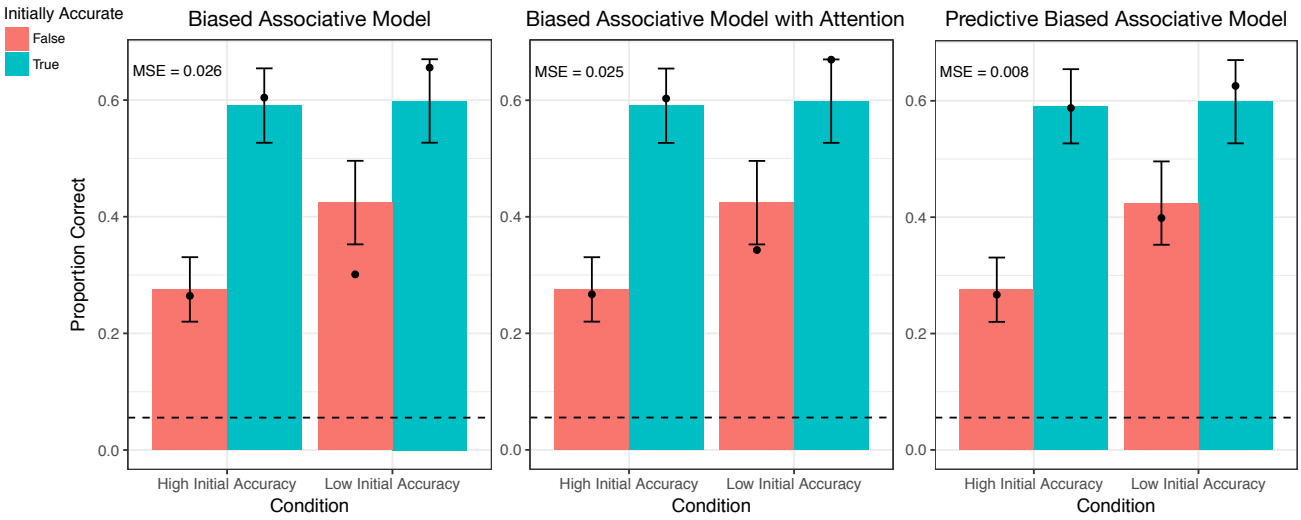

Figure 2: The Biased Associative Model (left) fails to show much benefit for initially inaccurate items in the Low IA condition, unlike people. This is largely true for the variant of the model that gives greater attention to trials with high-entropy stimuli (middle), while the associative model with prediction-error based learning (right) fits quite well (MSE=.008).

lower chance rate of the test format. However, we should note that our stronger manipulation resulted in a slightly higher proportional imbalance of item types per condition (67% vs. 33%)–although we did have more items of both types per condition. It's possible that this greater number of items influenced participants' awareness and thus their treatment of initially inaccurate items. However, we note that difficulty was similarly rated similarly in both groups, and engagement trended higher in the HIA group–opposite to what might be expected if more attention was drawn by the LIA condition.

Our item-level results show that initial accuracy predicts a greater chance of remembering the pairing of that item, which is in accordance with conventional assumptions. However, in the LIA condition initially inaccurate pairs are ultimately more likely to be learned. One explanation may be that errors draw attention selectively to initially inaccurate items. Analysis of fixation times in the eye-tracking experiment of Fitneva and Christiansen (2011) indeed suggests that attention to targets overall increases with greater error. Additionally, the pattern of our results suggests an attention effect: the HIA condition may have included too low a proportion of inaccurate items to draw attention attention away from the majority accurate items. In the LIA group, if there was an overall increase in attention, we should expect to see an increase in performance for initially-accurate (IA) items as well, especially as there were only six IA items in this condition. Our modeling results are consistent with this idea, as without a learning rate proportional to item-level prediction error the fit is notably poor for initially inaccurate items in the LIA condition.

Together with Fitneva and Christiansen (2011, 2015), our results suggest that cross-situational word learning is subject to prediction error-based learning. Our account suggests that when learners see referents they may predict which words will be heard. Subsequently, they allocate attention based on competing biases toward known associations and referents with uncertain associations (Kachergis et al., 2012), and learn at a rate proportional to their surprisal at hearing each word with the given referents. Further research is needed to determine whether this item-level prediction error-based learning mechanism accounts for human behavior—both in typical research settings which offer few inaccurate mappings, as well as in more naturalistic scenarios—to help us further understand the domain-generality of error-based learning.

A comprehensive examination of preschoolers' probabilistic reasoning abilities

Samantha Gualtieri (sgualtieri@uwaterloo.ca) & Stephanie Denison (stephanie.denison@uwaterloo.ca)
Department of Psychology, University of Waterloo
Waterloo, Ontario, Canada

Abstract

Historically, research on preschool-aged children's probabilistic reasoning abilities has yielded mixed results. Although some findings have suggested that young children can successfully evaluate probabilities, others have suggested that they may use strategies that only approximate true probabilistic inference and therefore sometimes make errors (e.g., Girotto et al., 2016; Piaget & Inhelder, 1975). To explore the factors that affect young children's probabilistic reasoning, we developed a battery of problems that contained features that affect the ease with which a problem is evaluated, and the types of alternative strategies that can be applied to solve them. The current experiments (total $N = 124$) assessed 3- and 4-year-old children's probabilistic reasoning using an experimental paradigm tailored to this age group. Results from both experiments suggest that young children are able to engage in true probabilistic inference, as they performed well-above chance on each problem. Nuances in children's performance are discussed, along with possibilities for future research.

Keywords: probabilistic reasoning; cognitive development; decision making

Introduction

Our ability to make inferences under uncertainty is critical to learning and decision-making, mimicking the contexts in which every day reasoning tends to occur. That is, we are typically in situations where we only have access to probabilistic information. Although sensitivity to base-rates is evident very early in development, questions remain regarding young children's strategies for using base-rates in their inferences, which can be diagnosed by asking children to make more complex proportional comparisons.

Non-human primates, infants, toddlers, and preschoolers correctly infer that an object of the majority type is most likely to be randomly sampled from simple probabilistic distributions (Denison, Konopczynski, Garcia, & Xu, 2006; Denison & Xu, 2010; Denison & Xu, 2014; Eckert, Call, & Rakoczy, 2017; Goldberg, 1966; Kushnir, Xu, & Wellman, 2010; Ma & Xu, 2011; Rakoczy et al., 2014; Téglás, Girotto, Gonzalez, & Bonatti, 2007; Téglás et al., 2011; Xu & Garcia, 2008; Yost, Siegel, & Andrews, 1962). For example, if a distribution has more red than white balls (e.g., 80 red and 20 white), they infer that a small sample taken from that distribution should also have more red than white balls. Although young children and non-human primates perform above chance on many probability problems, poor performance has been observed in some experiments, particularly in the 3- and 4-year-old age group (Girotto, Fontanari, Gonzalez, Vallortigara, & Blaye, 2016; Girotto & Gonzalez, 2008; Piaget & Inhelder, 1975). The current experiments explore whether some of this variability in performance is due to differences in problem difficulty by manipulating features of the problem that diagnose strategy use. We used a paradigm designed specifically for 3- and 4-year-olds to ensure that their abilities were not masked by difficulties with, or lack of engagement in, the task itself.

When adapting a task for a particular population, it is important to ensure that the paradigm is suitable to their abilities and still captures the essential aspects of the skill of interest. Issues regarding task-appropriateness have arisen throughout the course of research on children's probabilistic reasoning. Though Piaget's seminal work provides one of the first analyses of children's probabilistic reasoning abilities (Piaget & Inhelder, 1975), younger children's performance may have suffered due to the very high verbal demands of the task. Participants were asked which color item the experimenter was most likely to obtain on a random draw (Yost et al., 1962). Children's responses were then coded as correct based on their explicit reference of probabilistic concepts. From this work, it was concluded that children younger than 12 years of age struggled with probabilistic concepts. Conversely, presenting preschoolers with a choice paradigm suitable for infants and primates (e.g., Denison & Xu, 2014; Rakoczy et al., 2014) also appears to hinder their performance. When designing tasks for pre-verbal infants, experimenters use prompts that provide general encouragement (i.e., infants are told, "You can do it! Get the one you like!"). However, this prompt could make the task unclear to a preschooler with more advanced cognitive and linguistic abilities because these instructions are misleading. Children might recognize that when they choose something in a probabilistic context, they cannot guarantee that they will "get the one they want", they can only make a best guess. When this prompt was used with preschoolers, 3- and 4-year-olds' performance suffered (Girotto et al., 2016, Expt. 2). We used an age-appropriate method in the current experiments by asking children to provide a forced-choice response to a direct but simple probability question (see Procedure).

Moreover, there is considerable variability in the types of problems that have been presented to children in this age group. Falk, Yudilevich-Assouline, and Elstein (2012) outline this important point in their comprehensive assessment of school-aged children's probabilistic reasoning. Children were asked to choose between two small populations of items, each including a proportion of target and non-target items, to sample from in order to maximize their chances of obtaining a target item on a blind draw. The authors note that much previous research has overlooked the importance of manipulating numerical features of the presented problems when examining children's overall performance. Without manipulating these features across a variety of problems, it is difficult to know whether heuristic reasoning or true probabilistic inference led to correct responses in previous experiments. To combat this problem,

Falk et al. developed a battery of diagnostic problems that could not be solved using simple heuristic strategies (see Denison & Xu, 2014, for a similar approach with infants). For instance, in probability problems, children can use a heuristic in which they only compare the number of target items across populations, and thus ignore proportions. One can diagnose whether children are using this strategy by presenting them with problems that contain an equal number of target objects across two populations (e.g., 12 targets and 4 non-targets vs. 12 targets and 48 non-targets), and asking them to choose a population to draw from for the best chance of obtaining a target. This allows researchers to diagnose use of a strategy that solely focuses on choosing the population with more target objects, because children would be unable to solve such a problem if they tried to apply this strategy. One can also include problems in which there are more non-target objects in the more probable population to diagnose an avoidance strategy. Thus, children cannot succeed by simply choosing the population with more target items, or by choosing the population with fewer non-targets.

Notably, Falk et al. (2012) included problems in their experiment that assessed use of a good versus bad label shortcut. That is, instead of discerning the proportion of objects in each population, children could use a simpler shortcut that focuses on the majority type of objects in each population but does not require comparing proportions *across* populations. Many studies have presented children with a choice between, for example, a 75% target population and a 25% target population. A child could solve this problem by labelling the 75% population as "good", because the target objects are in the majority, and the 25% population as "bad", because the non-target objects are in the majority. This would lead them to approach the "good" population without carefully discerning and comparing the proportion of objects in each population. To assess use of this heuristic, Falk et al. included problems that were on the same side of ½. If a child who uses the good versus bad label shortcut was presented with two populations on the same side of ½, such as 75% and 95%, they would be unable to solve such a problem because both populations would receive the same label.

We attempted to tease apart preschoolers' use of true proportional reasoning from use of heuristics that approximate probabilistic inference. Because we were presenting these problems to children younger than those tested by Falk et al. (2012), we included problems that diagnosed use of simpler heuristics that may be used by preschoolers, as well as some of the more advanced ones described above. We included problems with more target objects in the less probable population and problems with an equal number of target objects in both populations. These features allowed us to examine if young children solely focus on target objects. Additionally, we included problems where the more probable population contained more non-target objects to examine if children attempted to avoid this option. We also included problems on the same side of ½ to gauge children's use of a shortcut that involves focusing on the majority of objects in individual populations.

Finally, closer, rather than more disparate, relative likelihoods (sometimes referred to as the "ratio of ratios") can make problems more difficult to evaluate. That is, when the likelihoods of each population are closer together, the problem can be more difficult to solve than when they are further apart because the populations themselves are more difficult to visually discriminate. For example, if Problem 1 contained a comparison between 80% and 75% targets, and Problem 2 contained a comparison between 90% and 60% targets, Problem 1 would be more difficult to solve because the relative likelihoods are closer and are more difficult to discriminate. Previous investigations of preschooler's probabilistic reasoning have not examined the impact of relative likelihood on their responses (but see Hoemann & Ross, 1971, for a similar manipulation using a spinner task), so we include a manipulation of this feature in the current experiments. Thus, for each problem type we included two versions, denoted 1 and 2, to mark, respectively, closer and further relative likelihoods.

Experiment 1

In Experiment 1, we presented 3- and 4-year-old children with a battery of probabilistic reasoning problems using a two-alternative forced choice procedure in a gumball machine paradigm. Children were tasked with selecting the population that was more likely to yield a blue object. We developed a set of problems to assess use of different strategies (see Figure 1). Problems A1 and A2 presented children with populations on the same side of ½. These problems also included more targets and more overall objects in the less probable population, so a child would not succeed on these problems if they were drawn to these features. Because this problem is challenging, the more probable population only contained target items, and thus the outcome was deterministic. Problems B1 and B2 were simple probabilistic comparisons that could be solved with multiple shortcuts. Although these simpler problems do not diagnose use of these shortcuts, we included them in our problem set to gauge the effectiveness of our paradigm with this age group, as 3- and 4-year-old children have solved these very simple problems in previous experiments. Problems C1 and C2 prevented children from selecting the population with more target objects, because the number of target objects was the same in both populations. Problem D presented children with two uniform populations in which one population only contained targets, and the other contained only non-targets to assess the effectiveness of the paradigm. This problem was always presented second to last, allowing us to gauge whether most children were following the task through such a large number of problems. Problem E was the inverse of Problem A1 and was included to diagnose whether children might use an avoidance strategy to solve problems (i.e., choosing a population that has fewer non-targets).

We included two versions of Problems A, B, and C to determine if probabilities that had higher relative likelihoods (i.e., problems that were further apart in probability, which were labeled with a 2), were easier for children to evaluate.

Methods

Participants Data from 50 3- and 4-year-olds were included in analyses (*mean age* = 4;2 [years;months]; *range* = 3;3 to 4;11). The sample size for the experiment was determined based on a power analysis for a larger study. An additional five children were tested and were excluded from analyses due to parental report of atypical development (n = 1), parental report of very low English exposure (i.e., hearing English less than 50% of the time; n = 2), and not finishing the task (n = 2). Participants were recruited from a database of families and received a small gift for their time.

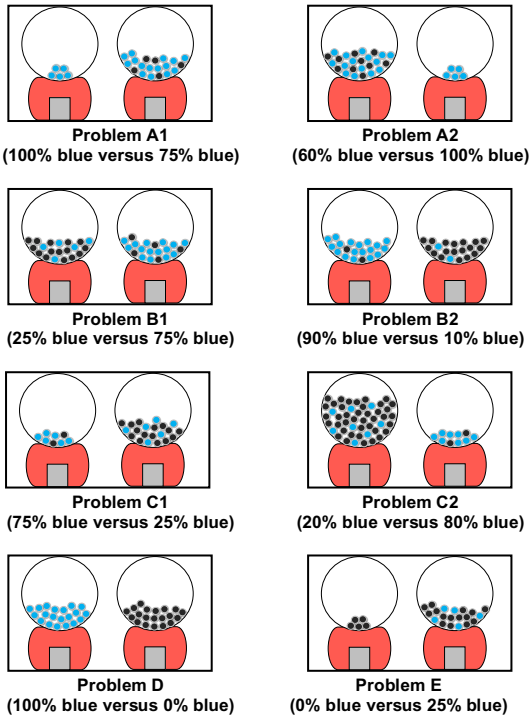

Figure 1: Probability problems presented in Experiment 1.

Materials and Procedure Participants were tested individually in a quiet room. The child and experimenter were seated together at a table. If the child's parent was present in the room, they were seated across the table from the child, unable to see the iPad's screen, and were asked to refrain from commenting or influencing their child's responses during the experiment. After the probability task, children completed measures assessing individual differences in their cognitive abilities (i.e., executive function and receptive vocabulary skills) as part of a larger study. Because the probability task was completed first, the additional measures had no impact on performance.

Probability problems were presented on an iPad, using a gumball machine paradigm. Prior to the test trials, the experimenter explained how gumball machines worked by showing participants two machines filled with a mixture of gumballs of various colors. To discourage children from focusing on the objects that were closer to the opening, the gumballs were then mixed and appeared in different positions in the machine, illustrating that any gumball in the population, regardless of its initial position, could be sampled. After mixing three times, each machine yielded one gumball. The experimenter told participants they had to choose between two machines and reiterated that each machine would only yield one gumball. Participants were told that they would receive a sticker if they chose a machine that yielded a blue gumball. Children then completed eight probability trials and were asked to choose the gumball machine that gave them the best chance of obtaining a blue gumball. On each trial, the machines always produced the more probable color gumball.

In populations that contained both colors, a blue and black gumball were positioned near the opening to ensure that children did not solely focus on the objects that were situated closer to the opening. The side of the correct gumball machine and the order each problem was presented were counterbalanced. Problems A, B, and C were counterbalanced in two blocks, with half of the participants completing version 1 in the first block. Problems D and E were always presented as problems 7 and 8, respectively. Problem D was presented second to last to so that we could assess whether children remained motivated throughout the task. Problem E was presented last; children were given a sticker for either choice, as black was the more likely outcome in both populations. Thus, it was presented last to ensure children did not expect to receive a sticker for a black gumball on subsequent problems.

Results and Discussion

Children received a score of 1 on each problem if they chose the machine that contained the higher proportion of blue (see Table 1 for means, standard deviations, and significance tests against chance for all problems).

Table 1: Children's performance in Experiment 1.

Problem	*M*	*SD*
A1	.82	.39
A2	.82	.39
B1	.90	.30
B2	.94	.23
C1	.82	.39
C2	.76	.43
D	.88	.32
E	.92	.27
Overall	.86	.17

Note: Individual problems were analyzed using binomial probabilities, overall score analyzed using single-sample t-test. All p values for the above analyses were ≤ .001.

We examined if children found some of the critical problem types (A through C) more difficult than others, and if they found problems with higher relative likelihoods easier to evaluate. To investigate this, we conducted a repeated-measures ANOVA with the critical problem types (A, B, C) and version (1, 2) as a within-subjects factor and child's age (younger half versus older half) as a between-subjects factor. There was a main effect of age, $F(1, 48) = 7.06$, $p = .01$, η^2_p

= .13, and problem type, $F(2, 96) = 4.15$, $p = .02$, $\eta^2_p = .08$, on children's scores. On average, the older children in the sample scored higher than the younger children (older children: $M = .91$, $SE = .04$; younger children: $M = .77$, $SE = .04$; $Mean_{Difference} = .14$, $p = .01$). Problem type B ($M = .92$, $SE = .02$) was significantly easier than problem type A ($M = .82$, $SE = .04$; $Mean_{Difference} = .10$, $p = .04$) and problem type C ($M = .79$, $SE = .05$; $Mean_{Difference} = .13$, $p = .01$). Problem version (i.e., relative likelihood) and all interactions were non-significant. Because problems D and E did not include these critical features and did not have a complement problem, we did not include them in these analyses. However, both problems were solved well-above chance (see Table 1). Performance on Problem D indicates that most children could still follow the task after they completed a number of more difficult problems. Moreover, the successful performance on Problem E suggests that children are not simply choosing the population with fewer non-targets.

To examine whether children's strong performance on probability problems was driven by learning over the course of the experiment (as the machines produced the more probable color on each problem type), we ran an additional repeated measures ANOVA with trial order (problem presented in place 1, 2, 3, 4, 5, 6) as a within-subjects factor. This analysis indicated that trial order did not significantly impact children's performance, $F(5, 240) = 1.22$, $p = .30$. Regardless of problem type, children performed well-above chance on trial 1 ($M = .90$, $SD = .3$, binomial, $p < .001$), which also suggests no effect of learning.

To summarize, Experiment 1 established that young children are able to solve probabilistic reasoning problems at rates well-above chance. Although the older children in our sample performed significantly better than the younger children, both age groups successfully solved the problems. Children performed significantly better on problem type B than types A and C, which is unsurprising due to the number of shortcuts they could have used to solve problems B1 and B2. Nevertheless, children still performed well on the more difficult problem types, suggesting that they do not solely rely on these heuristics.

Experiment 2

In Experiment 2, we presented a second group of children with more difficult problems to further test their use of various strategies. Because the children in Experiment 1 performed very well on our problems, we wanted to further explore their performance with a battery that contained some more challenging features (see Figure 2). Problems A1 and A2 presented children with two populations on the same side of ½, in which there were more targets and more overall objects in the less probable population. Problem types B and C presented children with two populations that had an equal number of target objects and more overall objects in the less probable population. Problems D1 and D2 contained more target objects and more overall objects in the less probable population. In this experiment, Problem E presented children with two uniform populations in which one population only contained blue gumballs, and the other contained only black (see Figure 1, Problem D). Because children in this experiment were presented with a more difficult set of problems, this problem was included again to gauge children's ability to follow the task. We included two versions of Problems A, B, C, and D to determine if probabilities that had higher relative likelihoods (i.e., problems that were further apart in probability, which were labeled with a 2), were easier for children to evaluate.

Methods

Participants Data from 74 3- and 4-year-olds were included in analyses (*mean age* = 4;2; *range* = 3;7 to 4;11). Again, the sample size was determined based on a power analysis for the larger study. An additional seven children were tested but were excluded from analyses due to parental report of atypical development ($n = 2$), parental report of very low English exposure (i.e., hearing English less than 50% of the time; $n = 2$), and not finishing the task ($n = 3$). Participants were recruited from a database of families and a daycare in the region. Children received a small gift for their time.

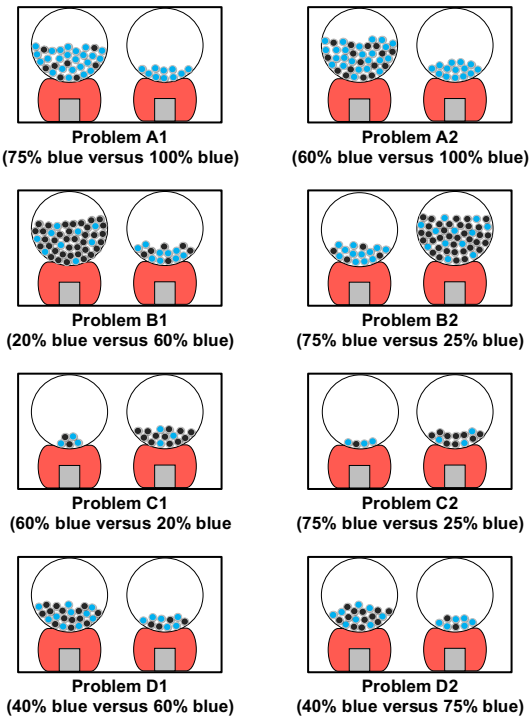

Figure 2: Probability problems presented in Experiment 2. *Note*: Problem E (not shown) was identical to Problem D in Experiment 1 *(see Figure 1)*

Materials and Procedure Participants were tested individually in a quiet room in the lab or at their daycare. The procedure was identical to Experiment 1, with the exception of the new battery of problems.

The probability problems were presented in the same manner as in Experiment 1. The side of the correct gumball machine and the order that each problem was presented were counterbalanced. Problems A, B, C, and D were

counterbalanced in two blocks, with half of the participants completing version 1 in the first block. To ensure that children remained motivated and followed the instructions throughout the task, Problem E was always presented last.

Results and Discussion

Children received a score of 1 on each problem if they chose the machine that contained the higher proportion of blue (see Table 2 for means, standard deviations, and significance tests against chance for all problems).

Table 2: Children's performance in Experiment 2.

Problem	*M*	*SD*
A1	.88	.33
A2	.88	.33
B1	.64	.49
B2	.76	.43
C1	.74	.44
C2	.84	.37
D1	.73	.45
D2	.78	.41
E	.93	.25
Overall	.80	.17

Note: Individual problems were analyzed using binomial probabilities, overall score analyzed using single-sample t-test. All p values for the above analyses were ≤ .001, with the exception of B1 (p = .03).

Similar to Experiment 1, we explored if children found some of the critical problem types (A through D) more difficult than others, and if they found problems with higher relative likelihoods easier to evaluate. To examine this, we conducted a repeated-measures ANOVA with the critical problem types (A, B, C, D) and version (1, 2) as a within-subjects factor and child's age (younger half versus older half) as a between-subjects factor. There was a main effect of problem type, $F(3, 216) = 5.36$, $p = .001$, $\eta^2_p = .07$, and version, $F(1, 72) = 4.65$, $p = .03$, $\eta^2_p = .06$, on children's scores. Problem type A ($M = .88$, $SE = .03$) was significantly easier than problem type B ($M = .70$, $SE = .04$; $Mean_{Difference} = .18$, $p < .001$) and problem type D ($M = .76$, $SE = .04$; $Mean_{Difference} = .12$, $p = .007$). Problem type C ($M = .79$, $SE = .03$) was marginally more difficult than problem type A ($Mean_{Difference} = -.09$, $p = .07$) and marginally easier than problem type B ($Mean_{Difference} = .10$, $p = .06$). Problems labeled with 2 ($M = .81$, $SE = .03$), comparisons that were further apart in relative likelihood, were significantly easier than problems labeled with 1 ($M = .75$, $SE = .03$; $Mean_{Difference} = -.07$, $p = .03$). Children's age and all interactions were non-significant. Because Problem E did not include these critical features and did not have a complement problem, it was not included in this analysis. However, as seen in Table 2, this problem was again solved well-above chance, indicating that most children still followed the task after they completed a number of more difficult problems.

To examine learning over the course of the experiment, we ran an additional repeated measures ANOVA that included counterbalanced trial order (problem presented in place 1, 2, 3, 4, 5, 6, 7, 8) as a within-subjects factor. There was an effect of trial order, $F(7, 511) = 2.31$, $p = .03$, $\eta^2_p = .03$, on children's scores, with scores improving over the session. Though this effect of order suggests that some learning may have occurred throughout the experiment, children performed well above chance on trial 1 ($M = .77$, $SD = .42$, binomial $p < .001$), indicating that learning did not entirely account for the strong performance.

In Experiment 2, we presented children with more challenging probabilistic reasoning problems. Although they were presented with this more difficult battery, children still performed at rates well-above chance across the age group. Problem type A was relatively easy for participants to solve, possibly because the correct option only contained target gumballs. Compared to the other problems, children found problem types B and D more difficult. On those problems, children were unable to rely on a number of cues, including the number of targets and the number of overall objects. We also found that children performed better on problems labelled with 2, which had relative likelihoods that were further apart and thus were easier to visually discriminate. Finally, although children performed above chance on the first trial, we observed an effect of trial order on performance, suggesting that learning may have contributed to performance.

General Discussion

In two experiments, we established that 3- and 4-year-old children are able to reason about probabilities at rates well-above chance. Though the older children in our sample performed significantly better than the younger children in Experiment 1, we did not find any age differences in performance in Experiment 2. Problems that contained multiple shortcuts or a deterministic outcome were easier for children to solve, and relative likelihoods impacted performance in Experiment 2 with our more difficult set of problems. Though children in both experiments performed above chance on the first trial, feedback may have affected children's scores over the course of Experiment 2.

Differences between our design and those of previous experiments may have facilitated performance in our paradigm. Children in our experiments were asked an age-appropriate question about probability. The verbal demands of the task affected preschoolers' performance in the past, as their performance suffered in paradigms with very high and very low verbal demands. In contrast to using verbal explanations as a dependent measure (as in Piaget & Inhelder, 1975), or using verbal cues that might have been too general (as in Girotto et al., 2016), children provided a forced-choice response to a simple, explicit question about probability. This method appears to have suited their abilities.

Children may have also found our gumball machine paradigm, which was presented on an iPad, engaging, and this may have helped maintain their interest over a number of trials. This design allowed us to display the contents of the gumball machine clearly, and the objects remained in view while the child made their choice. In some previous experiments, the experimenter sampled a hidden object from

each population and would ask the child to choose between the two hidden samples. Displaying the populations during the child's choice may have eliminated a working memory demand, because children did not have to maintain a representation of the populations during the sampling process. To disentangle the influence of these features, future work could again present children with two gumball machines on an iPad, though the populations would be covered while a hidden object is drawn from each machine. This would help us determine if clearly displaying the objects aids performance, and if hiding the objects during the sampling procedure creates a working memory demand.

We also provided children with feedback for their performance on each trial, and they were shown the most probable outcome from both populations after they made their choice. We used feedback to help sustain motivation over the course of the experiment because we were presenting very young children with multiple trials. Although we found no evidence of learning in Experiment 1, we found an effect of trial order on performance in Experiment 2. Nevertheless, children in both experiments performed above chance on the first trial prior to receiving any feedback. To further investigate learning in this context, future work could test the effectiveness of feedback at combating the use of overlearned strategies that approximate probabilistic inference. In turn, this work would shed light on how more sophisticated probabilistic reasoning strategies are acquired and fine-tuned with practice.

Moreover, the current experiments explored various strategies that children could use to approximate probabilistic inference. Though older children are drawn to populations with more target objects (i.e., denominator neglect; Falk et al., 2012), preschoolers in our experiments performed well on problems in which the less probable population contained more target objects, and when the number of target objects were equated. One notable difference between our problems and those that older children struggled with is that older children are typically presented with more difficult problems, in which the relative likelihoods are more difficult to discriminate. In our problems, the relative likelihoods were more distinct, making the problems easier overall. Surprisingly, preschoolers were drawn to populations with more *overall* objects (that is, target plus non-target). In both experiments, children's performance was slightly worse on problems where the less probable population noticeably contained more objects. Though older children are not drawn to populations with more objects (Falk et al., 2012), the current findings suggest that the overall number of objects is a salient feature for preschoolers. Because of this somewhat surprising finding, we are currently developing a battery of problems to further clarify how features of the problem, such as overall objects and number of targets, affect young children's probabilistic reasoning performance. Future work with a larger age range could also investigate how use of different strategies varies over the course of development.

We presented preschoolers with problems that were on the same side of ½ to explore nuances in their ability to compare proportions. Children in both experiments were able to make these comparisons and considered the proportion of objects in each population, even though the less probable population contained more target objects. Because we were unsure if preschoolers could solve these more difficult problems, the more probable population was uniform and only contained target objects. Inclusion of the uniform population allowed for a straightforward assessment of children's reasoning abilities, serving as a first step in pitting true proportional reasoning against a heuristic that focuses on the absolute number of target objects. Although this first step established that they are able to make these comparisons, future work should present preschoolers with two *probabilistic* populations (i.e., both contain target and non-target objects) on the same side of ½. This comparison is more difficult, because children are comparing two probabilistic populations and, by the nature of this design, the relative likelihoods are closer together. Though relative likelihood did not influence performance on Experiment 1, it impacted preschoolers' responses on the more difficult battery in Experiment 2. Thus, future work should continue to test the impact of relative likelihood on preschooler's performance, notably in cases where both populations are on the same side of ½.

Finally, we used two sets of problems to assess preschoolers' probabilistic reasoning in the current experiments. Though both batteries indicated that children could successfully reason about probability, one may wonder which battery would best provide an overall assessment of a child's abilities. For space and intended focus of the current paper, we did not report the results of a large set of individual difference measures that were collected with the children that assessed their executive function and receptive vocabulary abilities. These measures tend to correlate well with children's quantitative and general reasoning abilities during early childhood. However, the battery used in Experiment 1 correlated well with these measures, while the battery in Experiment 2 did not show as strong of a relationship. Therefore, at the present time, the problems in Experiment 1 might be the best set to use when gauging children's abilities in future work. We are currently working on another battery of problems, which include some problems from Experiments 1 and 2, and some additional problems of even greater difficulty to continue refining the set.

In sum, preschool children in both experiments solved probabilistic reasoning problems at rates above chance. The current findings illustrate the importance of using an age-appropriate paradigm when establishing the abilities of a particular population. Though children did not rely solely on erroneous strategies, future work is needed to explore how features of probabilistic problems impact performance.

Acknowledgments

These experiments were conceived of in collaboration with Tara McAuley and Bethany Nightingale as part of a larger project and we thank them for their insights. We thank members of the Developmental Learning Lab for help with data collection. Special thanks to parents and children for

participating. This research was supported by a grant from the Natural Sciences and Engineering Research Council of Canada to S. D.

Looking Patterns during Analogical Reasoning: Generalizable or Task-Specific?

Abstract

Given the importance of developing analogical reasoning to bootstrapping children's understanding of the world, why is this ability so challenging for children? Two common mechanisms have been implicated: 1) children's inability to prioritize relational information during initial problem solving; 2) children's inability to disengage from salient distractors. Here, we use eye tracking to examine children and adults' looking patterns when solving scene analogies, allowing for differentiation between attention to relations versus to featurally salient distractors. In contrast to a recent study with propositional analogies, our data suggest prioritization of source information does not differ between adults and children, nor is it predictive of performance; however, children and adults attend differently to distractors, and this attention predicts performance. These results suggest that feature-based distraction is a key way children and adults differ during analogical reasoning, and that the analogy problem format should be taken into account when considering children's analogical reasoning.

Keywords: analogy, attention, eye tracking, reasoning, pattern recognition

Introduction

Analogical reasoning involves identifying higher order similarities in relational structure shared between representations. This form of reasoning is used in many contexts, and is predictive of academic and professional success (Richland & Burchinal, 2013). Yet, analogical reasoning proficiency develops over time: young children often struggle to notice or extract deep underlying structures from comparison opportunities (Gentner & Smith, 2013). Given the importance of developing this ability, researchers have asked why analogical reasoning problems are challenging for children. Two common explanations in the literature implicate: 1) children's inability to prioritize attending to relational information during initial problem solving, or 2) children's inability to disengage from featurally salient distractors.

Prioritization of Relational Information

One explanation for children's difficulty with analogical reasoning problems is that they fail to attend to relational information that is crucial for correctly solving problems. Much of this work has used propositional analogies, in the format A:B::C:D. In these analogies, participants select from four choices a D item that is relationally similar to the C item in the same way that A and B are similar. For example, if A and B are both triangles, with B being a stretched version of A, and C is a square, the correct choice for D would be a stretched square. A featural distractor in the response choices might be a diamond of the same color as the square – color being a salient perceptual feature that could distract from the deeper, structural relation between C and the stretched square.

From eye tracking work, we know that adults generally attend to the A:B pair before fixating on C and the response choices, showing that they can maintain the overarching goal (i.e. find the picture that goes with C in the same way that A goes with B) (Starr, Vendetti, & Bunge, 2018). In contrast, 5- and 6-year-old children ignore the A:B items, and focus their attention on C and the response choices (Glady, French, & Thibaut, 2017; Thibaut & French, 2016). This suggests that children do not extract relational information before considering response options, instead focusing on the immediate task goal (i.e. find the picture that goes with C).

In support of this idea, using linear discriminant analysis, French and Thibaut (2014) found that children's visual attention during the first third of the trial can predict with 64% accuracy whether or not the problem would be answered correctly. This is especially true if attention is focused on the A:B pair. Glady and colleagues (2017) have shown that guiding children's attention to the A:B pair during initial problem solving significantly improved children's performance.

Featurally Salient Distractors

While attention during the task may be important, an alternative explanation for children developing proficiency on analogy problems emphasizes the effect of featurally salient distractors. In many situations that require analogical reasoning, the visual scene is complex. Although a higher order relational structure is present, children are more likely to make judgments based on mere appearance or surface-level similarities between representations – attending to items that are perceptually or semantically related to the item in question, rather than structurally related. Young children are particularly susceptible to this type of error, tending to shift from more object-based similarity matching to more relational reasoning over time, defined as the *relational shift* (Gentner, 1988). Adults also appear to make relational shifts when reasoning about information for which they have low knowledge, yet children tend to make featural errors even when reasoning about relations that are familiar (Richland, Morrison & Holyoak, 2006). This finding has led researchers to suggest that the inability to disregard salient featural information in favor of relational information may be, at least in part, attributed to still developing executive function (EF) resources, and that gains in EF allow children to increasingly manipulate complex relations in working memory and direct attention toward relevant aspects of an analogy (Richland et al., 2006; Simms, Frausel & Richland, 2018).

Behaviorally, this explanation has been supported using a variety of analogical reasoning tasks (i.e. scene analogy and propositional analogy paradigms). For example, Richland and colleagues (2006) asked children to identify relational similarities between two scenes (e.g. a source and target scene), while ignoring items with featural similarities. In their task, the goal was to identify something in a target scene that

corresponded relationally to a prompted item in a source scene. Importantly, a featural distractor, an item in the target scene that was not incorporated in the relation of focus and had great surface similarity to the prompted item in a source scene, was sometimes present in the target scene (Richland et al., 2006). For example, a pair of scenes might depict a relation of a dog chasing a cat (source scene) and a man chasing a woman (target scene). If the dog was prompted, the correct choice would be the man and the incorrect featural choice would be a perceptually similar dog in the target scene. For children ages 3-4, the perceptually similar match was an effective featural distractor, such that accuracy for the problems with distractors was 15% less than that for the problems without distractors. Individual differences in children's EF (working memory in particular) explained these patterns of performance (Simms et al., 2018). Further, these behavioral findings have been complemented by modeling work: Simulations in the LISA computational model of analogy (Hummel & Holyoak, 1997, 2003) suggest that changes in inhibition levels, along with relational knowledge accretion, account for young children's difficulty when reasoning analogically (Morrison, Doumas, & Richland, 2011; see also Doumas, Morrison, & Richland, 2018). Using the same task, the model replicates the experimental findings of Richland and colleagues (2006), such that the model was more likely to choose a featurally similar distractor object than an analogically correct choice.

Thibaut and colleagues (2010) demonstrated a similar effect of featural distractors using propositional analogies. Similar to scene analogy paradigms, correct responses require inhibition of salient features and a focus on common relational structure. As with scene analogies, children were more prone to errors when featural distractors were present. Indeed, later work using eye tracking revealed a negative association between the amount of time looking to a distractor and performance, such that the more time children spent looking at the distractor the worse they performed (Thibaut & French, 2016).

Distractor versus Prioritization

Whereas the majority of previous literature has considered these two mechanisms separately, Starr and colleagues (2018) examined both how looking to featural distractors and focusing on source relational information affected children's ability to solve propositional analogies. They argued that children's poor performance was due to an inability to prioritize attending to the A:B relation when initially processing an analogy, rather than an inability to disengage from perceptual lures. What is unknown is whether this finding is unique to propositional analogies, or consistent across all analogy types.

Current Study

Here, we examined visual attention while children and adults solved scene analogy problems similar to those used by Richland and colleagues (2006). If the main factor underlying children's poor performance on scene analogy problems is their non adult-like looking patterns (characterized in propositional analogies as a prioritization of relational information – A:B pair – during early problem solving) we should find that adults show greater attention to the source scene and key relationship than children, especially early in problem solving. We should also find that attending to the source relation predicts performance. Indeed, we already know that adults initially focus on the relations within a source scene – prioritizing the existing structural relation before considering the target scene (Gordon & Moser, 2007). However, if we do not find this difference in visual attention between adults and children, this would suggest that whereas adults may have a systematic approach to solving all analogy problems, the format of the problem may have a strong influence on how children solve these problems. In this case, Starr and colleagues' findings would be specific to propositional analogy problems.

The scene analogy task also allows us to measure looking to the featural distractor, determining whether children's looking patterns appear similar to or systematically different from adults'. Thus we will examine both looking to the source relation, as well as attention to featural distractors to assess which of these attentional mechanisms best explain children's developmental trajectory in solving scene analogies.

Methods

Participants

Data from 57 4- and 5-year-old children (29 females, M_{age} = 4.88, SD_{age} = 0.47) and 45 adults (37 females, M_{age} = 19.45, SD_{age} = 0.99) were analyzed for the present study[1]. Participants represented a diverse sample from a large metropolitan city. Children were recruited from schools and participated individually in one experimental session during a regular school day. Children were compensated with stickers and a certificate noting their participation in a research study. Adults were recruited from a participant pool at a university and participated individually in a lab setting.

Materials

Stimuli. Participants were shown scene analogies adapted from Richland et al. (2006). Each stimulus included a pair of scenes presented simultaneously on a *15-inch* Dell laptop. Pairs of scenes depicted one of two *relation categories* (i.e. chasing or reading) occurring between items (i.e. animals or people) within the scenes. Source scenes contained five

[1] Data from 57 children and 60 adults was collected. Although all children were included in analyses, a subset of data from particular timepoints were excluded from 8 children based on insufficient usable eye tracking data. Five adult participants were excluded for having lacking sufficient eye tracking data. For adult participants to be included in the sample, they must have > 75% accuracy. This was to ensure that we had a measure of successful, mature visual attention patterns. Ten adult participants were excluded for having < 75% accuracy across trials.

items: the two items within the relation that participants were to attend to, and three additional items (i.e., neutral inanimate objects). Target scenes also contained 5 items: the two items within the relation, two additional items, and a featural distractor.

Figure 1a. shows an example of a "*chasing"* relation depicted in both a source and a target scene. The source scene on the left shows a tiger *chasing* a woman (items within the chasing relation), and the corresponding target scene on the right side shows a lion *chasing* a horse (items within the chasing relation). Target scenes also contained a featural distractor that was featurally similar to the prompted source-scene item. In Figure 1a., the tiger in the target scene serves as the distractor because the tiger is prompted (i.e. circled) in the source scene. To maintain the same number of items across scenes, additional items were included. These items were *neutral*, meaning they were not involved in the chasing relations and were not the distractor (in Figure 1a, source scene: dog house, jeep, and plant, target scene: barn and soccer ball). Importantly, the distractor is never involved in the relation within the scene. Distractors were centrally located, increasing the likelihood that participants would notice them.

Figure 1b. shows an example of a "*reading"* relation in both a source and a target scene. Items depicting the reading relation were oriented towards each other with one character reading to the other character. In all source scenes, one of the two items within the relation of chasing or reading was prompted with a circle. The directionality of relations within a pair of scenes was reversed to avoid children making choices based on spatial location alone. For example, in Figure 1a., if chasing is depicted between characters to the left in a source scene, the chasing would then be depicted to the right in the target scene.

Eye Tracker. Eye tracking data were collected via corneal reflection using a TobiiPro X3-120 remote eye tracker affixed to a *15-inch* Dell laptop. Tobii software was used to perform a 5-point calibration procedure using standard animation blue dots. This step was followed by the collection and integration of gaze data with the presented instructional videos (described below) using Tobii Studio (Tobii Technology, Sweden). All gaze data was extracted from Tobii Studio Software for each participant.

Procedure

For the purpose of the present question, we considered a subsection of data from a longer study: eye tracking data during which children and adults visually attended to scene analogy problems without any training on how to solve them. For children, the data came from 12 pretest problems (6 chasing; 6 reading), after which children received training on how to solve scene analogies and completed 12 posttest problems. For adults, the data came from 24 problems (12 chasing; 12 reading). Items included in a child's pretest and posttest were counterbalanced, and all items were shown to adults.

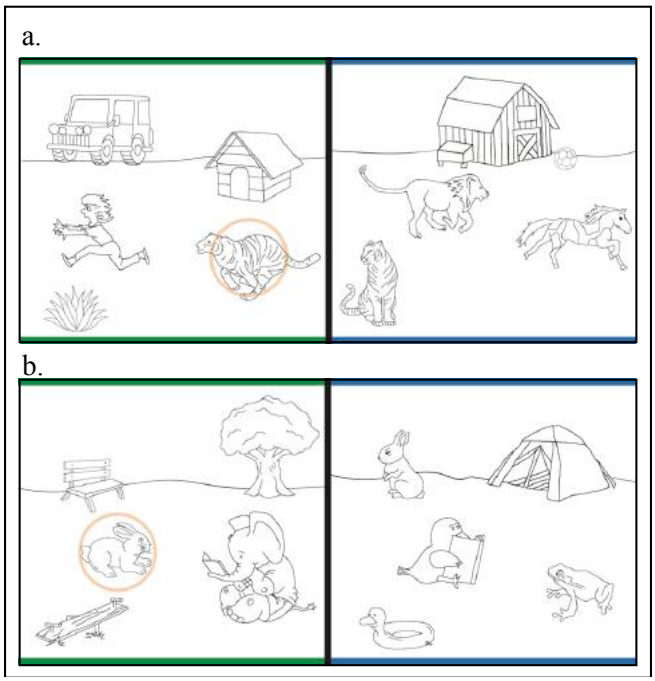

Figure 1. a. Example trial of *chasing* relation category. b. Example trial of *reading* relation category.

Introduction to Task and Calibration. Participants were told they were going to play a picture game and shown one example trial, orienting them to the layout of test trials (i.e., two pictures with different colored borders), and their task (i.e., that for each set of scenes their job was to figure out the pattern in the pictures). The experimenter described the chasing relation and asked the participant to solve the relation. For children, the explanation was repeated until they chose the correct item. This introduction ensured that when children incorrectly answered a trial, it was not because of a misunderstanding about the goal of the task.

Next, calibration on the eye tracker was completed: participants were seated approximately 40 cm in front of the laptop, familiarized with the eye tracker, and told it was important to remain still throughout the session.

Task. Participants completed a set of scene analogies while their visual attention was monitored. Participants were instructed to respond verbally to "*Which thing in the picture with the blue edges is in the same part of the pattern as the circled thing in the picture with the green edges?*". The task was self-paced, but if no response was given after a few seconds, the experimenter re-prompted. Responses were recorded for each trial.

Results

Areas of interest (AOIs) were generated for the items within the scene pairs using Tobii Studio (i.e. each trial had 10 AOIs, 5 in each scene). The remaining spaces outside of these AOIs were collapsed into an "Other" AOI. For analyses, we

considered visual attention to 1) the source relation (comprised of two relational items and analogous to the A:B items in propositional analogies) and 2) the distractor (analogous to a choice item in propositional analogies). Data were extracted and processed so that the AOI a participant fixated could be determined at 8 msec intervals across the entire length of each problem. Proportion of time spent looking to each AOI was calculated using the total gaze duration of a given trial (e.g., 1000 msec), and the amount of time spent looking at a given AOI during a particular trial. All analyses considered visual attention patterns and accuracy at the trial level, not aggregated across trials for a given participant.

Because prior work (Starr et al., 2018; French & Thibaut, 2014) suggests visual attention during initial solving has the most predictive power for whether a participant will arrive at the correct answer, we consider proportion of looking to these AOIs across the entire trial, as well as proportion of looking during an initial segment of each problem. In prior work, participants had set time limits for solving problems, thus, researchers could consider a set amount of time (e.g., the first third or fourth of a trial) when examining attention at the beginning of problem solving. Here, we used a self-paced design, which resulted in variability of trial length both across and within participants. Therefore, we considered the first 5 fixations of each trial as the first interval of problem solving.

Prioritization of Relational Information

Our primary goal was to establish whether visual attention to the source relation during scene analogy problems differed between age groups in the same way as for propositional analogies. Figure 2 shows the proportion of visual attention allocated to AOIs for both children and adults. In contrast to previous work using propositional analogies, both children and adults attended to the source relation about one-third of the time, across the entire solution time (adults: $M = 0.34$, $SD = 0.05$; children: $M = 0.33$, $SD = 0.66$). A generalized linear model supported the interpretation that attention to the source relation did not differ by age group ($\beta = -0.01$, $SE = 0.01$, $t = -0.39$, $p = 0.70$). Focusing just on initial solution time revealed that a higher proportion of looking to these items occurred when participants first viewed these problems than across the entire trial: adults spend nearly half of early problem-solving time focused on this relation ($M = 0.52$, $SD = 0.10$), and children allocated just under half of their attention to these items ($M = 0.44$, $SD = 0.18$). Again, there was no significant difference in this looking pattern between groups ($\beta = 0.00$, SE = 0.01, $t = 0.24$, $p = 0.81$).

In order to make conclusions about whether looking to the source relation supports successful reasoning, we must assess the relation between performance and visual attention patterns. Unsurprisingly, children performed poorly on scene analogies, answering less than one-third of the problems correctly ($M = 0.30$, $SD = 0.26$), whereas adults were much more accurate ($M = 0.92$, $SD = 0.06$). Because adults performed nearly at ceiling, we only assess whether looking patterns predict accuracy for child participants.

Binomial generalized linear models, with accuracy on each problem (0, 1) as the dependent measure, were used to determine whether looking to source relation is predictive of behavioral performance. In contrast to prior work, we found no relation between performance and looking to the source relation across the entire trial ($\beta = 0.30$, SE = 0.82, t = 0.34, p = 0.71), or during initial problem solving ($\beta = 0.05$, SE = 0.33, t = 0.16, p = 0.87) and learning. Overall, these results challenge previous work suggesting that children's lower performance on analogy problems can be explained by failures to attend adequately to the source relationship.

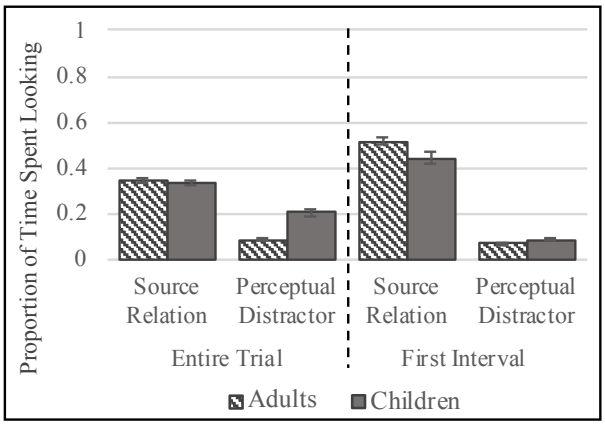

Figure 2. Proportion of time looking to source relations and distractors across entire trials and the first interval of trials.

Featurally Salient Distractors

When children and adults were not looking at the source relation, how did they allocate their attention? In line with previous work assessing children's visual attention during analogical reasoning, children spent roughly 10% percent more of their time looking to featural distractors ($M = 0.20$, $SD = 0.10$) as compared to adults ($M = 0.09$, $SD = 0.02$) across the entire problem-solving time. A generalized linear model indicated that children spend reliably more time looking towards the distractor than did adults ($\beta = 0.09$, $SE = 0.01$, $t = 6.31$, $p < .001$). However, during initial problem solving, both children and adults spent less than 10% of their time looking to the distractor (adults: $M = 0.07$, $SD = 0.03$; children: $M = 0.09$; $SD = 0.06$). A generalized linear model supported a lack of difference between age groups ($\beta = -0.05$, $SE = 0.03$, $t = -1.75$, $p = 0.08$). This indicates that, at first, children and adults explore the distractor equally, but children continue assessing the distractor throughout the trial.

Finally, we asked whether behavioral accuracy was predicted by looking to the distractor. Interestingly, in line with previous work, children performed better if they spent less time looking to the distractor across the entire problem-solving time ($\beta = -9.21$, $SE = 1.29$, $t = -7.16$, $p < .001$). However, when considering initial looking times only, there was no relation between looking to the distractor and performance ($\beta = 0.88$, $SE = 0.62$, $t = 1.41$, $p = 0.16$),

suggesting that initial attention to the scenes was not the key differentiating period.

Discussion

While previous work seems to be at a consensus about the differences between mature and immature visual attention patterns while solving propositional analogies, the current study was conducted to see if these patterns hold when children and adults solve scene analogies, which are arguably more similar to real world analogies. Specifically, previous work shows that when solving propositional analogies, children look less to the source relation (A:B) than adults, and that prioritizing attention to relational information early in analogical problem solving is predictive of later accuracy (Glady et al., 2017; Starr et al., 2018; Thibaut & French, 2016). Here, we do not find differences in patterns of attention to the source relation when solving scene analogies between children and adults, neither in their initial attention nor in the full problem-solving period. Furthermore, we do not find that children's attention to relational information is predictive of their performance, even though we replicate the pattern that children perform significantly worse than adults. We do, however, find that attention to the featural distractor predicted accuracy in children. Together, these results suggest the format of the problem influences attentional patterns and that prioritization of relational information is not always critical for successful problem solving across all analogy paradigms.

While both propositional and scene analogies require processing relational information in order to arrive at a correct solution, their structures differ significantly. This difference in structure may account for why children approach these problems in different ways. In analogies of A:B::C:D format, children who are not skilled at analogical reasoning seem to overlook the relational information contained in the A:B pair, and focus on 'C' and the response options, because they interpret the task as 'match 'C' to something' and treat A:B as irrelevant. In the example used previously from Thibaut & French (2016), children might ignore that 'shape' is the relational structure, such that B is a stretched version of A, and be more likely to pick an option that is similar to C on another dimension, such as 'color'. It seems that the salience of the A:B pair is not great enough to warrant attention from those children who do not understand the task goal. In contrast, in a scene analogy, children's visual attention is still drawn to the source relation initially, perhaps due to the circled item. Based on our results, the salience of the circled item draws both children and adults' attention equally at first, but unlike adults, children less often utilized that information to correctly solve the problem. Furthermore, the presence of a distractor lowered children's performance and drew children's attention. While looking to the source relation is obligatory for children and adults because of the circled item's salience, this looking pattern does not uniformly result in successful analogical reasoning.

Previous work has consistently demonstrated that adults prioritize relational information during initial problem solving, characterized by looking to the source relation (Gordon & Moser, 2007) or the A:B pair (Starr et al., 2018; Thibaut & French, 2016). Perhaps because adults understand that they need to identify the deeper structure in these problems, and therefore, are more proficient analogical reasoners, they are not restricted by the structure of the problem. Adults can organize their visual search in a particular way despite analogy format, whereas children's visual search during analogical reasoning is strongly influenced by problem structure, and, as will be discussed next, the presence of a featural distractor.

The secondary goal of this work was to ask if looking patterns to featural distractors are comparable between scene analogies and propositional analogies (Thibaut et al., 2010; Thibaut & French, 2016). Across the entire problem-solving episode, children allocated more of their attention to the distractor than adults, and this was negatively related to behavioral performance. This corroborates previous work using propositional analogies (Thibaut & French, 2016). However, when we only considered the first interval of problem-solving time, children and adults allocated an equal amount of time to the distractor, and this was *not* predictive of performance. This differs from previous work that has stressed the importance of initial looking patterns for predicting accuracy.

Based on these results, we can suggest that when solving scene analogies, adults and children both consider the distractor, but children continue their examination of the distractor across the entire trial. It is this continued focus on the distractor that leads to poor behavioral performance – initial consideration may be indicative of children and adults processing the items that appear in the source and target scenes before working to solve the problem.

Overall, incorporating our findings about children and adult's visual attention across the problem-solving process and during initial solving, and attention towards the source relation and distractor, we can conclude that children and adults organize their visual search in different ways when solving analogical reasoning problems: In processing analogies, adults begin by identifying the relational information necessary to understand the structure of the analogy. In contrast, children have more disorganized looking patterns, such that their visual search is dependent upon analogy format, rather than the overarching goal to identify relational structure. The consistent effect of featural distractors on children's visual attention, across analogy formats, lends further support for the conclusion that children have inefficient looking patterns. While consistently looking to distractors could be considered an 'organized looking pattern' because they perform this behavior somewhat reliably, in this case, it demonstrates children's difficulty attending to underlying relational structure. This conclusion is in line with the work of Glady and colleagues (2010), who found a clear difference between adults and children's visual strategies when solving analogy problems, such that adults have more organized search patterns (Glady, Thibaut, & French, 2010).

Although our work adds an important piece to understanding the development of analogical reasoning ability, it should be noted that one limitation of this work lies in the restricted comparisons that can be made between propositional and scene analogies. Specifically, previous analogical reasoning research has made strong conclusions about the differences between age groups in terms of looking to the C item in propositional analogies (A:B::C:D), such that children look more to the C item earlier in the problem solving process and focus their search around C, whereas adults will search in a more organized way by first examining the A:B pair and then looking at the C item and the possible answers (Starr et al., 2018; Thibaut & French, 2016). Unfortunately, there is not a functionally comparable item to C in a scene analogy. Items C and D are already in relation with one another in a scene analogy, whereas D must be chosen from multiple options by the participant in a propositional analogy. Therefore, in this study, we cannot make conclusions about looking to the C item. This, again, speaks to the structural difference between propositional analogies and scene analogies.

Overall, our results suggest that while there are some generalizable differences between how adults and children process analogies regardless of their format, there are other aspects of how attention is allocated that are dependent upon analogy type. These results allow us to resolve inconsistencies in previous work by identifying exactly how children's visual attention differs across analogy formats. Gaining a better understanding about these differences across the domain of analogical reasoning will better elucidate the attentional mechanisms underlying learning in this domain and inform teaching techniques. Determining how children view analogy problems will help us understand what underlies this behavioral ability in children and adults, and could lead to evidence-based practices for teaching analogical reasoning through guided looking. This work, and future work in this field, can begin to inform practical instructional techniques by helping educators design instruction that reaches diverse classrooms of learners, as they struggle to develop this difficult, yet important ability: analogical reasoning.

Abstract

How do societies develop categories for continuous sets of novel phenomena, as in the domains of art and technology? Seminal work in the nativist tradition argues that given the same stimuli, people can independently produce the same categories as a result of universal cognitive constraints. These constraints are said to account for cross-group coherence, where distinct communities and cultures have been shown to arrive at highly similar categories. Cross-group coherence is widely seen as incompatible with functionalism, which holds that categories are defined through communication, leading to divergent category systems. Here, we use an experiment to demonstrate that communication can generate either the divergence or convergence of category systems, depending on the size of the social network (2, 6, 8, 24, and 50). We find that large social networks amplify population biases, where a subset of slightly more frequent words become exponentially more likely to spread as network size increases.

Evaluating Models of Human Adversarial Behavior Against Defense Algorithms in a Contextual Multi-Armed Bandit Task

Abstract

We consider the problem of predicting how humans learn interactively in an adversarial Multi-Armed Bandit (MAB) setting. In a cybersecurity scenario, we designed defense algorithms to assign decoys to lure attackers. Humans play the role of cyber attackers in an experiment to try to learn the defense strategy after repeated interactions. Participants played against one of three defense algorithms: a stationary strategy, a static game-theoretic solution, and an adaptive MAB strategy. Our results show that humans have the most difficulty learning against the adaptive defense. We also evaluated five different models of attack behavior and compared their predictions against human data. We show that a modified version of Thompson Sampling and a cognitive model based on Instance-Based Learning Theory are the best at replicating human learning against defense strategies. We discuss how these models of human attacker can inform future cyberdefense tools.

Keywords: Cognitive Modeling; Reinforcement Learning; Intelligent Agents; Decision Making; Cybersecurity

Introduction

With the popularity of autonomous systems, the question of how humans interact with these systems becomes increasingly important (Gershman, Horvitz, & Tenenbaum, 2015). Humans are imperfect agents, but they are capable of learning and in some settings able to adapt to novel situations. Our ability to anticipate human behavior, to represent human decision making computationally, and to use these predictions to improve autonomous agents is critical to making autonomous systems more capable and secure.

We study an adversarial decision making setting framed in the context of cybersecurity. Humans attackers try to compromise a network while automated defender algorithms deploy decoys in the network (i.e., honeypots) to detect and thwart attackers. Honeypots are designed to waste the attacker's resources and provide information to the defender (Spitzner, 2003). Attackers try to avoid detection by honeypots. Deploying a fixed configuration of honeypots (i.e., a static defense) may capture an attacker in a single interaction. However, an adaptive attacker may learn the static honeypot defenses and actively avoid them in future interactions. A defender who can predict this attack learning dynamic should be able to deploy defensive strategies that are harder to learn and defeat over the long term. Our goal is to determine how human attackers behave against defense algorithms of various complexities, and to test cognitive models of adversarial behavior against other common behavioral models.

We model a cybersecurity scenario as a repeated Multi-Armed Bandit task (MAB) where a human attacker plays against an automated defender. MAB tasks have been useful in the study of human decision making, characterizing the common exploration-exploitation tradeoff (e.g., (Steyvers, Lee, & Wagenmakers, 2009)). However, our goal is to determine how a human attacker is able to learn the defender's deception strategy and avoid honeypots based on previous experience.

In a standard MAB, a decision maker select arms on a "slot machine" in each round and observes the outcome, typically with the value of each arm in the range $[0,1]$. The adversarial MAB considers an adversary (i.e., the algorithmic defender) who has control over the rewards of each node. Here, we consider a variation of the MAB in which each node i has bounded support interval $\{-c_i^a, v_i - c_i^a\}$. This allows the MAB agent to make more informed decisions in earlier

rounds. This maps naturally to an attacker who has probed the network prior to making an attack, and it relates to recent approaches to study learning and decision making under contextual MAB, where information about rewards is provided.

Learning in Multi-Armed Bandits

In a MAB, individuals learn by repeatedly choosing among multiple options that have varying probabilities of different rewards that are observed through immediate feedback after a choice. In theories of decisions from experience, two-arm bandit problems are a classical research paradigm used for modeling human decisions and learning from experience (e.g., (Gonzalez & Dutt, 2011)).

Experiments of human behavior have demonstrated that humans are able to learn in MABs by gradually transitioning from exploration of the available alternatives to exploitation of the most rewarding options while learning from feedback and experience (Gonzalez & Dutt, 2016; Mehlhorn et al., 2015). Sripa et al. notably ran an experiment with 451 human participants playing the MAB (Sripa et al., 2009), and applied a Bayesian learning model to explain the human data. Zhang et al. extended this work by improving the participant behavioral prediction with a Knowledge Gradient model (Zhang & Angela, 2013). Our current work differs from these works in that we consider differences in reward distributions. Specifically, the previously mentioned authors address human performance in stochastic settings. In this work, we consider humans in static, stochastic, and adversarial MABs settings and analyze the effects of each environment. Furthermore, we provide context to the human decision makers by advertising the potential gains and losses of each arm of the MAB.

Recent research has shown that humans are able to learn well in contextual MABs, and various algorithms have been used to replicate this human behavior, including Thompson sampling (Agrawal & Goyal, 2012; Speekenbrink & Konstantinidis, 2015). In contrast to these models often used in MAB tasks, cognitive models of human behavior represent the cognitive mechanisms (e.g, memory, learning, forgetting) which are essential elements for human learning (Gonzalez, Lerch, & Lebiere, 2003). We offer a unique paradigm to test cognitive models of human learning and decision making and pair them against other representations of behavior in MAB tasks, playing against defense algorithms of various complexities.

Honeypot Cybersecurity Game

In the Honeypot Cybersecurity Game (HCG) a defender places decoys to protect network resources (nodes) and the attacker aims to capture those resources. A screenshot of the user interface shows a network with 5 nodes (Figure 1). Each node in the network has the following values: v_i is the value of node i, c_i^a is the cost to attack node i, and c_i^d is the cost to defend node i. The reward $v_i - c_i^a$ for attacking a non-honeypot appears as a positive number on top of each node. The cost for attacking a honeypot $-c_i^a$ appears as a negative number at the bottom of the node.

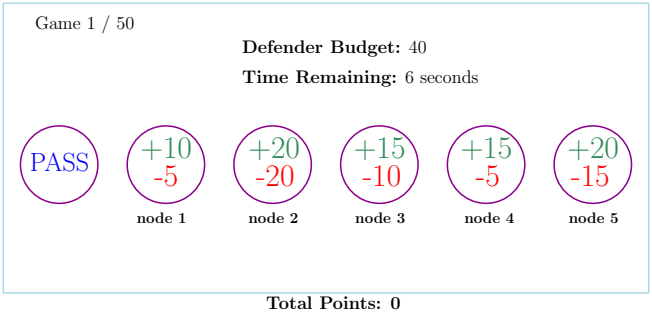

Figure 1: User interface for the HCG.

Table 1 shows the specific values used in the HCG for our experiments. We designed the node values to fit common risk-reward archetypes (e.g., low-risk/low-reward, high-risk/high-reward, low-risk/high-reward). The explicit values shown in each node give an attacker the possibility of making informed decisions that will be combined with experiential decisions as in (Lejarraga, Dutt, & Gonzalez, 2012).

	pass	node 1	node 2	node 3	node 4	node 5
v_i	0	15	40	35	20	35
c_i^a	0	5	20	10	5	15
c_i^d	0	10	20	15	15	20

Table 1: Node parameters for online human experiment.

At the beginning of each round, the defender spends her budget D to turn some subset of the nodes into honeypots, such that the total cost is $\leq D$. Once the defender deploys honeypots, the attacker selects a node to attack or passes. If the attacker's chosen node i is not a honeypot, the attacker receives the reward $v_i - c_i^a$, and the defender receives a reward of 0. If the attacker's chosen node i was a honeypot, the attacker receives the negative reward $-c_i^a$, and the defender receives the positive reward v_i[1]. At the end of a round with n trials, the game resets and a new round begins. The attacker and defender are only informed of the rewards they receive after each action, and do not directly observe the other player's choices (known as incomplete or semi-bandit feedback).

Defender Algorithms

We consider 3 different defender algorithms to investigate their impact on human adversarial decision making and learning. We expect these to create varying levels of difficulty for the human attackers to learn the defense policy.

The *Static Pure Defender* algorithm employs a "set and forget," defense that implements an unchanging, greedy strategy that spends the budget to protect the highest valued nodes. For the scenario in Figure 1, the defender always sets nodes 2 and 5 as honeypots, leading to nodes 3 and 4 being the optimal ones to attack. Against this defender, the attacker can gain a maximum of 750 total points in this specific scenario by always attacking node 3 or 4 for all 50 rounds.

[1]We assume $v_i \geq c_i^a$ and $\sum_{i \in N} c_i^d > D$.

The *Static Equilibrium Defender* plays according to a fixed probability distribution over the possible combinations of nodes to be honeypots. A new combination is selected randomly each round according to the distribution shown in Table 2. This is a game-theoretic Mixed Strategy Nash Equilibrium that optimizes the defender's expected utility assuming a single, non-repeated interaction against a fully rational attacker. The optimal strategy for the attacker against this strategy is to attack node 4, with an expected total value of ≈ 447 points for the attacker.

defended nodes	{1,3,4}	{2,3}	{2,5}	{3,5}
probability	≈ 0.303	≈ 0.095	≈ 0.557	≈ 0.0448

Table 2: Static Equilibrium Defender probabilistic strategy.

Algorithm 1 Learning with Linear Rewards (LLR)

If $\max_a |\mathcal{A}_a|$ is known, let $L = \max_a |\mathcal{A}_a|$; else, $L = N$
for $t = 1$ to N **do**
  Play any action a such that $t \in \mathcal{A}_a$
  Update $\left(\hat{\theta}_i\right)_{1\times N}$, $\left(m_i\right)_{1\times N}$ accordingly
end for
for $t = N+1$ to ∞ **do**
  Play an action a which solves the maximization:

$$a = \arg\max_{a\in\mathcal{F}} \sum_{i\in A_a} a_i\Big(\hat{\theta}_i + \sqrt{\frac{(L+1)\ln n}{m_i}}\Big), \qquad (1)$$

  Update $\left(\hat{\theta}_i\right)_{1\times N}$, $\left(m_i\right)_{1\times N}$ accordingly
end for

The *Adaptive Learning with Linear Rewards Defender (LLR)* (Gai, Krishnamachari, & Jain, 2012) plays an adaptive, learning defense strategy that tries to maximize reward by balancing exploration and exploitation using an approach designed for MAB learning. $\mathcal{A}_a$ in LLR is the set of all individual actions (nodes to defend). In the scenario from Figure 1, $\mathcal{A}_a$ is the set containing all 5 nodes. LLR uses a learning constant L, which we set to $L = 3$ since this is the maximum number of nodes we can play in a defense. LLR has an initialization phase for the first $N = 5$ rounds where it guarantees playing each node at least once. $\left(\hat{\theta}_i\right)_{1\times N}$ is that vector containing the mean observed reward $\hat{\theta}_i$ for all nodes i. $\left(m_i\right)_{1\times N}$ is the vector containing m_i, or number of times node i has been played. The vectors are updated after each round.

After the initialization phase, LLR solves the maximization problem in equation 1 and deterministically selects the subset of nodes that maximizes the equation each round until the end of the game. The algorithm tries to balance between nodes with high observed means (i.e., have captured the attacker often in the past) and exploring less frequently played nodes (which the attacker may move to in order to avoid capture). While LLR has no concept of an opponent, it indirectly adapts to the attacker based on the observations of previous rewards that depend on the attacker's strategy.

In this scenario, it is difficult for the attacker to fully exploit the strategy of the defender due to incomplete information. When facing a static defender in a static environment, the optimal node(s) will remain the same, but when facing LLR or another adaptive defender the node(s) providing the highest expected value may change from round to round.

Experimental Design

We recruited 304 human participants on Amazon's Mechanical Turk (AMT) where 130 reported female and 172 reported male with 2 participants reporting as other. All participants were above the age of 18, and the median age was 32. Participants interacted with one of the 3 defense algorithms for 50 rounds. 101 participants played against the Static Pure Defender; 100 played against the Static Equilibrium Defender; and 103 played against the LLR defender. Participants took roughly 10 minutes from start to finish. They were paid US $1.00 for completing the experiment and were given a bonus payment proportional to their performance in the 50 round game, ranging from US $0 to an extra US $3.25.

This task did not require cybersecurity knowledge and participants were given detailed instructions and definitions of the concepts needed to perform the task (e.g., honeypot). Participants were told that the defender has a budget $D = 40$ that limits the number of honeypot configurations (i.e., combinations of defended nodes). In each round, the participant attacks a node and receives either a positive reward $v_i - c_i^a$ or a negative reward $-c_i^a$ depending on the defender's action. The setup in Figure 1 was the same for every participant.

We analyzed 4 measures associated with participants' performance, and we compared predictive algorithms using the same measures. **Switching** is a common measure of exploration used in human decision-making and learning studies (Gonzalez & Dutt, 2016; Todd & Gigerenzer, 2000). High switching indicates high exploration and low switching indicates exploitation in the case of a static defender and static environment. **Switching with Honeypot** is a measure of switching after attacking a honeypot (i.e., receiving a negative reward). This corresponds with the "Lose-Shift" aspect of Win-Stay-Lose-Shift (WSLS) (Robbins, 1985), a common strategy studied in economics. **Switching without Honeypot** measures switching after attacking a real node (i.e., receiving a positive reward). This opposes the "Win-Stay" aspect of the WSLS (i.e., "Win-Shift"). Finally, **Optimal Play** is the fraction of decisions that have the actual highest expected value.

Behavioral Results

The results for the 4 dependent measures are shown in Figure 2. The rightmost graph in Figure 2 shows the frequency of optimal decisions over the 50 rounds. We note that participants playing against the static pure defender learn very early to play optimally and significantly improve over time, while the difference between the static equilibrium defender and adaptive LLR defenders is not clear early on. A significant advantage for LLR only emerges after at least 20 rounds.

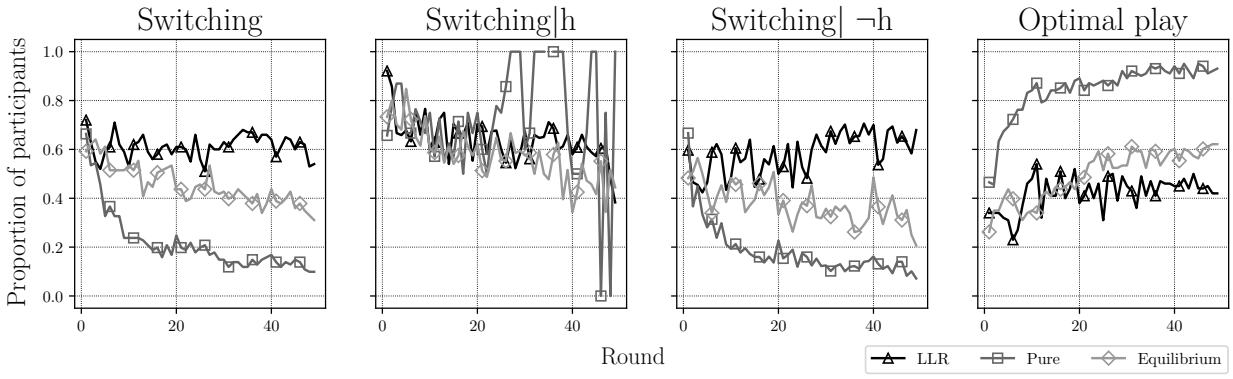

Figure 2: The proportions of participants switching nodes and playing optimally over time. The high switching after triggering a honeypot seen in round 26 from participants facing the static pure defender is a small portion of the population.

We also observe in the leftmost graph in Figure 2 that the overall proportion of switching decreases over time, particularly when participants face the static pure defender. When the participants face the adaptive LLR defender, they seem to have a high proportion of switching throughout the 50 rounds.

The middle left graph in Figure 2 describes the participants' switching behavior after triggering a honeypot. For the static pure defender, the attackers show noticeable spikes because only a few participants attacked the 20 point nodes (triggering the honeypots), upon which the players immediately switched. There are few differences between switching behavior when triggering honeypots of the participants who faced the equilibrium defender and those who faced adaptive LLR. We see a downward trend, hinting that the participants are moving from an early exploratory state to a more exploitative state. Since adaptive LLR updates it's beliefs about a node's expected payoff after playing it, if it captures an attacker that node will be more likely to be selected in the immediate future. Due to this adaptive behavior, switching when triggering a honeypot against adaptive LLR will be more beneficial than against the static equilibrium defender. When facing the static equilibrium defender in this scenario the attacker should always attack node 4, regardless of triggering a honeypot or not.

The middle right graph in Figure 2 shows distinct differences when the attackers did not trigger a honeypot (i.e., received a positive reward). Concerning the static pure defender and static equilibrium defender, decreases in switching demonstrate a move towards a more exploitative strategy and understanding of the static defense. Compare this with participants who faced the adaptive LLR defender where the switching remains high in comparison to the defenders. In general, adaptive LLR tries to react to the observed rewards and slowly moves from exploration to exploitation over time. High switching and remaining mobile is a good strategy against adaptive LLR. However, when we compare the participants' switching behavior with their performance versus adaptive LLR, it appears the participants were largely unable to learn the LLR strategy.

Overall, the pure defender predictably performed the worst (best for the human attackers), yielding an average score of 611.93 points. The equilibrium defender performed significantly better, yielding an average of 247.81 points. Finally, LLR was the most resilient defender against the human attackers with an average of 172.6 points yielded to the participants. Table 3 shows the aggregate statistics of the human attacker performance in terms of end-game attacker points.

	average	std. dev.	median	min	max
Pure	611.93	168.88	675	-375	750
Equ.	247.81	149.60	290	-185	570
LLR	172.6	123.02	160	-85	640

Adversarial Models

We evaluated 4 behavioral models and one cognitive model (IBL) (Gonzalez et al., 2003) to emulate participants' performance in the experiment. These models can give insights into the underlying mechanisms that influence decision making and support the development of better defense algorithms that hinder human attacker learning in cybersecurity settings. The models selected below are representatives of behavioral predictors that have been known to capture human performance in numerous MAB settings (Sripa et al., 2009; Zhang & Angela, 2013; Agrawal & Goyal, 2012).

Win-Stay-Lose-Shift: WSLS plays uniform randomly on the first round. If WSLS receives a positive reward, it attacks the same node again in the next round. Otherwise, it attacks another node uniform randomly. The "pass" action does not count as a positive reward.

ε-Greedy: This model addresses the exploration-exploitation dilemma directly with the parameter $\varepsilon \in \{0,1\}$. With probability ε, ε-Greedy attacks uniform randomly (exploration) and with probability $(1-\varepsilon)$, attacks the node with the highest observed average reward (exploitation).

ε-Greedy Decreasing: ε-Greedy Decreasing dynamically changes the parameter ε in order to prefer exploitation to-

Bold font indicates the lowest value in each column.

wards the end of the interaction. The predictor starts with $\varepsilon = 1$ and decreases it linearly towards $\varepsilon = 0$ at the end of the interaction, given a known finite horizon.

Thompson Sampling (TS): We follow the description of the TS algorithm as detailed by Agrawal and Goyal for Bernoulli Bandits (2012). We extend this version of the TS algorithm for the Bernoulli MAB by incorporating a support function $W_i(\theta_i)$ instead of selecting the action i with the maximum sample θ_i as described by Agrawal and Goyal. For this setting, we use a support function $W_i(\theta_i) = v_i \cdot \theta_i - c_i^a$ where $\theta_i \sim Beta(S_i + 1, F_i + 1)$ samples from a Beta distribution, thus the algorithm favors successes (S_i) over failures (F_i).

Instance-Based Learning: An IBL model (Gonzalez & Dutt, 2011) describes a learning attacker with an ability to recall and identify similar "instances" of past decisions using memory. An IBL instance represents a decision made in a specific situation, and the outcome feedback. The feedback here is the net payoff calculated as a difference between a successful and a failed attack, i.e., $v_i - 2c_i^a$. The IBL decision process has three main parameters: (1) decay, d, which specifies how past experiences are considered in current decisions based on time; (2) noise parameter σ, capturing random variability between experiences; and (3) the similarity, S, capturing the influence of the past on the present based on the similarity of the situations.

In the HCG game, an attacker can observe two possible outcomes of an attack on node i: a positive reward ($v_i - c_i^a$) when she attacks a real resource (success s_i) or a negative reward ($-c_i^a$) if the target is a honeypot (failure f_i). We denote an instance in memory representing a combination of situation, decision and outcome that was experienced in the past as $o(t') \in \bigcup_{i \in N} \{s_i, f_i\}$. In round t, an attacker targets a node i_t^* which maximizes a blended value (BV) as follows:

$$i_t^* \leftarrow \arg\max_{i \in N} BV_t(i) \tag{2}$$

$$BV_t(i) = (v_i - c_i^a) \frac{e^{A_t(s_i)}}{e^{A_t(s_i)} + e^{A_t(f_i)}} - c_i^a \frac{e^{A_t(f_i)}}{e^{A_t(s_i)} + e^{A_t(s_i)}} \tag{3}$$

$$A_t(o_i) = \ln \sum_{t' \in \{1,\ldots,t-1\}: o(t') = o_i} (t - t')^{-d} - \\ - S \sum_{i' \in N} (sim(i, i')) - \sigma \ln \frac{1-\gamma}{\gamma}, \tag{4}$$

where $\gamma \in (0, 1]$ is uniformly randomly sampled and *sim* is a similarity function. We used a linear similarity function that normalizes the net payoff from a decision based on the maximal payoff of 20 and is calculated as $sim(i, i') = 1 - |(v_i - 2c_i^a) - (v_{i'} - 2c_{i'}^a)|/20$.

We fit a separate IBL attacker model to human data when playing against each of the algorithmic defenders. We calibrated parameters values using exhaustive search over a wide range of values for each parameter with 350 repetitions for each combination. We used a multiobjective optimization minimizing average RMSE (see Equation 5) of all measures. The resulting three sets of parameters were: $(\sigma = 0.2, d = 0.1, S = 0.6)$ for the LLR defender, $(\sigma = 0.35, d = 1.2, S = 0.4)$ for the Pure defender and $(\sigma = 1.4, d = 0.5, S = 0.5)$ for the Equilibrium defender.

Simulation Results

To analyze the predictors' effectiveness in emulating human behavior we did a simulation with identical settings to the human experiment. Each predictor played against the 3 defenders in the same scenario 100 times. We consider the same performance measures as before. How well a predictor approximates human behavior is determined by a distance of a prediction $\{p\}_{t=1}^T$ from human data $\{hd\}_{t=1}^T$, calculated using the RMSE metric below where where m is a performance measure and T is a number of rounds.

$$RMSE_m(p, hd) = \sqrt{\frac{\sum_{t=1}^{50} (m(p_t) - m(hd_t))^2}{T}} \tag{5}$$

In Table 4, IBL accounted for the "most human" behavior on most of the measures when playing against the Pure and LLR defenders. In contrast, TS plays most closely to human performance when playing against the Equilibrium defender. This may be because the static equilibrium defender most closely reflects the standard stochastic MAB setting that TS was designed for. ε-Greedy, ε-Greedy Decreasing and WSLS perform poorly in general as predictors of human behavior.

However, these observations may only paint part of the picture. The actual overall point performance of human participants versus LLR is much lower than the 4 behavioral predictors as shown in Table 5. Nearly all 4 of the behavioral predictors double the median score of the human participants when facing the LLR defender. In contrast, the IBL model plays the most closely to human performance versus LLR. The IBL model comes rather close to the human data in relation to the

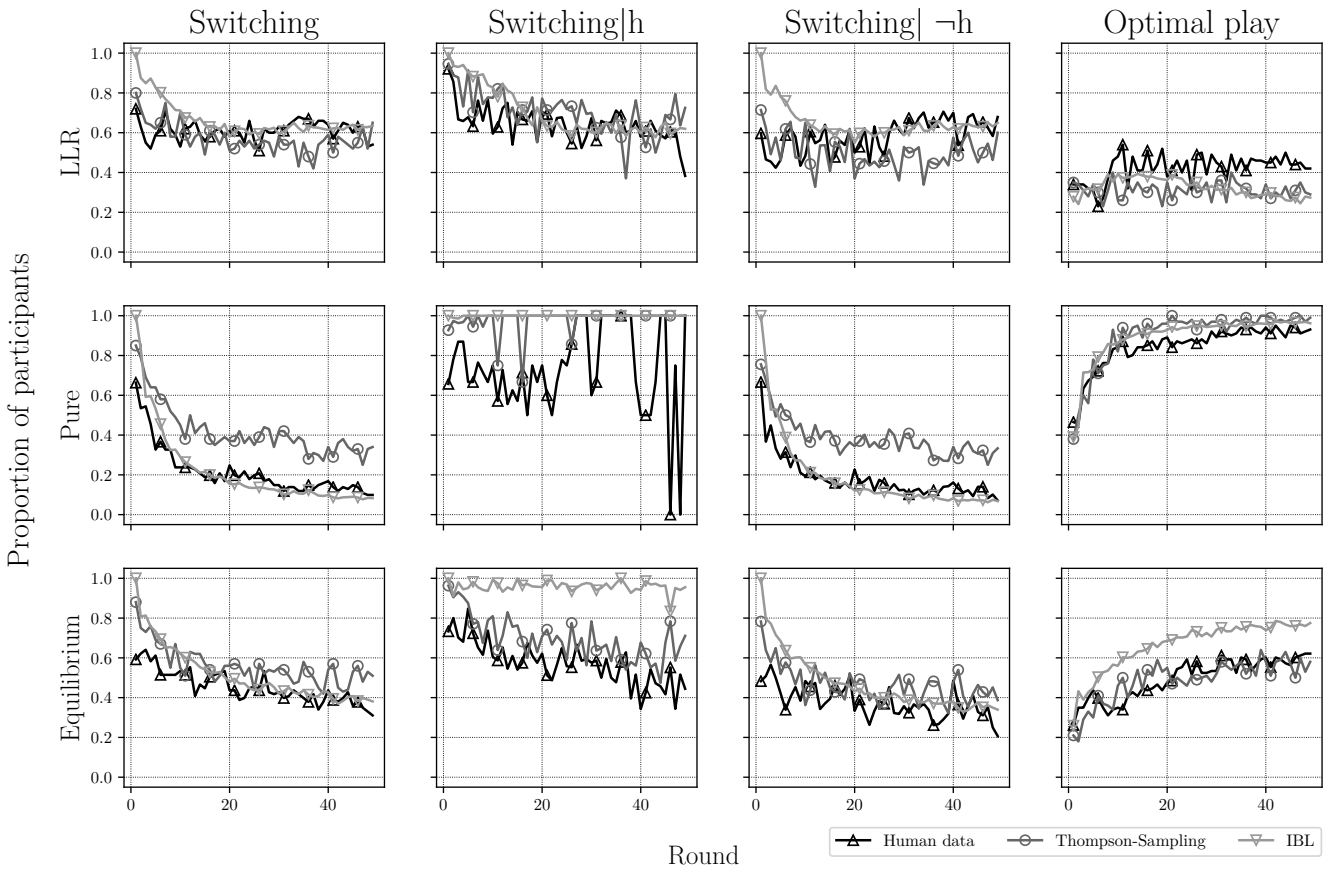

Figure 3: Comparison of the strategy predictions of TS and IBL with human data.

average and median scores. When considering all this information, it appears that the adaptive LLR defender exploited the human participants' learning mechanisms as well as IBL predicts. We can also see that humans may adopt different strategies depending on an opponent's strategy. Thus, when choosing a modeling approach there is a need to carefully select the granularity level at which predictions are needed: aggregate or individualized behavior. The IBL model can produce predictions at both levels.

Conclusion

We study how humans learn in a novel version of an adversarial, contextual multi-armed bandit scenario motivated by a real-world cybersecurity scenario where defenders use deceptive decoys and attackers must learn to avoid them. We evaluated three different types of defensive strategies and showed that an adaptive defensive strategy was clearly the strongest against human players, and the hardest for them to learn. We also made novel comparisons between predictive models for emulating how humans learn in this type of adversarial setting, comparing leading models from both the MAB literature and cognitive science. We find that the best models (Thompson Sampling and IBL) are able to predict human behavior quite effectively, but that human attackers use different strategies depending on the adversary they are up against, and the best predictor may depend on this context. There are many interesting opportunities to improve both types of models especially in making personalized predictions for individuals and specialized context. However, the results so far have immediate practical implications for how we can design better strategies for deploying decoy systems to enhance cybersecurity. In particular, these systems must be adaptive to prevent attackers from easily learning the defensive strategy. The predictive models of attacker learning we have developed will also allow us to develop defenses that actively mitigate the ability of attackers to learn the defensive strategy.

Abstract

Intuitively, human readers cope easily with errors in text; typos, misspelling, word substitutions, etc. do not unduly disrupt natural reading. Previous work indicates that letter transpositions result in increased reading times, but it is unclear if this effect generalizes to more natural errors. In this paper, we report an eye-tracking study that compares two error types (letter transpositions and naturally occurring misspelling) and two error rates (10% or 50% of all words contain errors). We find that human readers show unimpaired comprehension in spite of these errors, but error words cause more reading difficulty than correct words. Also, transpositions are more difficult than misspellings, and a high error rate increases difficulty for all words, including correct ones. We then present a computational model that uses character-based (rather than traditional word-based) surprisal to account for these results. The model explains that transpositions are harder than misspellings because they contain unexpected letter combinations. It also explains the error rate effect: expectations about upcoming words are harder to compute when the context is degraded, leading to increased surprisal.

Keywords: human reading, eye-tracking, errors, computational modeling, surprisal, neural networks.

Introduction

Human reading is both effortless and fast, with typical studies reporting reading rates around 250 words per minute (Rayner, White, Johnson, & Liversedge, 2006). Human reading is also adaptive: readers vary their strategy depending on the task they want to achieve, with experiments showing clear differences between reading for comprehension, proofreading, or skimming (Kaakinen & Hyönä, 2010; Schotter, Bicknell, Howard, Levy, & Rayner, 2014; Hahn & Keller, 2018).

Another remarkable aspect of human reading is its robustness. A lot of the texts we read are carefully edited and contain few errors, e.g., articles in newspapers and magazines, or books. However, readers also frequently encounter texts that contain errors, e.g., in hand-written notes, emails, text messages, and social media posts. Intuitively, such errors are easy to cope with and impede understanding only in a minor way. In fact, errors often go unnoticed during normal reading, which is presumably why proofreading is difficult.

The aim of this paper is to experimentally investigate reading in the face of errors, and to propose a simple model that can account for our experimental results. Specifically, we focus on errors that change the form of a word, i.e., that alter a word's character sequence. This includes letter transposition (e.g., *innocetn* instead of *innocent*) and misspellings (e.g., *inocent*). Importantly, we will not consider whole-word substitutions, nor will we deal with morphological, syntactic, or semantic errors.

We know from the experimental literature that letter transpositions cause difficulty in reading (Rayner et al., 2006; Johnson, Perea, & Rayner, 2007; White, Johnson, Liversedge, & Rayner, 2008). However, transpositions are artificial errors (basically they are an artifact of typing), and are comparatively rare.[1] It is not surprising that such errors slow down reading. This contrasts with misspellings, i.e., errors that writers make because they are unsure about the orthography of a word. These are natural errors that should be easier to read, because they occur more frequently and are linguistically similar to real words (*inocent* conforms to the phonotactics of English, while *innocetn* does not). This is our first prediction, which we will test in an eye-tracking experiment that compares the reading of texts with transpositions and misspellings.

Readers' prior exposure to misspellings might explain why reading is mostly effortless, even in the presence of errors. The fact remains, however, that all types of errors are relatively rare in everyday texts. All previous research has studied isolated sentences that contain a single erroneous word. This is a situation with which the human language processor can presumably cope easily. However, what happens when humans read a whole text which contains a large proportion of errors? It could be that normal reading becomes very difficult if, say, half of all words are erroneous. In fact, this is what we would expect in expectation-based theories of language processing, such as surprisal (Levy, 2008): the processor constantly uses the current context to compute expectations for the next word, and difficulty ensues if these expectations turn out to be incorrect. However, if the context is degraded by a large number of errors, then it is harder to compute expectations (and they become less reliable), and reading should slow down. Crucially, we expect to see this effect on all words, not

[1] For example, in the error corpus we use (Geertzen, Alexopoulou, & Korhonen, 2014) only 11% of the errors are letter swaps or repetitions, see Table 1.

just on those words that contain errors. This is the second prediction that we will test in our eye-tracking experiment by comparing texts with high and low error rates.

In the second part of this paper, we present a surprisal model that can account for the patterns of difficulty observed in our experiment on reading texts with errors. We start by showing that standard word-based surprisal does not make the right predictions, as it essentially treats words with errors as out of vocabulary items. We therefore propose to estimate surprisal with a character-based language model. We show that this model successfully predicts human reading times for texts with errors and accounts for both the effect of error type and the effect of error rate that we observed in our reading experiment.

Eye-tracking Experiment

The aim of this experiment was to determine how human reading is affected by errors in the input. As explained in the introduction, we expected different error types to affect reading differentially, as error types can differ in familiarity. In addition, we predicted the overall number of errors in a text to have an effect on reading behavior, because a high error rate degrades word context, which is crucial for computing expectations about upcoming material.

The experiment used a two-by-two factorial design, crossing error type (transpositions vs. misspellings) with error rate (10% of all words contain errors vs. 50%). Both of these variables were administered as between-text factors, i.e., we created four versions for each text, one with 10% transpositions, one with 10% misspellings, one with 50% transpositions, and one with 50% misspellings.

The two experimental factors were administered within participants, i.e., all participants read all our texts, each of them presented in one of the four versions. Versions were distributed across participants using a Latin square design, so as to ensure that every version was seen by the same number of participants.

Methods

Participants Sixteen participants took part in the experiment after giving informed consent. They were paid £10 for their participation, had normal or corrected-to-normal vision, and were self-reported native speakers of English.

Materials We used the materials of Hahn and Keller (2018), but introduced errors into the texts. These materials contain twenty newspaper texts from the DeepMind question answering corpus (Hermann et al., 2015). Ten texts were taken from the CNN section of the corpus and the other ten texts from the Daily Mail section. Texts were comparable in length (between 149 and 805 words, mean 323) and represent a balanced selection of topics. Two additional texts were used as practice items.

Each text comes with a question and a correct answer. The questions are formulated as sentences with a blank to be completed with a named entity so that a statement implied by the text is obtained. Three incorrect answers (distractors) are included for each question; these are also named entities, chosen so that they closely match the correct answer (e.g., if the correct answer is *Minnesota*, then the distractors are also US states).[2]

phonetics	deletion	swap/repeat	keyboard	insertion	other
36.2	16.7	11.0	10.5	8.3	17.3

Table 1: Percentages of different types of misspellings in the natural error condition.

We introduced errors into the materials of Hahn and Keller (2018) following the method suggested by Belinkov and Bisk (2018). These errors are automatically generated and are either transpositions (i.e., two adjacent letters are swapped) or natural errors that replicate actual misspellings. For the latter, we used a corpus of human edits (Geertzen et al., 2014), and introduced errors in our experimental materials by replacing correct words with known misspellings from our edit corpus. The percentages of different types of misspellings are listed in Table 1. By generating texts with errors automatically we were able to ensure that both error conditions (transpositions or misspellings) contain the same percentage of erroneous words for the two error rates (10% or 50% erroneous words).

Procedure Participants received written instructions, which mentioned that they would be reading texts with errors. They first went through two practice trials whose data was discarded. Then, each participant read and responded to all 20 items (texts with questions and answer choices); the items were presented in a new random order for each participant. The order of the answer choices was also randomized.

In each trial, the text was displayed over one or more pages (max 5, mean 2.1 pages), where each page contained up to eleven lines with about 80 characters per line. To get to the next page, and at the end of the text, participants again had to press a button. After the last page, the question was displayed, together with the four answer choices, on a separate page. Participants had to press one of four buttons to select an answer.

Eye-movements were recorded using an Eyelink 2000 tracker (SR Research, Ottawa). The tracker recorded the dominant eye of the participant (as established by an eye-dominance test) with a sampling rate of 2000 Hz. Before the experiment started, the tracker was calibrated using a nine-point calibration procedure; at the start of each trial, a central fixation point was presented. Throughout the experiment, the experimenter monitored the accuracy of the recording and carried out additional calibrations as necessary.

[2] We used the no questions preview condition of Hahn and Keller (2018), i.e., the questions were shown only after participants had read the whole text. The original paper also had a question preview condition, in which participants were shown the questions before they read the text.

Fixation rate	0.50	0.45	0.48
Accuracy	70%	72%	

Table 2: Left: per-word reading times, fixation rates, and question accuracies in the experiment of Hahn and Keller (2018), right: same measures for our experiments (same texts, but some of the words contain errors).

Data Analysis For data analysis, each word in the text was defined as a region of interest. Punctuation was included in the region of the word it followed or preceded without intervening whitespace. If a word was preceded by a whitespace, then that space was included in the region for that word. We report data for the following eye-movement measures in the critical regions: *First fixation duration* is the duration of the first fixation in a region, provided that there was no earlier fixation on material beyond the region. *First pass time* (often called gaze duration for single-word regions) consists of the sum of fixation durations beginning with this first fixation in the region until the first saccade out of the region, either to the left or to the right. *Total time* consists of the sum of the durations of all fixation in the region, regardless of when these fixations occur. *Fixation rate* measures the proportion of trials in which the region was fixated (rather than skipped) on first-pass reading. For first fixation duration and first pass time, no trials in which the region is skipped on first-pass reading (i.e., when first fixation duration is zero) were included in the analysis. For total time, only trials with a non-zero total time were included in the analysis.

Due to space limitations, we will only present analyses of the first pass time and fixation rate data in the remainder of this paper.

Results

In Table 2, we present some basic reading measures for our experiments, and compare these to the reading experiments of Hahn and Keller (2018), which used the same texts, but did not include any errors (the data is taken from their no question preview condition, which corresponds to our experimental setup, see Footnote 2). Even for words with errors, the reading measures in our experiments are similar to the ones reported by Hahn and Keller (2018). For words without errors, we find slightly faster reading times and lower fixation rates than Hahn and Keller (2018). Also the accuracy (which can only be measured on the text level, hence we do not distinguish words with and without errors) is essentially unchanged. This provides good evidence for the claim that human readers cope well with errors in text: they take longer to read words with errors and fixate them more compared to words without errors, but this this is a comparatively small effect. Overall, reading times, fixation rates, and question accuracy are very similar to those found in texts without any errors (such as the ones used by Hahn & Keller, 2018).[3]

In the following, we analyze two reading measures in more detail: first pass time and fixation rate. We analyzed per-word reading measures using mixed-effects models, considering the following predictors:

1. ERRORTYPE: Does the text contain mispellings (-0.5) or transpositions ($+0.5$)?
2. ERRORRATE: Does the text contain 10% (-0.5) or 50% ($+0.5$) erroneous words overall?
3. ERROR: Is the word correct (-0.5) or erroneous ($+0.5$)?
4. WORDLENGTH: Length of the word in characters.
5. LASTFIX: Was the preceding word fixated ($+0.5$) or not (-0.5)?

All predictors were centered. Word length was scaled to unit variance. We selected binary interactions using forward model selection with a χ^2 test, running the R package `lme4` (Bates, Mächler, Bolker, & Walker, 2015) with a maximally convergent random effects structure. We then re-fitted the best model with a full random effects structure as a Bayesian generalized multivariate multilevel model using the R package `brms`; this method is slower but allows fitting large random effects structures even when traditional methods do not converge. Resulting Bayesian models are shown in Table 3. We used the `brms` default priors (Bürkner, 2017), with four chains with 1000 samples each (and 1000 warmup iterations). The $\hat{R}$ values (≤ 1.01) indicated that the models had converged.[4]

The main effects of WORDLENGTH replicate the well-known positive correlation between word length and reading time (see Demberg & Keller, 2008, and many others). We also find main effects of ERROR, indicating that erroneous words are read more slowly and are more likely to be fixated. The main effects of ERRORRATE show that higher text error rates lead to longer reading times and higher fixation rates for all words (whether they are correct or erroneous). Additionally, we find a main effect of ERRTYPE in fixation rate, showing that transposition errors lead to higher fixation rates. This is consistent with our hypothesis that misspellings are easier to process than transpositions, as they are real errors that participants have been exposed in their reading experience.

Figure 1 graphs mean first pass times and fixation rates by error type and error rate. The most important effect is that

[3] Note that participants are not performing at ceiling in question answering; our pattern of results therefore cannot be explained by asserting that the questions were too easy.

[4] An analogous analysis for log-transformed first-pass times led to the same pattern of significant effects and their directions.

	First Pass	Fixation Rate
(Intercept)	248.41 (6.34)***	−0.16 (0.12)
ErrType	1.41 (1.32)	0.08 (0.02)***
ErrRate	7.20 (1.60)***	0.16 (0.02)***
Error	23.77 (4.12)***	0.21 (0.07)***
WLength	22.18 (2.02)***	0.83 (0.04)***
LastFix	3.10 (4.18)	0.22 (0.18)
ErrRate × LastFix	6.71 (2.77)*	0.16 (0.04)***
Error × LastFix	—	0.26 (0.10)**
WLength × LastFix	—	0.74 (0.10)***

$Pr(\beta < 0)$: *** < 0.001, ** < 0.01, * < 0.05

Table 3: Bayesian generalized multivariate multilevel models for reading measures with maximal random-effects structure. Each cell gives the coefficient, its standard deviation, and the estimated posterior probability that the coefficient has the opposite sign.

error words take longer to read and are fixated more than non-error words. The effect of error rate is also clearly visible: the 50% error condition causes longer reading times and more fixations than the 10% one, even for non-error words. We also observe a small effect of error type.
