Accuracy and hit, miss, correct rejection, and false alarm rates across all words are shown in Table 4. In overall old/new item recognition memory, there was a main effect of word type ($\chi^2(1) = 12.29$, $p < .001$), where memory was better for concrete words. Among targets only, there was no main effect of word type, nor was there a main effect of box retention. There was, however, an interaction between word type and box retention ($\chi^2(1) = 4.92$, $p = .03$; Figure 3). Accuracy was *worse* when the box color was retained in abstract concepts, again operating counter to the original hypothesis, and leading to the perhaps surprising conclusion that arbitrary episodic context may even be *suppressed* in abstract concepts.

Table 4
Mean Item Recognition Accuracy

Word type	Acc	Hit	Miss	CR	FA	d'
Abstract	.76	.76	.24	.78	.22	1.59
Concrete	.81	.80	.20	.84	.16	2.04

General Discussion

Abstract concepts are sensitive to context, but what is the mechanism by which this sensitivity emerges? The episodic memory system was identified as a potential candidate for encoding contextual information when processing abstract concepts. In Experiments 1 and 2, however, there was a concreteness advantage for recognizing episodic contexts. In Experiment 3, context preservation conferred a *disadvantage* for recognizing abstract concepts, suggesting the presence of a mechanism whereby arbitrary association are *inhibited* in the episodic experience(s) of the situations that activate abstract concepts.

In spite of these findings, across several literatures it is agreed that context is critical for understanding abstract concepts. However, there are differences across frameworks in terms of the *type* of context specified as being critical to processing abstract concepts, ranging from semantically constraining linguistic context in context-availability theory (Schwanenflugel & Shoben, 1983), to thematic associations in the qualitatively different representations framework (Crutch & Warrington, 2005), to meaningful situational and internal factors in grounded cognition (Barsalou & Wiemer-Hastings, 2005). While this study sought to uncover a basic mechanism that might unify these approaches (i.e., sensitivity to episodic information), the results unequivocally ran counter to our hypothesis: there is a concreteness advantage for encoding simple episodic detail.

Concreteness, context, and episodic memory

Concreteness is a powerful organizing factor in semantic memory (e.g., De Deyne, 2017; Hollis & Westbury, 2016), and concreteness effects are near ubiquitous in recognition memory studies. The present results suggest that such effects extend beyond stronger memory for concrete concepts to better associative. *relational memory* for concrete concepts, at least when the relation is a simple, arbitrary context. One important consideration here is the way in which we might expect context to be differentially recruited for processing concrete and abstract concepts, as this has implications for the relation between context sensitivity and concreteness.

In a review of the pervasiveness of context effects in cognition and perception, Yeh and Barsalou (2006) present two primary theses for how context affects concept processing: (1) contexts and concepts mutually activate each other, such that when processing a context, associated concepts are activated, and vice versa; and (2) when processing a concept in a particular context, properties of the concept which are relevant to that context become active. These two theses have different implications for the relation between context sensitivity and concreteness.

The first thesis resonates strongly with context availability theory, and likely suggests a concrete word advantage: concrete concepts activate contexts more strongly because they have stronger implicit ties to specific contexts. Thus, building implicit, direct associations between context and concept may have been facilitated by a similar mechanism to that which underpins context availability effects—if concrete concepts are typically associated with these sorts of contexts, then such contexts (such as boxes and

voices) might be more likely to be encoded with concrete concepts.

The second thesis may be more pertinent to abstract concept processing: when processing *decision* in the context of your choice of beverage at 9pm in the local café, the activated properties will be different from when processing decision in the context of a judge determining the appropriate sentence for a felon convicted of battery. That is, the schema-based knowledge necessary in these two situations differs considerably. *Decision* has a number of possible interpretations, and its precise meaning—and thus, the properties activated—depends on the situation and (systematically) associated schema-based knowledge. Research on the neural dynamics underpinning schema processing (e.g., van Kesteren et al., 2013) suggests that activating these systematic associations may in fact suppress the formation of associations with arbitrary elements of an episode. This dynamic is rooted in the interplay between neural systems in medial frontal and medial temporal lobe, where medial frontal activation when processing systematic associations may dampen activation of medial temporal lobe, thereby suppressing the formation of arbitrary bindings. Exploring these neural dynamics in this paradigm is an important direction for future work.

In summary, we contend that abstract concepts activate systematic—or *schema*-based—contextual information, and when processing *decision*, the activation of schema-based information may in fact *inhibit* formation of arbitrary associations. This would explain why our arbitrary episodic contexts were not well remembered for abstract concepts (Experiments 1 and 2) and why context retention may have even *inhibited* word recognition (Experiment 3). That is, abstract concepts may be particularly sensitive to *systematic* or *schema*-based contextual constraints, implicitly activating these associations when they are absent, and thus simultaneously inhibiting *arbitrary* contextual associations.

Limitations

The synonym judgment task used at encoding may have worked to a disadvantage: as abstract concepts tend to have more diverse meanings, synonym judgments may be more difficult for abstract concepts, as it must be determined whether *any particular sense* of the word is a synonym to the target (Hoffman et al., 2013). Thus, an abstract concept like *decision* when paired with *judgment* might leave fewer resources available to process immediately available relational information (i.e., in the present study, the box color or the voice) because we must search for a context in which *decision* and *judgment* are in fact synonyms (a recent computational model makes this prediction; Popov & Reder, 2018). Relatedly, if abstract concepts are simply more difficult to process, and the context does not help with accessing the meaning of the word, it could render the immediate context less salient. Thus, future research on context encoding in abstract and concrete concepts might benefit from departing from low-level episodic contexts. While we focused on arbitrary episodic detail, it might be fruitful to instead explore *systematic* contextual relations. For example, abstract concepts are thought to be represented in thematic or associative networks (e.g., *faith–church*), and so we might expect to see an abstract advantage in such contexts (for related evidence showing precisely this in relational vs. entity concepts, see Asmuth & Gentner, 2017). Finally, our finding that context reinstatement did not improve item recognition even for concrete words was perplexing. This may be because we only used two contexts—context-preservation advantages may not be observed when the context is shared across too many items (Park et al., 2006). That said, with just two contexts, reinstatement still *impaired* item recognition for abstract words, implying that a context preservation *disadvantage* can be detected with only two contexts. Nevertheless, further research is necessary to better understand the interaction between abstract concepts and arbitrary episodic contexts.

Conclusions

This research suggests that arbitrary episodic detail is better bound with concrete than abstract concepts. Abstract concepts rely on situational context for interpretation, and given that activation of situational information is known to inhibit formation of arbitrary associations (van Kesteren et al., 2013), formation of arbitrary associations may be *inhibited* in abstract concepts. More broadly, the way in which the episodic memory system is recruited appears to differ as a function of concreteness, suggesting that engagement of the episodic memory system is modulated by semantic content.

Abstract

What does it take to learn a new word? Many of the words we learn, we have learned from language itself – by encountering them in various informative contexts. Here, we investigate the limits of learning from context by studying how people learn new words from very sparse contexts, at the extreme, a context in which all content words are replaced by nonsense words. We find that participants exposed to even such extremely *sparse* contexts nevertheless learn something about the meaning of words embedded in those contexts. Performance tended to be better when knowledge was assessed by first directing people's attention to the part of speech of the target words.

Keywords: language; word learning; distributional semantics; syntactic bootstrapping.

Introduction

How do we learn the meanings of words? One way is by associating words with external referents. This is of particular importance in early word-learning when children's vocabulary is dominated by concrete nouns ("cup", "nose"), action verbs ("jump", "bark") and words used by children as imperatives ("more", "up"). As we become more mature language users, our vocabulary expands to contain a large proportion of items that do not have concrete referents (e.g., "terrible", "hope" and "fun"). These words must be learned through language itself.[1]

One way to learn word meanings through language is through explicitly provided definitions. For example, on encountering the sentence "The Celtics Coach was livid over the call, hurling an expletive at the officials.", one might look up "livid" to learn that a common meaning is "furiously angry". But we can also learn something about the possible meaning of livid through its context. Indeed, school-age children learn, on average, between 600 and over 3,000 new words per year (Nagy & Herman, 1984; Nagy, Herman, & Anderson, 1985). That these words are learned via direct instruction or through dictionaries is highly unlikely (Nagy & Anderson, 1984).

In this work we investigate the limits of learning from linguistic context. We already know that school-age children and adults are adept at learning from informative contexts such as the "livid" example above. We were curious whether learning something about a word's meaning is possible even when contexts are highly impoverished. At the extreme, we investigate learning meanings of nonce words from contexts in which all content words are replaced with nonce terms. How can people learn word meanings from contexts that themselves contain only nonce words? One way is through the use of morpho-syntactic cues.

The idea that people can learn words through morpho-syntax is generally known as "syntactic bootstrapping". Preschool children can use both morphology and syntax to infer the meanings of novel words (Gleitman, 1990; A. E. Goldberg, 2003; Naigles & Swensen, 2007). In a classic demonstration, Brown (1957) showed 3-5 year old children images such as a pair of hands emptying an odd container of a novel slushy material. The children were then told that "in this picture you can see sibbing/a sib/some sib", and were asked to point to another instance of sibbing/a sib/some sib. The finding that children were more likely to point to a substance when presented with "some sib" and an object when presented with "a sib" suggests that they are learning (coarse) aspects of meaning from morpho-syntactic cues. In a more recent study, Naigles presented 2-year old children with the novel word "gorping" and two videos of novel actions, one causative and one non-causative. The sentence frame in which the verb was presented influenced which action children chose for the verb (Naigles, 1990). Although these experiments show that even young children can make use of morpho-syntactic cues to learn something about what the word means, they do not tell us about the limits of our ability to learn word meanings in this way. In these classic studies, the to-be-learned are marked, e.g., by being the only unfamiliar word in the utterance. The contexts that are used tend to be quite informative and the meanings being learned are constrained by the accompanying pictures or videos. Lastly, the assessment of what is being learned in such studies tend to be quite limited. The children in Brown's study could answer "correctly" simply by inferring that "sibbing" is an action, without learning anything more specific about its meaning.

But we know that people can do more. For example, even in a language with relatively simple morphology – English – a sentence like "The gostak distims the doshes" is surprisingly meaningful. We can infer that a "gostak" is doing something ("distimming") and it is doing it to the "doshes" (Ingraham, 1903). We may further infer that a gostak may be an animate

[1] Indeed, in the largest set of concreteness/abstractness norms (Brysbaert, Warriner, & Kuperman, 2014), words were defined as "abstract" if their meanings could not be communicated via direct reference or through action, but rather would have to be explained through language.

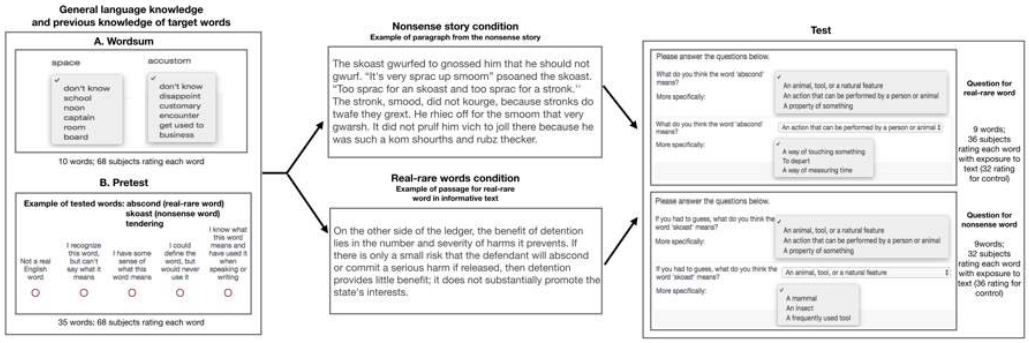

Figure 1: Schematic for Experiment 1.

agent and "distimming" is an action that the gostak is capable of performing. Remarkably, even without *any* referential context, exposure to sequences of such sentences appears to be sufficient for people to navigate an entire virtual world. Players of *The Gostak* (Muckenhoupt, 2001) quickly learn to *deave in the tavid dorl and gomb the stike*.

Another hint that language contains rich cues to word meanings comes from attempts to derive semantic representations from the ground up, by tracking word co-occurrences to learn that words occurring in similar contexts have similar meanings (Landauer & Dumais, 1997; Lany & Saffran, 2010; Levy & Goldberg, 2014; Mikolov, Chen, Corrado, & Dean, 2013; Redington, Chater, & Finch, 1998) – the so-called distributional hypothesis of word meaning (Firth, 1957). McDonald and Ramscar (2001) tested the distributional hypothesis by manipulating the linguistic context surrounding very rare or nonce words showing that judgments involving the target words are affected by the distributional properties of the manipulated linguistic environments.

Our main goal is to investigate the limits of people's ability to learn word meanings from linguistic context. We do this by exposing adult English speakers to contexts varying in informativeness ranging from fully informative contexts – passages of real English text containing real words unknown to most of our subjects, to highly sparse contexts that contain English morpho-syntactic cues (e.g., verb endings), but in which all content words have been replaced by nonsense words. We test people's knowledge of both part of speech information (the sole focus of much of the classic work on syntactic bootstrapping), *and* knowledge of more specific aspects of meaning.

Experiment 1

In experiment 1, we tested the role of the linguistic context in inferring word meanings for real, but rare English words (e.g., "kine") that were presented in informative contexts and for nonce words (e.g., "stronk") placed in highly *sparse* contexts which were stripped of almost all meaningful words.

Participants We recruited 114 participants from Amazon Mechanical Turk (52 Males of average age = 37; 62 Females of average age = 39). 68 of these participated in the main word-learning experiment (32 in the nonsense-story condition and 36 in the real-passages condition) and 46 participated in the salience-norming task.

Materials Participant were randomly assigned to one of two conditions: a nonsense-story condition and a real-passages condition. For the nonsense-story condition, all participants were exposed to the children's story *Why the cricket chirps*[2]. Participants were not provided with the story's title or any information about its content. Of the 604 total tokens in the story, 169 were open-class words. We replaced all the content words with nonce words taken from the ARC Nonword Database (Rastle, Harrington, & Coltheart, 2002). These words were created from orthotactically legal bigrams, onsets, and bodies. Fig. 1 shows a part of the resulting story. Of the 136 word types in the story that were replaced with nonce words, we selected 9 to serve as targets for later testing. Participants did not know ahead of time which words would be tested. The target words varied in frequency, occurring between 2 and 18 times, and parts of speech: 4 nouns, 3 verbs, 2 adjectives. Derivational and inflectional morphemes in the story were limited to a small number of cases (see Table 1 for morphological variation present for each target word).

For the real-passages condition, we matched each of the 9 target words in the nonsense-story condition with real, but rare English words that were unlikely to be familiar to our participants (e.g. "ratoon", "pronk, "rawky"; henceforth *real-rare* words). For each word, we selected 3-4 sentences in which the word appeared from the Corpus of Contemporary American English (COCA) and other online sources to serve as the context (see Fig. 1). Participants' word knowledge in all conditions was tested using "drill-down questions" designed to be sensitive to partial word knowledge. The first question provided three options for part of speech and the second question had participants choose between three word meanings all within the chosen part of speech: 1 fully correct, 1 partially correct, and 1 incorrect (see Fig. 1).

Quantifying word salience We expected that people's ability to infer word meanings would be influenced by the fre-

[2] https://www.freechildrenstories.com/why-the-cricket-chirps

quency with which the target word occurred in the passage. But we also suspected that aside from frequency, performance would also be related to a word's *salience* (C. M. Brown, 1993). There is no single definition of salience, but intuitively, a word is salient to the extent that it communicates the central point of a story. For example, words naming the actions performed by a central character are more salient than words describing aspects of the environment that a non-central character inhabits. We quantified the salience of each target word as the likelihood that it would be recalled by people who read the original (unaltered) story. We recruited 46 participants from MTurk to read the original story and then had 1 minute to recall all the words they could remember occurring in the story. Salience for each word was defined as the sum of the weights that the word obtained each time it was listed: the weight was calculated as exponentially decreasing in accordance with the order in which words were listed by participants [(for each time the word was listed) weight = (0.75^(word_n -1))] (see Table 1 for frequency and salience of each target word).

Table 1: Frequency, salience and morphological variation for target words

Target word	Frequency	Salience	Derivational Morphology	Inflectional Morphology
fly	18	6.59	1 derivational form (-er)	2 inflected forms (-ed; -ing)
cricket	16	31.69	none	1 inflected from (-s)
cold	7	5.69	none	none
wing	6	8.26	none	1 inflected from (-s)
fast	6	3.76	none	2 inflected forms (-er; -est)
chirp	5	8.49	none	3 inflected forms (-s; -ed; -ing)
ant	5	6.91	none	none
hop	5	1.06	none	none
snow	5	2.56	none	none
rub	4	1.90	none	2 inflected forms (-ed; -ing)
listen	4	1.47	none	none
warm	4	1.31	none	none
tree	3	0.44	none	1 inflected from (-s)
frozen	3	4.82	none	none
ground	2	0.00	none	none
owl	2	10.35	none	none

Procedure General procedure is shown in Figure 1. At the start of the task, participants completed a 10 item vocabulary test (Wordsum; Malhotra, Krosnick, & Haertel, 2007) and a pretest gauging familiarity with the target words. Participants were then randomly assigned to the real-passages or the nonsense-story condition. Those assigned to the real-passages condition saw each (meaningful) context and answered the two vocabulary questions for each of the 9 real-rare words (in random order). Each word was tested immediately after being presented in its context. The group was then tested on nonce words (skoast, etc.). In contrast, participants in the nonsense-story condition saw the entire 604-word nonsense-story and were then tested on the real-rare words, and then on 9 of the target nonce words (in random order). This design allowed each condition to serve as the control for the other condition. Subjects in the nonsense-story condition were asked to infer the meaning of the *real-rare* words without exposure to the passages and vice versa. As an attention check, scattered among nonce and *real-rare* words were questions about the meaning of familiar words (e.g. "little", "green").

Results and Discussion We analyzed the data using logistic mixed effects models. In the initial analyses, we treated partially and completely correct scores for specific meaning as the same (i.e., a binary contrast between an accuracy of 0 and 0.5/1). Figure 2 shows a clear interaction between condition (real-passages, nonsense story) and word-type (real-rare, nonce). This interaction was present both for part of speech [z = 7.3, SE = 0.28, $p < .001$] and word meanings [z = 9.1, SE = 0.29, $p < .001$] [accuracy ~ type_of_word*condition+(1|subj_id)]. Participants in the real-passages condition were significantly more accurate at selecting meanings corresponding to the correct part-of-speech of real words compared to participants in the nonsense-story condition (i.e., those not exposed to the real passages) [z = -3.7, SE = 0.39, $p < .001$]. They were also better at choosing the more correct specific meanings [z = 4.6, SE = 0.4, $p < .001$] [accuracy (for specific meaning or for part of speech) ~ condition+(1|subj_id)+(1|word)]. Note that above chance performance for the *real-rare* words is expected even without being exposed to real passages because some participants already know the meaning of these words. Not surprisingly, accuracy on *real-rare* words was positively associated with greater vocabulary as assessed by Wordsum. This was true both for part of speech [z = 2.8, SE = 0.17, p = .005] and specific meaning measures [z = 3.7, SE = 0.19, $p < .001$] [accuracy (for specific meaning or for part of speech) ~ condition*wordsum_score+(1|subj_id)+(1|word)]. Greater familiarity with the target *real-rare* words (pretest) was positively related to selecting the correct part of speech [z = 2.1, SE = 0.16, p = .033] and specific meaning [z = 2.9, SE = 0.16, p = .004].

The results for the real-rare words tell us what we already knew – people can infer word meanings from seeing the words in context. We now turn to the nonsense-story condition. Recall that these nonce words were seen in the context of a 600+ word story in which *all* content words were replaced by nonce words. Participants exposed to this extremely sparse context had significantly higher performance in inferring the correct part of speech for the nonce words [z = 3.9, SE = 0.23, $p < .001$] and in choosing the more correct meanings [z = 4.4, SE = 0.25, $p < .001$]. The benefit from reading the nonsense story was not limited to just helping people choose the correct part of speech. Restricting the analysis to only the trials on which participants chose the correct part of speech, we find that exposure to the nonsense-story still led to higher accuracy [z = 2.9, SE = 0.35, p = .004] [$\text{accuracy}_{\text{part\_of\_speech}}$ ~ condition+(1|subj_id)+(1|word)]. Neither Wordsum nor Pretest scores predicted performance for nonce words. Word frequency and word salience likewise did not predict performance ($z<1$, but see Exps. 2 and 3).

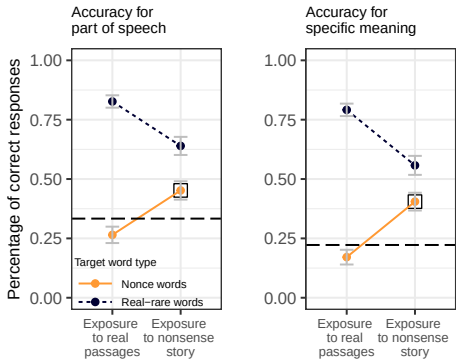

Figure 2: Accuracy for type of target word for Experiment 1. Horizontal dashed lines indicate chance-level. Error bars indicate +/-1SE of the mean. Significant effect of context exposure for nonce words in the nonsense-story is marked by a squared shape around the relevant data-point in the graph.

Experiment 2

Experiment 1 showed that people can benefit from very sparse contexts. One shortcoming of the study was that participants in the real-passages and nonsense-story conditions were exposed to contexts in a different way (short passages vs. one long story; tested after each word vs. tested on all words at once). In Experiment 2, we test participants in the same way on all the same words, varying just the informativeness of the context. We were also curious about whether it mattered how word knowledge was assessed. Instead of using the "drill-down" format that first asked about part of speech, we used a more standard multiple-choice text, presenting all the 9 options for each word at the same time. Lastly, we parametrically varied the informativeness of the context by replacing different proportions of content words with nonce words.

Methods Participants were randomly assigned to one of six conditions (see Table 2 for a summary). In the real-text condition we exposed participant to the original *Cricket* story, in which we replaced only the target words with *real-rare* English words. Thus, the linguistic context was still informative (i.e., the target words were surrounded by meaningful words) but it did not directly aim at communicating the meaning of the target words, e.g., *'You should find some shelter from the cold night,' said the smew. The mitius did not auscult, because mitiuses do whatever they want. He decided to rest on a pile of twigs.* We progressively decreased the information provided by the context by replacing various proportions of the remaining content words in the story with nonce words (40%, 60%, 90%, 100%). Lastly, we included a control group that was tested on their knowledge of the *real-rare* words without seeing any prior context.

Participants We recruited 246 participants from Amazon Mechanical Turk (112 Male of average age = 35; 132 Females of average age = 38). 38 participants were assigned to the real-text condition, 36 to the 40% condition, 39 to the 60% condition, 42 to the 90% condition, 52 to the 100% condition and 39 to the control condition.

Procedure Participants in each condition were initially tested on Wordsum and Pretest (following the procedure for Experiment 1) and then randomly assigned to one of the six conditions described above. All participants were then presented with the same 12 multiple choice questions (9 options per question) to assess their knowledge of the *real-rare* words.

Results and Discussion Results are shown in Fig. 3. Participants exposed to the full story clearly benefited in inferring both part of speech [z = 5.9, SE = 0.22, p $<$ .001] and specific meaning [z = 5.6, SE = 0.25, p $<$ .001] of *real-rare* words [accuracy˜overall ˜ control_vs_full_story +(1|subj_id)+(1|word)]. Similar results were found for the 40% and the 60% conditions, in which participants showed compelling effects for both part of speech [z = 4, SE = 0.22, p $<$ .001] and specific meaning [z = 3.8, SE = 0.25, p $<$ .001]. In contrast, when 90% or 100% of content words were replaced with nonce words, no significant benefit was observed for either part of speech [z = 1.2, SE = 0.2, p = .226] nor specific meaning [0.77, SE = 0.23, p = .444] results (Fig. 3).

Frequency of occurrence in the story was positively associated with accuracy for the real-text condition, [z = 2.7, SE = 0.16, p = .008] [accuracy ˜ condition*frequency+(1|subj_id)+(1|word)] and salience [z = 2.3, SE = 0.16, p = .023] [accuracy ˜ condition*salience+(1|subj_id)+(1|word)] in predicting accuracy for specific meaning. More frequent and more salient words benefited more from context. Similar effects were found in the 40% and 60% conditions for accuracy on specific meaning [frequency: z = 3.8, SE = 0.16, p $<$ .001; salience: z = 2.3, SE = 0.16, p = .023] [accuracy ˜ condition*wordsum_scores+(1|subj_id)+(1|word)]. Controlling for pretest scores, greater vocabulary knowledge (Wordsum) was positively associated with accuracy for both part of speech [z = 2.7, SE = 0.12, p = .006] and specific meaning [z = 2.7, SE = 0.14, p = .007]. Similarly, previous word knowledge was positively associated with part of speech accuracy [z =2.4, SE = 0.084, p = .018] and specific meaning accuracy [z = 2.9, SE = 0.086, p = .003] [accuracy ˜ condition*pretest_scores+(1|subj_id)+(1|word)]. These associations parallel the findings of the real_rare words condition of Experiment 1.

Exposure to a story in which 40%-60% of content words were replaced with nonce words still allowed participants to learn something about meanings of words occurring in the story. There were two noteworthy differences between the results of Experiment 1 and 2. First, unlike Experiment 1, participants' ability to benefit from the story context was positively associated with the frequency with which the word occurred in the story and the word's salience. These relationships may stem from people's greater baseline knowledge of the (real-rare) target words. Second, exposure to a story in

Table 2: Summary of type of context, type of target word and methods is assessing word meaning in each experiment.

Experiment	Condition Name	Type of Text	Type of Target Word	Example Words	Question Test Type
Experiment 1	Real-passages	Real-rare target words; informative text	real-rare words	ratoon; pronk; rawky	drill-down
	Nonsense-story	Nonce-target words; nonsense story	nonce words	stronk; sprac; crex	drill-down
Experiment 2	Real-text	Real-rare target words: real story	real-rare words	auscult; lollop; smuir	multiple choice
	Real-words-nonce-context: 40%	Real-rare target words; 40% of context replaced with nonce words	real-rare words	auscult; lollop; smuir	multiple choice
	Real-words-nonce-context: 60%	Real-rare target words; 60% of context replaced with nonce words	real-rare words	auscult; lollop; smuir	multiple choice
	Real-words-nonce-context: 90%	Real-rare target words; 90% of context replaced with nonce words	real-rare words	auscult; lollop; smuir	multiple choice
	Real-words-nonce-context: 100%	Real-rare target words; 100% of context replaced with nonce words	real-rare words	auscult; lollop; smuir	multiple choice
	Control group	No exposure to story	real-rare words	auscult; lollop; smuir	multiple choice
Experiment 3	Real-words-nonce-context: 100%	Real-rare target words; 100% of context replaced with nonce words	real-rare words	auscult; lollop; smuir	drill-down
	Control group	Nonsense story with all words replaced with nonce words	real-rare words	auscult; lollop; smuir	drill-down

which all the content words with nonce words did not lead to greater-than-baseline performance on the word test. Experiment 3 was designed to better understand this difference.

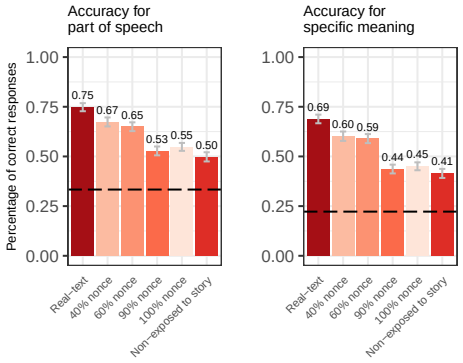

Figure 3: Group performance for Experiment 2. Horizontal dashed line indicated chance-level. Error bars indicate +/- 1SE of the mean.

Experiment 3

In Experiment 1, we found a significant effect of context exposure in inferring the meaning of nonce words from nonsense context. In Experiment 2 we assessed knowledge of *real-rare* words instead of nonce words, and embedded them in contexts of varying informativeness. Contexts in which 40-60% of content words replaced with nonce words were helpful, but those in which more (90%-100%) of content words were thus replaced, were not helpful. How do we reconcile this difference? Aside from testing nonce words vs. real-rare words, Experiments 1 and 2 differed in the way word knowledge was assessed. Experiment 1 first asked about part-of-speech. Experiment 2 presented all the meaning choices together, intermixing meanings from different parts of speech. We reasoned that explicitly asking people about parts of speech (which are more directly bootstrapped by morpho-syntactic cues) may make it easier for people to subsequently access more specific aspects of the word's meaning. In Experiment 3 we tested the effect of exposing people to a nonsense-story containing *real-rare* words as the *real-words-nonce-context (100%)* condition of Experiment 2, but using the drill-down question format of Experiment 1.

Methods Participants were randomly assigned to either the *real-words-nonce-context: 100%* or to a control condition. In the *real-words-nonce-context*, participants were exposed to a nonsense-story containing the *real-rare* target words and tested on those *real-rare* words (as in the 100% condition of Experiment 2). Participants in the control condition were shown a story with all nonce words (as in the nonsense-story condition of Experiment 1) but at test were asked about the meaning of the *real-rare* target words of the *real-words-nonce-context* condition (i.e., they were asked about words they did not see in the story).

Participants We recruited 81 participants from Amazon Mechanical Turk (39 Male of average age = 37; 41 Females of average age = 37). 41 to the *real-words-nonce-context: 100%* story condition and 40 to the control condition.

Procedure Participants in each condition were initially tested on Wordsum and Pretest (following the procedure for Experiment 1) and then randomly assigned to either the *nonsense-story* condition or to a control group that was not exposed to a story. All participants were tested on the same set of drill-down questions.

Results and Discussion Results are shown in Fig. 4. We found a significant effect of exposure to the linguistic context in inferring the part of speech [z = 3, SE = 0.18, p = .002] and the specific meaning [z = 2.6, SE = 0.2, p = .008] of *real-rare* words when compared with the control condition [$\text{accuracy}_{\text{overall}}$ ~ condition+(1|subj_id)] (Fig. 4). When examining only trials on which participants inferred the correct part of speech, the benefit of exposure to a nonce story on inferring the correct specific meaning was no longer significant [z = 0.5, SE = 0.31, p = .614] [$\text{accuracy}_{\text{part\_of\_speech}}$ ~ condition+(1|subj_id)+(1|word)]. To determine if the nonce-word context in the present study was more effective than in the equivalent condition of Experiment 2, we examined the interaction between experiment (*Exp. 2* vs. *Exp. 3*) and condition (*control group* vs. *real-words-nonce-context: 100%*) [accuracy ~ condition*experiment+(1|subj_id)+(1|word)]. This interaction was significant for both part-of-speech [z = 2.9, SE = 0.18, p = .003] and specific meaning [z = 2.5, SE = 0.21, p = .003]. As in Experiment 2, we found a significant effect of both frequency and salience of the target words. The benefit of being exposed to the nonce story was greater for more frequent words [for part of speech: z = 2.1, SE = 0.14, p = .035; for specific meaning: z = 2.5, SE = 0.15, p = .012] and more salient words [for part of speech: z = 2.2, SE = 0.14, p = .031; for specific meaning: z = 2.6, SE = 0.16, p = .009].

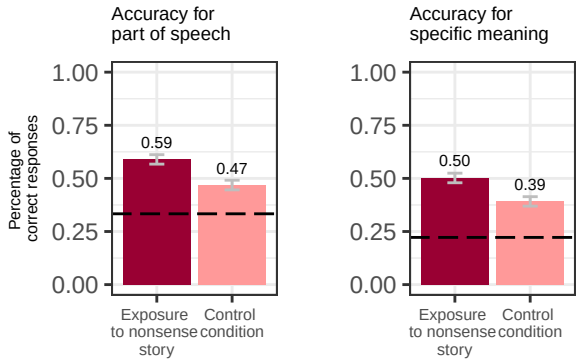

Figure 4: Group performance for Experiment 3. Horizontal dashed lines indicate chance-level. Error bars indicate +/-1SE of the mean.

Controlling for pretest scores, greater vocabulary knowledge (Wordsum) predicted higher accuracy for both part of speech [z = 3.4, SE = 0.091, p = .001] and specific meaning [z = 3.1, SE = 0.1, p = .002].

In Experiment 3, we observed an effect of context similar to that observed in Experiment 1. People were able to learn something about unknown words (here, *real-rare* words) from contexts in which all content words were replaced by nonce words. The only difference between Experiment 2 and the present study was in how word knowledge was assessed. A plausible conclusion – though in need of further testing – is that explicitly asking participants about a word's part of speech helps them deploy a more informative prior within which to consider the specific meanings.

General Discussion

What are the limits of learning word meanings from language? Our results show that participants were able to learn something about what a word means from brief exposures to such seemingly meaningless contexts as "The stronk rourthed daft to a dweave luk as the slom zeuded rhiecing." For example, after reading a 600+ word nonsense-word story containing sentences like the one just used, 38% of participants correctly inferred that "stronk" means "an insect" compared to 0% of participants who were not exposed to the story.

Our attempt to replicate and extend the results of Experiment 1 to using sparse contexts to inform the meanings of real, but rare and generally not known words (e.g., auscult, mitius), revealed that while partially informative contexts (40-60% of content words replaced with nonce words) were helpful, more sparse contexts (90%-100% of content words replaced) were not. We hypothesized that a key difference was the way that word knowledge was tested. In Experiment 1, participants' word knowledge was tested using a drill-down format that asked participants to first consider the word's part of speech. In Experiment 2, participants were asked to choose from among all the nine options visible at the same time making part of speech a less salient dimension of the word's meaning in the testing phase. In Experiment 3 we used the methods and materials of Experiment 2 with the test format of Experiment 1. Highlighting part-of-speech information using "drill-down" questions once again revealed that participants were able to use the nonce-story context to infer meanings of novel words.

Experiments 2-3 further showed that the effects of context were positively associated with frequency and salience. Words that were more frequent and more salient benefited more from context. While frequency is perhaps the most often used predictor in studies of word learning, to our knowledge, we are the first to examine the role of *salience*, defined here a the likelihood that people recall reading the word (see Table 1). What precisely makes a word salient requires future research.

What information did people use to infer word meanings? In the all-nonce-word conditions of Experiments 1 and 3, greater than baseline performance cannot be explained by reliance on the meaning of English content words because no recognizable content words were present. There were three remaining sources of information: closed-class words, inflectional cues, and syntactic cues. Consider one sentence from the story: "He thecked up into a dweave luk to fruth in for a sparf snurv." The remaining pronouns and prepositions combined with inflectional cues can clearly be used to infer that, e.g., "thecked" is an action being performed by an animate agent and that a "dweave" is likely to be some kind of place. Implicit knowledge of English syntax such that verbs follow "to" and objects tend to come after verbs offers further guidance. What is remarkable is that participants are making these inferences in parallel across dozens or even hundreds of words and that a single exposure to the story is sufficient to achieve above baseline accuracies.

Our work has two main limitations. First, successful use of sparse contexts involving mostly or exclusively nonce words clearly requires participants to already have sophisticated knowledge of English and so while it can help us understand how adults learn new words from context, it does not tell us how people learn enough English to make use of such sparse contexts. Second, present experiments do not tell us the relative importance of closed-class words, syntax, and morphology. Answering this question would require manipulating these sources of information independently. We can also gain additional insights by conducting studies such as this in more morphologically rich languages.

Conclusion

As has been long known, people are able to learn something about a word's meaning from encountering it in context. What is surprising is just how sparse and seemingly uninformative that context can be. The facility that people show in inferring word meanings from such sparse and seemingly meaningless contexts suggests that we may be underestimating the role that morpho-syntactic and distributional cues have on both learning word meaning and on acquiring semantic knowledge that is embedded in language.

Eye Blink Rate Predicts and Dissociates the Effective Execution of Early and Late Stage Creative Idea Generation

Abstract

In the present study, the correlations of eye blink rate (EBR) with the effective execution of early and late creative idea generation were explored. Participants engaged in a real-world idea generation task. Resting state EBR (before the task) and task-evoked EBR (during the task) were measured using eye-tracking. The results showed that resting state EBR negatively correlated with the amount of generated ideas during early stage, but not late stage idea generation. Task-evoked EBR did not correlate with the amount of generated ideas during early nor late stage idea generation. However, the change in EBR (from resting state to during early or late stage idea generation) positively correlated with the amount of ideas generated during early, but not during late stage idea generation. The contribution of this study is that it shows that EBR predicts and dissociates the effective execution of early and late stage creative idea generation.

Keywords: Creativity; Eye Blink Rate; Idea Generation.

Introduction

Eye behaviours such as fixations, eye blink rate (EBR), and pupil size are increasingly used to study creativity (See Salvi & Bowden, 2016 for a review) – the creation of ideas, solutions, or products that are both original and appropriate (Abraham, 2018). One important result of such studies is that eye blink rate, the average number of blinks per minute (de Rooij & Vromans, 2018), predicts and dissociates performance on different types of psychometric tests of creative potential (e.g., Akbari Chermahini & Hommel, 2010). Moreover, EBR has been used as a proxy for measuring fronto-striatal dopamine (Jongkees & Colzato, 2016), cognitive control (Akbari Chermahini & Hommel, 2010; 2012), motivation and affect (de Rooij & Vromans, 2018), and internal cognition (Salvi et al., 2015; Walcher, Körner, & Benedek, 2017). Studies of EBR and creative potential therefore inform theory about the involvement of these neuro-psychological factors in creativity. Psychometric tests of creative potential, however, often suffer from poor ecological validity, casting doubt over their explanatory power for actual real-world creative idea generation (Zeng, Proctor, & Salvendy, 2011). The present study therefore explores the correlations of EBR with the effective execution of the creative idea generation process, using a task that resembles real-world creative tasks more closely than psychometric tests of creative potential.

To enable creativity, people execute a creative process, which entails the execution of a set of cognitive processes and actions that enable a person to understand the problem that needs to be solved, generate ideas, and plan for further action (see Lubart, 2001 for a review). Idea generation is characterized by moving back and forth between generation and evaluation and is executed iteratively (Isaksen, Dorval, & Treffinger, 2010). In *early stages of idea generation* people typically retrieve concepts, which are synthesized into loosely formulated ideas, which process can involve remote association, conceptual combination, idea transformation, and analogical transfer (Finke, Ward, & Smith, 1992). The idea generation process evolves recursively, guided by the evaluation and selection of ideas for further development. Over iterations, and thus in *late stages of idea generation*, initially loosely formulated ideas are developed into more elaborately formulated ideas (Finke et al., 1992), and which process can be extended with combining previous ideas, filling in missing details, and simulating and testing implications and the validity of the ideas (Isaksen et al., 2010).

Previous research suggested that EBR predicts and dissociates performance on different types of psychometric tests of *creative potential*. *Resting state EBR* (i.e., EBR measured while a person is relaxed and not engaged in a thinking task) predicted the amount of different concepts (flexibility) used during the alternative uses task (AUT) (Akbari Chermahini & Hommel, 2010), a test where people are asked to list as many creative uses for a common object as they can (e.g., presented stimulus: *"Brick"*, possible response: *"Paper weight"*) (Guilford, 1957). This relationship was best described with a quadratic (inverted U-shaped) function. In the studies by Akbari Chermahini and Hommel no correlations, linear or otherwise, were found between resting state EBR and the amount of listed uses (fluency) or the statistical infrequency of the listed uses (originality). The results of a study by Ueda and colleagues, however, suggested that resting state EBR predicted the amount of listed uses during the AUT, which was also best described by a curvilinear (inverted U-shape) function (Ueda, Tominaga, Kajimura, & Nomura, 2016). Moreover, resting state EBR negatively correlated with the amount of correctly solved items during the remote associates task (RAT) (Akbari Chermahini & Hommel, 2010; Ueda et al., 2016), a test where people are asked multiple times to find the word that forms a compound word with each of the three given words (e.g., presented stimulus: *"Fox, Man, Peep"*, correct response: *"Hole"*) (Mednick & Mednick, 1971). In addition, Ueda and colleagues found that resting state EBR positively correlated with reaction time during the RAT.

Previous studies also suggested that *task-evoked EBR* (i.e., EBR measured while actively engaged in a task), predicts and dissociates performance on psychometric tests

of creative potential. That is, task-evoked EBR positively correlated with the amount of uses listed during the AUT (Ueda et al., 2016). In the same study, *task-evoked EBR* did not significantly correlate with the amount of correctly solved items during the RAT, but did positively correlate with reaction time during the RAT.

Studies on the *change from resting state to task-evoked EBR* add to these findings. That is, a study by Akbari & Hommel (2012) showed that the effects of stimulus induced increases in EBR on the amount of concepts used during the AUT differed significantly between people with low and high resting state EBR. That is, stimulus-induced increases in EBR led people with low resting state EBR to use more diverse concepts during the AUT than people with high resting state EBR. However, de Rooij & Vromans (2018) found no correlation or curvilinear relationship between the changes in EBR and the amount of uses, the amount of different concepts used, or the statistical infrequency of the responses during the AUT. Contrastingly, the same study showed that the change in EBR negatively correlated with the amount of correct responses to the RAT. However, when individual differences in positive and negative affect were taken into account, the interaction between a disposition to experience anxiety during creative tasks and the change in EBR positively correlated with the amount of correct responses to the RAT.

The main limitation of the currently available research though, is that psychometric tests of creative potential, such as the AUT and RAT, suffer from poor ecological validity (Zeng et al., 2011). Tests such as the AUT, for example, rarely correlate stronger than .30 with questionnaires and with performance on creative tasks with high ecological validity. Specifically relevant for creative idea generation, is that there is no clear necessity for iteration in such tests (Zeng et al., 2011), which is an essential aspects of idea generation process execution, that leads to differences in performance during early and late stage creative idea generation (Lubart, 2001). It is therefore not known if and how the processes that underlie performance during the AUT and RAT, are also involved in early and late stage idea generation. Moreover, the AUT and RAT are rather abstract tasks and lack goals with personal relevance that typically characterize real-world creative tasks (Kilgour, 2006). This ignores the essential role of domain-specific knowledge, and is likely to engage motivation differently than in real-world creative idea generation tasks (e.g., de Rooij & Jones, 2013). Thus, EBR may correlate differently, if at all, with performance during early and late stage idea generation in tasks that resemble real-world creative tasks more closely, than with performance during the AUT and RAT.

What is clear from these psychometric tests of creative potential, is that there is no indication of a correlation between EBR and qualitative aspects of idea generation (Akbari Chermahini & Hommel, 2010; 2012; de Rooij & Vromans, 2018; Ueda et al., 2016). That is, none of the studies showed correlations between EBR and the originality of the responses during these tests. Rather, results of these studies showed correlations between EBR and the quantity of responses (e.g., the amount of ideas during the AUT, the amount of solved items during the RAT). These studies therefore contribute that the correlations, if any, between EBR and performance during early and late stage idea generation is likely quantitative, and thus indicative of effective execution of the idea generation process, rather than directly of creativity.

Therefore, in *the present study* the correlations of EBR with the effective execution of the idea generation process (as measured by the amount of generated ideas) during early and late idea generation were explored, using a task that resembles real-world creative tasks more closely than psychometric tests of creative potential.

Method

To explore the correlation of EBR with the amount of ideas generated during early and late stage idea generation, an experiment was conducted.[1]

Participants

Seventy-eight people participated in this study (M_{age} = 23.34, SD_{age} = 3.46, 55 female, 23 male). They had normal or corrected-to-normal vision. Most (n = 76) were recruited via the participant recruitment system of a communication science department at a Dutch university. Participants received course credit as compensation for their time spent on the study. Two additional participants, recent graduates, requested to participate out of interest and did not receive compensation. On average, the participants self-reported to be moderately experienced with marketing (M = 3.79, SD = 1.11) (1 = *No experience*, 5 = *Very experienced*).

Idea generation task

The participants engaged in an idea generation task, were they were asked to generate creative marketing ideas aimed at helping a web shop that sells bicycles to attract more visitors to their website. Their idea generation process was split up into two separate tasks, both of which each participant completed, to capture early and late stage idea generation.

Task 1: Early stage idea generation

To capture early stage idea generation, participants were asked to generate as many creative marketing ideas as they could (Figure 1b). This, to elicit a range of pre-inventive structures that participants could then combine and elaborate upon in the subsequent late stage idea generation task. To enable the measurement of EBR, the early stage idea generation task was cued. Each trial started with a fixation dot (5 seconds), after which participants were asked

[1] Note that the data for this paper was collected as part of a larger experiment on eye behaviour and idea generation. Although the EBR data is used only in the study presented here, the participants, tasks, and procedure is the same as in other studies based on the same data set.

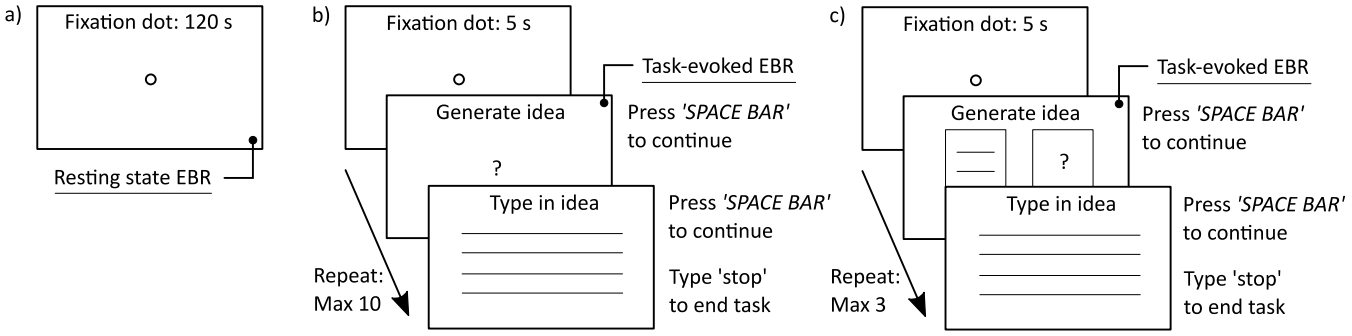

Figure 1: Trial structure of the a) resting state, b) early stage, and c) late stage idea generation tasks, including measurement points for resting state and task-evoked EBR.

to generate a creative marketing idea that was relevant to the provided problem description. There was no time limit. When a participant had generated an idea, the space bar could be pressed after which a text input field was presented on the screen where the participant could type in the idea they generated. This trial sequence was repeated a maximum of ten times. If the participants believed they could not generate any more ideas before the limit of ten trials was reached, they could type in 'stop' to end the early stage idea generation task, and start the late stage idea generation task.

Task 2: Late stage idea generation

To capture late stage idea generation, participants were asked to select two or more of their previously generated ideas to develop a more elaborate and detailed idea (Figure 1c). For example, if a participant generated the ideas to use an *"Instagram page"* and *"hire influencers to promote your Instagram posts"* during early stage idea generation, these could then be combined and developed into a more detailed elaborate solution, (e.g., *"where content developed for the Instagram page is suitable for hired influencers, with a follower demographic suitable for the web shop, which they can then share with their followers"*). Their previously generated ideas were available to the participants during this task (they were listed on the computer screen). The same trial structure was used as during the early stage idea generation task. That is, participants were instructed to look at a fixation dot for 5 seconds, after which they had time to combine previously generated ideas into more elaborate ideas. After generating an idea, they pressed the space bar on the keyboard, and a text input field emerged where they could type in their idea. There was no time limit. However, there was a maximum of 3 trials. If they believed that they could not generate any more ideas before they reached the limit of three trials, they typed in "stop" to stop the task, and with that end the experiment.

Assessment of the effective execution of the idea generation process

To gain insight into how effective the idea generation process was executed idea generation *fluency* was assessed (i.e., the amount of ideas generated). Fluency is a commonly used performance indicator used in studies of idea generation (Guilford, 1957). In the present study, participants generated on average 6.25 ideas during early stage idea generation (*SD* = 2.33), and on average 2.28 ideas during late stage idea generation (*SD* = .78).

Eye blink rate

Eye blinks were recorded with a head mounted eye-tracker, and were defined as eye-tracker signal loss with a duration of 40-400 milliseconds (de Rooij & Vromans, 2018). EBR was defined as the average amount of blinks per minute, and was calculated based on the amount of recorded eye blinks and the amount time during which these were recorded. The following measurements of EBR were used: (I) *Resting state EBR* - EBR recorded in resting state before the creative idea generation task, where participants were asked to relax and watch a fixation dot for 120 seconds (Figure 1a); (II) *Task-evoked EBR* - EBR recorded during early stage and during late stage idea generation. EBR was recorded only in the parts of the trials where participants were thinking about their ideas (Figure 1b and 1c); (III) *Change in EBR (task-evoked – resting state EBR)* - The change in EBR from resting state to early stage and to late stage idea generation.

To reduce measurement error, only data from eye blinks recordings after 2 seconds of the start, and before 2 seconds of the end of each measurement, were used to calculate EBR. This helped prevent blinks due to changing screens at the start of a task, and pressing ENTER when an idea was generated, to confound the EBR measurements (de Rooij & Vromans, 2018). Three participants did not blink during resting state. This may indicate that participants simply did not blink for 120 seconds, but may also indicate measurement error. Since the latter cannot be ruled out resting state EBR of these three participants was not used in the analysis. Finally, as EBR is only stable in the morning, midday, and afternoon (Barbato et al., 2000), the experiment was organised only between 9 am to 5 pm.

Apparatus

Materials were presented using dark letters against a grey background on a 22" Dell P2210 monitor (1680×1050 resolution). EBR was recorded using the EyeLink II head-mounted eye-tracker (SR Research Ltd.) at 250Hz. The cable that connected the eye-tracker to the computer was attached to the ceiling to reduce perceived weight and pull that may negatively affect comfort. LED lighting was used to diffuse environmental lighting as evenly as possible. The experiment was in OpenSesame with the PyGaze library (Dalmaijer et al. 2014).

Procedure

Participants received a written introduction to the experiment, signed informed consent, and filled in a short questionnaire about their socio-demographics and marketing experience. Information about the true purpose of the experiment was withheld at this stage. Participants were seated behind a computer screen in a sound proof booth. The head-mounted eye-tracker was installed and calibrated using a 5-point validation. The distance to the screen was approximately 70 cm. Then, participants could practice with the experiment software. After this, participants were asked to relax and look at a fixation dot for 120 seconds. Next, participants read the provided problem statement, and started with the idea generation task. Finally, the participants were debriefed in full, and after being asked whether they could guess the purpose of the experiment.

Analysis

The data obtained in the present study were analysed using generalized linear mixed models. The models were calculated using Satterthwaite approximation to account for the relatively small sample size. Robust covariances were used for the tested of fixed coefficients to handle violations of model assumptions. For models with the amount of generated ideas as the target, a negative binomial distribution was used with a log link. For the model with EBR as the target, a normal distribution with an identity link was used. Model terms and targets are presented in Table 2.

Results

Table 1: Descriptive statistics of EBR during resting state, early stage (task evoked), and late stage (task evoked) idea generation.

	EBR		
	M	*SE*	*n*
Resting state	13.23	1.21	75
Early stage	7.18	.60	78
Late stage	3.91	.40	78

Note. *M* = mean, *SE* = standard error, *n* = count.

[2] Quadratic models were also tested by adding the squared EBR terms to the models presented in Table 2. No significant coefficients were found that add to the results obtained with the linear models. We also refer to Figures 2b-2d for visual inspection.

The descriptive statistics are presented in Table 1. The results showed a significant main difference between the tasks for EBR, $F(2, 228) = 32.07$, $p < .001$ (Figure 2a).[2] The pairwise comparisons (not corrected) showed a significant difference in EBR between resting state and early stage, estimated difference = -6.06, $t = 4.48$, $p < .001$, 95% CI[-8.72, -3.39], and late stage idea generation, estimated difference = -9.32, $t = 7.30$, $p < .001$, 95% CI[-11.84, -6.81]; and between early and late stage idea generation, estimated difference = -3.27, $t = 4.52$, $p < .001$, 95% CI[-4.69, -1.84]. These findings suggest that in the present study, EBR decreased from resting state, to early stage idea generation, to late stage idea generation.

Table 2: Correlations and effects (GLMM) of resting state EBR, task-evoked EBR, and their difference with fluency during late and early stage idea generation.

Model terms	Correlations of Fluency with EBR		
	Resting state	Task-evoked	Change EBR
Intercept	.83** (.06)	.86** (.08)	.81** (.06)
Early stage	1.12** (.08)	.92** (.10)	1.08**(.06)
Late stage	.[a]	.[a]	.[a]
EBR	>-.01 (<.01)	-.01 (.02)	>-.01 (<.01)
Early stage x EBR	-.01* (<.01)	.02 (.02)	.01 (<.01)**
Late stage x EBR	.[a]	.[a]	.[a]

Note. Data are unstandardized coefficients and standard errors (between parentheses). [a] Reference variable. * p < .05, ** p < .01.

The results showed a significant and negative interaction between idea generation stage and resting state EBR for the overall amount of generated ideas, $b = -.01$ $t = 2.00$, $p = .049$, 95% CI[-.02, -.01] (Table 2). Pearson correlations showed that this interaction effect could be explained by a significant and negative correlation between resting state EBR and the amount of generated ideas during early stage idea generation, $r = -.170$, $p = .043$, and a negative but not significant correlation between resting state EBR and the amount of generated ideas during late stage idea generation, $r = -.039$, $p = .675$ (Figure 2c). These findings indicate that resting state EBR negatively correlates with the effective execution of early but not late stage idea generation.

The results showed no significant correlations between task-evoked EBR and the amount of generated ideas; and no significant interaction between idea generation stage and task-evoked EBR for the amount of generated ideas (Table 2, Figure 2b). These findings indicate no relationship between task-evoked EBR and the effective execution of the creative idea generation process.

Furthermore, the results showed a significant and positive interaction between idea generation stage and the change in EBR from resting state to each task, for the overall amount of generated ideas, $b = .01$, $t = 3.04$, $p = .003$, 95% CI[.01, .02] (Table 2). Pearson correlations showed that this interaction effect could be explained by a significant and

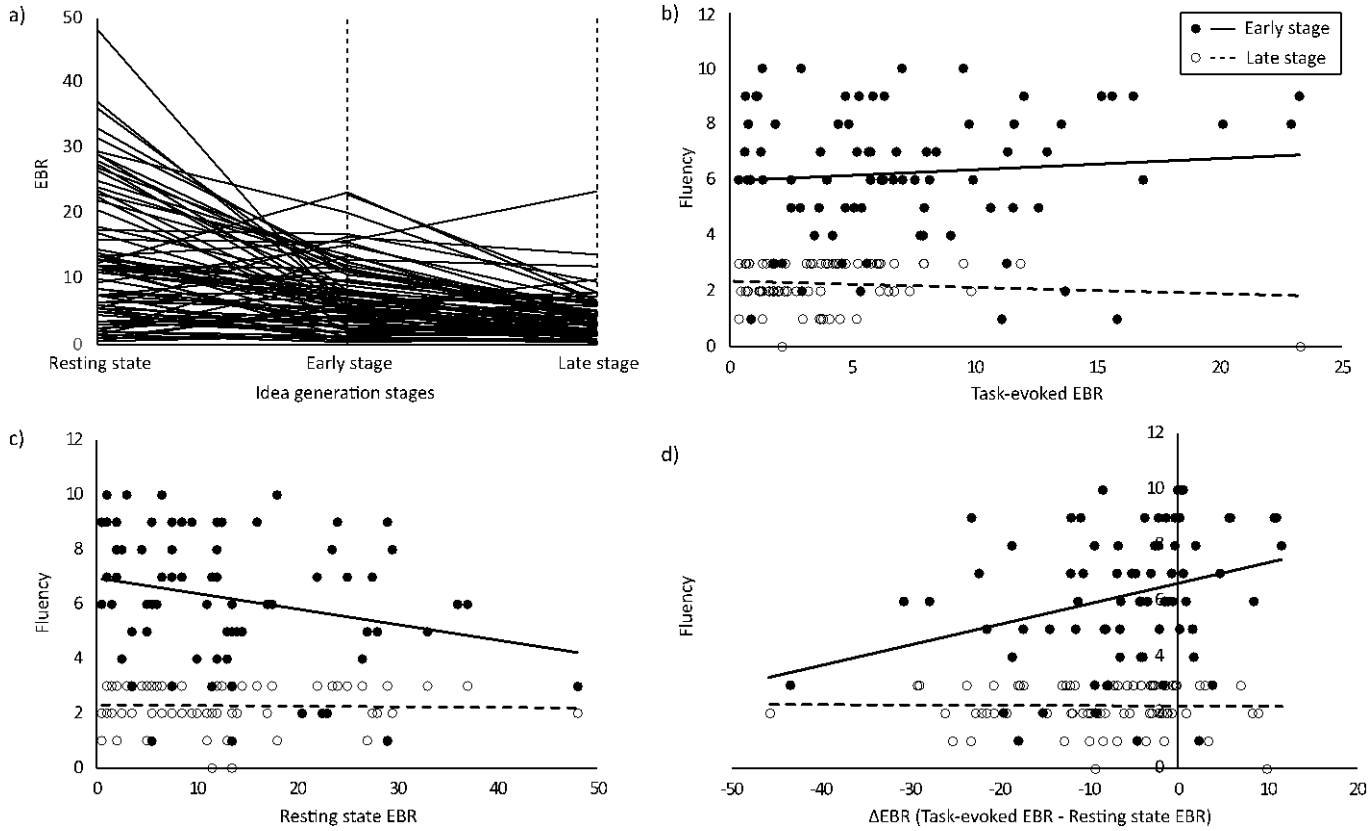

Figure 2: a) Spaghetti plot showing EBR measured at resting state, early stage, and late stage idea generation for each participant; b) Scatter plot of fluency and task-evoked EBR for early and late stage idea generation; c) Scatter plot of fluency and resting state EBR for early and late stage idea generation; and d) Scatter plot of fluency and the difference between task-evoked and resting state EBR for early and late stage idea generation.

positive correlation between the change in EBR and the amount of generated ideas during early stage idea generation, r = .298, p = .010, and a negative but not significant correlation between the change in EBR and the amount of generated ideas during late stage idea generation, r = -.014, p = .904 (Figure 2d). These findings indicate that the change in EBR positively correlates with the effective execution of early but not late stage idea generation.

Discussion

In the present study, the correlations of EBR with the effective execution of the idea generation process (as measured by the amount of generated ideas) during early and late idea generation were explored, using a task that was designed to closely resemble real-world creative tasks.

The results showed that resting state EBR negatively correlated with the amount of generated ideas during the early stage, but not during the late stage of creative idea generation (Figure 2c). This finding contrasts with previous research that suggested that the relationship between resting state EBR and the amount of generated ideas during the AUT best described with an inverted U-shape function[2] (Ueda et al., 2016), or that no significant correlation between the amount of ideas generated during the AUT and resting state EBR exists (Akbari Chermahini & Hommel, 2010). Possibly, this finding is more in line with previous research that indicates that the amount of solved items during the RAT negatively correlates with resting state EBR (Akbari Chermahini & Hommel, 2010), but this finding has been inconsistent across studies, cf. (Ueda et al., 2016).

The results also suggested that task-evoked EBR does not correlate with the amount of generated ideas during early nor during late stage idea generation (Figure 2b). This differs from previous research, which indicated task-evoked EBR positively correlated with the amount of uses listed during the AUT (Ueda et al., 2016); but is in line with results from the same study, which suggested that task-evoked EBR did not significantly correlate with the amount of correctly solved items during the RAT. In addition, differences between early and late stage idea generation could also be explained by previous findings that suggest that EBR quickly increases right before generating problem solutions via spontaneous insight (Salvi et al., 2015). Speculatively, moments of insight could appear more frequently in early than in late stage idea generation, as in the latter people focus more on recombining existing ideas. The results of the present study, however, also suggested that the change in EBR (from resting state to during the tasks) positively correlated with the amount of ideas generated during early, but not during late stage idea generation (Figure 2d). This is in line with previous research

that suggests that there are circumstances in which the change in EBR positively correlates with the amount of solved items, but not with related findings that suggest a negative correlation between the change in EBR and the amount of solved items during the RAT (de Rooij & Vromans, 2018).

There are, of course, also limitations that threaten the validity of the results. Although the present study purports to use a task with high ecological validity, no claims can be made on specific aspects of its validity. That is, due to the novelty of the task no tests of validity have been done (cf. de Rooij, Vromans, & Dekker, 2018). Furthermore, to enable measurement of EBR, idea generation was cued and split up into two tasks, representing early and late stage idea generation. In reality, such an artificial separation does not typically happen, and may hamper the often free flowing nature of creative idea generation (Lubart, 2001), which threatens the ecological validity of the used creative idea generation task, (cf. de Rooij & Vromans, 2018). Furthermore, to accommodate eye-tracking measurements responses were cued and limited to 10 responses during early, and 3 responses during late stage idea generation, limiting variance. The limited variance of late stage idea generation could therefore alternatively explain why no correlation between EBR and the amount of ideas generated in late stage idea generation was found. Decisions made to support ecological validity also came at the cost of introducing potential confounding factors. That is, no counterbalancing between early and late stage idea generation is possible, so any found differences could be confounded by adaptation to light conditions. Finally, due to the use of a novel task, it is difficult to compare the results obtained in the present study to results from previous related work. This limits the degree to which the results of this study can be grounded in such previous work. Limitations such as these should be taken into account when interpreting and building upon the present study.

The contribution of the present study is therefore that it shows for the first time that EBR predicts and dissociates the effective execution of early and late stage creative idea generation, using a creative task that resembles real-world creative tasks more closely than psychometric tasks of creative potential. Differences in the results between the present and previous studies using these psychometric tasks, show the importance of using tasks with higher face validity, as indeed, the results differ. This has implications for the development of theory on how the neuro-psychological correlates of EBR relate to creative idea generation.

Abstract

Prior research showed that young children prefer to seek help from actors who have demonstrated active learning competence. What inferences do people make based on the ability to search effectively, for example by asking informative questions? This project explores across two experiments to what extent adults and children (3- to 9-year-olds) generalize the ability to ask informative questions to other abilities/characteristics. We presented participants with one monster who always asked informative questions and one who always asked uninformative questions. Participants had to choose which monster they thought was more likely to possess/was better at 12 different characteristics/abilities. Our results show a clear developmental trend. Three- and 4-year-olds draw unsystematic inferences from the monsters question-asking expertise. Five- and 6-year-olds identified the better question asker as better at everything. Seven- to 9-year-olds showed adult-like response patterns, selectively associating the ability to ask good questions to related characteristics/abilities.

Keywords: active learning; social cognition; question asking.

Introduction

Children are natural born active learners. However, while some skills and knowledge (e.g., basic laws of physics or object functions) can be acquired by first-hand active exploration or from observations, some other abilities (e.g., language) strongly rely and build on social interactions. Indeed, a vast body of research suggests that children are *programmed* to learn from others since the very beginning. Already 6- to 9-month-old infants are equipped with special attentional mechanisms to detect when a social partner is willing to transmit information (Senju & Csibra, 2008; Csibra & Gergely, 2009), and 9-month-olds use strategies such babbling or social referencing to seek explanations from their caregivers when presented with unfamiliar objects (Goldstein & Schwade, 2009; Walden, Kim, McCoy, & Karrass, 2007).

As soon as they can talk, children have more explicit ways to elicit explanations or request information: they can ask questions. Question asking is a powerful learning tool that children rely on to enlarge, deepen, enrich and adaptively revise their knowledge about the physical and social world (Callanan & Oakes, 1992; Campos, 1981; Chouinard, Harris, & Maratsos, 2007; Meltzoff, 1988b, 1988a, 1990). Previous work demonstrated that children are very selective when deciding whom to ask questions to, or more generally which informants to rely on. This research suggests that children's trust is driven by a complicated mixture of inferences drawn from the *quality* of the information provided (e.g., accuracy, completeness; see Pasquini, Corriveau, Koenig, & Harris, 2007; Koenig, Clément, Harris, & Clement, 2004; Jaswal, Croft, Setia, & Cole, 2010; Koenig & Jaswal, 2011) and the characteristics of the *agent* providing the information (e.g., expertise, age, familiarity, culture; see Lutz & Keil, 2002; VanderBorght & Jaswal, 2009; Kinzler & Spelke, 2011). As an example, Kushnir, Vredenburgh, and Schneider (2013) have shown that preschoolers use the quality of the information provided as a cue to infer the informants' scope of expertise. In their first study, they presented 3- and 4-year-olds with two informants (a *labeler* and a *fixer*), two familiar tools (a screwdriver and a wrench) and two unfamiliar electronic toys with interesting light or sound effects. The *labeler* provided accurate labels for the tools that he had to use to fix a broken toy, but did not manage to fix it. The *fixer* labeled the tools inaccurately but managed to fix the toys. Both 3- and 4-year-old children asked the labeler for help when they needed to know labels for novel toys, and turned to the fixer when they had to fix a broken toy, thus inferring expertise from the quality of the information provided (Kushnir, Vredenburgh, & Schneider, 2013).

Recent work shows that preschoolers are also sensitive to the effectiveness of the active learning strategies of a potential informant. In particular, children identify and rely on the most informative between two given questions already at age 4 (Ruggeri, Sim, & Xu, 2017), although they cannot reliably *generate* the most effective questions from scratch until age 10 (e.g., Herwig, 1982; Mosher, Hornsby, Bruner, J, & Oliver, 1966; Ruggeri & Feufel, 2015; Ruggeri & Lombrozo, 2015; Ruggeri, Lombrozo, Griffiths, & Xu, 2016). This research suggests that the cognitive machinery to support effective question asking may develop much earlier than the ability to generate effective questions from scratch. Why is this the case? On the one hand, it might be that what hinders younger children's effective question-generation is that their verbal abilities and vocabulary are not sufficiently developed. On the other hand, one intriguing possibility is that children's early ability to evaluate questions' informativeness allow them to assess another persons learning competence-a cue that can be used to identify role models to imitate and to *learn how to learn* from. Along these lines, a recent study showed that 3- to 7-year-old children preferentially sought help from a competent *active learner* who had figured out how to solve a problem by herself, over learners who

had learned through passive observation or direct instruction. Yet, this preference emerged only when the problem children needed to solve was similar to the one the learners had previously solved, where they thought the active learners competence would be relevant (Bridgers, Gweon, Bretzke, & Ruggeri, 2018). This paper investigates one crucial question arising from this perspective: *How* do children use active learning competence to identify role models, that is, what do they infer based on someone's ability to ask effective questions: Are good question-askers smarter, more knowledgeable, or better at solving problems? Do adults make similar inferences and generalizations? To address these questions, we explore to what extent adults (Study 1) and 3- to 9-year-old children (Study 2) generalize question-asking competence to other abilities/traits/characteristics.

We implemented a paradigm similar to that used in previous studies investigating the inferences and generalizations children make based on the informants' expertise and characteristics. For instance, Brousseau-Liard and colleagues (2010) presented 4- and 5-year-old children with two puppets that labeled 4 familiar objects. One did so correctly, and the other incorrectly. At test, children were asked to indicate which puppet they thought was more likely to possess 12 different skills/characteristics encompassing six categories: knowledge of words (e.g., Who knows words for lots of different machines?), talents (e.g. Who can draw pretty pictures?), knowledge of facts (e.g., Who knows that cats can see at night?), pro-social behavior (e.g., Who always shares her toys?), and two control-questions on possessions and situation-specific knowledge (e.g., Does she have a cat?; Who knows where I put my books?). Their results suggest that 5-, but not 4-year-olds, used the puppets' past accuracy to make explicit predictions about relevant characteristics such as her knowledge of words and facts and her pro-social behaviour, but not about her talents, possessions or situation-specific knowledge (Brosseau-Liard & Birch, 2010). Along the same lines, Lane and colleagues (2013) presented 3- to 6-year-old children and adults with three story books in which two pictured characters exhibited contrasting traits: Honest-dishonest, nice-mean, and smart-not smart. During the test phase, participants were tasked to ask - and endorse - characters' testimony about novel objects' names, about the content of a box that both characters had seen, and to attribute knowledge about the content of a different box, where only the negative informant had access to this information. Their results show that children and adults prefer to ask and endorse information about novel objects' names provided by people who are nice, honest and smart, whereas knowledge attribution seems to be influenced by the informants traits, following an age-graded decrease: 3- to 5-year-olds wrongly attributed knowledge to the positive informant, as opposed to 6-year-olds and adults, who correctly inferred the negative character's situation-specific knowledge (Lane, Wellman, & Gelman, 2013).

Based on the results discussed above (e.g., Lane et al., 2013), we expect to find an overall age-related decrease in the extent of generalizations from question-asking expertise to unrelated traits, abilities and characteristics, with older children and adults being generally more selective than younger children (see Mills, 2013 for a review on the development of selective trust). However, because very few studies investigating generalizations of expertise have considered a broad children age range as well as adults, we don't know when mature, adult-like selectivity would emerge.

Study 1

The goal of this study was to assess adults' intuitions about the relationship between question-asking competence and 12 different abilities/traits/characteristics.

Participants Thirty adults (11 males; M_{age}= 28.09; SD = 7.63) participated in this study. All participants were recruited and tested at the Museum für Naturkunde in Berlin, Germany. Participants belonged to various social classes and were native German or fluent in German. IRB approval was obtained and participants gave informed consent to participate in the study. One additional participant was excluded from the analyses due to missing data.

Design and procedure

The procedure consisted of two phases. The familiarization phase was designed to introduce participants to two agents (i.e., monsters), one who always asks informative questions and the other who always asks uninformative questions. In the test phase, we asked participants to rate the strength of the association between the question-asking competence illustrated in the familiarization phase and 12 given abilities/traits/characteristics. We detail the two phases below.

Familiarization phase Participants were asked to read a short storybook introducing two monsters, Bobo and Kila, who ask their friend Toma some questions to find out what happened on her first day at the new school. The storybook consisted of five pages. Each of the first four pages presented a different event taking place on Toma's first day at the new school (e.g., Toma drew a surprise welcome gift from a bag; see Figure 1 for an example) and two related questions that Bobo and Kila asked Toma (e.g., "Did you get a teddy bear?" or "Did you get a red toy car?"). On the bottom of the page, 8 cliparts, arranged in a row, illustrated the options to be considered (i.e., the hypothesis space; e.g., which gifts were inside the bag). Across the four scenarios, one of the monsters always asked informative questions, whereas the other always asked uninformative questions. The informative question targeted half of the hypotheses considered, either by asking a hypothesis-scanning question that referred to a single hypothesis presented 4 times (e.g., "Did you get a teddy bear?", where there were four teddy bears in the bag), or by asking a constraint-seeking question that addressed a feature shared by four of the hypotheses (e.g., "Did you get a round-shaped toy?", where there were four round-shaped toys in the bag). The uninformative question targeted either an object that was

not included in the hypothesis space (e.g., the red toy car; hypothesis-scanning question) or a feature shared by all the objects (e.g., a toy; constraint-seeking question). A fifth page presented again the two monsters and summarized the lesson to be learned from the familiarization phase, reminding participants that "Bobo/Kila always asks good/bad questions, because they are very informative/not informative at all. She is a good/bad question asker!"

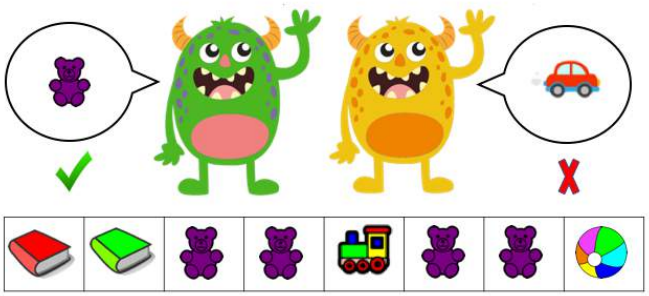

Figure 1: One scenario of the familiarization phase in which Bobo, the green monster, asks an informative question and Kila, the yellow monster, asks an uninformative question. In this example, the informative question refers to a single hypothesis presented 4 times, whereas the uninformative question targets an object that was not included in the hypothesis space.

Test phase In the test phase, participants were asked to complete a paper-and-pencil survey consisting of 12 questions, presented in random order. For each question, participants were asked to rate how much 12 different abilities, traits or characteristics (see Table 1) related to the ability to ask informative questions (e.g., "How much is being good at treasure hunting related to the ability to ask informative questions?"), on a scale from 0 ("not related at all") to 10 ("strongly related"). The questions presented were selected to include a set of abilities/traits/characteristics of different kinds (i.e., intellectual skills vs. physical abilities, individual preferences or irrelevant characteristics) that, according to our intuitions and to pilot survey data, are more or less related to the ability to ask informative questions, e.g., involve a stronger or weaker strategic component. For instance, being good at treasure hunting or at solving riddles might require the ability to search for information and explore strategically, whereas knowing many animal names refers to a domain-specific knowledge that is more strategy-independent.

Results and Discussion

As can be seen from Table 1, "being clever" and "being good at school" were rated as the most related to the ability to ask good questions. The association with abilities with a strategic component (i.e., "being good at treasure hunting" and "being fast at completing puzzles") were rated as medium-strong, and that with domain-specific knowledge (i.e. "knowing many animal names") was judged as medium-weak. Interestingly, "being friendly" was also rated as having a moderate-weak association with question-asking competency, although it had the highest between subjects variability. One possible interpretation could be that being good at asking questions is considered by some people, but not others, to indicate of a person being socially smart, sociable or just generally more likely to interact with others (Good, Slavings, Harel, & Emerson, 1987). Physical abilities or skills were rated low overall, independently of whether they were more likely to involve a strategic component ("being good at playing soccer") or not (i.e., "kicking a ball the furthest"). As expected, individual preferences (e.g., "liking ice cream") or irrelevant characteristics (e.g., "seeing the farthest","having siblings") were rated very low, that is, were judged as not at all related to the ability to ask informative questions.

Taken together, these results suggest that adults make distinct, graded, meaningful and fairly consistent inferences and generalizations based on the ability to ask good questions. Some abilities, traits and characteristics are considered to be strongly related to question-asking competency, whereas some others are considered to be only weakly related, or completely unrelated.

In Study 2 we explored to what extent such inferences and generalizations undergo a developmental change across childhood, and when adult-like intuitions might emerge.

Table 1: Study 1. Mean ratings of the strength of the association between question-asking competence and the abilities/traits/characteristics presented to adults in Study 1.

Abilities/traits/characteristics	Mean	SD
Being good at school	8.36	1.83
Being clever	8.30	1.91
Being good at treasure hunt	6.76	2.21
Being fast at completing puzzles	5.76	2.67
Knowing lots of animal names	4.20	2.68
Being friendly	3.56	3.16
Having siblings	2.13	2.53
Being good at playing soccer	1.63	2.08
Seeing the farthest	1.37	2.35
Scoring lots of goals	1.33	2.22
Kicking a ball the furthest	1.10	2.19
Liking ice cream	0.67	1.39

Study 2

Participants Participants were 40 3- and 4-year-old children (21 males; M_{age}= 48.41 months; SD = 7.19 months), 40 5- and 6-year-olds (19 males; M_{age}= 7.18; SD = 6.52 months) and 40 7- to 9-year-olds(18 males; M_{age}= 101.59 months; SD = 9.74 months), recruited and tested at local museums in Berlin. Participants belonged to various social classes and were native German or fluent in German. IRB approval was obtained and parents gave informed consent for their children

to participate before the study. Twenty-four additional participants were excluded from the analyses due to technical issues (n = 2) and for failing the attention (n = 7), the memory check (n = 9; see below), or both (n = 6; see below).

Design and procedure The design and procedure of Study 2 was identical to that of Study 1, with the following exceptions: First, the task (storybook and survey) was implemented on a 10" Tablet. Second, the familiarization story and the test questions were read to children by an experimenter, who also reminded them, at the end of each scenario, which monster was a good and which one was a bad question asker. Third, in the test phase, instead of being asked to provide a rating from 0 to 10 as in Study 1, children were asked, for each question, to select the monster they thought was more likely to possess/was better at the presented abilities/traits/characteristics. Two cards illustrating the monsters were used to help children indicate their preference. Finally, as an attention and memory check, we asked children both at the beginning and at the end of the test phase to indicate which monster was the best at asking questions.

Results

Children's selections were coded as "1" when they indicated the good question asker, or "0" when they indicated the bad question asker. Results are presented in 2. We performed a multivariate regression with adults' ratings in Study 1 as predictors of children's selections in Study 2. This analysis revealed that adults' ratings predicted 7- to 9-year-old children's response pattern ($\beta = .025$, $t(12) = 3.19$, $p = .01$; $R^2 = .455$, $F(1, 12) = 10.20$, $p = .01$), but not 5- and 6-year-olds' ($\beta = .018$, $t(12) = 1.65$, $p = .12$; $R^2 = .137$, $F(1, 12) = 2.75$, $p = .12$) nor 3- and 4-year-olds' ($\beta = .010$, $t(12) = .84$, $p = .41$; $R^2 = -.027$, $F(1, 12) = .716$, $p = .41$). We then performed a series of binomial tests to assess whether children' preference for the question asker on each ability/trait/characteristic differed from chance (50%). The results (see Table 2) show that the the extent of children generalizations strongly varies between age groups. Generally, 3-to 4-year-olds' showed a very unsystematic response pattern: They had no preference for the good question asker for abilities, traits and characteristics that both adults and older children deemed related to question asking (e.g., "being good at school", "being good at treasure hunting"), but displayed a strong preference for some clearly irrelevant questions (e.g., "having siblings", "seeing the farthest"). Five- to 6-year-olds clearly overgeneralized: They extended question-asking competence to both related and unrelated domains, selecting the good question-asker above chance for 10 of the 12 questions presented ("being good at school", "being clever", "being good at treasure hunting", "being fast at completing jigsaw puzzles", "knowing many animal names", "being friendly", "having siblings", "being good at playing soccer", "seeing the farthest", "liking ice cream"). However, 7- to 9-year-olds showed a systematic and meaningful attributions of relevant abilties/traits/characteristics to the good question-asker, very similar to the one found with adults in Study 1.

General Discussion

In this project we explored across two experiments to what extent adults (Study 1) and 3- to 9-year-old children (Study 2) generalize question-asking competence to other abilities/traits/characteristics. Taken together, our results suggest a clear developmental trend: Three- and 4-year-olds drew unsystematic inferences from the monsters question-asking expertise, showing no preference for the good question asker when evaluating abilities, traits and characteristics that both adults and older children deemed strongly related to question asking (e.g., "being good at school", "being good at treasure hunting"). At the same time, they showed a strong preference for the good question asker on some clearly irrelevant questions (e.g., "having siblings", "seeing the farthest"). Five- and 6-year-olds identified the good question asker as better/more likely to have nearly every presented ability/characteristic. Seven- to 9-year-olds showed adult-like response patterns, selectively associating question-asking competency to some, relevant abilities and characteristics (e.g., "being good at school" and "being clever"), but not to others (e.g., "kicking a ball the furthest", "seeing the farthest" and "liking ice cream").

Three- and 4-year-olds in our study failed to associate traits and abilities such as "being good at school" and "being good at treasure hunting" with question-asking expertise, an association rated strong by adults and older children. We should notice that these two characteristics might have been difficult to understand for children this age. On the one hand, they probably do not have yet a clear idea of what "being good at school" means, as they are not in school yet. On the other hand, they might not appreciate the strategic component underlying the ability of being good at treasure hunting. This component seems to be more evident for them in the ability of solving puzzles. Moreover, their preference response for "knowing many animal names" suggests that young children might consider semantic knowledge as connected to question asking and maybe, more generally, to active learning competence. This is in contrast to the results obtained by Fusaro and colleagues (2011) and Brosseau-Liard and Birch (2011). In their studies, 4-year-olds generalized behavior to traits (e.g. inferred that an accurate puppet would have been smart), but did not make any generalization from behavior to semantic knowledge (e.g., knowing animal habits; Fusaro, Corriveau, & Harris, 2011) or did not endorse the accurate puppets' testimony about situation-specific knowledge (e.g., knowing the content of a box; Brosseau-Liard & Birch, 2011).

Our results suggest that 5- and 6-year-olds considered effective question asking as an indicator of global rather than a domain- or ability-specific expertise and of general likability. This over-generalization trend is in line with some previous findings suggesting that children at this age tend to make broader generalizations when the informant possesses some

Table 2: Mean proportion of children who indicated the best question asker as more likely to possess each ability against chance (50%; binomial test) in Study 2.

	3-to 4-year-olds			5-to 6-year-olds			7-to 9-year-olds		
Abilities/traits/characteristics	Mean	CI	*p*	Mean	CI	*p*	Mean	CI	*p*
Being good at school	.60	.43 - .75	.20	.83	.67 - .92	<.001	.83	.67 - .92	<.001

Liking ice cream	.50	.33 - .66	1	.75	.58 - .87	<.01	.50	.33 - .66	1

kind of semantic knowledge (e.g., labels objects accurately, Brosseau-Liard & Birch, 2010; knows causal properties of an object, Sobel & Corriveau, 2010) and demonstrates sociomoral goodness (Cain, Heyman, & Walker, 1997). However, Bridgers and colleagues (2018) demonstrated that already at age 4, children selectively generalize active learning effectiveness only to tasks where this competence is deemed relevant. This apparent inconsistency might indicate that children have different intuitions and make different generalizations depending on the different *kinds* of active learning competency an agent display (e.g., physical exploration versus question asking), and this differential pattern might interact with age. It would be interesting to explore this question in future research.

The adult-like response pattern of 7- to 9-year old children, who selectively associated question-asking competence only to related abilities and traits, is in line with the few results from previous research focusing on this age group (e.g., Lane et al., 2013; Danovitch & Keil, 2004. For example, Danovitch and Keil (2007) presented 6, 8 and 9- year-olds with four short vignettes illustrating a character facing a moral dilemmas (e.g., respect another's privacy) or involved in a scientific problem (e.g., building a rocket). Following each vignette, participants were asked to choose what characteristics the character would have needed to solve the problem (e.g., "Does he need to be nice with other people" or "Does he need to be smart"). Their results showed that only starting at age 8 children consistently indicated that scientific skills were necessary to solve scientific problems and that moral characteristics were needed to solve moral dilemmas (Danovitch & Keil, 2007). Finally, it might be that to make selective, meaningful inferences about question asking, one has to be good at asking questions herself. In this respect, the developmental trend found in this study might be reflective of children's improvement in question-asking effectiveness. Future research should explore whether and how children's ability to ask informative questions or search effectively more in general can impact the inferences and generalizations they make based on others' active learning competence. Moreover, it seems clear that even older children's responses did not always and perfectly reflect adults' intuitions. This difference could be resulting from the different ways in which participants were asked to elicit their intuitions in Study 1 and 2.

It is crucial to note that in our studies the good question asker was simply contrasted with a *bad* question asker, who was not given any other positive nor neutral attributes, whereas in many studies focusing on generalizations, including those reviewed above, informants are presented as experts in different domains (e.g., (Lutz & Keil, 2002; Kushnir et al., 2013; Jaswal et al., 2010; Koenig, 2012). We are currently finishing data collection on a follow up study in which we implement the more traditional version of paradigm, contrasting an agent who is good at asking questions and "finding out things" with one that has a domain-specific expertise (e.g., knows everything about fish). Future work should also investigate the impact of such inferences and generalizations on children's learning and social behavior, for example examining under which conditions children would prefer to imitate, learn or ask for help to someone they identify as an effective active learner.

To conclude, this study is a first attempt at exploring what children infer based on someone's ability to ask effective questions. We found an interesting developmental pattern from unsystematic generalization, to overgeneralization, to adults-like selective generalization, suggesting that children at different ages use information about an agent's active learning competence in different ways. This is a first step in understanding whether and how children use their sensitivity to others' active learning competence to navigate the social world, identifying good role models to learn, and to *learn how to learn* from.

Acknowledgments

We thank Federico Meini for developing the app used for this study, Lola Hermann and Andreas Sommer for assistance in recruiting and data collection. We would also like to thank our collaborators in Berlin, the Museum für Naturkunde, Labyrinth Kindermuseum, Science Center Spectrum and the FRÖBEL-Kindergarten im Lützelsteiner Weg for providing research space.

Abstract

Prior knowledge has long been recognized as an important predictor of learning, yet the term prior knowledge is often applied to related but distinct constructs. We define a specific form of prior knowledge, *ancillary knowledge*, as knowledge of concepts and skills that enable learners to gain the most from a target lesson. Ancillary knowledge is not prior knowledge of the lesson's target concepts and skills, and may even fall outside the domain of the lesson. Nevertheless, ancillary knowledge affects learning of the lesson, e.g., lower ancillary knowledge can hinder performance on lesson-related tasks. We measured ancillary knowledge, prior knowledge of the domain, and controlled for general ability, and found that (a) stronger ancillary knowledge and general ability predicted better performance on transfer tasks, but (b) prior knowledge of the domain did not. This research suggests that enhancing instruction by remediating gaps in ancillary knowledge may improve learning in introductory-level courses.

Keywords: prior knowledge; ancillary knowledge; domain-general knowledge; far transfer; introductory courses

Introduction

Learners in any given class often vary widely with respect to their knowledge of both the current material and the skills and concepts that may be considered ancillary to and supportive of the current material. At the college level, this is perhaps most evident in introductory-level courses, which by definition enroll many learners who are novices in a domain, and yet who bring all types and degrees of prior knowledge into the classroom. Before attending Introduction to Cognitive Psychology, for example, students may or may not have taken a general psychology course that included a high-level introduction to many topics. They are also likely to have had different degrees of exposure to and practice with concepts and skills that could be considered supportive of learning Cognitive Psychology, e.g., graphing and experimental design. These topics, which may have been learned in the context of psychology or a different science or math context, are likely useful to students as they learn about cognitive psychology hypotheses, study designs, graphed results, and whether the data support these hypotheses. Despite the clear relevance of graphing and experimental design knowledge, rarely are they measured or their gaps addressed during instruction.

We wished to evaluate whether such ancillary knowledge would predict performance on assessment items related to a new lesson better than prior domain (cognitive psychology) knowledge or knowledge of the specific lesson, which would suggest that this unmeasured and often unaddressed type of knowledge plays an important role in learning.

Background

Researchers have long considered prior knowledge critical for learning (Ausubel, 1968; Dochy, 1988; Jonassen & Grabowski, 1993). Across studies, it represents one of the largest sources of variance in pre/post-test measures, accounting for 30 to 60 percent of the difference in scores (Dochy, 1988). Prior knowledge explains performance over and above general ability. For example, it predicted learning of science concepts better than mental capacity and developmental level (Lawson, 1983) or formal reasoning ability (Zeitoun, 1988), and comprehension of text passages after accounting for IQ (Langer & Nicolich, 1981).

The importance of prior knowledge for learning is well established, yet many studies do not provide explicit definitions of prior knowledge or use similar terms to reference distinct constructs (Dochy & Alexander, 1995). Consequently, important dimensions of prior knowledge may be overlooked, and research becomes inconclusive. In addition, some benefits of prior knowledge may be due to prior knowledge in the domain, ancillary knowledge, or both; similarly, learning difficulties may be due to knowledge gaps of either type. More generally, if learners vary in both types of prior knowledge, but the two types are not distinctly assessed, their role in learning cannot be clearly understood.

Our research aims to distinguish these two types of prior knowledge: *prior knowledge in the domain*, i.e., concepts and skills within the target domain, from *ancillary knowledge*, i.e., knowledge of the concepts and skills that are outside of the target domain (but may be utilized in the target domain and additional domains; see Dochy, 1988). See *Figure 1* for a graphical representation. In order to be considered ancillary knowledge, these concepts and skills should enable better learning of the new material, such as knowledge of graphing and experimental design may for many cognitive psychology topics. Bloom's (1976) term for this idea was "cognitive entry behaviors," which he defined as "those prerequisite types of knowledge, skills, and competencies which are essential to the learning of a particular new task or set of tasks" (p. 122).

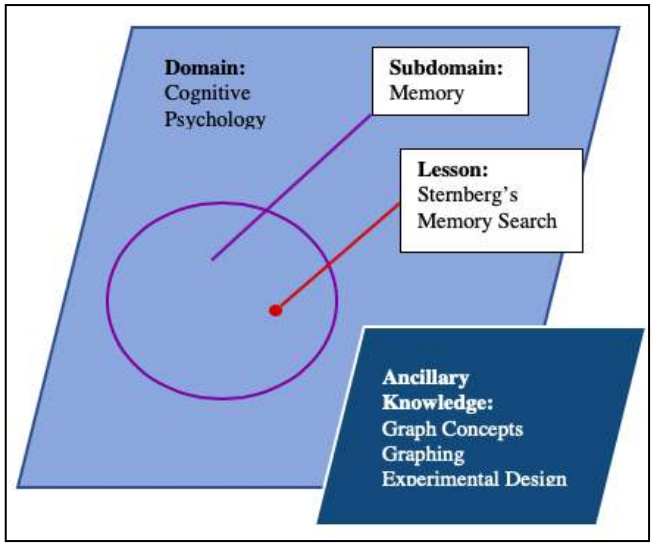

Figure 1: Levels of domain knowledge include the domain, subdomains, and concepts and skills within the domain. Ancillary knowledge is domain-independent, but may nevertheless support learning in the domain.

The mechanisms of support for learning are likely the same for both types of prior knowledge, including freeing up attentional resources and enabling greater comprehension and problem solving (Fincher-Kiefer, Post, Greene, & Voss, 1988; Kintsch, 1994; Schauble, Glaser, Raghavan, & Reiner, 1991; Siegler, 1986; Willingham, 2007). The key difference is that prior knowledge in the domain is obviously relevant and ancillary knowledge is often overlooked or deemed out of scope of the current instruction.

This is particularly problematic for undergraduates, who are likely to have gaps in the types of ancillary knowledge that readily support experts as they encounter new topics. Schunn and Anderson (1999) contrasted experts' and undergraduates' performance on an experimental design task and found that the latter did not demonstrate the experimental design skills of using theory to design their experiment and relating results back to the theories at a proficient level. On the other hand, experts have a wealth of domain knowledge and tools they can bring to bear in new situations, such as knowledge of related studies or formulas typically used.

Despite this, undergraduates have often acquired a measurable degree of general knowledge (Means & Voss, 1985), general strategies (de Jong & Ferguson-Hessler, 1996), and even subject-specific knowledge (Dochy & Alexander, 1995). Variability is heightened because the knowledge may have been learned and forgotten, partially learned, or not abstracted at a high enough level to be useful in new contexts. In other words, undergraduates' base levels of knowledge are more sophisticated (tending toward greater richness) than younger students, but also more tenuous and incomplete than experts' knowledge. Therefore, instead of categorizing subjects as experts or novices, we took a quantitative measure of ancillary and domain knowledge in our target population in order to pick up on this variability.

In addition, in order to investigate the role of ancillary knowledge in undergraduate learning, we utilized a situation typical in introductory courses, namely one in which ancillary knowledge and domain knowledge were expected to vary greatly, but prior knowledge of the lesson was uniformly low (i.e., not at play). The specific lesson we chose was the Sternberg memory search paradigm and experimental results, as taught in an introductory Cognitive Psychology course at Carnegie Mellon University. A key advantage of this lesson was that several questions on the assessments were adapted from materials that had been used in the course and therefore already deemed suitable (i.e., challenging but within grasp) for the average ability level of our sample.

We analyzed the lesson to determine what would qualify as ancillary knowledge – i.e., independent of the target lesson and yet expected to enhance learning of that lesson. We identified the following as relevant ancillary knowledge: variable selection and measurement, facility with graphed data and the lines that fit these data, and interpretation of graphed results in terms of theoretical relationships between variables. Consistent with this list, a reviewer of this paper shared that a lack of ancillary knowledge related to graphing prevented his or her students from fully understanding Sternberg's hypothesis, his various independent variables and study results. In other words, missing ancillary knowledge (i.e., an inability to apply knowledge about y-intercept and slope) affected the extent to which students were able to gain lesson-specific knowledge.

In order to separate ancillary knowledge fully from the domain of cognitive psychology, we situated the pre-test questions in other domains, such as physics (for graphing questions) or social psychology (for experimental design questions). We measured prior knowledge in the domain by assessing knowledge of the subdomain of memory (e.g., chunking, serial position effect), as well as prior knowledge of the lesson (e.g., Sternberg's paradigm, hypothesis, and results). See *Table 1* for sample questions.

Conceptual and Procedural Knowledge

Our measures also differentiated between types of ancillary knowledge based on another dimension that is often included in studies of learning and performance: conceptual versus procedural knowledge. The classification of knowledge as conceptual or procedural is both common (Baroody, Feil, & Johnson, 2007; Crooks & Alibali, 2014) and useful for studying learning and performance. Researchers and educators sometimes call conceptual knowledge "knowing that" and procedural knowledge "knowing how," or, even more simply, concepts (conceptual) and skills (procedural).

Determining *how* to measure conceptual apart from procedural knowledge became a secondary focus of our work. Even though the labels conceptual and procedural suggest the idea of two independent categories, these knowledge types are often related. Rittle-Johnson and Siegler (1998) reported positive correlations between amounts of conceptual and procedural knowledge in four areas of math learning.

Table 1: Sample item from each of the six (6) knowledge types assessed at pre-test.

Knowledge Type		Sample Item
Ancillary Knowledge – Graphing	*(1) Conceptual*	Here is a Boxplot (also called a Box and Whisker plot). Circle any feature that can be determined.
	(2) Procedural	What does the slope of an object accelerating uniformly look like on an acceleration vs. time graph? Hint: Sketch a graph with acceleration on the x-axis.
Ancillary Knowledge – Experimental Design	*(3) Conceptual*	A social psychology researcher is interested in whether cheerfulness and extroversion determine a person's attractiveness. She does an experiment in which several participants view videos of interviews of everyday people and then rate the interviewee's perceived cheerfulness, extroversion, and attractiveness […] Are the results correlational or causal?
	(4) Procedural	Advertisements for an herbal product, ginseng, claim that it promotes endurance. As a researcher, how would you design a controlled experiment to test this claim? Describe each of the following: (e.g., groups, controls, dependent measure)
Prior Knowledge – Subdomain (Memory)	*(5) Conceptual*	While recalling a mobile phone number, splitting it into groups of 3 or 4 digits tends to be easier to remember than a single long number. *Why* does this chunking process work?
Prior Knowledge – Lesson (Sternberg)	*(6) Conceptual*	What did some researchers find surprising (counter-intuitive) about the mental search process Sternberg proposed?

Furthermore, Rittle-Johnson, Siegler, and Alibali (2001) described conceptual knowledge as knowledge of principles, concepts, and rules and when to apply those principles, and procedural knowledge as routinized knowledge acquired from explicit practice of a given problem type. From this view, any novel problem requires conceptual knowledge, because it has been neither practiced nor routinized. This presented a challenge, as we wished to gauge procedural knowledge of graphing and experimental design via the pre-test and then assess performance on novel procedural transfer problems at post-test. As stated, at pre-test, we addressed this issue by giving problems from outside the domain of cognitive psychology with the assumption that the procedural skills had been learned elsewhere. However, this was not possible at post-test, which was given in the context of the current lesson.

At post-test, we assessed procedural knowledge as knowledge of steps that we considered scriptable, and therefore teachable, whether or not students actually learned that procedure in the context of our lesson. Procedural assessment items included finding a slope, determining the ratio of two slopes, designing an experiment, determining the nature of a novel search process by executing a learned algorithm, etc., all in the context of lesson-specific concepts. By contrast, conceptual items tested facts, principles, or declarative knowledge, for example asking students to recall a fact, explain an answer, label a diagram, graphically depict a concept, etc.

Research Questions

We tested two research questions. First, does ancillary knowledge predict performance on near and/or far transfer questions, controlling for both general ability (i.e., SAT scores) and prior knowledge in the domain (i.e., the subdomain of memory)? We hypothesized that ancillary knowledge would predict learning but that prior knowledge of the domain would not.

Second, did we sufficiently distinguish conceptual and procedural knowledge types in the psychology domain? We measured concepts and procedures separately, on both the pre- and post-tests. Evidence that these variables are acceptably independent in terms of their correlations would be suggestive that our operationalization was successful. In addition, evidence that conceptual or procedural ancillary knowledge had differential patterns of association with the various post-test measures would also provide some support.

Method

Participants

80 undergraduate students (M_{age}=19.85 years, 63.8 percent female) completed the study for course credit.

Design and Procedure

A correlational design was used to study how natural variation in ancillary knowledge (pre-test question types 1-4 below) would relate to performance at post-test. On the pre-test, four questions each assessed (1) graphing conceptual knowledge, (2) graphing procedural knowledge, (3) experimental design conceptual knowledge, and (4) experimental design procedural knowledge. In addition, four questions assessed (5a) prior knowledge of memory, and two questions assessed (5b) prior knowledge of the lesson. These last two questions (5b) were the only ones that repeated between pre- and post-test. They were ultimately not used as a pre-test measure, because we determined that participants' knowledge of the target lesson was uniformly low/absent.

Due to limited time for the experiment, our goal on the pre-test was to sample sufficiently from each area of prior knowledge in order to determine a quantitative measure of

probable degree of knowledge in each area, not to try to assess each area in depth.

Next, participants read a two-page lesson, which was about 700 words with several figures, adapted from J.R. Anderson's 8th Ed. Textbook, *Cognitive Psychology and Its Implications*. Then, participants completed a practice activity that was either conceptual or procedural in nature. The results of the practice manipulation and two additional measures of conceptual knowledge following the practice manipulation are not reported in this paper.

Next, participants completed the Post-Test. To measure participants' learning, we created four types of questions (and therefore four outcome measures): (1) Text-based Questions could be answered successfully if participants formed an adequate mental model of the text as they read. Participants did not need to bridge inferences, but rather draw from their memory of the text in order to recall information (see Kintsch, 1994; McNamara et al., 1996). (2) Near-transfer conceptual items were related to the lesson, but had not been stated directly in the text and therefore required bridging inferences. (3) Near-transfer procedural items required participants to perform procedures in the context of newly learned lesson concepts. For example, participants were asked to determine and compare the slopes of lines depicting the relationship between lesson-specific variables. This drew on preexisting knowledge of procedures (i.e., finding slopes and comparing their ratios) in the context of the lesson concepts. (4) Far-transfer items required participants to apply knowledge and skills they had learned (i.e., types and levels of variables, graphed data, and underlying hypotheses from Sternberg's memory search paradigm) to other types of mental processes, including a visual search task and a mental rotation task. See *Table 2* for sample post-test questions. Finally, participants were asked to provide demographic data and aptitude scores.

In sum, there were nine predictor variables. Five were taken from the pre-test: (1) Ancillary Graphing, conceptual, (2) Ancillary Graphing, procedural, (3) Ancillary Experimental Design, conceptual, (4) Ancillary Experimental Design, procedural, and (5) Prior Knowledge Memory, conceptual. As stated, knowledge of the lesson was excluded from analysis because the pre-test items related to the Sternberg lesson were answered incorrectly or left blank (with only one subject answering one item correctly).

The other four variables were covariates: (6) SAT Verbal scores, (7) SAT Math scores (if ACT scores were given, they were converted), (8) Reading Time, a measure of how long the participant spent on the lesson, and (9) English Native, a categorical variable indicating whether the student was a native English speaker from at least the age of six.

Table 2: Sample item from each of the four (4) outcome measures assessed at post-test.

Knowledge Types		Sample Items
Text-based	*(1) Conceptual*	What did some researchers find surprising (counter-intuitive) about the mental search process Sternberg proposed?
Near Transfer	*(2) Conceptual*	Which independent variable from the list above has the greatest influence on the slope of the line in the graph?
	(3) Procedural	The graph below shows the relationship between Memory Set Size and Response Time for Foil trials (A) and Target trials (B). Compared with the increase in reaction time for B, the increase in reaction time for A is…
Far Transfer	*(4) Conceptual & Procedural (mixed within each question)*	Consider a new type of mental task. This one involves conducting a visual search for an item, such as a red circle in a field of distractors (similar items). In Feature search, a person is asked to find the red o in a field of green x's and o's. (a) A feature search is most like a _____ (parallel/serial) search. (b) Graph the lines for Target and Absent trials on the graph below. Label the lines.

Analyses and Results

Predictor Variables

Predictor variables were tested for normality. Several of the variables were negatively skewed and/or kurtotic, including both pre-test concept variables (graphs, experimental design) and SAT scores. In these cases, each score was reflected and then logarithmically transformed. These transformations resulted in acceptable normality, and these variables were re-reflected after transformation to aid in interpretation of beta coefficients.

Procedural Knowledge types (i.e., Graphing, Experimental Design), Reading Time, and Prior Knowledge-Memory, were normally distributed. The categorical variable English Native Speaker was answered "yes" seventy-percent of the time. Four cases did not report SAT scores and so the variable means were imputed for those cases.

Tests to see if the data met the assumption of collinearity indicated that multicollinearity was not a concern, with all $VIF < 2$. Correlations between each pair of predictor variables are reported in *Table 3*. The highest pairwise correlation was 0.55, between SAT Math and Verbal, below the conservative cutoff of 0.7 for multicollinearity. Seven pairs of predictor variables were significantly, positively correlated.

Table 3: Correlations between predictor variables.
** Correlation is significant at the 0.01 level (2-tailed). * Correlation is significant at the 0.05 level (2-tailed).

	Graphing Concepts	Graphing Procedures	Exp. Design Concepts	Exp. Design Procedures	Memory Concepts	SAT Verbal	SAT Math	Reading Time
Graphing Concepts	1							
Graphing Procedures	**0.336****	1						
Exp. Design Concepts	0.060	0.135	1					
Exp. Design Procedures	0.090	**0.252***	0.183	1				
Memory Concepts	0.209	0.172	0.169	0.095	1

Reading Time	-0.170	0.009	-0.177	0.072	-0.159	-0.064	-0.067	1

Linear Regressions

We regressed each of the Post-Test measures (Text-based Questions, Near Transfer Concepts, Near Transfer Procedures, and Far Transfer) on the nine explanatory variables in order to determine whether ancillary knowledge, prior knowledge in the domain, or general ability predicted performance. The model for Text-based Questions was the only model that was not significant.

The Near Transfer Concepts model was significant, $F(9,70) = 3.508$, $p = 0.001$, $R^2 = .311$, *Adj.* $R^2 = .222$. Greater Ancillary Knowledge of Graphing Concepts ($\beta = 4.426$, $t = 1.957$, $p = 0.054$) predicted better performance on near transfer concept questions.

The Near Transfer Procedures model was significant, $F(9,70) = 4.542$, $p = 0.001$, $R^2 = .369$, *Adj.* $R^2 = .288$. Greater Ancillary knowledge of Graphing Procedures ($\beta = 0.779$, $t = 3.574$, $p = 0.001$) predicted better performance on near transfer procedural questions.

The Far Transfer model was significant, $F(9,70) = 5.814$, $p = 0.001$, $R^2 = .428$, *Adj.* $R^2 = .354$. Higher SAT Math score ($\beta = 2.259$, $t = 2.330$, $p = 0.023$) and greater Ancillary Knowledge of Experimental Design Procedures ($\beta = 1.370$, $t = 4.114$, $p = 0.001$) each predicted better performance.

Finally, to test whether model fit was better when the four types of ancillary knowledge were entered as separate predictors in the model, as we had done, versus entered as a single predictor (and therefore treated as having a similar effect on learning), we compared *Adj.* R^2, AIC score, and BIC score for each of the models. *Adj.* R^2 and BIC are more sensitive to number of predictors and therefore penalize more for model size than AIC. The remaining predictors entered into the model were the same: SAT scores, Prior Knowledge of Memory, Reading Time, and English Native.

Model fit scores are shown in *Table 4*. All six models were significant at the 0.001 level. In addition, the single score for ancillary knowledge was a significant predictor in each of those three models. There was a slightly higher *Adj.* R^2 (0.005 more variance explained) for the single predictor model for Near Concepts, and a lower *Adj.* R^2 with the single predictor model for Near Procedures (0.009 less variance explained) and for Far Transfer (0.045 less variance explained). BIC, which penalizes more for number of predictors than AIC, was unsurprisingly lower in the single predictor models than the separate predictor models, signifying less overfitting. AIC was similar across the models, with the AIC for the single predictor model being slightly lower for Near Concepts and Near Procedures, but slightly higher for Far Transfer.

Table 4: Model fit for separate vs. combined (i.e., a single, additive score) ancillary knowledge predictors. The separate ancillary predictor models had nine predictors, whereas the single ancillary predictor models had six.

	Separate Ancillary Predictors Model (df=9)				*Single Ancillary Predictor Model (df=6)*			
For Outcome Measure:	R^2	*Adj.* R^2	*BIC*	*AIC*	R^2	*Adj.* R^2	*BIC*	*AIC*
Near Concepts	0.311	0.222	437.24	411.04	0.286	0.227	428.20	409.15
Near Procedures	0.369	0.288	356.78	330.58	0.334	0.279	347.44	328.38
Far Transfer	0.428	0.354	439.22	413.02	0.362	0.309	432.46	413.41

Discussion

This research identified ancillary knowledge and skills that predicted performance on near and far transfer assessment questions related to a cognitive psychology lesson. In each case, more ancillary knowledge led to better performance. We measured four types of ancillary knowledge that had a low degree of intercorrelation, namely conceptual and procedural knowledge of graphing and experimental design. Furthermore, specific ancillary measures predicted the various post-test measures, and statistical models that treated the ancillary knowledge as distinct accounted for the same or more variance than those that treated the ancillary knowledge as monolithic.

In addition, we found encouraging evidence that it is possible to operationalize assessment questions that differ on the conceptual and procedural knowledge dimension, and thereby measure them as distinct constructs, in this domain (i.e., cognitive psychology) and at this lesson and instructional level (i.e., introductory college coursework). Even though procedural assessment items are clearly dependent on a grasp of the lesson concepts in this context, we crafted procedural post-test questions that were predicted by ancillary procedural knowledge as assessed by pre-test problems in a different domain, suggesting that the procedural knowledge itself was uniquely important and domain independent. We do not interpret these results as implying that only procedural knowledge was needed for any of the assessment questions we labeled procedural (that is, independent of conceptual knowledge of the lesson).

SAT Math scores were also predictive of success in the Far Transfer model. And while not reported above, SAT Verbal was nearly significant ($p = 0.068$) in the Near Transfer Concepts model, and SAT Math was nearly significant ($p = 0.076$) in the Near Transfer Procedures model. It is not surprising that aptitude played a role in learning, particularly unsupported learning (e.g., no instructor) of a novel lesson, as students had to make sense of the material for themselves. Even so, ancillary knowledge was predictive over and above aptitude in the models.

In contrast to ancillary knowledge and general ability, prior knowledge in the memory subdomain of cognitive psychology was not predictive in any of the models. This should not be interpreted as domain-specific knowledge failing to predict performance in general, however. Schunn and Anderson (1999) found that domain-specific knowledge contributed to the performance of experts, and we expect that if students continued studying in the domain, domain-specific knowledge would be more and more predictive of their performance. In this study, however, the novice status of the participants lent greater importance to the variability in their ancillary knowledge and its role in their learning.

Finally, neither time spent reading the lesson nor native English speaker status from the age of six was predictive of performance, which is not surprising given that all students in our sample regularly do coursework in English, and that we also included a verbal aptitude measure in the model.

One final note about the specific assessment questions written for each of the outcome measures, some of which came from an actual cognitive psychology course and some of which were written for this lab study. The type of ancillary knowledge that predicted greater success on each transfer measure was arguably both a function of the outcome type (conceptual or procedural) and also the specific questions written for the category. As seen in Table 2, many of the questions written for the Near Transfer Concepts measure asked students to assess the relative influence of study variables in graphs of data and as they related to various theories, and so knowledge of graphing concepts is a logical predictor. Many of the questions written for the Near Transfer Procedures measure asked students to apply procedures related to graphing and experimental design in the context of the newly learned topic. For example, they were asked to predict values of various independent variables (e.g., stimulus quality, biasing) in Sternberg's experiment, imagine a graph for Accuracy instead of Reaction Time in Sternberg's experiment, etc., and so knowledge of graphing procedures is likewise a logical predictor.

For the Far Transfer measure, questions required students to apply their new lesson knowledge to mental processes that they had not previously encountered in their reading. Applying knowledge of the Sternberg paradigm in order to graph data and predict results for novel mental processes would likely benefit from greater knowledge of experimental design. Had we written different assessment questions, we expect that different ancillary knowledge structures would have been useful to the students, and a task analysis would have revealed that relevant knowledge. Furthermore, we consider it probable that ancillary knowledge structures beyond graphs, graphing, and experimental design could be measured and found predictive of better success at post-test.

Our study had several limitations. First, we tested our hypotheses regarding ancillary knowledge in the context of one lesson, so demonstrating the generalizability of these findings will be critical. Psychology is a domain that is conceptually rich, and therefore future studies should include a greater number of ancillary constructs. Second, the design was correlational, so we could not rule out other possible causes of performance differences. Third, we did not attempt to remedy gaps in knowledge structures that we identified in order to determine how such intervention would impact learning. Studying methods of remediating specific skills in the context of a new lesson versus outside the context of the lesson could suggest productive instructional practices once gaps are identified. Finally, work to further differentiate conceptual and procedural ancillary knowledge would be useful. Due to time limits, we were only able to take gross measures of ancillary knowledge at pre-test. A greater depth of pre-assessment, paired with the use of methods such as think-aloud protocols, to detect conceptual or procedural processing during the assessment would aid our understanding of how undergraduates construct, structure, and utilize their knowledge when encountering a new lesson.

Conclusion

We have defined a type of prior knowledge, ancillary knowledge, that differs from other types of prior knowledge in important ways. It is both domain-independent and yet relevant to learning of a target lesson. We also provide evidence that ancillary knowledge can be productively differentiated into various subtypes of knowledge (i.e., graphing vs. experimental design; conceptual vs. procedural).

The distinction between ancillary knowledge and prior knowledge of the domain is relevant for researchers who study learning, and may have bearing on the design of pre-tests. If the target population of students varies in level of domain-independent knowledge that may still have direct bearing on the lesson, pre-testing for ancillary knowledge (in addition to prior knowledge of the domain or lesson) would be relevant and potentially important for understanding patterns of learning.

In addition, distinguishing ancillary knowledge has implications for the design of instructional materials. Finding ways to identify and close gaps in ancillary knowledge could enhance the effectiveness of instruction for novice learners and ultimately improve learning and transfer.

Parents' Linguistic Alignment Predicts Children's Language Development

Joseph Denby and **Daniel Yurovsky**
{jgdenby, yurovsky}@uchicago.edu
Department of Psychology
University of Chicago

Abstract

Children quickly gain enormous linguistic knowledge during early development, in part due to low-level features of their parents' speech. Some posit that parents contribute to their child's language development by tuning their own language according to their child's developmental abilities and needs (Bruner, 1985; Snow, 1972). Here, we investigate this hypothesis by examining 'alignment' at the level of syntax and function words in a large-scale corpus of parent-child conversations and measuring its association with language development outcomes. To do so, we employ a statistical model of alignment to estimate its presence in our dataset and its predictive impact on a measure of vocabulary development. Our results corroborate previous findings, showing strong alignment for both parents and children; in addition, we demonstrate that parental alignment is a significant predictor of language maturity independent of demographic features, suggesting that parental tuning has strong ties to a child's language development.

Keywords: Language acquisition; statistical modeling; vocabulary development

Introduction

Children make vast linguistic strides within their first few years of life. In light of this, some researchers have offered the linguistic tuning hypothesis, arguing that parents bolster their child's early language learning by calibrating the complexity of their speech to the particular abilities and needs of their children (Montag & MacDonald, 2015; Snow, 1972; Thiessen, Hill, & Saffran, 2005). The idea is intuitive, but it is unclear at what level of language tuning occurs (Hayes & Ahrens, 1988; Sokolov, 1993; Spivey & Dale, 2006) and how overt it is (Brown & Hanlon, 1970; Chouinard & Clark, 2003; Hirsh-Pasek, Treiman, & Schneiderman, 1984).

A parallel yet complementary vein of language development research investigates the presence of low-level cues in parental speech and their influence on child language learning. From this research, we know that child-directed speech contains features that facilitate language learning, and that more exposure tends to result in better outcomes (Cameron-Faulkner, Lieven, & Tomasello, 2003; Weisleder & Fernald, 2013). Related, caregivers from families of high socioeconomic status (SES) tend to converse more with their children than their lower SES counterparts, and these increases are associated with improved development outcomes such as vocabulary size and school performance (Hoff, 2003; Walker, Greenwood, Hart, & Carta, 1994). Moreover, differences in SES-based language development are largely explained by low-level features of parental child-directed speech such as lexical diversity and sentence complexity (Hoff-Ginsberg, 1998; Rowe, 2008). So, given that granular aspects of parental speech can have substantial effects on a child's language development, it may be that linguistic tuning occurs at this level in subtle ways, particularly when it comes to non-content words (i.e., words that are not central to the topic of discussion.)

This idea of assessing the direct impact of a parent's usage of non-content words on language development relates to linguistic alignment, a phenomenon whereby conversational partners tend to align aspects of their communicative style and content according to various external influences (Pennebaker, Booth, Boyd, & Francis, 2015). Alignment can occur at various levels of language, with some research (including ours) focusing on the level of quasi-syntactic categories (e.g., Ireland et al., 2010; Niederhoffer & Pennebaker, 2016). These categories don't strictly describe syntax; instead, they aim to capture function words, which are more invariant to context than content words. However, we often use the phrase 'syntactic alignment' here as shorthand for 'alignment within function word categories.' As an example, see the exchange between a child and parent presented in Table 1. The parent's usage of "across" directly following their child's usage of "across" presents alignment within the category of prepositions. Alignment need not involve repetition however; the child's use of "I" following their parent's use of "I'll" serves as alignment within a category as well (the category of 'I' pronoun words.) Alignment between parents and children may lend support to the linguistic tuning hypothesis - if parents align to their children in a way that changes across development, and that alignment has a concrete impact on a child's language acquisition, the tuning hypothesis could be vindicated (Bruner, 1985).

Yurovsky, Doyle, & Frank (2016) investigates linguistic alignment in CHILDES (MacWhinney, 2000), a natural language corpus of conversations between parents and children to assess whether tuning occurs at the level of function word categories. They find that alignment does occur between both parents and children; moreover, parents align less over time, suggesting that the relationship their speech shares with their child's changes as a function of development. These results present a powerful proof of concept that alignment within function word categories exists between parents and children

and changes over time, but it remains unclear whether alignment bears any sort of concrete, impactful relationship to language development.

Parent	I don't know . I'll have to think about it .
Child	I was going to do the people across street .
Parent	across the street ?
Child	yeah .

Table 1: Excerpt from exchange between 38 month old child and mother in LDP.

Here, we extend Yurovsky, Doyle, and Frank's (2016) model by applying it to the Language Development Project (LDP) (Goldin-Meadow et al., 2014), a corpus of ecological conversations between parents and their children over time, collected from a socioeconomically diverse sample of parent-child dyads. The variability present within this dataset aids our estimation by offering a more robust picture of alignment as it actually occurs. We follow their method of assessing alignment only within function words. Moreover, we use alignment estimates alongside demographic information to predict measures of vocabulary development, supporting the linguistic tuning hypothesis by concretely showing how parents' sensitivity to their child's linguistic needs and abilities covaries with their development.

Model

The linguistic tuning hypothesis predicts that parents will calibrate their language in part by assessing their child's needs and abilities. So, we predict that parents will exhibit high alignment to their young children, but will reduce their alignment as their children mature (and improve in linguistic maturity.) To test this prediction, we employ an extended version of the Hierarchical Alignment Model implemented in Yurovsky et al. (2016) which both estimates the impact of a speaker's use of function word categories on their conversational partner's usage and uses these alignment estimates to predict language outcome scores.

At base, for each utterance the model predicts whether the speaker will produce a word from a given function word category. This prediction is generated by two factors: the speaker's baseline propensity towards using that category and the speaker's tendency to align, producing words from a category just used by their partner. In the model, the primary computation mimics a standard logistic regression - the production of a category within an utterance is treated as a binary outcome variable impacted by a linear combination of predictor variables (here, baseline usage and alignment.) The model's hierarchical structure then allows the estimates of baseline usage and alignment effects to be pooled across individual speakers and categories in a way that ensures statistical robustness.

The model used here then incorporates these alignment and baseline usage estimates as predictors in a linear regression model of the Pearson Peabody Vocabulary Test (PPVT) (Dunn & Dunn, 1997), a widely used inventory for tracking language development. Measures of vocabulary like the PPVT offer a robust snapshot of overall language abilities throughout early language development, with PPVT scores in particular correlating with various other measures of cognitive ability (Hodapp, Gerken, & 1999, 1999; Naglieri, 1981). As one of various measures of cognitive and language ability present within the LDP dataset, we selected the PPVT for its reliability and validity in addition to it being a measure not based solely on parent report. At this stage, PPVT is estimated as a linear combination of predictors reflecting alignment and baseline usage estimates for both parents and children, alongside other features representing demographic variables (e.g., child's gender, mother's education) and the child's age. Moreover, the PPVT was administered to each child in LDP at least twice, allowing us to estimate interaction effects between parameter and demographic variables with age.

Table 2: LIWC Categories with example words.

Model Details

The structure of the model used here greatly resembles that used in Yurovsky et al. (2016), in that it operates over utterances represented as binary vectors, with indices indicating the presence or absence of each of the 14 LIWC categories used within alignment literatures (Pennebaker et al., 2015) to designate function words (Table 2). The probability of producing each category in each utterance is computed via two parameters: the speaker's baseline usage of that LIWC category (η^{base}), and the change in that speaker's baseline as a function of interacting with the listener (η^{align}). So, for a given category c, for replies to utterances that don't contain c, the production parameter for that category is computed by applying the inverse logit function to the appropriate baseline log odds:

$$P(Production_c) = logit^{-1}(\eta_c^{base})$$

Alternatively, replies to utterances that *do* contain c, the parameter computation takes into account the sum of the baseline and alignment log odds:

$$P(Production_c) = logit^{-1}(\eta_c^{base} + \eta_c^{align})$$

To accommodate the variance in production across the LIWC categories, each baseline usage parameter was drawn from an uninformative prior ($\eta^{base} \sim Uniform(-5,5)$); alignment parameters were regularized towards 0 by way of implementing a conservative prior ($\eta^{align} \sim Normal(0,.25)$).

All parameters were estimated hierarchically, which allows intelligent pooling of data across participants in the dataset. To start, each subpopulation (i.e., parents vs. children) obtained an estimate. Then, every speaker had an alignment estimate drawn from their appropriate subpopulation (e.g., if Speaker 22 is a child, their alignment estimate is drawn from the estimate for children overall.) Category-level alignment estimates were then drawn for each speaker (e.g., the alignment estimate for Speaker 22's usage of determiners is drawn from Speaker 22's overall alignment estimate.) The order was flipped for baseline estimates in order to better reflect empirical baseline usages across LIWC categories; subpopulation estimates produced category-level estimates, which then produced speaker-level estimates. As in Yurovsky et al. (2016), we also include parameters that allow baseline and alignment probabilities to change linearly over time (β and α respectively).

Next, we extend the model used in Yurovsky et al. (2016) by using estimated alignment (i.e., η parameters) to predict PPVT scores, a measure of vocabulary development (Dunn & Dunn, 1997). To do so, we implement a regression model where PPVT scores are modeled as linear combinations of various predictor variables. These predictor variables included the child's age, alignment parameter estimates for the child and their parent, the mother's education, the child's gender, as well as interaction effects for all variables with age. We use mother's education as a well known proxy for socioeconomic status (Hollingshead, 1975). Error variance for the model (σ) was also estimated.

The model implemented here then serves two purposes: (1) It extends the analysis of Yurovsky et al. (2016) to a new dataset, aiming to replicate previous findings in a more diverse and representative sample, and (2) It incorporates alignment estimates in a predictive model of early language outcomes, serving to test the hypothesis that alignment has a significant relationship with language development, even in the presence of demographic features. To be specific, we hope to replicate non-zero estimates for η parameters (demonstrating that alignment between parents and children exists across datasets), positive β for children (showing that children increase their baseline usage of categories over time), and negative α for parents (showing that parents decrease their alignment as their children age.) If the PPVT model estimates for parameters corresponding to the main or interaction effects of alignment are non-zero in the presence of demographic variables, we can infer that alignment has a relationship with vocabulary development independent of features like socioeconomic status, bolstering the linguistic tuning hypothesis.

Analysis

Data and Methodology

Conversations between parents and their children were drawn from the Language Development Project Corpus (Goldin-Meadow et al., 2014). Participants in the project were video-recorded in their homes for $\sim$ 90 minutes every four months starting when the child was 14-months and ending at 58-months. Additionally, all participants took the PPVT on at least two occasions during the observation period. Participants were selected in order to produce a diverse sample demographically representative of the broader Chicagoland area. LDP is smaller than other comparable corpora of child-parent conversations (e.g., CHILDES), but it stands alone in its broad representation of families across the socioeconomic spectrum.

We selected for analysis all children who were typically developing and completed at least 10 of the 12 planned recording sessions. Our sample consisted of 59 target children, 28 of whom were girls, 12 were Black and 6 were Multiracial. Children were also socio-economically diverse, as measured by mother's education: 2 mothers had some highschool education, 7 had a highschool degree, 10 had some college or trade school, 19 had college degrees, and 21 had advanced degrees.

Following Yurovsky et al. (2016), successive utterances from a speaker within a transcript were concatenated into a single utterance. Individual utterances were then transformed into binary vectors with indices indicating the presence or absence of each of the 14 LIWC categories. This pre-processing turned every transcript into a speaker-reply format: each utterance within a transcript was both a reply to the preceding utterance and a message to the next one.

Each transcript was then compressed, yielding 4 numbers for each LIWC category. For a pair of speakers A and B in a transcript, for each LIWC category, we computed the number of utterances from A to B containing the category (N^{align}), the number of utterances from A to B not containing the category (N^{base}), the number of utterances containing the category responding to an utterance containing the category (C^{align}), and the number of utterances containing the category responding to an utterance not containing the category (C^{base}). Aggregating in this way provided the platform for the model's sampling - for each transcript, C^{base} and C^{align} were drawn from Binomial distributions parameterized by N^{base} and N^{align} chances respectively, with probabilities computed via the logistic regression models outlined above.

Sampling was performed using Stan, a probabilistic programming language that implements Hamiltonian Monte Carlo sampling methods (Carpenter et al., 2017). Posterior distributions for each parameter in the model were estimated using 500 iterations of Bayesian sampling, generating mean assess-

ments with appropriate confidence intervals. [1]

Results

Alignment estimates (η^{align}) for parents and children were both estimated above zero, corroborating the findings of Yurovsky et al. (2016) in showing that both groups exhibit alignment (Figure 1). We also replicate the finding that parents appear to align more to their children than children align to their parents.

The model estimates changes in baseline category production across development (β) at approximately zero for parents, but significantly above zero for children, replicating previous findings. Alignment is estimated as having a significantly negative age effect (α) for parents in this dataset, replicating an earlier finding that alignment from parents to children tends to decrease over their child's development (Figure 3).

The mean estimates for PPVT predictors are presented in Table 2; they illustrate effects on a child's average PPVT score as well as estimates of interaction effects with age (i.e., the rate at which PPVT improves over development.) As expected, PPVT is positively associated with the age of the child and their being female. Moreover, female children tend to have a decreased age effect on PPVT; female children have a higher average PPVT score relative to male counterparts, but their scores improve over time more gradually. Mother's education is negatively associated with PPVT, but has a slight positive age effect. Alongside these demographic effects, we see robust alignment effects on PPVT: child and parental alignment are both associated with increased PPVT, but with decreased age effects.

Discussion

In an effort to understand and investigate how children rapidly acquire language, some argue that the language parents produce to their children is somehow calibrated to the child's particular needs and abilities (Snow, 1972). While the idea is theoretically compelling, empirical work has produced mixed results, with strong results in favor of (Chouinard & Clark, 2003; Hirsh-Pasek et al., 1984) and against (Brown & Hanlon, 1970; Hayes & Ahrens, 1988).

However, much of this prior work investigates tuning as an overt effort on behalf of parents or tuning with respect to content words, with less examining the potential role of low-level syntactic influence (Hoff, 2003). Yurovsky et al. (2016) presents just such an examination, demonstrating using Bayesian hierarchical modeling that parents align to their children according to their particular language usage at the level of function word categories. This paper extends their model by applying it to a new socioeconomically diverse sample of families (Goldin-Meadow et al., 2014) and leveraging the model's alignment estimates to predict language development outcomes.

The analysis presented here replicates the findings of Yurovsky et al. (2016), showing strong alignment effects for both parents and their children, a substantial age effect for baseline useage in children, and a significant negative effect of age on alignment for parents. Moreover, we demonstrate that these alignment estimates have substantial power in predicting vocabulary development measures, even in the presence of demographic features such as gender and socioeconomic status. We corroborate previous findings that female children tend to have higher PPVT scores that improve more gradually over time (Kaushanskaya, Gross, & Buac, 2013; Lange, Euler, & Zaretsky, 2016). We conflict with other findings that positively associate child PPVT scores with mother's education (Di Cesare, Sabates, & Lewin, 2013; Schady, 2011); this may be due to idiosyncracies of our dataset, including its limited size.

We show that parental alignment is associated with a relatively large boost in average PPVT scores, but with a negative

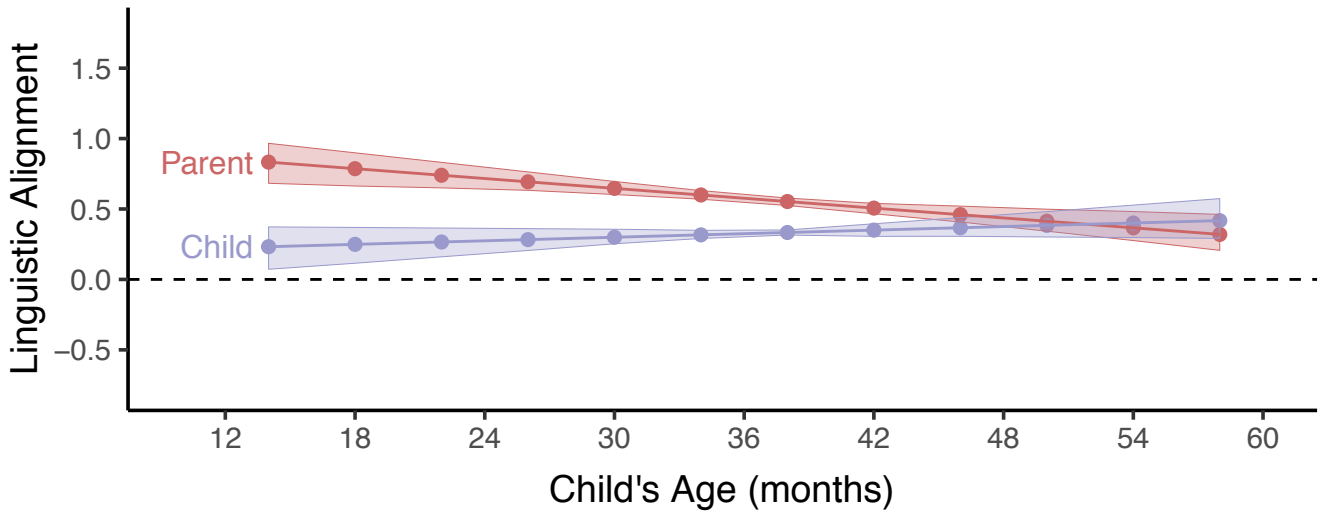

Figure 2: Model-estimated changes in linguistic alignment over development. Points indicate the mean of the posterior distribution; shaded regions indicate 68% highest probability density intervals, equivalent to one standard deviation, for visualization purposes.

age effect. The negative age effect may source from a ceiling on PPVT - children with higher average scores may simply have less ground to cover. Nevertheless, these results are consistent with a concrete effect of parental alignment on vocabulary development, and the linguistic tuning hypothesis more broadly. A similar story is evident from child alignment estimates: alignment has a small association with overall PPVT score and an age effect comparable to parental alignment. Here there may be a confound with childrens' baseline language production, in that children with lower production will have lower PPVT and diminished alignment as a result; future work should assess this interaction to better isolate the effects of alignment.

Overall, these results show that parental alignment within function word categories is a robust effect that appears to have a relationship with childrens' language development independent of demographic correlates, serving to further the linguistic tuning hypothesis.

Abstract

Is the nested sets approach to improving accuracy on Bayesian word problems simply a way of prompting a natural frequencies solution, as its critics claim? Conversely, is it in fact, as its advocates claim, a more fundamental explanation of why the natural frequency approach itself works? Following recent calls, we use a process-focused approach to contribute to answering these long-debated questions. We also argue for a third, pragmatic way of looking at these two approaches and argue that they reveal different truths about human Bayesian reasoning. Using a think aloud methodology we show that while the nested sets approach does appear in part to work via the mechanisms theorised by advocates (by encouraging a nested sets representation), it also encourages conversion of the problem to frequencies, as its critics claim. The ramifications of these findings, as well as ways to further enhance the nested sets approach and train individuals to deal with standard probability problems are discussed.

Keywords: Nested Sets; Natural frequencies; Bayesian; Base rate neglect

A recent meta-analysis (McDowell & Jacobs, 2017) conclusively demonstrated that when a Bayesian word problem is presented according to natural frequency (NF) principles, normative responding increases relative to the 'standard probability' format (SP), with an average accuracy of around 24%. Both versions of the classic medical diagnosis problem can be seen below (statistical notation added).

Standard probability format (individual chance): The chance of breast cancer is 1% [P(Ca)] for women at age forty who participate in routine screening. If a woman has breast cancer, the chance is 80% [P(Po|Ca)] that she will get a positive mammography. If a woman does not have breast cancer, the chance is 9.6% [P(Po|¬Ca)] that she will also get a positive mammography. A woman in this age group had a positive mammography in routine screening. What is the chance that she actually has breast cancer [P(Ca|Po)]? ____%

Natural frequencies: 10 [F(Ca)] out of 1000 women at age forty who participate in routine screening have breast cancer. Out of the 10 women with breast cancer, 8 [F(Po&Ca)] will get a positive mammography. 95 [F(Po&¬Ca)] out of every 990 women without breast cancer will also get a positive mammography. Here is a new representative sample of women at age forty who got a positive mammography in routine screening. What proportion of these women do you expect to actually have breast cancer [P(Ca|Po)]? ___ %

We can see several differences between these formats. Most obviously, the NF format uses frequencies (indicated by the 'F' notation) rather than percentages / probabilities (P), but more importantly, the figures are not normalized. In the SP format, the figures are normalized by the use of a standard denominator (percentages are one way of achieving this with a hidden denominator of 100, but normalized frequencies with other denominators are also possible). This difference in normalization firstly has a known effect on the number of computations required to solve each problem. In an NF format there are thought to be only two computational steps[1]: (1) summing the number of individuals with a positive result and cancer F(Po&Ca) with the number of individuals with a positive result but no cancer F(Po&¬Ca) and then (2) dividing F(Po&Ca) by this sum. The same formula can be used if those same numbers are given in percentage or probability format.

$$\frac{F(Po\&Ca)}{F(Po\&Ca)+F(Po\&\neg Ca)} \; or \; \frac{P(Po\&Ca)}{P(Po\&Ca)+P(Po\&\neg Ca)}$$

However, normalized formats require an additional pre-step (you won't see any of these figures in the standard probability format to the left). P(Po&Ca) must itself first be calculated by multiplying the proportion of individuals with cancer who get a positive result (P[Po|Ca]) with the total proportion of individuals with cancer P(Ca). Similarly, P(Po&¬Ca) must be calculated by multiplying P(Po|¬Ca) with P(¬Ca). For example, to calculate the proportion of women without breast cancer and a positive result, we multiply the percentage of women without breast cancer (99%) by the percentage of those women who get a positive result (9.6%). This may be a trivial calculation for most, but crucially, the solver first has to have an accurate representation of the problem in order to know that we (A) need to calculate this figure to solve the problem and (B) should multiply these two particular values rather than using some other figures or operation to compute it.

As has been noted, in the natural frequency format, this figure is provided for us, which has widely been accepted as a potential confound by subverting the need for (A) entirely (however see Brase & Hill, 2015 for work suggesting this may not be an important factor). However, NF

[1] In fact, in some natural frequency versions, the final question is: 'How many of these women do you expect to actually have breast cancer? ___ out of ___' This reduces the computational steps further, to one only: calculating the total positives.

proponents (e.g. Gigerenzer and Hoffrage, 1995) tell the story the other way around: normalization is an artificial (and relatively recent) human construct which transforms problems from a natural and solvable format to an unnatural and difficult one. These authors propose that normalization adds an additional difficulty by changing the structure of the information from that which would be obtained through 'natural sampling' i.e. if we observed 1000 women one by one, taking note in each case whether they had cancer and whether they got a positive result. This information structure of the natural frequency format is thought to replicate the natural format that human beings experience in the world, and thus are predisposed in some way to work with, which is the true reason for the increased normative responding (Gigerenzer & Hoffrage, 1995).

One concrete change however is that when information is presented in this way, the denominator of F(Po&¬Ca) (990) matches F(¬Ca). Other authors (e.g. Evans, Handley, Perham, Over & Thompson, 2000; Sloman, Over, Slovak & Stibel, 2003) have therefore claimed that rather than this having anything to do with 'natural' formats, this simply makes the 'nested sets' structure of the problem transparent (e.g. that women with a positive mammography but no breast cancer are a subset of the larger group of women without breast cancer). Nested sets advocates argue that this set structure revelation should be considered the more ultimate cause. They have sought to demonstrate that any method which reveals the nested sets structure of the problem will be equally successful. One example, using normalized percentages for the false positive and negative rates like the SP format but framing these in terms of proportions of groups (PP) rather than individual chance (an approach developed by Macchi [2000]), can be seen below:

Nested Sets (Proportion Percentages): 10 F[Ca] out of 1000 women at age forty who participate in routine screening have breast cancer. Out of the women with breast cancer, 80% [P(Po|¬Ca)] will get a positive mammography. Out of those women without breast cancer, 9.6% [P(Po|¬Ca)] will also get a positive mammography. Here is a new representative sample of women at age forty who got a positive mammography in routine screening. What proportion of these women do you expect to actually have breast cancer [P(Ca|Po)]? ___ %

Macchi (2000) found an improvement in accuracy compared to an SP format, and no significant difference to an NF format. Following this and similar papers, NF proponents (Hoffrage, Gigerenzer, Krauss & Martignon, 2002) have argued that nested sets formats simply encourage solvers to construct an NF version of the problem for themselves, which is the ultimate reason for increased accuracy. This criticism seems all the more plausible for Macchi's format, given that unlike the standard probability format, it presented the base rate as a frequency. It is important to note however that Gigerenzer and Hoffrage (1995) originally theorized based on evolutionary grounds that the phenomena of neglecting base rates (P[Ca] and P[¬Ca]) during solution should generalize to non-NF formats because that information is not required for solution in an NF format, which people are adapted to:

"Base rate information need not be attended to in frequency formats (Result 3). If our evolutionary argument that cognitive algorithms were designed for frequency information acquired through natural sampling is valid, then base rate neglect may come naturally when generalizing to other information representations, such as the standard probability format (Gigerenzer & Hoffrage, 1995, pp. 29)

While the authors refer specifically to the standard probability format here, the key point is that in evolutionary history humans have never had to complete the 'pre-step' required in the normalized format, because information has always been presented to them in the natural frequency format (and in which they can compute the normative answer without using the base rates), and so they may lack the capacity to do this, regardless of whether that normalized format is presented in the SP way, or in Macchi's PP way. The simple fact that nested sets results defy this has been widely overlooked in the field, and in fact suggests a potential harmony between the two approaches, rather than a discord, at least at the pragmatic level. While people do indeed seem more capable of solving a Bayesian word problem in a natural frequency format, than in a standard normalized format, nested sets results show us that, with the right framing, people can solve normalized Bayesian problems too.

A preliminary aim of this paper is to replicate Macchi's approach, as it has only been demonstrated in a single experiment. Furthermore, it needs replication in a wider range of more ecologically valid situations, including with the base rate presented as a percentage (as mentioned, Macchi's original format used a frequency base rate unlike the SP format) and with non-whole numbers. These factors may be present in real-world contexts and may add sufficient complexity to undermine the value of the format. We also aim to test the format in both simple (all women with breast cancer get a positive result) and hard (some women with breast cancer get a false negative) problems as both versions have been used widely in the literature.

A more ambitious aim of this paper is to assist in settling the highly debated connection between nested sets and natural frequency formats. Over the past few years repeated calls have been made to resolve these differences between the two camps (Brase & Hill, 2015; McNair, 2015; Johnson & Tubau, 2015; McDowell & Jacobs, 2017). Given that these are fundamental questions about cognitive process, the same authors have repeatedly called for more process-focused experiments. While two previous experiments (Gigerenzer & Hoffrage 1995; Macchi, 2000) used a 'think aloud' (TA) approach (where participants record their thought processes while solving the problem) in both cases

this was only used to report the types of errors participants make. We aim to make greater use of this data to shed light on the following questions. Does the nested sets approach work, as claimed by its advocates, by encouraging a representation of e.g. P(Po&¬Ca) as a subset of P(¬Ca) at the first, de-normalization step? Does the nested sets approach encourage individuals to construct a natural frequency representation for themselves, as claimed by Hoffrage et al. (2002)? Which of these are predictive of success on the problem? Finally, what else can we learn about the mechanisms by which Macchi's nested sets approach achieves greater accuracy?

Method

521 participants were recruited through Amazon MTurk (55.3% female; mean age = 34.2 [SD = 11.6]). The experiment had eight between-subjects conditions, using a 2 (standard probability [SP] vs proportion percentages [PP]) x 2 (simple vs hard) x 2 (whole vs decimal) design. The PP-hard-decimal condition can be seen below (with statistical notation, not shown to participants), and further materials and experimental data are available at https://osf.io/nd46g/. This is considered a decimal version because the product of computational step 1 (e.g. 10% x 76% = 7.6%) is a non-whole number.

Every year the government advises women to take part in routine mammography screening using an X-ray machine to determine if they have breast cancer. Among women at age forty who participte in this routine screening 10% [P(Ca)] have breast cancer, while 90% [P(¬Ca)] do not. However, the screening test is not always accurate. Specifically, out of those women who have breast cancer, only 76% [P(Po|Ca)] will actually get a positive mammography. Furthermore, out of all of those women who do not have breast cancer, 15% [P(Po|¬Ca)] will also get a positive mammography. What percentage of women at age forty who get a positive mammography [P(Po)] in routine screening actually have breast cancer[P(Ca|Po)]? ___%

Participants were also required to record their thought process in an open text box. They could only submit their numerical response after they had submitted their thought process. All qualitative analysis of the TA data was undertaken blind to condition. Analysis was coded by two authors separately, with over 90% agreement. Discrepancies were resolved through the decision of a third coder.

Participants were given a 'normative' label if their numerical response was within 1% of the Bayesian normative value. Beyond this however, we found seven participants who clearly demonstrated accurate reasoning, including all necessary computational steps, but made an arithmetic error. These participants were also labelled as normative. One of these participants was in the nested sets conditions, while six were in the standard probability conditions.

Results

General Results

The overall proportion of the sample providing the normative response for the experiment was 13.5% with an average of 9.0% for the SP conditions and 18.1% for the PP conditions. In Figure 1, normative proportions for all eight conditions can be seen.

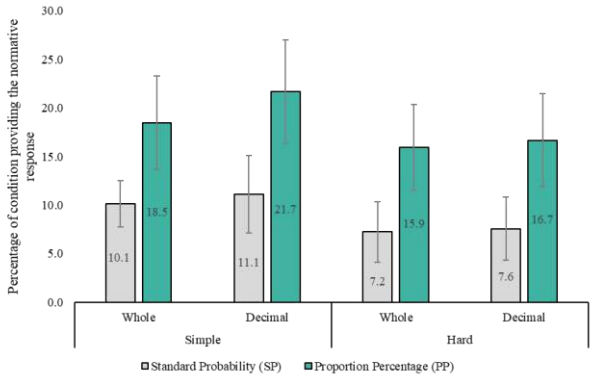

Figure 1. The percentage of participants providing the normative Bayesian answers across all eight conditions. Error bars represent one standard error.

A binary logistic regression (BLR) using 'normative response' as the dependent variable and the three condition-comparisons (SP vs PP; whole vs decimal; simple vs hard) as independent variables found a main effect for the SP-PP comparison (Wald $X^2 = 8.984$, p=.003), no main effect for the whole-decimal comparison (Wald $X^2 = .184$, p=.668) and no main effect for the simple-hard comparison (Wald $X^2 = 1.350$, p=.245). All subsequent analyses on 'condition' therefore compare SP to PP only.

Nested Sets Representation

Across all conditions, 87 (16.7%) individuals expressed a 'nested sets representation' of the problem. For this classification, participants had to explicitly, in words, depict the group of individuals who had both a positive test result but not cancer (P[Po&¬Ca]) as a subset of the total individuals without cancer (P[¬Ca]). In the hard condition, they also had to express the group of individuals who had a positive result and cancer (P[Po&Ca]) as a subset of the individuals with cancer (P[Ca]). A mathematical formula was not sufficient to be assigned this code. An example comes from P261 who stated, "Of the 90% who do not have cancer, 15% will get a positive mammography". Here we can see a word-based representation of the individuals who do not have cancer but got a positive test result as a subset of those who do not have cancer. This classification was applied conservatively. For example, P498 who said "First what is 15% of 90%, that is 13.5%" did not receive the classification. An example from the hard condition which did get this

classification comes from P138 who said "We know 10% of women will have breast cancer in the screen and 80% of those will show up positive […] Of the remaining 90 women who do not have breast cancer 10% will be given a false positive so an additional 9 women."

A BLR showed that this representation was unsurprisingly more common within the PP (24.0%) condition, which expressed the problem in this format, than in the SP (9.7%) condition (Wald $X^2 = 18.0$, $p<.001$), which used an individual chance format. However clearly some individuals in the SP condition re-represented the problem in terms of nested sets. Furthermore, in both conditions, this representation was highly associated with normativity, as can be seen in Table 1.

A BLR was run with normativity as DV, and condition and NS-representation as IV's, and a unique predictive effect of NS-representation (Wald $X^2 = 123.6$, $p<.001$) was found, but no unique effect of condition (Wald $X^2 = 0.04$, $p=0.837$).

Conversion to frequencies

Across all conditions, 87 participants (16.7%) also converted the base rate in the problem from a percentage into a frequency before attempting solution (i.e. before providing an NS-representation or completing the first computational step). For this classification, a 'sample' or 'population' of individuals as a frequency rather than a percentage or probability had to be expressed. For example, P105 said 'To make my math easier, I am going to assume there are 100 women.' and P186 began 'Out of 100 women, 10 have breast cancer, while 90 do not.' Out of the 87 participants who converted the problem to whole numbers, 73 converted to a population of 100 women. The number of individuals who made this conversion in each condition, crossed with those providing the NS-representation and the proportion of these subgroups providing the normative response can be seen in Table 1. A BLR with conversion as DV and condition as IV showed a predictive effect (Wald $X^2 = 7.3$, $p=.007$). A BLR with normative response as DV and condition and conversion as IV's showed a unique effect of conversion (Wald $X^2 = 128.9$, $p<.001$) and a potential unique effect of condition (Wald $X^2 = 5.2$, $p = 0.041$).

To simultaneously test the impact of condition, NS-representation and conversion upon normativity, a BLR was run. No main effect of condition was seen (Wald $X^2 = 0.172$, $p=0.68$), but a unique effect of NS-representation (Wald $X^2 = 93.2$, $p<.001$) and of conversion (Wald $X^2 = 8.3$, $p=0.004$) was seen. A table depicting these relationships can be seen below.

Table 1. Percentage of individuals providing the normative answer organized by condition, NS-representation and conversion (total number of individuals in each subgroup regardless of normativity in parentheses).

		Standard Probability			Proportion Percent		
		No NS-representation	NS-representation	Total	No NS-representation	NS-representation	Total
No-Conversion		1.4 (221)	69.2 (13)	5.1 (234)	2.8 (176)	45.8 (24)	8.0 (200)
Conversion		5.0 (20)	84.6 (13)	36.4 (33)	5.9 (17)	78.4 (37)	55.6 (54)
Total		1.7 (241)	76.9 (26)	(267)	3.1 (193)	65.6 (61)	(254)

From the raw data, we can see that in the absence of the NS-representation, conversion only appears to be associated with a small (~3%) increase in normativity, while in the presence of the NS-representation, converting appears to be associated with a much larger (~15-30%) increase. To check this, we ran two BLR's, predicting normativity from conversion. Within those who did not produce an NS-representation, no predictive relationship was seen (Wald $X^2 = 0.81$, $p=0.21$) while within those who did produce an NS-representation, a predictive relationship was seen (Wald $X^2 = 6.4$, $p=0.011$). Dependency of this sort was not seen for the NS-representation, which was a significant predictor of normativity among those who did not convert (Wald $X^2 = 69.3$ $p<.001$) as well as those who converted (Wald $X^2 = 27.6$, $p<.001$). For some individuals their process could not be determined (e.g. if they just provided a mathematical formula) but a few individuals were able to solve the problem without converting and also while apparently using a chance representation, such as P40:

"There is a 10% chance that any woman over 40 has breast cancer [and] there is a 10% chance that a woman who does not have breast cancer over 40 gets a positive result. This means there is a 9% chance of [a false positive] and a 19% chance that someone tests positive for breast cancer. Out of this there is a 10/19% chance that the diagnosis is correct meaning there is a 52.63% chance."

Errors

The most common error within the SP condition (21.7%) was to provide the complement of the false positive rate, (1-P[Po|¬Ca]). This was much less common within the PP condition (5.5%). The TA data was coded for insight into common reasoning and a single piece of reasoning was highly prominent (45.8% of cases). This was the confusion of P(Po|¬Ca) with P(¬Ca|Po). Following this confusion, the subsequent accurate

deduction was made that 100% minus this value would give P(Ca|Po). For example, P228 said 'The fact that 15% of positive mammographies are invalid means that 85% are valid. She therefore has an 85% chance of actually having breast cancer', P20 said 'I guess since 10% of positive tests are inaccurate, that means there's a 90% chance of her having cancer' and P133 said 'Also of all the women who get a positive mammogram, 15% will not have breast cancer, so I think it is 85%.' Each of these participants use language reflecting P(¬Ca|Po) but accompanying the percentage value representing P(Po|¬Ca), strongly suggesting a confusion between the two. P177 expressed this confusion more explicitly, saying 'But there is a 10 percent chance that a woman without breast cancer will get a positive mammogram [true, P(Po|¬Ca)], so 10 percent of the positive mammograms are not accurate [false, P(¬Ca|Po)]'. In the remainder of these participants' TA data, the reasoning could not be extracted from the data. For example, many participants simply provided mathematical notation.

Computational Steps

A cumulative graph depicting the proportion of individuals reporting each of the three computational steps, step 1 the calculation of P(Po&Ca) and P(Po&¬Ca), step 2 the summing of these and step 3 the division of P(Po&Ca) by the sum as well as whether the participant provided the normative numerical value can be seen below for both conditions. For both conditions, the majority of individuals do not achieve step 1, with further substantial but smaller drop-off between this and step 2, and no substantial subsequent drop-off between these and step 3 or the normative response. In short, highly similar curves were seen for both the SP and PP conditions. The major difference between the two conditions was the number of individuals reporting step 1 (with more individuals reporting this in the PP condition). Similar proportional drop-off was subsequently seen in both conditions. Indeed, while condition was predictive of step 1 (Wald X^2 = 15.3, p<.001), when controlling for step 1, condition was not predictive of step 2 (Wald X^2 = 0.19, p=.891), step 3 (Wald X^2 = .988, p=.320) or the normative response (Wald X^2 = 0.076, p=.783).

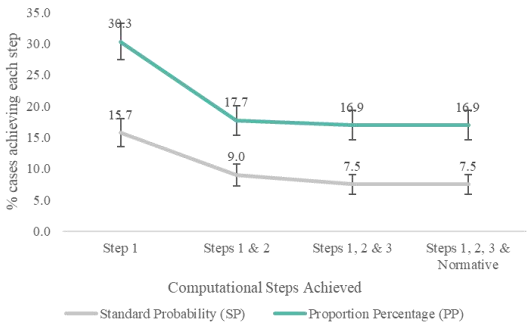

Figure 2. Drop-off graph for each computational step. Error bars represent one standard error.

Discussion

We replicated Macchi's (2000) finding in a larger sample, and across a range of different format types, including with percentage base rates with and without the possibility of false negatives and with whole numbers and non-whole numbers. In each case, Macchi's proportion percentage format improved normativity over and above the SP format, with an overall increase from 9.0% to 18.1%.

We found that normativity is highly associated with the individual reporting a representation of P(Po&¬Ca) as a subset of P(¬Ca) in their think aloud data, and in the hard condition, also P(Po&Ca) as a subset of P(Ca). This finding is not surprising within the proportion percentage group, as it could be argued that these individuals are simply regurgitating the text from the problem. However, crucially, this relationship also held within the standard probability format, where an 'individual chance' probability format (i.e. 'If a woman has cancer, her chance of …) was presented. This observational finding should also be considered in the context of previous experiments (e.g. Evans et al, 2000; Sloman et al, 2003) showing that attempts to assist individuals in creating exactly this representation of the problem have been successful in increasing accuracy. Here we show that some individuals, without any prompt to do this, spontaneously adopt this representation, and this correlates highly with normativity. We also found some evidence that the NS-representation may have a mediating effect on the impact of the NS format. This provides some complementary evidence to those papers that the mechanism by which nested sets formats achieve greater accuracy is at least partially that which they have espoused: by encouraging a nested sets representation of the structure of the problem.

We also found that many individuals make a further spontaneous re-representation of the problem, and that this also correlates highly with normativity. This is the conversion of the problem from a percentage format into a frequency format. Interestingly, conversion alone seemed not to be predictive of normativity, however in combination with the NS-representation it was associated with higher rates of normativity than the NS-representation alone. The same was not true of the NS-representation. This was still highly predictive of normativity with or without conversion. Importantly, the majority of individuals who converted did so to a base of 100, making no mathematical change to the problem. This therefore seems to demonstrate a preference among our sample for working with frequency values over percentages, even when the absolute numbers (e.g. 20% vs 20 women out of 100) and therefore calculations, are identical. Of course, we cannot resolve the ultimate reason for this, be that a greater evolutionary exposure towards frequencies or a current greater exposure to frequencies during our participants' lives. We tentatively suggest a third

possibility. It may be difficult to mentally represent a percentage, abstract as it is, without it being a percentage of something tangible. Imagining 100 women may simply provide a concrete mental image which can be divided and sub-divided according to the percentages. It may also provide a platform for a simple internal narrative about these women and what happens to them. Whatever the ultimate reason however, this result does partially confirm Hoffrage et al's (2002) conjecture.

These findings have some relevance to the question of whether the elements that are thought to comprise the natural frequency format are separable, and if so, which elements are doing the 'work' in improving accuracy. Nested sets advocates have argued that the nested sets structure is doing all the work, and the frequencies are superfluous. Natural frequency advocates have argued that the two are inseparable. Here we find some tentative evidence that the two are separable (individuals who form a nested sets representation but do not convert to frequencies are still more successful than those who do not form that representation). However, even if separable, both the nested sets structure, and the use of frequencies (as opposed to percentages) appear to uniquely contribute to success, with the combination of both being more strongly associated with success than either alone. Importantly, without the nested sets structure, conversion to frequencies did not predict success, which may mirror findings that normalized frequency formats are no better than the standard probability format (e.g. Evans et al., 2000).

In terms of further investigation into the mechanisms of Macchi's nested sets format, we presented evidence that relative to the SP format, more individuals achieve step 1 (de-normalization). However, controlling for this, the proportion of participants achieving subsequent steps is not different to the SP format. Related to this, an analysis of errors between conditions has shown that the classic 1-P(Po|¬Ca) error was drastically reduced from 21.7% of total responses in the SP format to 5.5% in the PP format. This error, in line with previous theorizing (e.g. Braine and Connell, 1990) has been found here to principally stem from a confusion between the false positive rate P(Po|¬Ca) and P(¬Ca|Po). As has been mentioned, the clarification of the false positive rate (and the true positive rate in the hard condition) by encouraging individuals to see it as a subset of P(¬Ca) has long been theorized to be the mechanism by which nested sets formats work. The reduction of this error in the PP condition therefore seems to further support this theory. Given that the false positive rate is required for step 1, it also provides further evidence that the impact of Macchi's format is principally achieved at this step.

As noted, Macchi's format does not appear, upon the current evidence, to provide any additional support in the later stages of solution, most notably in getting from computational step 1 to step 2. At this step individuals need to recognize (A) that they require the total number of positive results, and (B) that they need to combine the false positives with the true positives to achieve this. So far, research has been principally focused on helping solvers form a representation of e.g. P(Po&¬Ca) as a subset of P(¬Ca). However, success on the final two steps may instead be a product of recognizing a different set relation, that of P(Ca&Po) and P(¬Ca&Po) as subsets of P(Po). We can clarify this distinction by displaying two tree structures of the medical diagnosis problem below. The top shows the classic structure, widely published, with the hypothesis, 'Cancer' as the first 'division', or first set of child nodes. However, the opposite structure is also possible, shown at the bottom, with the data, 'Positive' as the first set of child nodes.

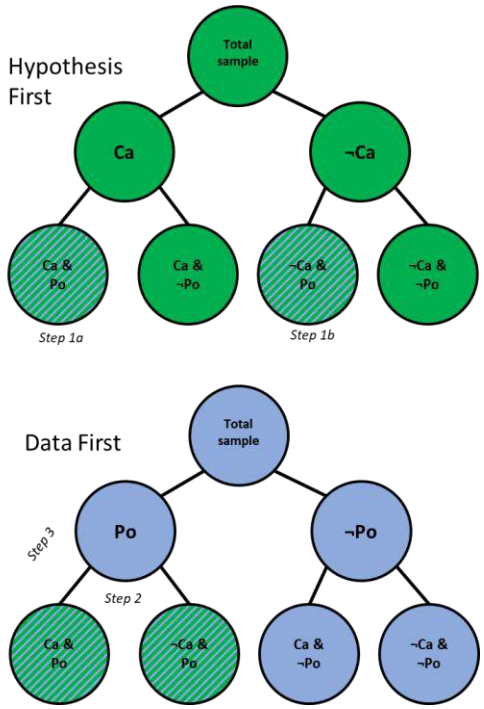

Figure 3. 'Hypothesis First' and 'Data First' tree diagram representations of the medical diagnosis problem.

While perceiving the set relations in the hypothesis-first version seems key to step 1, steps 2 (calculating total positives) and 3 (dividing cancer & positive by total positives) would seem to require an understanding of the set relations in (at least the left half) of the data-first diagram. For step 2, the addition, one must understand that P(Ca&Po) and P(¬Ca&Po) are subsets of P(Po). It seems to us that step 3, the division, should require only that same set relation i.e. that P(Ca&Po) is a subset of P(Po). To our knowledge this distinction has not been made before. We believe that in order to improve framing methods further, focus should be on helping individuals form these latter set representations at the most appropriate time to facilitate steps 2 and 3.

In the medical diagnosis problem, the information related to steps 2 and 3 are contained within the question. In

our nested sets format, this is changed into a proportion form i.e. *'What percentage of women at age forty who get a positive mammography…*', unlike the SP format, which is chance framed. While plausibly this could have helped solvers form exactly this latter subset representation, the current evidence suggests this did not have an impact. Future work may look to combine Macchi's format with a question form used by Girotto and Gonzalez (2001) which was divided into two parts: first explicitly requiring the calculation of step 2, and only then requiring calculation of step 3.

Finally, it should be noted, that the accuracy percentage for participants in our NS group was lower than the average from the recent meta-analysis for natural frequency (~24%). It is difficult of course to make confident comparisons but given that we have found that the nested sets approach works via very similar mechanisms to the natural frequency approach, but requires one extra step (de-normalization), and in some versions two extra steps, and furthermore that we have found a unique beneficial effect of frequencies, some greater accuracy on natural frequency versions seems plausible to us. Pragmatically therefore we would still advocate for natural frequencies as the primary method for communicating Bayesian problems to the public where that is possible, with proportion percentages as a backup where it is not.

However, unfortunately when individuals do encounter Bayesian problems in the real world, they are often in the standard probability format. Sedlmeier & Gigerenzer (2001) have investigated the merits of preparing individuals via training to convert these into natural frequency versions themselves when they encounter them. This however requires considerable training. Our findings suggest that solvers can do more of the work themselves than was assumed by that research (i.e. can de-normalize the problem themselves) and therefore may only need to remember fewer 'conversion' steps. This may be valuable where the brevity of the training is important. In fact, our findings tentatively suggest substantial accuracy gains may be obtained by training people to following two simple rules when faced with an SP problem:

1. Imagine 100 women (or whatever unit you're dealing with).
2. Imagine the percentages you've been given as proportions of these 100 women.

Abstract

While many solutions to the apparent civic online reasoning deficit have been put forth, few consider how reasoning is often moderated by the dynamic relationship between the user's values and the values latent in the online content they are consuming. The current experiment leverages Moral Foundations Theory and Distributed Dictionary Representations to develop a method for measuring the alignment between an individual's values and the values latent in text content. This new measure of alignment was predictive of bias in an argument evaluation task, such that higher alignment was associated with higher ratings of argument strength. Finally, we discuss how these results support the development of adaptive interventions that could provide real-time feedback when an individual may be most susceptible to bias.

Keywords: myside bias; moral foundations theory; distributed dictionary representations; civic reasoning

Introduction

The rise of social media has been accompanied by a rise in smaller, decentralized media sources. One clear negative consequence of this democratization of media has been an increase in access to unreliable or misleading news stories. Despite their lack of credibility and veracity, these stories are persuasive and appealing. Some estimates suggest that Americans fall for fake news headlines approximately 75% of the time (Silverman & Singer-Vine, 2016), and that these stories are generally more engaging than stories produced by traditional news outlets (Silverman, 2016).

The proposed solutions to these problems generally fall into two categories. The first category leverages various machine learning methods (Conroy, Rubin, & Chen, 2015) to create "fake news detectors." While some of these classifiers are quite sophisticated (Wang et al., 2018), these detectors tend to limit their scope to the detection of stories that are patently false. More nuanced instances of stories that are merely misleading are generally beyond the purview (and perhaps ability) of these systems (McGrew, Ortega, Breakstone, & Wineburg, 2017). Moreover, even if accurate classification was possible, one might question whether it is in our best interest to delegate this task to machines, potentially allowing our own ability to critically evaluate media sources to languish in the process.

In contrast to the content-driven detectors, other solutions focus on improving the critical thinking skills of the media consumers themselves. There is certainly evidence of a deficit in this regard. A recent study of students in middle school, high school, and college summarized the student's "civic online reasoning" (e.g. evaluating arguments, recognizing spin) as simply, "bleak" (Wineburg, McGrew, Breakstone, & Ortega, 2016). Non-detector solutions tend to focus on strengthening these kinds civic reasoning skills. For example, *Factitious* is a game created by the American University Game Lab (Hone, Rice, Brown, & Farley, 2018) that is marketed as a way to test the player's ability to distinguish fake and real news stories, but along the way teaches the player to identify features like reliable sources and neutral language.

While the detectors focus on the media content itself (hoping to fill the role of editor in the new democratized news space), the civic education solutions focus instead on the media consumers, with the hope that better critical thinkers might be more or less immune to the appeal of misleading content. Both of these approaches unfortunately tend to neglect the dynamic relationship between the media content and the media consumer. Consider the following actual fake news headline:

> "Pope Francis Shocks World, Endorses Donald Trump for President"

If you happen to be a religious Trump supporter, this story may seem plausible. After all, if you, a person of faith, have found reason to endorse him, why shouldn't another person of faith. This headline confirms what you already believe to be true. However, if you are not a Trump supporter, this headline might raise several red flags. It is in that wave of skepticism that you may dart your eyes to the URL in order to check the credibility of the source. Because this headline runs counter to your beliefs, you go searching for evidence to disprove it. In either case, the degree of critical thought that is brought to bear on the content is, at least to some extent, dependent on the values and beliefs of the reader.

This tendency to evaluate arguments more favorably when they align with your own views or beliefs (and conversely, more critically when they do not) is formally known as *myside bias* (Baron, 2000). Numerous studies have shown the effects of myside bias on reasoning to be reliable and

strong (Klaczynski & Robinson, 2000; Stanovich & West, 1997), irrespective of intelligence (Stanovich & West, 2007; Stanovich, West, & Toplak, 2013). Haidt's Social Intuitionist Model of moral reasoning (Haidt, 2001) suggests that the power of myside bias is likely due to the fact that the primary drivers of our moral judgments are intuitions and heuristics. According to the Social Intuitionist Model, when we encounter a new piece of information, we have an immediate and powerful intuition about whether we agree or disagree with the information. Haidt argues that the vast majority of these judgments are made automatically, using Kahneman's (Kahneman & Egan, 2011) System 1 thinking. Rational (or System 2) thinking always comes after an intuitive judgment has already been made, and only comes online if we are asked to justify our position. In short, we are not, by default, the rational thinkers we think we are. Moreover, when we do make use of our capacity for rational thought, it's generally to justify a decision we have already made, not to search for the truth.

Misleading and false news stories can exploit this vulnerability by designing stories that strongly align with the prior-held beliefs of the target audience. Because the reader wants to believe the story is true (to affirm their reality), System 2's critical reasoning skills are never engaged. The bias literature suggests that overcoming the strength of this intuitive appeal may require more than detecting falsehoods or training consumers to be more critical. Solutions that ignore the dynamic relationship between the user's beliefs and the beliefs latent in the misleading media content are perhaps ignoring the very feature that makes the target content so powerful.

Accurately capturing user beliefs is a daunting challenge. Each user likely possesses countless individual beliefs, and new beliefs are constantly being created in response to their current political context. One solution is to instead measure the foundational values that inform our beliefs. Moral Foundations Theory (Haidt & Graham, 2007) argues that moral decision making can be traced to a small set of foundational values (Care, Fairness, Loyalty, Authority, and Sanctity). These moral foundations have been empirically shown to be highly predictive of both general voting behavior (Franks & Scherr, 2015) as well as more specific political beliefs (e.g., "Climate change is real") (Koleva, Graham, Iyer, Ditto, & Haidt, 2012; Rottman, Kelemen, & Young, 2014). Moral Foundations Theory allows us to approximate beliefs in a theory-driven, context-general way. This is crucial for any solution intended for deployment on the internet, where the number of unique-contexts is virtually infinite.

After deriving a measure of user values (as a proxy for beliefs), the system must also be able to estimate the values latent in the text they are reading. Recently, Garten et al. (2018) developed a methodology for estimating the values latent in short pieces of text (tweets), and demonstrated that their methodology can accurately classify a tweet's most salient moral foundation (as measured by human raters). What remains to be seen is if value classification methods (like Garten's) can be combined with measures of user values to estimate the degree of alignment between the values of the media consumer and the content they are consuming.

We would expect that any measure that accurately captures this relationship between consumer and content should also be able to predict the presence of myside bias. That is, when alignment between user and content values is high, we expect that the user will be biased to evaluate the content more favorably. In this paper, we propose a method for measuring this dynamic relationship between consumer and content values, and demonstrate that the resulting metric can be used to predict bias in argument evaluation. Specifically, we test whether the alignment between participants' values and the values latent in an argument predicts participants' ratings of argument strength. We hypothesized that higher alignment between participant and content values will be associated with higher ratings of argument strength, and that this relationship will be present even in arguments specifically designed to confuse our natural language processing method.

Practically, this methodology lays the groundwork for future hybrid solutions that leverage technology alongside human critical thought to mitigate the impact of content designed to confirm our values rather than disseminate true information. Perhaps more importantly, this methodology presents a novel, context-independent way to estimate the impact of myside bias, a known, powerful moderator of everyday reasoning.

Methods

Participants

Eighty (80) participants were recruited using the participant recruitment platform Prolific. Participants were required to be between 18-65 years of age, U.S. citizens, and not have participated in any of our research group's prior studies (due to content similarity). Five participants exited the study before completing any significant portion of the main experiment and were excluded from analyses. The estimated completion time (based on prior pilot studies) was approximately 15 minutes, and participants were paid $2.50 ($10/hour) for participating.

Data Quality We mitigated the impact of potential gamers in several ways. First, the post-test questionnaire included a reading-check question. Participants who failed the reading-check (n=7) were excluded from analyses. We also used timing data to identify participants who were likely clicking through the problems without reading the prompts. Specifically, participants who selected an answer less than two seconds after a prompt loads (roughly the time needed to select an answer after the page loads), at least 10 times (for half of the problems), are labeled as gamers. We chose a threshold of 10 problems for two reasons: 1) it is reasonable to assume that participants who begin the experiment with the intention of gaming the system will exhibit this behavior for at least half of the problems, and 2) if we set this threshold too low, we risk excluding participants who begin the experiment with

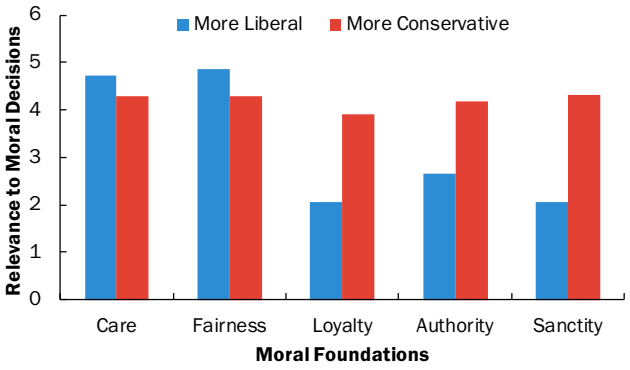

Figure 1: Relevance to Moral Decisions by Moral Foundation for more conservative and more liberal participants. These values closely match previously observed values for liberals and conservatives (Haidt & Graham, 2007), suggesting that our sample was politically diverse.

good intentions, but get fatigued towards the end. Eight participants met this criteria for gaming, and were excluded from analyses.

Demographics Of the remaining 60 participants, 38 identified as male, 20 as female, and 2 as other. Participants ranged in age from 18-62 years old (M=31.10). With respect to race and ethnicity, 50 participants identified as Caucasian, 6 as Hispanic, 3 as Black, and 1 as Asian. The majority (59%) of participants reported having completed a college level education or higher, and a high number of participants reported completing a master's degree (n=19).

Political Diversity One of the key benefits of recruiting participants from Prolific is that participants are drawn from all over the country. If instead, we were to recruit participants from our local community, we would likely get an unbalanced distribution of political beliefs (as our city has a history of voting overwhelmingly in favor of one party). Recruiting from across the country gives our sample a degree of political diversity that would be impossible to achieve otherwise.

To evaluate if our sample was indeed politically diverse, we used the composite measure of the Moral Foundations Theory Questionnaire (described below), called *progressivism*, to divide our sample into two groups along the mean score. Then, for each of the two groups we graphed the mean scores of each foundation and compared them to known averages. Figure 1 shows the mean scores for more liberal and more conservative participants across the five moral foundations. These values closely match previously observed values for liberals and conservatives (Haidt & Graham, 2007), suggesting that our sample was politically diverse.

Experiment Environment and Procedure

Participants completed the experiment online by navigating through a web-based application. After completing a consent form, participants were informed that the study consisted of two sections. In the first section, they were asked to complete a questionnaire (described below), and in the second section, they were asked to rate a series of arguments (presented in random order). After completing the two sections, the participants were directed to a post-test questionnaire where demographics information was collected, and then finally, to the debriefing page, which clarified that any facts and figures used in the study were entirely fictitious. The experiment was estimated to take approximately 15 minutes to complete (actual median completion time was 12 minutes).

Moral Foundations Theory Questionnaire In the first section of the experiment, each participant was required complete the Moral Foundations Questionnaire (MFQ) (Haidt & Graham, 2007). This 30-item questionnaire is designed measure how relevant each one of the five moral foundations (Care, Fairness, Authority, Loyalty, Sanctity) is to one's moral decision making. For example, participants are asked to indicate the degree to which they agree with the following statement: "Respect for authority is something all children need to learn." The final output of the questionnaire is a vector of five scores that indicate the relative importance of the five moral foundations to the participant's moral decision making. Ultimately, we are interested in constructing a model that relates the values latent in text to the values and beliefs of an individual person. This vector of five scores represents the human side of that relationship.

It is worth noting that having the participants take the MFQ before answering arguments designed to evoke moral decision making is not ideal. The questionnaire may cause participants to be more conscious of their beliefs than they might normally be if encountering these arguments in the real world. However, this ordering is unfortunately necessary for later stages of this project, where adaptive interventions designed to promote analytic thinking use an individual's scores on the MFQ to decide when targeted feedback is needed most. These future directions are explored in more detail in the *Discussion* section.

Rating the Strength of Arguments Participants were asked to read and rate the strength of 20 arguments on a nine-point Likert scale (1=Very Weak; 9=Very Strong). Each argument had three key features. First, each argument was designed to evoke a specific moral foundation. For example, the following argument was designed to evoke the *Authority* foundation:

> Greenville School District requires students to address all adults as "Sir" or "Ma'am" and their students always score higher on state tests than ours. Instilling a strong respect for authority for their teachers helps students learn.

Regardless of the argument's actual strength, we would expect that if a participant believes that respecting authority is important, this argument will resonate with them. Each of the five foundations is the focus of an argument four times, for a

total of 20 arguments.

The second key feature is the relative quality of an argument. This is a categorical feature with two levels, *high quality* and *low quality*. The above argument is an example of a *low quality* argument. In contrast, consider the following argument:

> The number of suspensions at Redbridge School District has been slowly increasing for the past 5 years. Last year they added three police officers to their staff and saw a 10% decline in suspensions. The presence of a strong authority figure reduces bad behavior.

While this argument is certainly not airtight, it has several attributes that make it a relatively higher quality argument. First, it shows the reversal of a long-term trend, in contrast to the *low quality* argument where no temporal context is established. Second, it uses concrete figures that are relative to the norm, as opposed to the *low quality* argument which uses vague terms like "higher" to quantify changes. In general, high quality arguments include information that can be used to rule out some alternative explanations. Low quality arguments leave open the possibility of alternative explanations. Of the 20 arguments, half are *high quality* and half are *low quality*.

The third key feature is *congruence* with the target foundation. A potential limitation of the distributed dictionary representation methodology (described below) is that statement representations are formed using the representations of single words. This means that, while this methodology should have no problem knowing that the word "son" in the context of the word "king" likely refers to the concept "prince," it will likely have more difficulty identifying the cultural nuances between statements like "God is good" and "God is dead." The *congruence* feature is designed to test the robustness of this methodology's ability to adapt to these kinds of unfavorable circumstances. Consider again the two previous example arguments. Both arguments 1) use language that evokes the authority foundation, and 2) are supportive of that foundation. In contrast, consider the following argument:

> Woodford School District doesn't allow teachers to reprimand students, and last year they had fewer detentions than our district. Students behave better when they're treated like equals instead of children

While this argument also evokes the Authority foundation, this example argues against an increased respect for authority. We would expect that participants that value authority will be more skeptical of the claims in this argument, because they violate their intuitions. Whether the model's representation of the values latent in the argument is nuanced enough to make the distinction between *incongruent* and *congruent* arguments is an open question. Again, half (10) of the arguments are *congruent*, half *incongruent*.

Analysis

Distributed Dictionary Representations The broad goal of this experiment is to evaluate a method for comparing an individual's values with the values latent in the media they are consuming. Using the MFQ, we are able to generate a theory-driven estimation of the participant's values. The next step is identifying the values latent in a particular piece of text. While historically this has been done using word-frequency methods (i.e., counting the number of times terms in a concept dictionary appear in the target text), these methods are much less effective for analyzing small bodies of text (e.g., news headlines, tweets), which may not contain any of the dictionary terms.

In contrast to word-frequency methods, distributed representations (Mikolov, Chen, Corrado, & Dean, 2013) estimate the meaning of words by comparing the numerous, varied contexts that the word appears in within a large text corpus. These models are rooted in the distributional hypothesis, which states that words that appear in similar contexts likely share some semantic features. The distributed representation of a word is simply that word's location in a low-dimensional (10-10,000 dimensions) space. This location can be represented as a vector, which allows us to compute the semantic distance between two concepts using cosine similarity.

Garten et al. (2018) extends this work in distributed representations to incorporate concept dictionaries. A distributed dictionary representation is computed by simply averaging the distributed representations of all the words in the dictionary. The result is a point in the semantic space that amplifies the shared, core features of each of the component dictionary terms. Because we are ultimately using an abstract representation of a concept, our dictionaries can be highly focused, including only the most relevant terms. The current study uses five such dictionaries (one per moral foundation), and each dictionary contains four positive words (e.g., fairness, equality) and four negative words (e.g., unfair, injustice) related to the moral foundation (e.g., fairness). Using distributed representations allows for the effective analysis of small bodies of text (such as the short arguments used in the current study), because the method does not require any of the dictionary terms to be present in the text. We used gensim (a Python implementation of Word2Vec (Mikolov et al., 2013)) and the pre-trained Google News corpus (approximately 100 billion words) Word2Vec model[1].

Alignment The output of the distributed dictionary representation analysis is a vector of five values, indicating the average semantic distance between the words in the argument and the words in each of the five moral foundation concept dictionaries. To compute *alignment*, we compute the cosine similarity between this vector and the vector of moral foundation relevance scores outputted by the Moral Foundations Questionnaire (i.e., the participant's values). We then used a

[1]The pre-trained Google News model can be found here: https://code.google.com/p/word2vec/

normalized log-transformation to correct for skew. *Alignment* is computed for each participant and argument combination.

Linear Mixed Effects Models Because it is impossible to determine an objective rating of argument strength for the arguments used in this study, we are less interested in the individual rating of each argument and more interested in how a participant rates arguments relative to one another (i.e., high alignment vs. low alignment or high quality vs. low quality). To make use of all the data while accounting for differences in ratings across participants, we use a series of linear mixed effects models, with *participant* as a random effect. Similarly, to control for unintended variations in argument strength, we include *Argument ID* as an additional random effect. We compare models to one another using the Akaike information criteria (AIC), which estimates the fit of a model (lower scores are better). All reported coefficients are standardized.

Results

We used a series of mixed effects models to examine the relationship between *alignment* (between participant and argument values) and ratings of argument strength. To reduce the possibility that any effect of *alignment* on ratings could be attributed to differences in demographics, we tested for collinearity between *alignment* and each demographic variable (*age*, *gender*[2], *race*, and *education level*). A series of one-way analyses of variance (ANOVA) between *alignment* and each of the three categorical variables (*gender*, *race*, and *education level*) showed no evidence of collinearity. Similarly, there was no significant correlation between *alignment* and *age*.

A mixed effects model with *participant* and *argument ID* as random effects, ratings of strength as the outcome variable, and *gender*, *race*, *educational level*, and *alignment* as fixed effects was generated[3]. *Alignment* was a significant predictor of ratings when included alongside these demographics variables ($\beta = 2.48$, $p < 0.01$), providing further evidence that any effect of *alignment* on ratings was not due to differences in demographics.

Impact of Alignment when Controlling for Quality To test if *alignment*'s impact persists when controlling for argument quality, we built a mixed effects model with *participant* and *argument ID* as random effects, ratings of strength as the outcome variable, and *alignment* and *argument quality* as fixed effects. We found that *alignment* was predictive of ratings despite the presence of *argument quality*. It should be noted that although participants on average rated high quality arguments as significantly stronger ($t(59) = 8.07$, $p < .001$) than low quality arguments ($M = 5.06$, $SD = 1.72$) (suggesting some categorical validity), the labels "high" and "low" are very much subjective labels. As such, we cannot objectively compare the impact of *alignment* to the impact of quality. Still, we can make a meaningful, subjective comparison between the impact of *alignment* and "quality" (as operationally defined in this context). In this context, the impact of *alignment* on ratings of strength ($\beta = 3.06$, $p < 0.001$) was greater than the impact of *argument quality* ($\beta = 1.33$, $p < 0.01$).

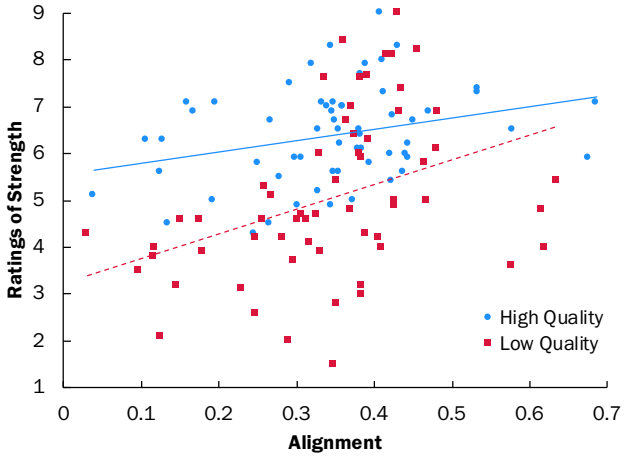

Figure 2: Relative impact of alignment on the ratings of high and low quality arguments. Each data point represents the average rating and alignment for all arguments within a category (high or low quality) for one participant. On average, participants rated high quality arguments as stronger than low quality arguments. The ratings of both types of arguments were associated with alignment scores.

While on average, participants rated congruent problems ($M = 5.89$, $SD = 1.35$) as significantly stronger ($df(59) = 2.27$, $p = 0.02$) than incongruent problems ($M = 5.57$, $SD = 1.40$), *congruence* was not a significant predictor of ratings when added to this model.

Interaction between Age and Alignment Previous research suggests that, because reliance on heuristic reasoning increases with age, older adults may be more likely to exhibit biases in everyday reasoning (Klaczynski & Robinson, 2000). To test whether this was true of our sample, we built a mixed effects model with *participant* and *argument ID* as random effects, ratings of strength as the outcome variable, and *argument quality* and *alignment*age* as fixed effects (where *alignment*age* is an interaction term). We found that there was a significant interaction between *alignment* and *age* ($\beta = 15.01$, $p < 0.001$), such that *alignment*'s impact increases as *age* increases. This finding aligns with previous research. Additionally, this *alignment*age* interaction model had a better fit (AIC=5033.05) than the previous model built without the interaction term (AIC=5058.63).

[2]Participants identifying as "other" were excluded from this analysis because the sample was very small (n=2).

[3]Note that age was excluded from the model because a one-way ANOVA between *age* and *education level* indicated a significant relationship between *age* and *education level*. A Tukey's HSD test showed that participants at the graduate level ($M = 35.33$, $SD = 5.38$) were significantly older than those below the college level ($M = 27.96$, $SD = 9.05$). A likelihood ratio test showed that *education level* was more explanatory than *age*, so *age* was excluded in favor of *education level*.

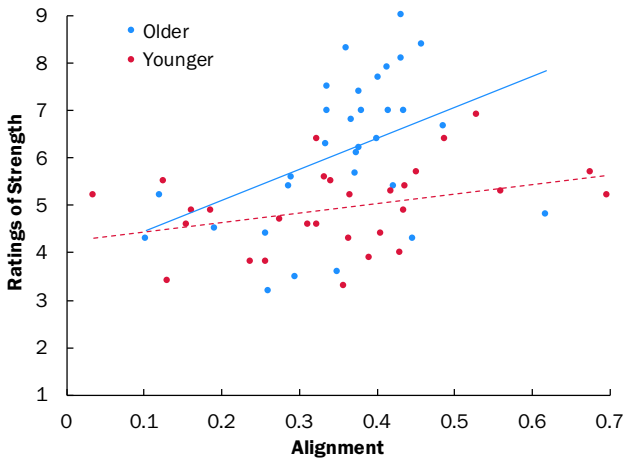

Figure 3: The interaction between age and alignment. Each data point represents one participant's average rating and alignment scores. Alignment had a much larger impact on ratings of strength for older participants (participants above the median age) than younger participants. This conforms with previous findings examining the relationship between bias in argument evaluation and age.

Performance on Incongruent Problems A potential limitation of this particular NLP method is its reliance on the semantic relationships between isolated words. A robust methodology should be able to accurately determine the valence of an argument that may contain several words related to a foundation, but nonetheless is incongruent with the beliefs of someone who values that foundation. To test the robustness of our method, we built another iteration of the above, best performing mixed effects model (including the *alignment*age* interaction), but selected only *incongruent* arguments (previously both *congruent* and *incongruent* problems were used). The impact of *alignment* on ratings of *incongruent* arguments also appears to be dependent on *age*, as the interaction term *alignment*age* was again a significant predictor of ratings of argument strength ($\beta = 15.01$, $p < 0.001$). To examine this relationship further, we divided the sample into two groups (older and younger) along the mean age, and then calculated the correlation between participants' mean *ratings* and mean *alignment* for each group. While we found a significant correlation between *ratings* and *alignment* in the older group ($r = 0.26$, $p < 0.001$), we found no such correlation in the younger group (see Figure 3).

Discussion

Our results demonstrate that distributed dictionary representations (DDR) combined with a measure of user values may provide a reliable method for identifying when users may be prone to biased reasoning. Because our method does not require labeled text data, it can be easily applied to real-world data (such as social media posts). The only limitation on this front is the identification of the user's values. We do this formally with the Moral Foundations Questionnaire, but research has demonstrated that political orientations can be predicted with a high degree of accuracy purely based off of social media activity (Colleoni, Rozza, & Arvidsson, 2014). Whether these predictions are as nuanced as those generated by the theoretically grounded Moral Foundations remains to be seen, but the potential for a fully automated method for measuring a user's susceptibility to myside bias exists.

We used *incongruent* problems to test the robustness of our methodology. These problems were intentionally designed to confuse the DDR method, and produced some interesting results. While alignment was predictive of ratings on incongruent problems, this was only true for older participants. One potential explanation for this difference is a lack of clarity about what low scores on the moral foundations questionnaire mean (specifically in this context as a proxy for beliefs). High scores indicate a value is relevant, but do low scores indicate indifference or impassioned opposition? Future work will require a qualitative exploration of these nuances.

Toward Adaptive Interventions

Our results suggest that we can leverage the dynamic relationship between user and content values to predict when the user may be prone to biased reasoning. This work is the first step toward providing adaptive, targeted interventions when high alignment between user and content values is detected (i.e., when the user is most prone to biased reasoning). It is in these cases of high alignment that we are least likely to move from System 1 (intuitive) to System 2 (rational) thinking, and engage the reasoning processes that may mitigate bias. Adaptive interventions may be able to facilitate the engagement of System 2 thinking in exactly these critical moments, making users less vulnerable to content designed to exploit natural biases. This kind of hybrid solution leverages the strength of sophisticated machine learning methods, while still preserving the need for and power of human reasoning.

Conclusion

In this paper, we demonstrated that a measure of alignment between a participant's values and the values latent in short arguments was a significant predictor of ratings of argument strength. This was true even for nuanced arguments, designed to confuse our methodology. These results underscore the impact of values on the evaluation of everyday arguments, and lay the groundwork for adaptive interventions designed to mitigate everyday reasoning biases.

Building blocks of computational thinking: Young children's developing capacities for problem decomposition

Griffin Dietz [1], **James A. Landay**[1], **Hyowon Gweon**[2]

Abstract

Computational thinking (CT) refers to a range of problem-solving skills applicable to computer science and everyday life. Although recent research in developmental cognitive science suggests mental capacities relevant to CT may emerge quite early in life, research on CT, and computer science education more generally, has made little contact with this literature. As a way to better bridge these fields, we explore the development of problem decomposition, a critical feature of CT, in the spatial domain. We ask whether young children can break a complex spatial problem down into subcomponents that can be reassembled to solve the overarching problem. Across two experiments (Exp.1: 4- to 7-year-olds; Exp.2: 3- to 5-year-olds) that involve constructing block structures, we demonstrate that some of the key capacities underlying problem decomposition begin to emerge in preschool years and develop throughout early childhood. Although preschool-aged children struggle to solve an open-ended decomposition problem that requires generation and execution of decomposition plans, even 4-year-olds can successfully evaluate the viability of these plans. These results suggest that experimental methods in developmental cognitive science can inform CS education research that focuses on promoting CT; by identifying when and how CT concepts emerge in early childhood, we can better create age-appropriate educational tools.

Keywords: computational thinking; problem decomposition; problem solving; cognitive development; intuitive physics

Introduction

The ability to break down a large problem into smaller parts is important for many real-world tasks. To decompose a problem effectively, one must understand its constraints, generate potential solutions, and evaluate the strengths and weaknesses of those solutions. Importantly, these steps are often better taken *before* one actually acts; attempts to achieve a complex task without proper planning can lead to unnecessary effort to correct a mistake or even irreversible failure. But what does it take to be good at problem-solving and planning?

More than a decade ago, Wing (2006) popularized the concept of computational thinking (henceforth CT). CT is a term that collectively refers to a range of skills that are crucial to effective problem-solving, and it incorporates various cognitive strategies considered fundamental to computer science (CS) (Wing, 2006; Barr & Stephenson, 2011; Brennan & Resnick, 2012). Mental activities like abstraction (i.e., generalizing problem features to preserve only relevant information; Kramer, 2007) and problem decomposition (i.e., breaking a complex problem into solvable subcomponents; Barr & Stephenson, 2011) are key components of CT. Indeed, these skills are critical to building good computer programs; anyone who has engaged in programming understands the importance of abstracting away from a problem to identify its basic structure and decomposing that structure into solvable parts.

Yet, the importance of CT reaches far beyond programming (Wing, 2006). Abstract thinking, problem decomposition, and the ability to evaluate potential plans are skills that allow us to tackle a range of everyday tasks as well as larger, more complex problems that involve multiple sub-goals, such as conducting scientific research or building an architectural project. In particular, to successfully achieve these larger goals, one must: (1) represent the current state of the world (i.e., what does the empty lot look like?, what materials do we have?) as well as the state of the desired end-goal (i.e., what do I want to build?), (2) identify the units that comprise the end goal (i.e., what sub-goals should I complete?) and construct the possible future states from applying these units (i.e., what will the structure look like given these components?), and (3) evaluate the viability and effectiveness of different sets of potential units and interventions (i.e., should we build the columns or the roof first?, which size columns are most suitable?). In other words, effective problem-solving involves the representational and inferential abilities to *generate* possible ways to decompose the problem space and *evaluate* the viability of a potential decomposition plan. By engaging in these mental processes prior to executing a given plan, one can solve a problem with less trial-and-error.

While CT has been a useful construct to raise awareness of the relevance of these skills in both computing and everyday life, it remains a difficult concept to operationalize or measure. This difficulty may arise from the fact that CT is not a single thing; it is a collection of various mental operations whose cognitive mechanisms are poorly understood. Furthermore, although CT presumably involves reasoning abilities that have been topics of interest in cognitive development research, this body of work has remained rather disconnected from the literature in CS education, leading many CS educators to believe that CT develops relatively late in childhood (Guzdial, 2015). Our goal is to take a step towards synthesizing these fields, and build on prior work to ask whether the ability to decompose a complex problem—a key component of CT—is present early in life. In the following, we summarize related work on young children's inferential capacities and introduce a novel task for testing problem decomposition.

Prior work in cognitive development has revealed rich, sophisticated abilities in young children to engage in abstract reasoning and learning (Gopnik, 2012; Schulz, 2012). Although these studies are primarily aimed at identifying the developmental origins of the human ability to engage in sci-

entific thinking, collectively their findings suggest that the basic representational and inferential capacities supporting CT may emerge much earlier than previously thought. For instance, preschool-aged children construct novel hypotheses from observations via inductive generalization and design novel experiments to test these hypotheses by engaging in selection and isolation of relevant variables (Cook, Goodman, & Schulz, 2011; Legare, 2012). These abilities are foundational to successful problem solving.

Furthermore, CT involves the understanding that good plans achieve a goal effectively and efficiently. Evidence suggests the rapid development of planning abilities between ages 4 and 6, including an increase in the number of steps children can plan ahead to solve a problem (Klahr & Robinson, 1981) and improvements in the ability to deploy appropriate strategies depending on the task (Gardner & Rogoff, 1990). Prior work has also shown that even infants expect rational agents to act in ways that minimize cost (Gergely, Nádasdy, Csibra, & Bíró, 1995; Scott & Baillargeon, 2013), and they infer the reward an agent assigns to a goal based on the cost incurred to achieve it (Liu, Ullman, Tenenbaum, & Spelke, 2017). By age 5, children can even design informative experiments to infer the subjective costs or rewards of achieving a goal (i.e., an agent's competence or preferences) by systematically manipulating the objective rewards or costs of completing a task (Jara-Ettinger, Gweon, Tenenbaum, & Schulz, 2015; see Jara-Ettinger, Gweon, Schulz, & Tenenbaum, 2016 for a review). Collectively, these early-emerging capacities to generate and test hypotheses, engage in advance planning, and reason about efficiency suggest that the basic aspects of CT may emerge earlier than commonly believed.

Building on this prior literature, we designed a novel block-building task to study one of the key components of CT: problem decomposition. Block-building tasks are familiar to young children, and have historically been considered a useful domain for studying the development of planning and problem-solving. Block construction has been shown to be an indicator of early spatial skills (e.g., mental rotation, Brosnan, 1998), which correlate highly with later success in programming and STEM (Cooper, Wang, Israni, & Sorby, 2015; Verdine et al., 2014; Wai, Lubinski, & Benbow, 2009). Thus, studying children's ability to generate and execute an effective block-building plan can provide a unique window into understanding the early development of CT. Yet, prior work is largely limited to exploring childrens bottom-up building processes, allowing them to build the target structure in a piecemeal manner. Whether or not children can engage in top-down problem decomposition remains an open question.

A key strength of our task is that it requires more than merely copying a model block structure: children must figure out a viable plan within the constraints of the task by decomposing the structure into appropriate parts. In simple block-building tasks, one might succeed by accumulating raw materials (i.e., individual blocks) in a piecemeal fashion. Similar to the ways beavers or birds build their dams or nests, a child could repeatedly stack blocks to create a tower. However, imagine a child wants to build a structure resembling the bridge in Figure 1. Simply accumulating individual blocks isn't sufficient; the child must first assemble the "legs," and then place a horizontal bar on top. If a child starts by creating "pillars" that are as tall as the bridge itself (3 blocks), then a single block in the middle would not stay in place. This example demonstrates how a bottom-up building process can be insufficient even for seemingly simple tasks. Rather, this problem resembles the way that we approach larger, real-world engineering projects; we must take the desired goal, break it into smaller problems, and determine how those components should be solved and assembled within the constraints of the task. Thus, the goal in designing our task was to provide a context in which children would approach a complex problem in a similar manner under clearly defined task parameters.

Recent work demonstrates that both adults and children leverage intuitive physics when evaluating the stability of block structures (Battaglia, Hamrick, & Tenenbaum, 2013; Kamps et al., 2017; Yildirim, Gerstenberg, Saeed, Toussaint, & Tenenbaum, 2017), that children as young as 4 can gauge the difficulty of building such structures (Gweon, Asaba, & Bennett-Pierre, 2017), and that they are capable of copying a model block structure when given the required pieces (Cortesa et al., 2018). Critically however, start-to-end construction requires intelligently *generating* those pieces as well. Computational models optimized to generate instructions for the construction of block structures identify structural components while accounting for the effect of gravity on future layers (Zhang, Igarashi, Kanamori, & Mitani, 2017). However, the ability to determine the required subcomponents based on an intuitive understanding of task-specific constraints has not been tested in young children, even though such ability might provide the key foundation for a more general ability to engage in problem decomposition.

In Experiment 1, we embedded the process of *generating*, *evaluating*, and *executing* an appropriate decomposition plan into a fun, engaging block-building task. Given a target structure, children had to identify the underlying substructures, simulate ahead to determine if those substructures could combine into a self-supporting building, and then execute this plan to complete the task. In Experiment 2, we use a simplified version of the task to ask whether young children's difficulty in Experiment 1 comes from the process of *generating* a plan with the appropriate subcomponents, rather than the process of *evaluating* the viability of a given plan by engaging in physical simulation.

Experiment 1

Methods

Participants A total of 112 children (Age: 4.00–7.99) were recruited from a local children's museum and a university-affiliated preschool (38 4-year-olds: $M = 4.56$ (4.04–4.99); 31 5-year-olds: $M = 5.43$ (5.01–5.96); 23 6-year-olds: $M = 6.49$ (6.14–6.99); 20 7-year-olds: $M = 7.61$ (7.08–7.99)). They

were randomly assigned to either the Standing Bridge condition (N=62) or the Sideways Bridge condition (N=50). We planned to recruit at least 40 children in each condition who successfully completed the task (10-12 in each age group). Twenty-nine children were unable to accomplish the task, and the successful subgroup included N=42 in the Standing Bridge condition and N=41 in the Sideways Bridge condition. An additional 20 participants were dropped from analyses because they: (1) did not speak English (N=3), (2) ended the study early (N=7), (3) failed the warm-up task (N=6, see Procedure), or (4) the experimenter made an error (N=4).

Stimuli For the main test trial, the model bridge was comprised of seven one-inch wooden cubes (three across the top and two on each side as supports) painted metallic silver. In the Standing Bridge condition, this bridge was presented upright, and in the Sideways Bridge condition, it was lying down (see Fig. 1). Children were given 3 individual unpainted wooden blocks with which they could create substructures using a "magic box." The magic box (see Fig. 1) was a cardboard box covered in felt with a small coin slot and an output window. A wire connected this box to the "construction zone" (a flat piece of foam core covered in black felt) and a large plastic button, suggesting they were all part of one causal mechanism. A coin was required each time the child operated the magic box to create a substructure. Inside the box were pre-assembled metallic structures. For the main task, where children had 3 individual blocks, there were 4 possible configurations of shapes that children could make; we prepared 4 metallic structures for each shape for a total of 16. We included additional structures for the practice trials.

Procedure Children were introduced to the experimenter's "magic box" which could turn a set of one-inch wooden blocks into larger, metallic blocks of varying shapes. The child had to first build a structure on the construction zone using individual wooden blocks; after putting a coin in the slot, children could press the plastic button to generate a single metallic block that had the same shape as the structure on the construction zone. In reality, when the child operated the magic box, the experimenter surreptitiously reached into the box through a hidden opening, found the corresponding metallic block, and placed it in the magic box output window (see Fig. 1). From the child's view, this created the illusion that the child's button press operated the magic box to generate the metallic structures.

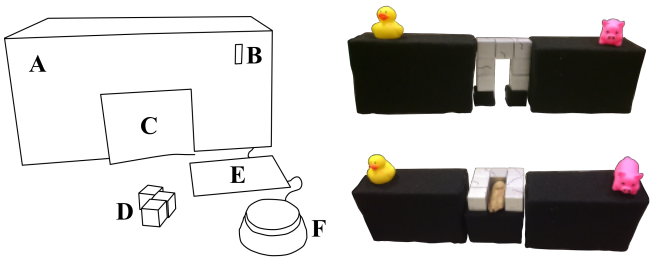

Figure 1: Left: Experimental setup. A) magic box, B) coin slot, C) output window, D) 1" wooden blocks, E) construction zone, F) plastic button; Right: Standing bridge (top) and sideways bridge (bottom).

A brief warm-up task ensured that the child understood the purpose of the main task and how to operate the magic box. In the warm-up, the child was given four wooden blocks, and was asked to build a 4-block 'T' shape (Trial A), a 3-block 'L' shape (Trial B), a single block (Trial C), and an 8-block cube (2x2x2) composed of two 4-block squares (Trial D). We excluded children who failed to complete this pretrial task from subsequent analysis to ensure that all children included in the study understood the magic box paradigm and were able to use the magic box to build metallic block pieces.

In the main task, children were asked to build a bridge using the blocks and the magic box. Critically, children had only three wooden blocks such that the metallic blocks they could build using the magic box was limited to a particular set of shapes. They were also given 11 coins; this limited the number of possible times children could generate a metallic structure, providing a pressure to solve the task efficiently.

In the Standing Bridge condition, the upright bridge was subject to the forces of gravity, and thus required a specific block set and assembly sequence (i.e., set up two 2-block bases and place a 3-block horizontal bar on top). The Sideways Bridge condition was identical to the Standing Bridge condition except that the bridge was laid flat (and thus not subject to the force of gravity). While the task still forced children to decompose the structure, there were multiple possible solutions and the order of construction did not matter. Thus, the Sideways Bridge condition still required the ability to follow task instructions, create parts, and assemble the final structure. However, the need to engage in advance planning to generate the "correct" decomposition plan and evaluate its viability was not as critical for success.

The children were given up to 10 minutes to build the bridge, after which the experimenter stepped in to help and ended the study. Often the child got stuck (signaled by asking for help or a period of inactivity) or distracted, so to encourage the child to reengage, the experimenter offered one of two pre-scripted prompts. Additionally, after an extended period of inactivity or running out of coins, children were given the option of restarting the task in the remaining time.

Results and Discussion

This was an exploratory study to see whether children could engage in effective problem decomposition, rather than a test of a priori hypotheses. However, we could imagine seeing a few general trends in the data. First, we expected that children would become more successful and more efficient at completing the task with age. We measured efficiency using two different metrics: completion time (in seconds) and number of coins used (3 was the minimum). Second, independent of increasing performance with age, we also expected that children would perform better (i.e., higher success rate, as well

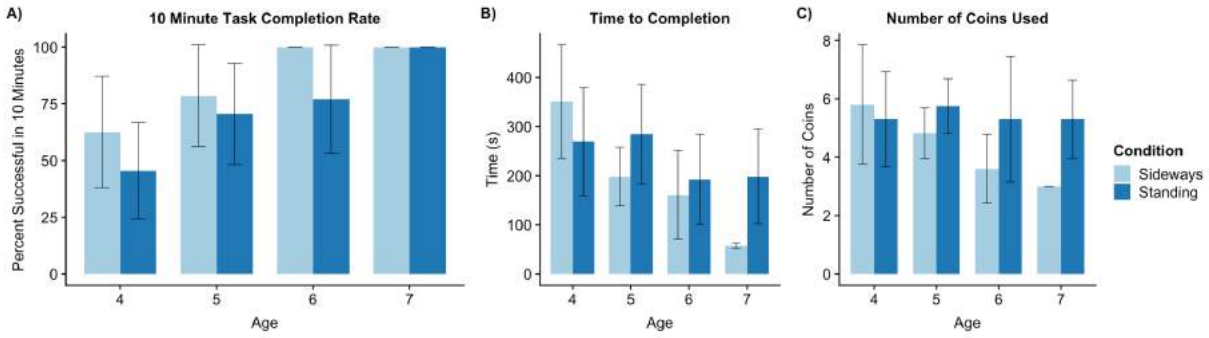

Figure 2: (A) Success rate in each age bin and in each condition. (B-C) Time-to-completion (B) and number of coins used to complete the task (C) among the successful children, split by age and condition. Error bars: bootstrapped 95% CI.

as more efficient completion) in the Sideways Bridge condition than the Standing Bridge condition, because the Standing Bridge had just one viable 3-part decomposition solution. Third, we predicted an age by condition interaction; the condition difference would decrease with age as children become more proficient at finding solutions without trial and error.

A logistic regression with condition (discrete) and age (continuous) confirmed a relationship between age and success rate ($z = 2.41$, $p = 0.02$). However, we did not see a significant effect of condition ($z = 0.47$, $p = 0.64$) nor an interaction between age and condition ($z = -0.73$, $p = 0.47$).

Given the increase in success rate with age, we further analyzed data from the 83 successful children to see if children become more efficient problem-solvers with age. First, we looked at time-to-completion; a linear regression with both age (continuous) and condition (discrete) as predictors showed that older children take a shorter amount of time to complete the task ($t = -4.47$, $p < .001$). While children in the Sideways Bridge condition did not complete the task faster than those in the Standing Bridge condition ($t = -1.73$, $p = 0.09$), we did find an interaction between age and condition. However, the effect was in the opposite direction than we had initially predicted: the difference in completion time between conditions increased with age ($t = 2.06$, $p = 0.04$).

Another measure of efficiency—the total number of coins used—also showed a similar pattern. A linear regression on the 83 children who successfully completed the task revealed that the number of coins children used to complete the building task decreased with age ($t = -3.14$, $p = .002$); also consistent with time-to-completion, we did not find an effect of condition ($t = -1.49$, $p = .14$) but the difference between conditions increased with age ($t = 1.96$, $p = .05$).

We then looked at the proportion of children who completed the task with maximal efficiency (i.e., successfully building the bridge using just 3 coins). A logistic regression with condition and age showed an effect of age ($z = 3.61$, $p < .001$). Children were also more likely to perform optimally in the Sideways Bridge than in the Standing Bridge condition ($z = 2.08$, $p = 0.04$), and this tendency increased with age (age by condition interaction, $z = -2.54$, $p = 0.01$).

Overall, data from this exploratory study showed a few notable patterns. First, unsurprisingly, children became more successful and more efficient at solving the task with age across a number of measures: success rate, time-to-completion, and number of coins used to finish the task. These results are consistent with prior work showing that the ability to plan ahead to solve problems develops rapidly during preschool years. Second, we also found that the proportion of children who finished the task with maximal efficiency varied across conditions. This pattern is also reasonable given that the Standing Bridge required a more principled, planned approach for success; due to the constraint of gravity, there was only one viable decomposition solution whereas the Sideways Bridge could be built in a few different ways. Third, we found an age by condition interaction in measures of efficiency (time-to-completion and number of coins used); however, the difference between conditions in efficiency increased with age, rather than decreasing with age. In other words, only the older children showed the expected difference between conditions. This suggests that the task was generally quite difficult for young children; even though 4- and 5-year-olds still successfully passed several practice trials and understood the task instructions, many of them struggled to complete the task in both conditions.

Collectively, these data provide an informative window into how children engage in problem decomposition to solve a complex task. Older children's near-perfect performance in the Sideways Bridge condition suggests that they were able to create substructures and use them to assemble the bridge correctly. Thus, the primary challenge children faced in this task may have been identifying and generating a plan to construct the "correct" components prior to building, especially when there was just one solution (Standing Bridge condition).

The fact that younger children struggled in both conditions raises questions about whether preschool-aged children suffer from a genuine lack of ability to engage in problem decomposition. However, the results do not allow us to directly explore this possibility because the task in Experiment 1 was open-ended and required children to engage in all aspects of problem decomposition—generating, evaluating, and ex-

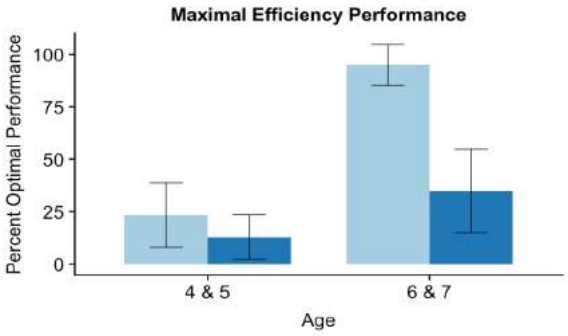

Figure 3: Percentage of children who completed the task with maximal efficiency (only used 3 coins), collapsed into age bins. Error bars are bootstrapped 95% CI.

ecuting solutions. However, there are reasons to believe that, when the demands for generating the plans are removed, even younger children can successfully *evaluate* the viability of a given plan. Compared to the process of generating a plan for decomposing a problem or a structure, evaluating the viability of an existing plan is arguably an easier task. Prior work suggests that preschool-aged children can easily assemble structures (Cortesa et al., 2018) and evaluate the relative difficulty of building different structures (Gweon et al., 2017), suggesting that even though the younger children in Experiment 1 (4- and 5-year-olds) struggled to generate and execute the plans themselves, they may be capable of evaluating the viability of existing decomposition plans.

In Experiment 2, we test this hypothesis with a simple binary-choice paradigm where we asked children to choose one of two pre-generated plans (i.e., choose the plan that would result in a self-supporting structure). Given the simplicity of the task, in addition to 4- and 5-year-olds, who we expected would succeed, we also tested 3-year-olds; while we did not have strong a priori predictions regarding the 3-year-olds' performance, having a broader age group would allow us to capture the developmental trajectory of this ability.

Experiment 2

Methods

Participants A total of 78 children were recruited from a local children's museum and a university-affiliated preschool (28 3-year-olds: M = 3.51 (3.02–3.98); 26 4-year-olds: M = 4.42 (4.01–4.93); 24 5-year-olds: M = 5.52 (5.03–5.93)). An additional 12 children were dropped from analyses because: (1) they did not speak English (N=1), (2) they did not complete the study (N=4), (3) they failed the pretrial task (N=3, see Procedure), (4) parents interfered (N=1), or (5) the experimenter made an error (N=3).

Stimuli Stimuli were similar to the blocks structures used in Experiment 1. A 'T' shaped structure (practice trial) and the upright bridge from Exp. 1 (main trial) were used as target structures. For both trials we prepared two sets of blocks, preconfigured in the shape of the target structure and laid flat on the surface. Critically, only one of the two sets would result in the correct self-supporting structure (see Fig. 4).

Procedure Children were introduced to block pieces of various shapes. In the practice trial, the experimenter presented the T-shaped block structure along with two potential solutions, and asked: "Can you help me build a new building that looks just like this one and can stand up all by itself? We can use these blocks (pointing to one set) or these blocks (pointing to the other set). Only one will work."

After the child selected one set of blocks, the experimenter allowed the child to use the selected blocks to construct the target structure. Regardless of whether or not the child chose correctly, the experimenter allowed the child to attempt construction with the other set. After the child succeeded in constructing the structure with the correct block set and failed with the incorrect set, the experimenter reiterated that the child could build the building with one set of blocks but not with the other, as it would fall over, so only one set would work. We excluded children who failed to select one of the block options in this pretrial task or who began playing with the blocks before listening to the full explanation.

In the main task, the children were asked to choose one of two solutions that would result in a standing bridge. We marked a child as having made a selection when they physically picked up one of the sets of blocks. The position of the correct solution (L/R) was counterbalanced across subjects.

Results and Discussion

We first ran a logistic regression on children's choice with age as a continuous variable. The effect of age was trending towards significance ($z = 1.81$, $p = 0.07$). We then looked at each age group separately. Three-year-olds' responses did not differ from chance (M = 0.57, CI = 0.39–0.75), whereas four-year-olds (M = 0.81, CI = 0.65 – 0.92) and five-year-olds (M = 0.83, CI = 0.67 – 0.96) showed robust success.

To succeed at this task, a child had to be able to understand the constraints applied to the problem (gravity) and physically simulate the stability of the resulting structure to choose the appropriate solution. The success of four- and five-year-old children on this task provides suggestive evidence that they are already capable of such sophisticated physical reasoning. The results also suggest that, even though children in this age group struggled to complete the task in Experiment 1, their difficulty with that task did not stem from an inability to assess the viability of a given plan.

General Discussion

Our goal was to assess whether the basic capacities for problem decomposition—one of the key components of CT—are present even early in childhood. In Experiment 1, we used a block-building task that involves generating, evaluating, and executing an appropriate decomposition plan to build a physical structure. The results suggest that capacities for top-down design and problem decomposition continue to develop well past the preschool years, and that children become more successful and efficient with age. Although many younger participants failed to complete the task in Experiment 1, in Experiment 2 we find evidence for one of the key steps in successful problem decomposition: children as young as age 4 were able to evaluate the viability of potential solutions.

Experiment 1 featured a rather complex task with high verbal demand for understanding the instructions, which may have increased the task load. Furthermore, this study jointly required top-down design to generate appropriate solutions, evaluation of those solutions, and the actual execution of the plan to assemble the components. Children's struggle with this task could reflect their difficulties in any or all of these steps. Experiment 2 isolates one particular aspect of problem decomposition. Results suggest that 4- and 5-year-old children can compare and evaluate two different decomposition solutions and select the correct one. These results complement prior work (Cortesa et al., 2018) which showed that young children can construct target structures from predetermined components; beyond using a given set of components to assemble the target structure, our results show that 4-year-olds are able to reason ahead under the constraints of a task to infer the correct set of components, even before they engage in actual assembly. Collectively, these findings indicate that some basic underlying capacities for problem decomposition may begin to emerge in preschool years, but they also continue develop well beyond this age.

One might wonder whether children's abilities to engage in problem decomposition in our task is restricted by the physical/spatial domain. Prior work indicates that the ability to engage in basic spatial reasoning emerges early in life (Newcombe & Huttenlocher, 2003). For instance, 5-year-olds show successful mental rotation of a paper cut-out object on a 2-D plane (Frick, Hansen, & Newcombe, 2013) and understand how a scene would look from another person's perspective (Borke, 1975). Our results suggest that even 4-year-olds can mentally rotate a 3-D structure to assess its stability.

Our study focused on a concrete problem with a clear visual representation. Our tasks were intentionally reflective of a thinking pattern common to programming. To solve a programming problem a programmer must identify independently solvable pieces, construct them separately, and then recombine them into a cohesive solution. Of course, throughout this process, the programmer must weigh constraints to make decisions about optimal components or solutions. Similarly, in Experiment 1, children had to identify, construct, and reassemble components of a larger physical structure; there was no possible way to build it directly. Thus, one important question is whether the ability to decompose a problem in the spatial domain extends to more abstract CT problems. Future work might ask whether children's success in this task transfers to decomposition of larger tasks in other STEM areas, such as programming. One possibility is that training children to engage in decomposing a physical structure might also help them decompose a larger programming problem.

Another interesting avenue for future exploration is that the use of concrete objects in physical space might make it easier for children to engage in successful decomposition even in these more abstract domains. Indeed, adults often transform complex abstract tasks into concrete forms, such as diagrams, to avoid trial-and-error in a complex project. We look forward to future work that asks whether physical affordances and manipulatives support children's abstract problem solving in a similar way.

Mark Guzdial, a leading researcher in CS education, wrote: "An open research question is what an elementary school child can learn about computing and what should be taught at what ages" (2015). Our work, along with prior research in cognitive development, suggests that CT is not a unitary construct that emerges at any single age. It involves a range of mental operations which may involve independent developmental trajectories. While children might be able to identify flaws in systems or construct those systems from predetermined parts in preschool, they may not develop the ability to generate those parts until much later. Capacities underlying other CT concepts, such abstraction, data representation, or parallelization, likely also develop in a piecemeal manner that remains to be discovered.

We look forward to more future work that bridges the gap between cognitive development and CS education research. Our work here represents a first step at demonstrating children's developing capabilities in a critical component of computational thinking: problem decomposition. We show that children may be able to learn basic computational thinking skills as early as preschool, but that these capacities continue to develop well into elementary years. As educators continue to develop CS curriculum, these results can inform when and how to teach early programming concepts to young students.

A Familiarity-dependent Retrieval Threshold in ACT-R

Cvetomir M. Dimov (cdimov@andrew.cmu.edu)
Department of Psychology, Carnegie Mellon University,
5000 Forbes Avenue, Pittsburgh, PA 15213, USA

Abstract

In their current functional form, ACT-R's retrieval equations do not account for the left side of the RT-distance relation, that is, that as memory activation decreases, so does response time for retrieval failures. To accommodate this effect, I propose that the memory system uses the familiarity of the encoded object to gauge how much effort it should devote to retrieval. I quantify the degree of familiarity through the match score, which is the output of a global matching process. Familiarity, in turn, directly determines what the retrieval threshold should be. Adding a familiarity process orthogonal to recollection is in line with neuroimaging results, which uncover parallel familiarity and retrieval processes. The developments in this paper extend ACT-R's memory theory into a dual process theory.

Keywords: ACT-R, declarative memory, familiarity, retrieval threshold

Introduction

Perhaps uniquely among current theories of memory, ACT-R's memory theory (Anderson & Schooler, 1991; Schooler & Anderson, 1997) assumes a recall process, but no familiarity process. Despite being a single-process theory, it has successfully accounted for both responses and response times (RTs) of not only various recall processes (e.g., Anderson, Fincham, & Douglas, 1999; Anderson & Rader, 1999), but also of various recognition processes (e.g., Anderson, Bothell, Lebiere, & Matessa, 1998; Schneider & Anderson, 2012). Yet, at least one aspect of recall that ACT-R does not currently account for is the shape of the RT curve of "No" responses. Here I put forth a proposal of extending this memory theory such that it can also accommodate the RT distribution of recall failures. This proposal is consistent with recent neural evidence of separate familiarity and recall processes (e.g., Borst and Anderson, 2015). Specifically, I suggest that (1) familiarity in ACT-R is modeled with a global-matching process and (2) the retrieval threshold is strategically varied as a function of familiarity.

The Memory Theory behind ACT-R

ACT-R makes the distinction between representations, which inhabit the symbolic level, and the equations governing them, which lie at the subsymbolic level. At the symbolic level, ACT-R represents items in declarative memory as chunks, which are a collection of one or more slot-value pairs. Facts, such as "Otters hold hands" and "Cherry coke tastes like cyanide", and experiences such as "I rappelled off a bridge on Sunday" are all stored as chunks in declarative memory.

At the subsymbolic level, several equations determine whether chunks are likely to be retrieved or not and how long that will take. These equations take into account the prior history of encounter of the episodes or facts encoded in chunks as well as their relevance to the current context, and bind those together into a single quantity – a chunk's activation. Each chunk *i* has an activation, A_i, associated with it that quantifies its strength. Activation is a dynamic quantity that models the logarithm of the odds (i.e., the *log-odds*) that a chunk is needed at this point in time in this context to achieve the goal the agent strives for. Activation is composed of *base-level activation*, B_i, the *spreading activation*, SA_i, and noise, ε:

$$A_i = B_i + SA_i + \varepsilon \quad (1)$$

The base-level activation is a function of the chunk's history:

$$B_i = \ln \sum_{k=1}^{n_i} t_k^{-d}, \quad (2)$$

where the *decay parameter*, d[1], specifies the rate of forgetting over time, which is modeled with a power function. The power function was chosen, because the likelihood of encountering items in the real world also decays as a power function as time passes and the memory system is hypothesized to have adapted to this regularity (Anderson & Schooler, 1991). The parameter n is the number of encounters with the information that chunk i represents, and t_k is the time since the k^{th} encounter.

Spreading activation SA_i assesses a chunk's relevance to the current context, where the current context consists of all chunks currently in the focus of attention (i.e., all chunks currently in the *buffers* of the various *modules* that ACT-R consists of). SA_i assumes that chunks in declarative memory related to or previously encountered with chunks in buffers are more likely to be needed than those that are not. The amount of spreading activation to chunk i in declarative memory is a function of the associations between that chunk and the currently attended to chunks j:

$$SA_i = \sum_j W_j S_{ji}, \quad (3)$$

where the associative strength, S_{ji}, between chunks i and j is weighted by the source activation, W_j, of chunk j in a buffer. The associative strengths, S_{ji}, between chunks is approximated by

$$S_{ji} = S - \ln(fan_j), \quad (4)$$

where S denotes the maximum associative strength and fan_j is the number of chunks associated with a chunk j. The more

[1] Typically set to $d = 0.5$.

chunks are associated with a chunk in memory, the lower the associative strength between it and each of its associates becomes. Equation (4) is approximation of the Bayesian memory analysis that ACT-R is based on (Anderson & Milson, 1989) which assumes that each association of chunk *j* is equally likely to be needed. This approximation usually accounts sufficiently well for experimental regularities, but in some cases the full Bayesian equation needs to be summoned (see Anderson & Reder, 1999).

Equations 2-4 determine the activation components summed in Equation 1, which then determines probability of retrieval and retrieval failure as well as retrieval time. Specifically, whenever A_i is above the *retrieval threshold* τ, the chunk can be retrieved, while if it is below that threshold, the chunk is not sufficiently active to be retrieved, resulting in a probability of retrieval p_i as a function of threshold:

$$p_i = \frac{1}{1+e^{-\frac{\mu_{A_i}-\tau}{s}}}, \quad (5)$$

where $\mu_{A_i} = B_i + SA_i$ is the mean of the activation distribution. Retrieval time is also exponentially related to activation:

$$t_{retrieval} = Fe^{-A_i}. \quad (6)$$

The *latency factor F* scales the resulting quantity into units of seconds. If the activation is below the retrieval threshold, the resulting retrieval failure time is constant:

$$t_{retrieval\ failure} = Fe^{-\tau}. \quad (7)$$

ACT-R and Familiarity

Recognition tasks in ACT-R have typically been modeled with the same retrieval process that recollection is modelled with, but with different parameters (see Anderson, Bothell, Lebiere, & Matessa, 1998), whereby no fluency or familiarity processes are mentioned. Yet, familiarity processes are explicitly mentioned in at least one (decision) model constructed in ACT-R, the *fluency heuristic* (Schooler & Hertwig, 2005).

The Fluency Heuristic

The fluency heuristic is a memory-based decision strategy that infers which of two alternatives scores higher on a criterion by choosing the alternative that is more fluent (i.e., more familiar). The fluency heuristic does not require a separate familiarity processes running in parallel to retrieval to model fluency. Instead, in its original definition, the fluency heuristic operationalizes fluency as the time it takes an object to be retrieved (Schooler & Hertwig, 2005). Later, this heuristic was redefined to rely on the newly developed ACT-R module for prospective time interval estimation (Taatgen, van Rijn, & Anderson, 2007), thus comparing the subjectively perceived retrieval times of the two alternatives and choosing the one that is subjectively faster to retrieve (see Dimov, Marewski, & Schooler, 2017; Fechner et al., 2016; Marewski & Schooler, 2011). Still, even in its updated version, the fluency heuristic does not assume a separate familiarity process, but continues to rely on a recall process paired with a process for estimating the time recall takes.

Neural Evidence of Familiarity

While, for the most part, the memory and decision tasks modeled with ACT-R did not necessitate two separate mnemonic processes, recently several neuroimaging studies examining the time course of associative recognition have provided evidence in favor of two processes operating in parallel: a familiarity process and a recollection process. Specifically, due to fMRI not providing the temporal resolution necessary to observe sub-second retrieval processes, both EEG (Borst and Anderson, 2015) and MEG (Borst, Ghuman and Anderson, 2016) were used to record brain signatures during this retrieval task. The brain signatures during associative recognition indicate the existence of a familiarity process commencing in parallel with a recollection process and finishing typically before, but not substantially before the recollection process. How can we model this familiarity process with ACT-R?

A Global-Matching Process in ACT-R to Model Fluency

My first proposal is that familiarity in ACT-R is related to *blending* (Lebiere, 1998). Blending is a process in ACT-R's declarative memory that produces a weighted average of a quantity over all chunks in memory that hold a value of that quantity, whereby the contribution of each chunk is weighted by its activation. The output of blending is a chunk holding the weighted average value. This mechanism has been used to model mistakes that children make when engaging in arithmetic (Lebiere, 1999), choices in dynamic decision making tasks (e.g., Gonzalez & Dutt, 2011; Gonzalez, Lerch, & Lebiere, 2003) and belief updating in repeated games (Spiliopoulos, 2013) among others.

At the subsymbolic level, the blended chunk is described with a *match score M*, which is the analogue of activation for the blended chunk. Just as the blended value, the match score is a function of the activations of the set of all chunks included in the blending process (called the *match set MS*):

$$M = \ln \sum_{i \in MS} e^{A_i}. \quad (8)$$

At first sight unintuitive, Equation 8 becomes clearer once we consider that activation is on a logarithmic scale (see Equation 2) and that all observables (Equations 5-7) are related to the exponent of activation. Summing the exponents of all relevant chunks' activation and then taking the logarithm renders the resulting match score equivalent to the activation resulting from the cumulative experience of all blended chunks. For example, if we consider only base level activation, the resulting match score would be:

$$\begin{aligned} M &= \ln \sum_{i \in MS} e^{A_i} = \\ &= \ln \sum_{i \in MS} e^{\ln \sum_{k=1}^{n_i} t_k^{-d}} = \\ &= \ln \sum_{i \in MS} \sum_{k=1}^{n_i} t_k^{-d}, \end{aligned} \quad (9)$$

which is the activation a chunk would have had it had the prior history of all blended chunks.

While activation is interpreted as the log-odds of a chunk being needed, the match score is the log-odds of *any* chunk in declarative memory being needed. The specific relationship that I propose is that the familiarity of an input is quantified by the match score produced by the blending process, that is, familiarity serves as a coarse gauge if any of the input is relevant to the task at hand.

The RT-distance Relation and ACT-R

In a recognition task, responses are classified as Hits and False Alarms (whenever the response is "yes") and Misses and Correct Rejections (whenever the response is "no"). Whether responses are correct or not, there is a well-established relation between the time that those responses take (RT) and how frequently the item was presented in the experiment or encountered in life: the RT-distance relation (Koppell, 1977). This relation states that response time is fast whenever items were presented very frequently or very rarely, resulting in a memory trace with a very high or very low strength. However, whenever the memory strength is in the middle ground, close to the retrieval threshold, responses take more time. In other word, RT decreases as the memory strength of an item lies further away (either to the left or to the right) from the retrieval threshold (see Figure 1 for an idealization). Consequently, both Hits and False Alarms become faster the higher memory strength is of retrieved items. Moreover, both Misses and Correct Rejections speed up the lower memory strength of the items that fail to be retrieved.

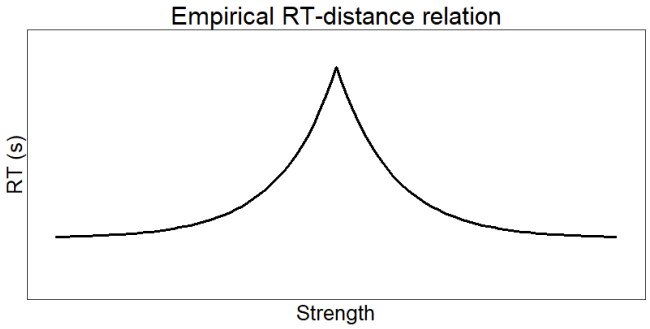

Figure 1: RT-distance relation in recall. A memory item with a medium strength provides ambiguous information about whether it has been encountered in the past or not and, consequently, requires a longer time to be retrieved. Memory items with either very high or very low strength are both responded to quickly.

In its current form, ACT-R's memory theory accounts for half of the RT-distance relation: that related to successful retrievals (Hits and False Alarms). Yet, following from Equation 7, when an item of memory fails to be retrieved (Misses and Correct Rejections), ACT-R predicts a constant RT (see Figure 2), which contradicts the empirically found RT-distance relation.

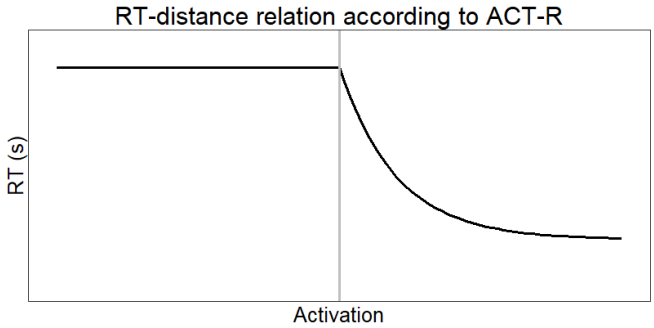

Figure 2: Relation between chunk activation and response time according to ACT-R. The grey line indicates the location of the threshold. Above the threshold, successful retrievals get progressively faster as one moves away from the threshold. Below the threshold, retrieval failures take a constant time irrespective of their distance from the threshold.

Fluency Determines Threshold

My second proposal aims to modify ACT-R's memory to account for the RT-distance relation using the fluency process earlier introduced. Specifically, I propose that the retrieval threshold τ is not constant, but that it is a function (i.e., the negative) of an item's familiarity (which I proposed to model with the match score):

$$\tau = -M. \qquad (10)$$

Since M is the log odds that any chunk in memory is needed, $-M$ is the log odds of no chunk being needed:

$$-M = -\log\left(\frac{need}{\neg need}\right) = \log\left(\frac{\neg need}{need}\right) \qquad (11)$$

In plain language, my proposal can be interpreted as the memory system dynamically adjusting the amount of effort it is willing to invest into a retrieval (as described by the retrieval threshold) as a function of how likely it is that no chunk in memory is ever needed, which is estimated via the fluency signal. If the global fluency signal is weak, that is, if the odds that any chunk in memory is needed at this moment is low, then the system will invest less resources into a retrieval attempt and abort it earlier. On the other hand, if the fluency signal is strong, the memory system will be ready to invest a lot of time into retrieval as it is more certain that it will retrieve a relevant chunk, even though in practice it will invest very little time as a successful retrieval will soon arrive.

Resulting RT-distance relation

When chunks are very distinct or, in the extreme case, when all chunks spread 0 activation to each other, the predominating factor in the match score is the activation of the chunk being probed as only this chunk will be included in the match set MS. In this case, the resulting RT-distance relation is almost entirely symmetric (see Figure 3)[2].

[2] The code used to generate Figures 2, 3 and 4 can be found in the Appendix.

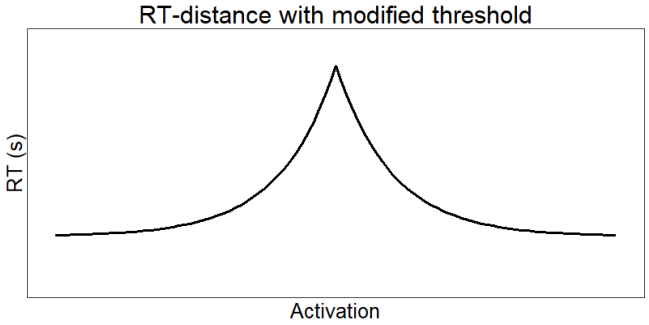

Figure 3: Relation between chunk activation and response time according to our modification of the retrieval threshold in ACT-R. I assume that the only chunk in the match set is the chunk being probed.

On the other hand, when other chunks are similar to the probed chunk and, thus, included in the match set, they increase the likelihood that any chunk in declarative memory will be needed. Consequently, the activation of the chunk representing the item being probed crosses the retrieval threshold at a lower value and, moreover, RT on retrieval failures decreases less and less steeply (see Figure 4)[3].

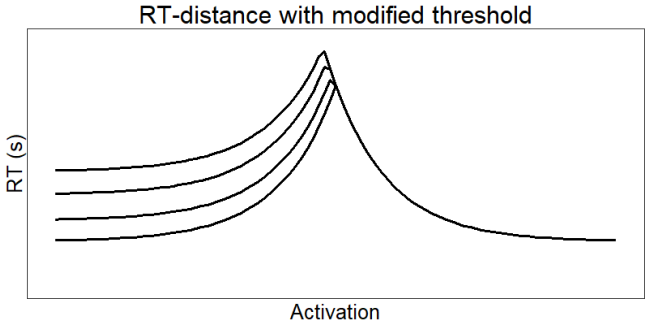

Figure 4: Relation between chunk activation and response time according to our modification of the retrieval threshold in ACT-R. The different curves correspond to various contribution to the match score of chunks that represent other items than the item being probed. As the similarity to the probed chunk increased, RT of retrieval failures increases.

Discussion and Conclusion

I proposed that familiarity in ACT-R is modeled with the match score from blending. This extends ACT-R's memory theory to a dual-process theory of memory. Moreover, I hypothesize that the memory system relies on the familiarity signal to assess the amount of effort it should invest in retrieval before aborting it. This allows ACT-R to account for the RT-distance relation. Finally, the prediction that retrieval failures will take longer when the probed chunk is confusable with other chunks in memory also follows from this new formulation. The modification interprets the blending module as a global-matching component of ACT-R's memory and puts it in the tradition of many a memory models in psychology, which include TODAM (Murdock, 1982), MINERVA 2 (Hintzman, 1984) and SAM (Gillund & Shiffrin, 1984; Raaijmakers & Shiffrin, 1980; for an overview of global-matching models, see Humphreys, Pike, Bain, & Tehan, 1989). I will proceed by briefly comparing the proposed extension of ACT-R to two related theories of memory and discuss the potential issues with the current proposal.

Comparison to Source of Activation Confusion

A theory that shares its lineage with ACT-R's is *Source of Activation Confusion* (*SAC*, Diana, Reder, Arndt, & Park, 2006). This theory has been used to model a wide variety of memory phenomena in various tasks, among which cued recall (Reder, Park, & Kieffaber, 2007), perceptual match effects (Diana, Peterson, & Reder, 2004) and feeling of knowing (Schunn, Reder, Nhouyvanisvong, Richards, & Stroffolino, 1997).

SAC is not based on the rational analysis of memory, yet many of the processes that it assumes are the same as those of ACT-R. First, it assumes that events and objects are encoded as chunks. Second, those chunks' activations are also separated into a base-level and spreading-activation components. Third, base-level activation decays with time as a power law, while spreading activation is a function of co-occurrence frequencies. Yet, there are at least two points of departure between ACT-R and SAC. First, SAC assumes that spreading activation slowly decays with time once the chunk that spreads activation is removed from the focus of attention, while in ACT-R this happens instantaneously. Second, in SAC a working memory of a limited capacity is populated with all chunks above a certain level of activation.[4]

Unlike ACT-R, SAC is a dual-process theory: it includes both a familiarity and a recall process. The familiarity (or feeling-of-knowing) process stems from retrieval of the concept node, which is the internal representation of the probed item. Activation then spreads to associated nodes, which leads to cued recall. Thus, unlike the current proposal of extending ACT-R's memory theory, in SAC familiarity does not result from a global-matching process, but from a retrieval of a single chunk.

Note, however, that adding a global-matching process that determines the retrieval threshold can also benefit SAC. First, just like ACT-R, SAC does not model the RT-distance relation related to retrieval failures, because it assumes a constant threshold. By adding a threshold that is inversely related to the global-matching signal, SAC should also be able to accommodate this relation. Second, SAC assumes that the familiarity (those related with retrieval of the concept node) and recollection processes (those related to retrieval of episode nodes) rely on different thresholds, whereby the

[3] I have relied on a single parameter to quantify the total amount of spreading activation that comes from chunks not corresponding to the presented item. See the Appendix for model code.

[4] Note that ACT-R's notion of working memory is more complicated in that it includes the buffers of all of its modules and potentially the content of the imaginal module, which stores task-relevant information.

concept threshold is typically higher than the episode threshold. I posit that Equation 10 would accommodate that a higher threshold for the concept than for the episode node. Specifically, during retrieval, activation spreads from the concept and the context into the episode node. If the activation of the episode is high enough, it will be retrieved. In this case the high activation of the episode node would also imply a high overall match score and, consequently, a low retrieval threshold. On the other hand, if the episode node cannot be retrieved and, instead, the concept node is relied upon, this would imply that the episode node has a lower activation. Consequently, the overall match score will be lower, implying a higher retrieval threshold.

Comparison to Retrieving Effectively from Memory

Retrieving effectively from memory (*REM*; Shiffrin & Steyvers, 1997) is a memory model that stems from the tradition of SAM. REM is a global matching model – it assumes that the recall probe is matched to all memory traces in parallel. Similar to ACT-R's memory theory, which is based on rational analysis, REM assumes that the memory system is optimally weighing signal and noise, and computing the likelihood that the probe has been encountered before in order to respond whether a presented item is recognized or not.

REM has been extended to also model various cued recall (e.g., Diller, Nobel, & Shiffrin, 2001) and free recall (e.g., Lehman & Malmberg, 2013) phenomena. To this end, REM was complemented with a trace recovery process, which is executed if the global matching process indicates a likely past experience with the probe. The current extension of ACT-R to include familiarity as a global matching process is similar to REM in that (1) it is a dual process model, (2) familiarity is a global matching process, (3) recollection is the recovery of a single memory trace, (4) whether effort is invested in recollection is strategically determined by the familiarity signal.

In addition to these similarities, there are several core differences between the two models. First, ACT-R assumes that base-level activation decays with time, while in REM and its extensions memory decay is generally absent. Second, ACT-R assumes that memory traces monotonically increase in activation with the number of encounters of the objects or events that they represent, while in REM a new trace can be created to store the encoded event/object or an already existing trace can be updated to store a more complete representation of the object. After a certain number of presentations, the object is perfectly encoded and no further updates of the memory trace(s) takes place. Which of those approaches provides a better description of memory phenomena is subject to further investigations.

Limitations of the Current Proposal

ACT-R's theory of memory assumes that our memory system makes a guess about which items of memory are most likely to be needed, what the cost and benefits of retrieval will be, and optimally combines those. The current analysis does not take into consideration costs and benefits. Yet, this might be problematic as the blending process is much more computationally intensive than the retrieval process itself: the activations of all chunks are computed and inserted into Equation 8 and, moreover, the blended value needs to be computed. Perhaps one way to alleviate these considerations would be to separate the computation of the match score from the computation of the blended value. This way the familiarity process would only require the computation of the match score, which sums chunks activation – values that need to be computed for retrieval in any case. Moreover, this would make the proposed familiarity process as complex as that of any other global matching theory.

To conclude, the current analysis is limited to only memory processes. Yet, neural data indicate that recollection, in addition to having a different neural signature than familiarity, also includes an additional decision phase (Borst, Ghuman, & Anderson, 2016). My analysis does not speak to the nature of these decision processes. Future work should focus on better understanding them.

Appendix

Here I include the R code used to generate Figures 2, 3, and 4. The two parameters that I specify are (1) the latency factor F and (2) the perceptual-motor time t_{pm}. The precise values of these parameters (0.35 s and 0.8 s) were chosen to be realistic. Yet, their values do not change the functional form, which is what we are ultimately interested in.

To generate Figure 2, I used the standard ACT-R equation (Equations 6 and 7), which assumes a constant RT below the threshold τ (here τ is set to 0) and an activation-dependent RT above threshold:

```
F = 0.35;
t_pm = 0.8;
RTACTR <- function(A){
  tau <- 0
  if (A < tau){
    return(F + t_pm)
  } else {
    return(F*exp(-A)+t_pm)
  }
}
```

To generate the data for Figures 3 and 4, I the modified equation that I propose:

```
RTACTR_new <- function(A,A_rest){
  M <- log(exp(A)+exp(A_rest))
  tau <- -M
  if (A < tau){
    return(F*exp(-tau)+t_pm)
  } else {
    return(F*exp(-A)+t_pm)
  }
}
```

where A_{rest} is the contribution to the match score of all non-target items. To generate Figure 3, I assumed that A_{rest}=0, while I used values of -10, -2, -1.2, and 0.8 to generate the plot in Figure 4.

Decoding Affirmative and Negated Action-Related Sentences in the Brain with Distributional Semantic Models

Abstract

Recent work shows that distributional semantic models can be used to decode patterns of brain activity associated with individual words and sentence meanings. However, it is yet unclear to what extent such models can be used to study and decode brain activity patterns associated with specific aspects of semantic composition such as the negation function. In this paper, we investigate the extent to which distributional semantic models of action-verbs correlate with brain activity associated with negated and affirmative sentences containing hand-action verbs. Our results show reduced correlations for sentences where the verb is in the negated context, as compared to the affirmative one, within brain regions implicated in action-semantic processing. The results lend support to the idea that negation involves reduced access to aspects of the affirmative representation and pave the way for further testing alternate distributional-based semantic models of negation against human semantic processing in the brain.

How time spent on feedback influences learning and gaze in categorization training

Abstract

Feedback is essential for many kinds of learning, but the cognitive processes involved in learning from feedback are unclear. In models of category learning, feedback is typically treated as an error signal without a temporal component. We conducted two simple category learning experiments that manipulated the duration of feedback (1s vs. 9s) and investigated the effect on learning and gaze. In two different category structures, participants in the longer feedback condition learned faster. The analysis of gaze data showed several findings. Participants in the 9s condition had longer fixations, and in both conditions and experiments, participants spent far more time looking at stimulus features than the feedback. Overall, our findings provide empirical support for the idea that feedback processes, and temporal factors more generally, have much to tell us about how people learn categories.

Reinforcing Rational Decision Making in a Risk Elicitation task through Visual Reasoning

Abstract

Metrics seeking to predict financial risk-taking behaviors typically exhibit limited validity. This is due to the fluid nature of an individual's risk taking, and the influence of the mode and medium, which presents a decision. This paper presents two experiments that investigate how an existing risk elicitation task's predictive capacity may be enhanced through the application of an interactive model of visual reasoning in a digitized version. In the first experiment, 60 participants demonstrated their reasoning process. In the second experiment, 225 participants were randomly assigned into three groups, with the validated risk elicitation task compared as a control to interactive digital and non-interactive digital stimuli with pie charts. The experiments yielded significant results, highlighting that when participants interact with a graph to reason their choices, it leads to consistent choices. The findings have implications for improvement of the risk task's validity and the deployment of digital interactive assessments beyond laboratory settings.

Keywords: visualization, decision-making, risk-taking, external representations, reasoning

Introduction

The ability to elicit the degree to which an individual or demographic is risk-taker or -averse has a value across various fields. Existing risk elicitation tasks have shown to have predictive capacity; however, in risk elicitation tasks that involve lotteries, a key constraint is participants' limited understanding of the probabilities, representing the risk associated with each choice, in those tasks. If participants do not understand a probability-based question, their answers lack internal consistency. Whilst within these tests internal checks for validity exist, these alone allow only for the exclusion, rather than accommodation, of participants with low numeracy skills that have limited understanding of the probabilities presented in the task. As a result, findings can be skewed towards a subset of a larger sample, limiting validity and predictive capacity.

Towards resolving this issue, this paper presents the findings of two empirical studies that were conducted to investigate the use of visualization reasoning methods as an assistive tool for users to understand the probability described and choose consistently in a risk elicitation task. Experiment 1 sought to explore the most effective reasoning methods used by 60 participants in a risk elicitation task, by asking participants to illustrate their thought-process. Visual reasoning was identified as having the strongest positive effect, among all external representations used by the participants, on the consistency of their choices in the risk elicitation task (Holt & Laury, 2002), showing that it helped them understand the probabilities in the risk task. To confirm whether visual reasoning, which can be defined as using visuals to reason a probability problem, on risk elicitation task can help participants with low numeracy level, Experiment 2 translated the existing risk-elicitation task to two versions; a non-interactive visual digital version and an interactive visual digital version, in addition to the standardised (control) numerical format task. Our discussion and conclusions reflect on the relevance of the findings in terms of increasing the accessibility and meaningfulness of risk-elicitation tasks to less numerate participants by using visual reasoning processes and also the implications for the use of digital and interactive visual media in place of standardised paper based tasks.

Background

Methods of risk-elicitation tasks can be broadly categorized into self-report questionnaires describing hypothetical situations; hypothetical choice problems; or computerized methods (Rohrmann, 2005). A range of moderating variables have been observed to affect the validity of the majority of these methods, leading to inaccurate results and predictions (Andersen et al., 2006; Dave et al., 2010). This can limit the scalability of an elicitation-exercise, and relates to a fundamental challenge in transferability of results to different contexts: any psychometric tool seeking to establish or predict behavior must consider the fluidity of individual characteristics, and furthermore how a slight change may result in a meaningful change in decision-making.

The Multiple Price List (MPL) task belonging to the category of hypothetical choice problems, wherein participants need to choose between a 'safe' or 'risky' bet over ten different lotteries, has demonstrated predictive capability and can be implemented straightforwardly (Andersen et al., 2006; Dave et al., 2010; Rohrmann, 2005). Holt and Laury's variant of the MPL task has been examined in several studies (e.g.Nielsen, Keil, & Zeller, 2013; Dave et al., 2010), demonstrating significant predictive value but only for people with higher numerical skills who understand the

probabilities for each of the parameters (Dave et al., 2010). The additional value of Holt Laury's MPL method is its capacity to identify the inconsistency rate in an individual's responses, allowing these choices to be excluded. However, this results in decreasing the validity of the metric.

To increase participants' understanding of the probabilities presented in the Holt and Laury MPL method, researchers have explored the use of visual display formats to represent the lotteries which reflect the losses and gains of the two options, allowing for more consistent and rational choices (Boughera, Gassmann & Piet, 2011; Bauermeister & Mußhoff, 2016; Habib et al., 2016). According to empirical evidence, using visualization tools to illustrate the uncertainty of the variables has a significant merit for people's informed decision making (Deitrick & Edsall, 2006). Integrating visualizations in the reasoning process could help users with low numerical skills to choose meaningfully regarding the risk related choices (Padilla et. al, 2018). Given that numeracy is an observed, reliable predictor of responses in risk elicitation tasks, a goal here is to address demographics or individuals who may have lower numeracy skills, but for whom a predictive mean of assessing their risk-taking or aversion holds value. Additionally, cognitive thinking style has been suggested to be another influential factor in a person's risk related choices (Frederick, 2005). Therefore, lower inconsistency rate achieved by presenting problems, which allows a wider range of individuals to respond consistently, would yield more reliable data. Research has illustrated the capacity of visualization to make probability reasoning more intuitive, and therefore better understood by participants (Hegarty & Kozhevnikov, 1999). In turn, this is shown to improve predictive validity. In the following section, visualization and external representations are briefly discussed.

Visualizations and external representations

Visualizations can become a reasoning process through interaction (Khan, Breslav & Hornbæk, 2018). For problems that involve probabilities, the individual relies on both internal visualization of the problem and the use of external representations such as sketches or diagrams to facilitate the solution. Visualizations serve as cognitive aids in problem solving situations (Khan, Breslav & Hornbæk, 2018; Padilla et al. 2018). However, individual differences, personality traits and cognitive abilities can have a significant effect on the use of a method that can aid the problem solving process (Ziemkiewicz et al., 2012; Gray & Holyoak, 2018). Therefore, visualization may not be the most appropriate external representation to assist in decision making for every individual (Starns et al., 2018). Even more, the type of visualization that can support the decision making for various tasks can differ significantly (Starns et al., 2018).

According to Corter and Zahner (2007) when investigating external representations, there is a division into two categories: the first refers to external visual presentations, which are provided towards influencing or informing a decision-making process (Corter, & Zahner 2007). The second involves understanding the internal representations the individual uses to reason when faced with a decision. The second involves the effects of user-generated visual representations while engaged in decision making and problem-solving activity. These internal representations, which can be defined as visual imagery (Corter & Zahner, 2007), have a core role in the production of knowledge. When externalized, they can provide valuable insight into individual's decision-making and aid successfully with problem solving (Gilbert, 2008). Empirical evidence suggests that using external representation to reason probabilities helps individuals to solve problems successfully (Corter & Zahner, 2007; Zhang 1997). In studies for logical reasoning, it has been argued that graphical representations allow the successful interpretation of abstract concepts (Zhang, 1997).

As the body of research suggests that external representations may be able to aid the reasoning process in probability problems, the following studies investigate the use of external representations to help individuals choose rationally in a risk elicitation task with lotteries. The first experiment is looking to determine whether there is a significant relationship between level of education, numeracy level and cognitive thinking style in rational decision-making in risk elicitation tasks. The second experiment investigates whether an interactive pie chart approach can influence the rational decision making in those tasks.

Experiment 1

Method

Participants Sixty volunteers from the UK participated in the study. The participants were divided into two groups depending on their educational level:

Group 1: Thirty-five participants (21 m, 14 f) with an age range between 22 and 53 (M=29.5) volunteered to participate in the experiment and had completed a degree level or higher qualification. The participants were invited through snowball effect via the network of a UK SME in the energy sector, and a British University.

Group 2: Twenty-five students from a further education college in the UK (4 f, 21 m), ranging in age 18-37 (M =20.64) volunteered to participate in the experiment and had not completed any degree-level qualification. The male participants outweighed significantly the number of females, this would be perceived as influencing the design and implementation of our study. All of them were assigned to the same experimental task as Group 1; similar research ethics procedures were also applied to this group. Participants were students in the Game Design and Web Design courses at a remedial programme. None of the participants had attended a course at a university level.

Measures The Lipkus Numeracy scale developed by Lipkus, Samsa and Rimer (2001) was used for this study. It was selected among others as a numeracy assessment tool for this study because it has been used in similar research to assess basic arithmetic skill in the variety of groups (Peters et al., 2006; Schapira et al., 2012). It is a short task, involving only

11 items, and consists of basic probability questions. These 11 items assess how well people can transform probabilities to percentages, percentages into probabilities while also performing simple mathematical operations using percentages or probabilities. The possible total sum scores range 0 to 11, where higher scores indicate better numerical skills compared to lower scores.

The Cognitive Reflection Test (CRT) (Frederick, 2005) is a three-item test, which is designed to assess individual's ability to suppress an impulsive wrong answer in place of a more deliberative cognitively processed correct answer. CRT reveals a reflective thinker over an impulsive as the most intuitive answer of the task is the wrong one. The individual needs to reflect before finding the solution. This measure is scored by adding up the correct answers. Participants who scored 0 and 1 out of 3 were classified as low reflective thinkers, and those who scored 2 or 3 were classified as high reflective thinkers (Frederick, 2005).

The Holt and Laury standard version comprises of two options in ten different rows. The probabilities for the higher amounts are 10% and 90% for the lower amounts. The probabilities change from row to row while the payoff remains the same. Hence, the expectation values of the two options change in each row. In the first four rows, the expected value for option A is safer, and option B is riskier. Form the fifth row, and below the risky option, B has higher expected value. If participants are consistent with their choices, they change after some point from option A to option B. The time that they switch over, determines their risk attitude. All rows are presented at once to the participants, and they are asked in each row to decide which option they would prefer. This measure was not used as a risk assessment. Rather, it was used to identify whether any of the other parameters such as education, numeracy, cognitive thinking style or external representations would be able to predict the rational evaluation of option and which external representation used by the participants would facilitate consistent choices.

Procedure Participants were given the participant information sheet informing them about the study and the informed consent form to sign. After the informed consents were obtained, participants started filling in the tasks using pen and paper. On average, each participant needed thirty minutes to complete all of the questionnaires.

The participants were given the Holt and Laury task and they were instructed to answer using whatever external representation was more appropriate to them. All of the participants had 20 minutes to complete the Holt and Laury task.

Results The independent variables were the education, numeracy, cognitive thinking style and external representational way. The dependent variable was the rational choice of the probabilities in the Holt and Laury task. In the context of this paper, is reflected as the participants' random choices in the task which indicate that participants either change lotteries in each row or choose only one Option between the two lotteries over the ten rows which has been supported as an inconsistent pattern by other studies (Jacobson & Petrie 2009; Dave et al. 2010). A coding system was used to categorize the external representations that participants used for the Holt and Laury task. The coding of the external representations was based on the coding adapted from previous research studied (Corter & Zahner, 2007; Zahner & Corter, 2010). The identified types were numbers, graphs, pictures, non-diagrammatic (text), and we added the blank page that it was not included in the coding method of Corter and Zahner (2007). Each representation was coded with one according to the above-mentioned types and added to a table. For instance, if a participant approached the problem solution using numbers, pictures and words then these types were coded with 1 and the rest, graphs and the blank page with zero. To assess the reliability of the coding, two independent raters coded the responses. Cohen's kappa was run to determine if there was agreement between the two raters'. A Cohen's kappa of .957 and .977 represented almost absolute agreement between the two examiners for each of the five categories in the Holt and Laury task. To test the hypothesis whether participants who graduated from university would be more likely to answer rationally in the Holt and Laury task, a chi-square test of independence was performed. This test showed that participants who graduated from university were not more likely to answer rationally in the Holt and Laury compared to participants who had not graduated from university, $X2$ (1, N=60) = .429, p = .513.

To determine the relationship between specific variables and the rational decision making in Holt and Laury task, a chi-square test of independence was used. Therefore, to examine whether participants who scored lower in the validated numeracy scale, was associated to their rational choices in the Holt and Laury, a chi-square test of independence was performed. Numeracy performance was divided into two groups, one group with participants who were scored high (9-10-11 correct) and another group with those that scored less (2-8 items correct). Because the distribution of data was highly skewed, as mean numeracy was 8.1 out of 11 (a =.63), a median split was used for analysis, although it was taken under consideration that this split can cause loss of power (Peters et al. 2006; MacCallum, et al., 2002). The data were binary (0 for most numerate and 1 for less numerate). The chi- square was statistically significant X^2 (1, N= 60) = 4.176, p = .041, showing that people who scored higher in the validated numeracy scale had a greater chance of choosing rationally in the Holt and Laury compared to those who scored lower.

A chi-square test of independence was also performed to find out whether gender is associated with answering rationally or not in the Holt and Laury, to exclude it as a factor which influences the rational decision-making in this task. The results showed that there is no gender association with participants' rational choices, X^2 (1, N=60) = .019, p = .890. To test the hypothesis that participants who had graduated from university, would be more likely to use different

external representations compared to the participants who did not attend university, a chi-square test of independence was performed which showed that there is no difference among the external representations both groups used, X^2 (4, N= 60) = 3.642, p = .457. To test the hypothesis that there was an association with correct answers in the CRT and the rational choices in Holt and Laury, Fisher's Exact Test was performed. It revealed that participants who answered correctly more questions in the cognitive reflection task, they were more likely to answer rationally in the Holt and Laury, p<.05. The relation between numeracy and CRT was not examined as it was out of the context of the study.

A logistic regression was performed to investigate if using any specific way of external representations would be more likely to predict a rational answer. The logistic regression model was statistically significant at p <.02 according to the model chi-square statistic, meaning that the use of external representations can predict the rational choices in Holt and Laury. According to the logistic regression, graphs were shown to predict the rational choices in Holt and Laury and blank page, which included the answers where there was no verbal, mathematical or visual decision making process to reason the choices in the task and resulted in irrational choices (Table 1). The software used for the statistical analysis was SPSS.

Table 1. Statistical significance of the independent variables in the logistic regression whether any of the external representation would be more likely to predict a rational answer.

	B	S.E.	Wald	df	Sig	Exp(B)
Numbers	-1.438	1.478	.947	1	.330	.237

Constant	-1.695	1.362	1.548	1	.213	.184

Experiment 2

Method

Participants In total 225 undergraduate computer science students, from a UK University, completed the tasks and the questionnaires. Participants in this study included 66 females and 159 males (M age = 29, age range 18 – 32). The allocation of the participant in three groups that were divided based on the respective format of Holt and Laury was randomized. Participants entered a lottery to win a £50 Amazon voucher as incentive to take part in the experiment, which was communicated during the introduction session.

Materials The materials used for this study include the Holt and Laury standardized version, the digital Holt and Laury displayed with pie charts and the digital Holt and Laury asking participants to fill in the pie charts before choosing the option.

In the Holt and Laury task displayed with pie charts (Figure 1), every option between the two lotteries is represented with a pie chart, and there is a text describing the proportions about the payoffs on the pie chart. Next, to the pie chart, the relevant payoff was displayed textually. The task was deployed in Unity Game Engine and logged all user actions and choices.

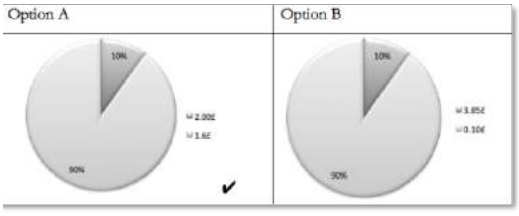

Figure 1. Holt and Laury displayed with non-interactive pie chart.

The stimuli developed for this study (Figure 2), involved 10 "empty" pie charts divided in 10 pieces with the proportions of each probability option of the lottery presented textually above them. Participants had to click on the region of the pieces on the pie chart to "fill them in" with specific colours according to the probabilities outlined in text and mark the pay offs of those pieces. For example, fill in with red one out of ten pies and fill in with blue nine out of ten. This way the participant can see clearly which option is more likely to happen. After the participants filled in the pie charts, they would choose one option. The stimuli was developed in a way that it did not allow the participant to choose the option before "filling in" the pie chart. Visually, the risk-taking task was very simple reflecting the standardised pen and paper HL task to avoid the effect of visual elements on participants' decision making process.

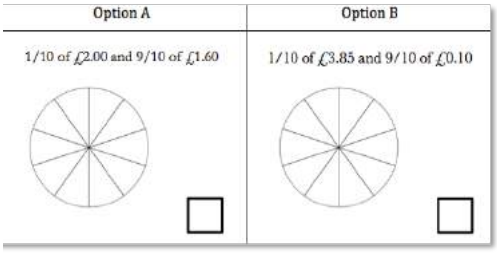

Figure 2. The empty circles where the participants had to "fill in" the parts for each pie chart before choosing the option.

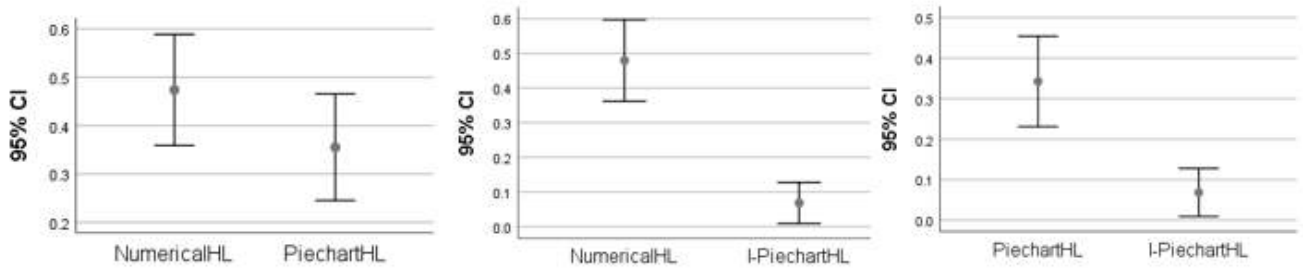

Figure 3. Participants' choices over the three different display formats with 95% Confidence Intervals. Dependent variable was the inconsistency rate in each display format of the Holt and Laury task. The lower mean shows a more consistent rate.

The numeracy test used is the Lipkus Numeracy scale (Lipkus, Samsa, & Rimer, 2001). A couple of demographic questions regarding participant's age and gender and a self-report of difficulty task were also involved in the experimental procedure. After they had completed the Holt and Laury tasks. They were asked to answer a question about task's level of difficulty. The question about difficulty level was formed as follows: On a scale of 1-5 with one being very easy and five being very difficult, how difficult was this lottery task for you? The participants were asked to answer in a 5-pont Likert scale where one was very easy and five was very difficult.

Procedure The experiment took place at the Faculty of Computer and Engineering at Coventry University and lasted approximately 30 minutes. It was divided into three stages. In the first stage, participants were given the participant information sheet informing them about the study and the informed consent form to sign. After the consent forms were obtained, in the second stage, the participants were given the numerical test and the demographic questions. When these were also collected, in the final stage, the participants were directed to five different rooms. Four rooms had computers where the interactive and non-interactive stimuli were set up. In the fifth room, the standardized Holt and Laury task was set up. The allocation of the participants to the rooms was random. The four rooms with the computer could fit 40 people each and the fifth room was a lecture theatre for 200 students' capacity. Participants were instructed that they would have 20 min to fill in the tasks. The participants were randomly assigned to go into one of the five rooms. Finally, 76 participants filled in the numerical display, 76 completed the pie chart display and 73 the interactive pie chart Holt and Laury task. Hence, Group 1 received the textual Holt and Laury task, Group 2 the Holt and Laury digital task displayed with pie charts and Group 3 received the digital interactive Holt and Laury method. The results are presented in the following section. After the completion of the task, each participant selected a small note from a lottery ball, all notes included numbers except from one that had the letter A and was referring to an Amazon Voucher of £50.

Results According to participants' irrational choices, 35 out of 76 (46%) participants showed an inconsistent behavior in Holt and Laury task numerical format, 27 out of 76 (35.52%) participants in the pie chart format and only 4 out of 73 (5.47%) participants in the interactive pie chart Holt and Laury task format (Figure 4). McNemar's test for related samples was applied between the interactive pie chart and numerical Holt and Laury format, which revealed a significant difference in the inconsistency rates between both display formats, $p < .00$ (Figure 3). McNemar's test for related samples was also applied between interactive pie chart and pie chart Holt and Laury format w hich showed a significant difference between their inconsistency rates, $p < .00$ (Figure 3). McNemar's test for related samples between the pie chart format and the numerical Holt and Laury format showed no significant difference between their inconsistency rates (Figure 3).

Additionally, a binary logistic regression was performed to ascertain whether participants' irrational choices in each display format (numerical, pie chart and interactive pie chart) could be predicted based on their age, gender, the level of their perceived difficulty and numeracy score in the validated scale. For the numerical Holt and Laury format, the binary logistic regression was statistically significant at the .00 level according to the model chi-square statistic suggesting that numerical level (Wald statistic equal to 12.2), difficulty perception (Wald statistic equal to 8.8) and the age (Wald statistic equal to 4.7), were shown to be significant at the .00 level. Hence, they can predict participants' choices in the Holt and Laury numerical task. For the pie chart Holt and Laury, the binary logistic regression showed that the model is not statistical significant, $p < .178$. The binary logistic regression for interactive pie chart Holt and Laury was statistical significant at the level of .025 according to the model chi-square statistic. The coefficient on the perceived difficulty had a Wald statistic equal to 5.42, which is significant at the .02 levels. The rest dependent variables of age, gender and numerical level were not statistically strong predictors of participants' choices in the interactive Holt and Laury format.

Participants took from 4 to 17 minutes to complete the Holt and Laury task using each representation type. The mean time taken to answer the task was 8.7 minutes with the interactive

pie chart, 8.3 using the passive pie chart and 8.5 for the numerical. Even though the mean differences show that using the passive pie chart took them slightly less to fill in compared to the interactive and numerical, there is no significant difference between the times spent in each format.

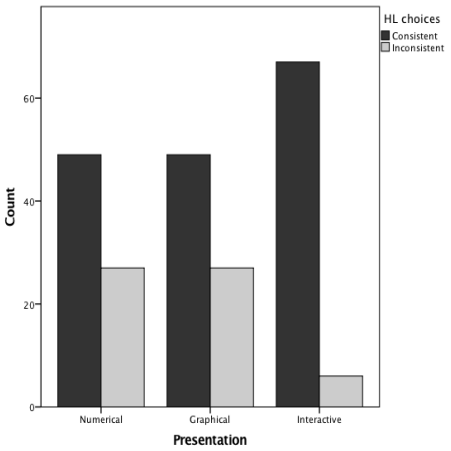

Figure 4. Participants' choices in relation to the presentation method of Holt and Laury.

Discussion

This paper presents the results of two experiments that investigated the methods that would assist in choosing rationally in a risk elicitation task. The findings from the 1st experiment validated empirical evidence that the use of external representations helps participants to understand the lotteries in the risk elicitation task. It also showed that using graphs has greater likelihood of choosing rationally in a risk elicitation task, compared to using images or any other way of external representation, as it has been supported by Hegarty and Kozhnenikov (1999). The study also showed that participants' years of education did not influence their rational decision making. However, as participants were students from the United Kingdom this may not hold true for other cultures or audiences. Even though, it was found that there were no disparities between Groups 1 and Groups 2 with substantially dissimilar educational levels, this may not be true for educational levels defined in qualitatively different ways from other participants, or contexts.

Pie charts were shown to be better suited as they are better known from the general public and easily comprehensible to compare the size of two proportions when they are accompanied by labels (Nelson, Hesse, & Croyle, 2009). A step further though was demarcated in terms of asking participants to draw the pie charts themselves according to the label of probability along with the payoff displayed on the task, to test whether using external representation of pie charts would help them reason rationally. This outcome confirms the findings suggesting using graphs as external representation to facilitate successful probability problem solving (Hegarty, & Kozhevnikov, 1999) and thus rational choices in the Holt and Laury task. In the 2nd experiment, it was shown that participants who scored low in the numeracy scale chose more rationally in the Holt and Laury task when interacted with pie charts than any other format, confirming the need for a visual reasoning process to assist problem solvers (Carlsson, Johansson-Stenman, & Martinsson, 2004; Brase 2009). The interactive pie chart format was filled in rationally from those that scored high and low on the numeracy scale, as it was indicated by the low consistency rate in the task (6.8%). This has a significant implication for future implementations of the task. This rational choice is linked to a meaningful contribution to the task for three main reasons. First, the task could be used by people with low numerical skills and reflect their accurate risk preferences. Second, when assessing population with specific characteristics to predict risk-taking behaviour in similar investment choices, participants' choices in the task would be accurately predicted. Third, there would be less noise in the data and there would be less cases (if any) that data would be excluded from the analysis. However, a point that should be considered is that as the individuals are guided to answer consistently, the more consistent their answers the more variance would tend towards zero, thus the validity of the metric might be affected. Therefore, for future studies the validity of the metric needs to be examined and reassured. As this approach was only examined with UK University students, there is a limitation on generalizing to other cultures and audiences. Deploying a qualitative approach in conjunction to the quantitative methodology would enable to investigate more in depth on the underlying factors of why interacting with pie charts help people to understand the lotteries better. Finally, even though the average time spent in each display format of the task did not show any significant differences, future studies, need to explore whether using graphs to reason the choices in the Holt and Laury task, force the individuals with impulsive cognitive style to reflect more on their choices and aid their decision making.

This interactivity with graphs where participants could engage with filling in the proportions of lotteries with one click and then choose the option for the task they would prefer, automatically simplifies the task for less numerate people and allows for employing digital mediums, such as mobiles, for experimentation outside of laboratory settings. The data supports the hypothesis that the use of interactive pie charts, is more likely to result in consistent choices. This outcome may extend to other interactive artefacts such as games, simulations or analytics software, for crowdsourcing data for cognitive science of specific groups' (e.g. farmers) outside of the laboratory.

Abstract

We propose a unified explanation of contrastive and assimilative adaptation aftereffects from the perspective of higher-level cognitive processes: rational category learning and categorical perception. We replicate (twice) previously reported assimilative and contrastive effects (Uznadze illusion in visual modality), propose a rational computational model of the process, and evaluate our model performance against the Bayesian logistic regression baseline. We conclude by discussing theoretical implications of our study and directions for further research.

Keywords: adaptation aftereffects, perceptual biases, set illusion, Uznadze illusion, computational modeling, categorical perception

Introduction and Background

In many experimental settings, repeated exposure to stimuli affects the perception of subsequent ones. These phenomena are often referred to as the aftereffects of adaptation (Gibson & Radner, 1937). For example, if a participant is repeatedly presented with two circles, one bigger than another, she might perceive equal circles as being different during the test trial (Figure 1). Similar effects are manifest across a wide range of experimental conditions, in different modalities, and on different levels of abstraction. Behavioral studies demonstrate adaptation aftereffects in situations that run the gamut from simple shape and motion perception under brief presentation (Suzuki & Cavanagh, 1998; Chalk et al., 2010) to perception and recognition of faces, facial expressions, gender, and race (Webster & MacLeod, 2011; Leopold et al., 2001).

Contrastive and assimilative effects

It is possible to split all known adaptation aftereffects into two broad categories: **contrastive** and **assimilative** (Howard & Rogers, 1995). Contrastive aftereffects take place when the test stimulus seems more **different** from those seen during the adaptation phase (adaptors) than it would be perceived under normal conditions. Assimilative aftereffects, in turn, produce a reversed effect: the test stimulus is perceived as being more **similar** to adaptors. There is evidence that these two types of effects could occur in very similar and even identical experimental settings (Uznadze, 1958; Fritsche et al., 2017; Chopin & Mamassian, 2012). This raises a question: **what determines whether a contrastive or assimilative aftereffect will be present in a given trial**?

A broadly accepted view is that the probability of contrastive aftereffects occurrence grows with increasing difference between the test stimuli and the adaptors, increased length of adaptor presentation, as well as with the increase of overall stimuli salience and contrast (Howard & Rogers, 1995; Palumbo et al., 2017; Fritsche et al., 2017; Chopin & Mamassian, 2012).

Finding a mechanism that would explain the onset of both types of adaptation aftereffects turned out to be challenging. Previously dominant framework of adaptation as neural fatigue proved unsuccessful in accounting for the wide range of observed phenomena (Thompson & Burr, 2009). Recent studies predominantly focused on uncovering the mechanisms of a particular type of aftereffect: either contrastive (Webster & MacLeod, 2011; Rhodes & Jeffery, 2006; Grill-Spector et al., 2006; Stocker & Simoncelli, 2006; Chopin & Mamassian, 2012) or assimilative (Chalk et al., 2010; Palumbo et al., 2017).

There are, however, models that propose potential mechanisms of both contrastive and assimilative effects in visual (Wei & Stocker, 2015) and audial (Kleinschmidt & Jaeger, 2011) modalities. Wei and Stocker (2015) explained the opposite perceptual biases as a result of efficient coding constraints in a rational observer framework. Unfortunately, this model falls short in accounting for the influence of the difference between the test stimulus and the adaptors on illusion type (it predicts that this factor has no impact). At the same time, similar aftereffects in phonetic adaptation were modeled as Bayesian belief updating over two competing phonetic categories (Kleinschmidt & Jaeger, 2011). The limitation of this model is that it is designed for the task of forced choice between two categories that are given in advance. In most real-world and experimental adaptation scenarios, however, the alternative categories are implicit.

Overall, none of the existing models provide a complete account of the existing phenomena, which warrants further research in this direction.

Adaptation aftereffects and categorization

We propose a high-level interpretation of adaptation biases from a categorization standpoint. We argue that during the adaptation phase a person forms the categories of "typical" and "other" (atypical) stimuli. Learning is formalized using the ideal observer approach. The structure of the "typi-

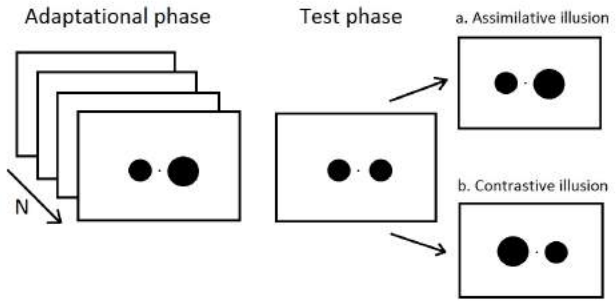

Figure 1: Uznadze visual illusion experimental procedure
During the adaptation phase, a subject is repeatedly exposed to two circles, one being bigger than another. On the test trial, two equal circles are presented, and the subject responds whether they appear **the same (no illusion)** or, if not, which one appears bigger (**contrastive** or **assimilative** illusion).

cal" category is estimated from observed adaptors, while the "other" category is determined through its relationship to the already learned one. The main assumption is that an observer expects different visual categories to lie relatively far from each other in the feature space. On the test phase, the observer reconstructs the most likely true stimulus, given the learned category structure and the noisy sensory observation.

There is some evidence that provides conceptual support for our approach. First, in the domain of category learning, there is a notion of **categorical perception** which refers to phenomena whereby the same stimuli seem more different or similar, depending on whether they belong to the same or different categories in the learned conceptual structure (Goldstone, 1994, 1995; Goldstone & Hendrickson, 2010; Kuhl & Iverson, 1995). Second, in the domains of color and speech perception, perceptual bias toward the category prototype was formalized as an optimal statistical inference of real stimulus in high uncertainty conditions (Feldman et al., 2009; Cibelli et al., 2016). These perceptual shifts resemble the assimilative aftereffects. Third, a similar idea was successfully applied earlier in the domain of face perception: it was shown that the contrastive aftereffects are directed precisely toward the anti-prototype of the seen examples (Leopold et al., 2001, 2005; Rhodes & Jeffery, 2006). Assimilative aftereffects were not, however, considered in these studies.

Overall, there is evidence that category attribution plays an important role in perception. Although visual adaptation is most commonly viewed as a low-level process, current low-level models may not be able to fully capture the broad spectrum of visual adaptation aftereffects and their dynamics (Leopold et al., 2005) and are hardly compatible with interocular transfer of adaptation biases (Raymond, 1993). We believe that the difficulties encountered by low-level explanations, together with the successes of categorical perception models, warrant considering alternative, high-level explanations of perceptual aftereffects.

Our model builds upon the previous results and provides a simple and unified interpretation of both assimilative and contrastive aftereffects from a categorical perception standpoint.

To test our interpretation, we use a visual version of the Uznadze illusion (Figure 1). We replicate previously reported results on the association between the probabilities of opposite illusions with the length of the adaptation phase and the difference between the adaptation stimuli (Uznadze, 1958, 1966). After that, we evaluate the performance of our model on these data.

Experiment 1

This experiment replicated the findings reported in Uznadze (1958, 1966).

Hypothesis: Difference between the adaptors and the test stimulus, together with the number of adaptation trials, determine the probability of assimilative vs contrastive aftereffect occurrence. In particular, the assimilative aftereffect is associated with lower differences between stimuli sizes and smaller numbers of adaptation trials, while the contrastive aftereffect onset probabilities follow a reversed pattern.

Procedure

Pairs of circles of different sizes were presented as adaptors. We varied the magnitude of difference between adaptation stimuli (from 1 to 3 individual differential thresholds) and the number of adaptation trials (from 1 to 8) to evaluate their effect on the probabilities of assimilative and contrastive illusions. The procedure is illustrated in 1.

1. **Estimation of individual differential thresholds.** Two circles (diameters: left 2.5cm, right 2.5 or 3.0cm) were presented to participants. They were asked to focus on the dot in the center of the screen. We estimated participants' differential thresholds by the method of adjustment (Gescheider, 1997). That is, subjects saw two different circles and altered the size of one of them until the circles appeared equal to each other. In the second condition, the circles were initially the same and subjects made them different. We repeated this procedure six times and averaged the results to obtain the differential threshold estimate.

2. **Adaptation phase.** Subjects focused at a central dot on the screen, while they were exposed to two circles (for 150 ms) several (1-8) times. The difference in size between the two circles was 1, 2 or 3 individual differential thresholds.

3. **Test phase.** Participants saw two equal circles for 150ms and reported whether they appeared the same. If there was a perceived difference, participants identified which of the two appeared larger. They were instructed to respond as fast as possible and to rely only on their sensations. The test trial was repeated until the "same" relationship was reported 3 times in a row. This ensured that the aftereffect has faded before the start of the next trial. We did not analyze

the fading dynamics and only used the first test response in further analysis.

This procedure was repeated 24 times for every participant using all the combinations of experimental conditions. The order of conditions was randomized.

4. **Post-experimental interview.** Participants shared their experience and strategy. The results of this stage were used to check whether subjects responded purely based on what they saw (as opposed to realizing that they experience an illusion and correcting their answers).

Experiment was programmed and presented using PsychoPy software package (Peirce, 2007).

Participants

The initial sample consisted of 30 adult participants. Data from 4 participants were excluded after the post-experimental interview: they figured out that test circles are always equal, and based their answers on this assumption, not on their actual perception. This results in a final sample of 26 participants (11 male, 15 female) aged from 18 to 47 years (mean age: 22.27, sd: 5.65). All had normal or fully corrected vision.

Experiment 2

The second experiment investigated how robust are the observed regularities. In particular, whether it is necessary to account for individual differential thresholds.

Procedure

Experiment 2 replicates Experiment 1 with one qualitative change: the difference between adaptation circles varies in **absolute units**, not in individual differential thresholds. Therefore, there is no stage of differential threshold estimation. The left circle again has the diameter of 2.5cm, and the diameter of the right circle is 0.1, 0.2, 0.3, 0.4, or 0.5cm bigger. The number of adaptation trials varies from 1 to 6. The conditions are randomized.

Participants

Initial sample consisted of 55 adults. 5 adults were excluded from subsequent analyses, because they figured out that test circles are always equal and based their responses on this assumption. This results in a final sample of 50 participants (22 male, 28 female) aged from 18 to 34 years (mean age: 22.91, sd: 3.47). All of them had normal or fully corrected vision. The sample was divided into two groups based on the results of post-experimental interview:

1. **Naive (35 adults).** These participants did not realize that test circles are always equal.

2. **Non-naive (15 adults).** These participants realized that test circles are always equal, but followed the instruction and tried to base their responses only on their sensations.

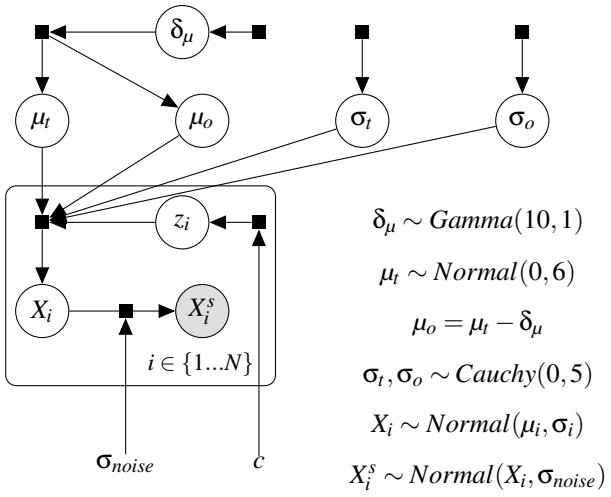

Figure 2: Graphical model

Variables: X_i - real stimulus; X_i^s - perceived stimulus (after adding perceptual noise); z_i - indicator variable for the class from which a real stumulus was generated (distributed according to the Chinese Restaurant Process); μ_t and σ_t - μ and σ of the typical class; μ_o and σ_o - μ and σ of another (unobserved) class; δ_μ - the expected difference between two classes; c - coupling probability for CRP; σ_{noise} - perceptual noise.

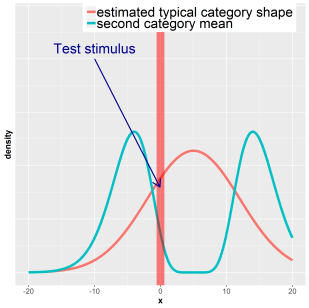
Computational Model

We formalize the process of adaptation as rational acquisition of the "typical" and "other" stimuli categories. Perception is modeled as an optimal probabilistic inference over the true stimulus parameters given the learned category structure and the noisy sensory input. Graphical model is presented on Figure 2.

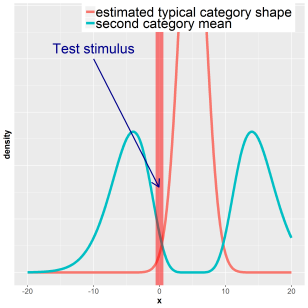
1. **Category learning**. Category learning during the adaptation phase is modeled as Bayesian inference of the "typical" category structure. Stimuli in our experiment could be aligned along one relevant dimension (the magnitude of difference between two circles) so we formalize a category as a univariate normal distribution in this dimension. An observer assumes that the true stimuli come from a normal distribution with a mean difference between two circles μ and a standard deviation σ. These are the parameters she estimates to represent a category. Priors on the category's μ and σ are chosen arbitrarily and are set to be relatively diffuse (given the scale of our feature): $\mu \sim normal(0,6)$ and $\sigma \sim cauchy(0,5)$. These parameters are estimated purely from the adaptive stimuli for every particular experimental trial. The adaptive stimuli, in turn, are randomly generated from a normal distribution where μ is the difference between adaptional stimuli in a given condition, and σ_{noise} is some random perceptual noise. We used 0.2 as a noise in final model evaluation, however, we also checked that changing this number does not influence the results. At the end of this stage, the observer has estimations of μ and σ

of the category.

2. **Representation of the unknown category**. The key assumption of a rational observer in our model is that the **centers of two categories are more likely to be relatively distant from each other** than to be close (Figure 3). It is formulated by adding a new parameter: *difference between category prototypes* δ_μ with a prior $Gamma(10,1)$ (modeling the opposite symmetric tail is not necessary in this case, as its likelihood is always practically zero on the test trial). Then, the estimation of the "other" category's mean (μ_o) for each experimental condition is simply $\hat{\mu}_t - \delta_\mu$. Hence, the prior assumptions on the structure of the unknown category are shifted outward from the learned one. Thus, the prior on μ_o is completely defined by an estimated μ of the typical stimuli and the assumption on the difference between categories.



(a) After a small number of trials, there is still a lot of variation in the estimated typical distribution shape. The noisy test stimulus is attributed to the typical category with higher probability and thus the reconstructed true stimulus is shifted towards the "typical" category prototype.



(b) After more trials, the estimated typical distribution shrinks, thus making the attribution to the typical category unlikely. Thus the reconstructed source of the noisy stimulus is shifted towards the closest peak of the "other" category.

3. **Test phase**. Perception of the test stimulus is determined by the decision of what category ("typical" or "other") is more likely to have generated it. Conditional probabilities of the categories are calculated using Bayes' rule (where z_i is a variable indicating category membership):

$$P(z_i = j|X_i^s) = \frac{f(X_i^s|z_i = j)\cdot P(z_i = j)}{f(X_i^s)} = \\ = \frac{f(X_i^s|z_i = j)\cdot P(z_i = j)}{\sum_{j=1}^{\#cat} f(X_i^s|z_i = j)\cdot P(z_i = j)} \quad (1)$$

Likelihoods of the test stimulus for both categories are taken from the corresponding estimated normal probability density functions. The priors on whether a new stimulus is coming from the known or a new category are estimated using the Chinese Restaurant Process (Anderson, 1991; Navarro & Kemp, 2017). Thus, the prior probability that a new stimulus is generated from the "typical" category is

$$P(z_{n+1} = typical) = \frac{c\cdot n}{1-c+c\cdot n} \quad (2)$$

where c is a probability that two observation come from the same category (the coupling probability) and n is a number of adaptation trials. The prior probability that a new stimulus comes from an unknown category is

$$P(z_{n+1} = other) = \frac{1-c}{1-c+c\cdot n} \quad (3)$$

To efficiently reconstruct a real stimulus, perception is shifted toward the probability density of its category. Due to the aforementioned inference bias, the "atypical" and "typical" category densities are shifted in opposite directions. Thus, assimilative illusion onset is formalized as *Bernoulli* random variable with $p = P(typical|test)$, and the contrastive - as *Bernoulli* r.v. with $p = P(other|test)$ respectively.

Model fits 3 parameters: c (coupling probability), δ_μ (difference between prototypes of two categories), and σ (standard deviation of the "other" category).

Bayesian modeling for the paper was implemented using Stan probabilistic language (Carpenter et al., 2017).

Results

Experiment 1

Assimilative aftereffect appeared 103 times (17%), contrastive - 153 times (25%). Notably, more than 50% of the data consisted of the reports of stimuli equality, which correspond to no illusion registered. "No illusion" instances were excluded from the analysis. We applied mixed effects logistic regression and Bayesian mixed effects logistic regression (with non-informative priors). We used the difference between adaptation circles and the number of adaptation trials as predictors, and the illusion type (contrastive (1) vs assimilative (0)) as the outcome variable. This model can be expressed using the following formula:

illusion type $\sim$ number of adaptation trials + difference between stimuli sizes + (1|participant)

The ANOVA comparison with a zero model was significant ($p < .001$), as well as the tests for both individual coefficients: number of adaptation trials ($p < .001$, $est. = .133$, $sd = .036$, $BF_{10} = 2.5$) and difference between stimuli' sizes ($p < .001$, $est. = .365$, $sd = .108$, $BF_{10} = 56.3$). Both estimates are positive, in line with the the initial hypotheses.

Experiment 2

Assimilative aftereffect appeared 164 times (11%), contrastive - 402 times (28%). To analyse these data, we applied the same frequentist and Bayesian mixed effects models to the three (all, naive, and non-naive) groups separately.

1. For the whole sample, the difference between adaptation circles and the number of adaptation trials are significant predictors with $p < .001$ ($est. = .537$, $sd = .093$, $BF_{10} = 47995.7$) and $p < .05$ ($est. = .171$, $sd = .07$, $BF_{10} = 4.8$) respectively.

Table 1: Performance of Cognitive Model and Bayesian Logistic Regression.

Standard deviations are indicated in parentheses.

	Measure	Bayesian LR	Cognitive Model
Experiment 1: assimilative	Recall	0.296 (0.086)	**0.577** (0.082)
	Precision	0.521 (0.12)	**0.522** (0.034)
Experiment 1: contrastive	Recall	**0.817** (0.065)	0.65 (0.056)
	Precision	0.637 (0.018)	**0.701** (0.032)
Experiment 2: assimilative	Recall	0.057 (0.0049)	**0.293** (0.057)
	Precision	0.378 (0.228)	**0.426** (0.044)
Experiment 2: contrastive	Recall	**0.97** (0.03)	0.845 (0.032)
	Precision	0.73 (0.006)	**0.754** (0.012)

2. For the group of naive participants, the difference between adaptation circles is a statistically significant predictor ($p < .01$, $est. = .489$, $sd = .163$, $BF_{10} = 215.5$). The number of adaptation trials is not significant ($p > .05$, $est. = .105$, $sd = .9$, $BF_{10} = 0.5$).

3. For the non-naive participants, both predictors are statistically significant: the number of adaptation trials ($p < .05$, $est. = 1.21$, $sd = .523$, $BF_{10} = 23.8$) and the difference between stimuli sizes ($p < .001$, $est. = .518$, $sd = .151$, $BF_{10} = 254.6$).

The subsequent ANOVA model test (frequentist) was significant ($p < .05$) for all groups. All the estimates are positive, in line with the initial hypotheses.

Model Evaluation

We compared our cognitive model against the Bayesian logistic regression baseline:

$$\textit{illusion type} \sim \textit{number of adaptation trials} + \textit{difference between stimuli sizes}$$

Both the regression and the cognitive model have 3 parameters. Bayesian logistic regression was chosen as a baseline, since it is a very successful descriptive model with the same amount of parameters. In particular, it outperforms a frequentist logistic regression for our data.

The cognitive model fits the whole dataset better than the baseline logistic regression models, but this does not guarantee that the cognitive model would demonstrate better performance on the out-of-sample data as well. Therefore, we used random subsample cross-validation in order to evaluate and compare the **generalization** performance of the models.

1. The data were randomly split into two subsets: train (50% of assimilative data, 50% of contrastive data) and test (remaining 50% of assimilative and 50% of contrastive data)

2. Parameters of the models were estimated on the training set

3. The performance measures (precision and recall) were calculated for models' predictions for the upheld test subset.

We repeated the above steps 50 times and calculated mean precision and recall measures for both assimilative and contrastive classes, along with their standard deviations. The results are shown in the Table 1.

Evaluation metrics: **Precision** and **Recall** measures allow us to compare models based on their sensitivity and accuracy for both classes. **Recall** shows the proportion of the target class occurrences that were accurately predicted. **Precision** shows the proportion of the target class occurrences among the predictions of that class.

The cognitive model repeats the main regularities found in both experiments. In particular, it predicts assimilative illusion more frequently for the smaller differences between adaptive stimuli and number of trials, while the predictions of contrastive illusion follow the reverse pattern. Importantly, the logistic regression does not yield these types of regularities when it predicts assimilative illusion.

The estimates of the "other" category center were always negative, which corresponds to the **contrastive** shifts in perception.

Discussion

Replication

We replicated the results reported in Uznadze (1958, 1966). The difference between adaptation stimuli sizes was a significant predictor of the aftereffect type in all collected datasets. The number of adaptational trials was not a significant predictor for naive participants in the second experiment, but it was significant in the remaining datasets. The signs of all the coefficients were consistent with the initial hypotheses. The effect proved robust to the scale of the differences between stimuli, and overall, Experiments 1 and 2 yielded similar results.

We view this replication as an important impact of our paper. The works of Uznadze are predominantly focused on the study of "set", or "set illusions", which denote the same group of phenomena as perceptual aftereffects. He performed extensive studies of these effects in visual, auditory and haptic modalities (Uznadze, 1966). Nevertheless, although the so-called "Uznadze illusion" (perceptual aftereffect in haptic modality) received some attention (Janzen et al., 1976;

Wohlwill, 1960), most of his contributions remain untranslated and almost entirely unknown to the scientific community outside the post-Soviet space. We find, however, that some of his findings are still relevant and could lead to a better understanding of perceptual aftereffects. We hope that our results would encourage further use of Uznadze visual illusion in the studies of perceptual adaptation aftereffects.

Modeling

The proposed cognitive model performs better than Bayesian logistic regression, which makes it a useful baseline for further research. In particular, it is sensitive to both types of aftereffect and yields more accurate predictions within these categories.

More importantly, our model provides a simple and unified interpretation of seemingly disparate phenomena of assimilative and contrastive aftereffects. This explanation is based on the principles of rational analysis and an intuitive assumption about the category structure inductive bias (different categories have non-coinciding centroids). Thus, our model shows that the apparently low-level perceptual aftereffects may be explained from the logic of higher-level cognitive processes, such as categorization. Moreover, it allows us to view the role of adaptation aftereffects in perception from a new angle: we demonstrate that they may serve as an important part of an optimal stimuli reconstruction process, as opposed to being an artifact or an epiphenomenon.

Future directions

Our model is based on the high-level logic of perception and is not bound to specific low-level mechanisms. This greatly broadens the scope of its potential applications.

Firstly, there is a number of promising extensions of our model **within the domain of adaptation aftereffects**:

- The model could be extended to account for the cases of **illusion absence** (this could be done by incorporating individual perceptual differential thresholds). Since the "no illusion" case is very common in our data, this would make our account of the perceptual aftereffect phenomenon much more complete.

- The model can be scaled to higher dimensions by using a multivariate normal distribution for category representation. This makes it a good candidate for describing perception of high-dimensional realistic objects, such as faces. In case of success, such a unified explanation of higher- and lower-level perceptual processes may contribute to the ongoing debate about the role and even mere presence of top-down effects in perception (Firestone & Scholl, 2016).

Secondly, our model may be broadly applicable **outside of the domain of visual perceptual adaptation**:

- There is a number of well-known spatial context effects in the visual modality (demonstrated by Delboeuf, Ebbinghaus, and Müller–Lyer illusions, among many others (Goto et al., 2007)). The patterns of contrastive and assimilative bias onsets in this domain are very similar to the temporal illusion we studied in this paper (Goto et al., 2007) and may be interpreted in an analogous fashion.

- Our proposed rational categorical perception model could account for **enhanced discriminability** and **perceptual tuning** effects resulting from long-term adaptation. Chinese Restaurant Process used in our model allows to optimally refine the learned category structure as a number of seen examples grows. Shifting percepts towards the true category will be more and more beneficial as the category structure is updated and refined.

Overall, the proposed model has a high promise in demonstrating the role of category learning in perception. While the potential importance of categorical perception has been studied before (e.g. Kuhl & Iverson (1995)), such studies focus on situations when the category structure is known in advance. Our results suggest that assuming that a person always tries to group stimuli into categories (even in the short-term experiments where no obvious categories are apparent) can greatly broaden the scope of this approach and provide a unified explanation to a wide range of perceptual effects.

To facilitate further research, we make all the data, analyses, and code openly available [1].

Modeling socioeconomic effects on the development of brain and behavior

Abstract

We used a population-level connectionist model of cognitive development to unify a range of empirical findings on the influence of socioeconomic status (SES) on behavior and brain development. The model captured qualitative patterns of *development* in behavior and brain structure, including reductions in connectivity across development (gray matter, cortical thickness) as behavioral accuracy increases. *Individual differences* in SES were implemented by altering the level of stimulation available in the environment. At the brain level, the model simulated non-linear effects of SES on cortical surface area (Noble et al., 2015), and faster cortical thinning across development in children from lower SES backgrounds (Piccolo et al., 2016). At the behavioral level, the model simulated the effect of SES on IQ, whereby gaps are observed to widen across development (von Stumm & Plomin, 2015). The model's main shortcoming was insufficient growth in connection magnitude across development in lower SES groups, implying that some aspects of the growth of connection strengths may be maturational (e.g., myelination) rather than experience dependent.

Keywords: socioeconomic status, brain, behavior, connectionist networks, multi-scale models, population modeling

Introduction

Differences in socioeconomic status (SES) have marked effects on cognitive development (Farah et al., 2006). These effects are not uniform across all areas of cognition and are stronger in the development of language and cognitive control (executive functions), where lower scores are observed in children from lower SES families. SES effects have been observed on intelligence (IQ) and indeed, it has been reported that gaps between children widen across development (von Stumm & Plomin, 2015; see Figure 1). SES refers to a marker for multiple potential causal pathways acting on cognitive development, among them effects on prenatal brain development, post-natal nurturing, and post-natal cognitive stimulation (Farah, 2017; Hackman, Farah & Meaney, 2017).

Recent work in neuroscience has focused on the impact of SES on measures of brain structure, demonstrating that cortical surface area and cortical thickness in children and adolescents show small but reliable associations with differences in family income and parental education; in some cases, associations have been observed between SES and the size of particular brain structures, such as the hippocampus and amygdala (e.g., Noble et al., 2015). Although small in size, these effects can be non-linear: for example, while lower SES is linked with reduced cortical surface area, the impact is larger for the lowest SES groups (Figure 2). Moreover, effects on brain structure are strongest in areas linked with language (temporal) and executive functions (prefrontal); and measures of cortical surface area (but not thickness) have been shown to mediate the relationship between SES and behavior (Noble et al., 2015). SES can be seen to influence the *rate of change* of brain structure over development. The cortex usually thins from mid-childhood onwards. In children from low SES backgrounds, thinning was observed to be faster. Piccolo et al. (2016) found that while cortical thickness showed no main effect of SES, it thinned more quickly in lower SES children; conversely, cortical surface area was reduced in the lower SES children, but showed similar rates of change across SES groups. Neuroscience data, then, confirm the impact of SES, but do they point to the causal pathways by which it operates?

Two challenges present themselves. First, we need a mechanistic account to explain how environmental influences produce linked effects on brain and behavior, which would provide a basis to evaluate competing accounts about causal pathways. Second, any putative causal explanation of SES effects must accommodate a range of other empirical phenomena: on developmental changes in brain structure, on the relationship between cognitive ability and various measures of brain structure, and on the origin of individual differences. The main qualitative patterns that must be captured are as follows.

First, although behavioral accuracy typically increases across development, this is not the case for all measures of brain structure: some measures increase (white matter volume, cortical surface area) but others decrease following a peak in early or mid childhood (gray matter volume, cortical thickness) (e.g., Giedd et al., 1999; Sowell et al., 2004). The mechanisms that drive these changes are still debated, but include myelination and pruning of local connectivity (synapses, dendrites, axons), but not generation or loss of neurons.

Second, although environmental measures such as SES predict individual differences, a large proportion of variance in cognitive ability, brain structure, and change in brain structure across development is predicted by the genetic similarity between people – that is, these phenotypes are

highly heritable (Plomin et al., 2013). Heritability may be modulated by SES: it has been observed that in individuals from low SES backgrounds, the heritability of IQ can be reduced (e.g., Tucker-Drob & Bates, 2016).

Third, brain structure is correlated with intellectual ability, with one meta-analysis showing correlations of 0.1-0.3 between brain volume and IQ (McDaniel, 2005). Ritchie et al. (2015) found that brain volume explained 12% of the variance in general cognitive ability, cortical thickness another 5%, and all structural measures together up to 21% of the variance. These individual differences data imply that having more neural resources is better for cognition. IQ is also related to the rate of thinning of the cortex with age (Shaw et al., 2006). Higher IQ is associated with faster thickening of cortex across early childhood, and then faster thinning of cortex from mid-childhood onwards. Since cognition improves as gray matter reduces, the developmental data imply that having fewer neural resources is better for cognition. This inconsistency is rendered more puzzling by the observation that faster thinning of the cortex is linked with lower SES (Piccolo et al., 2016). Lower SES is associated with lower IQ (von Stumm & Plomin, 2015). How can higher IQ and lower SES both be linked to faster thinning of cortex, when higher IQ is itself associated with higher SES? This complex set of effects is summarized in Table 1.

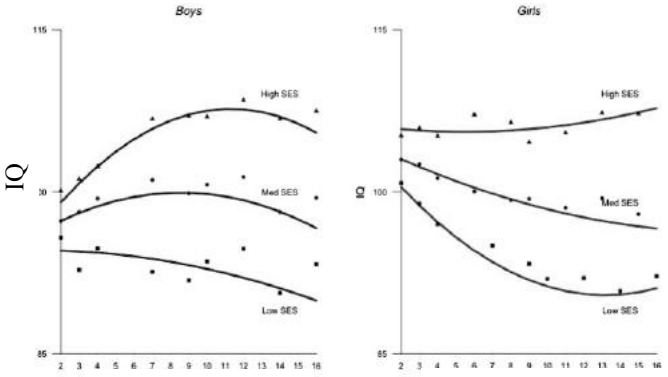

Figure 1: SES gaps in intelligence widen across development (von Stumm & Plomin, 2015)

In the current work, we use a multi-scale model to try and unify this complex pattern of data. The model is based on an artificial neural network (ANN) trained with backpropagation. In a multi-scale model, constrains are included at several levels of description (Thomas, Forrester & Ronald, 2016). Crucially, because the data concern both development and individual differences, it is necessary to simulate a population of individuals, and to model the influences on development that produce individual differences. Because the data span behavior, brain, SES, and genetics, the model must have analogues of each of these in its design.

In connectionist models of cognitive development, abstract principles of neurocomputation are embodied in systems whose activation states correspond to concepts and whose inputs and outputs can be linked to behavior (see, e.g., Thomas & McClelland, 2008). Thomas (2016) argued

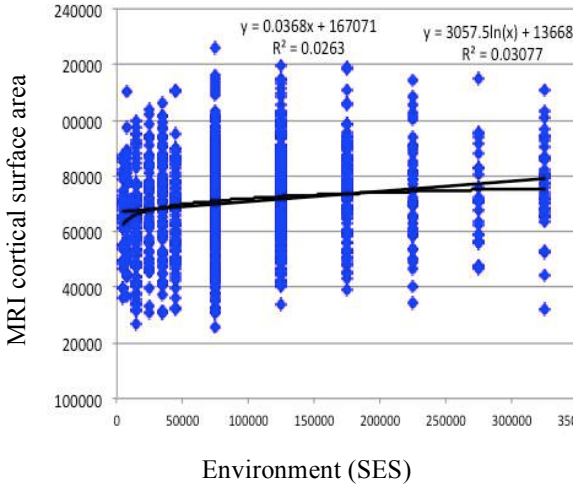

Figure 2: The link between cortical surface area and family income (data re-plotted from Noble et al., 2015).

Table 1: List of empirical phenomena to be simulated

1.	Behavioral accuracy increases across development
2.	Some measures of brain structure increase across development (white matter, cortical surface area)
3.	Some measures of brain structure reduce across development (gray matter, cortical thickness)
4.	Lower SES is associated with lower IQ and gaps widen across development
5.	Lower SES is associated with reduced cortical surface area, with larger effects at lowest SES levels
6.	Lower SES is associated with faster thinning of the cortex over development
7.	Lower SES is associated with reduced cortical surface area but no modulation of rate of development
8.	Cortical surface area partially mediates the relationship between SES and behavior
9.	Individual differences in behavior and brain structure are highly heritable
10.	Low SES can reduce the heritability of IQ
11.	Brain volume correlates with IQ
12.	Across development, higher IQ is associated with faster thickening and then faster thinning of the cortex

that with a simple addition – the onset of pruning of unused connectivity after a certain point in training – these models could give plausible analogues to measures of brain structure, where the total number of connections would serve as an analogue to properties that decrease over development (gray matter, cortical thickness) – under the view that unused connections are pruned away, causing a

loss of volume; and the combined magnitude of connection weights (excitatory and inhibitory) would serve as an analogue of properties showing increases (white matter, cortical surface area) – under the view that retained connections are optimized through myelination, causing an increase in volume. We use the same scheme here.

To capture genetic influences on behavior and structure, each network must have a genome and genomes must vary between individuals. To the extent that cognition is seen as information processing in the brain, genetic effects must translate to influences on neurocomputational properties. Accordingly, Thomas et al. (2016) used a method to simulate individual differences where the neurocomputational parameters of an ANN (e.g., number of hidden units, learning rate) were encoded in an artificial genome. Genetic variation produced parameter variation. In behavior genetics, the heritability of a phenotype such as behavior or brain structure is usually assessed using the twin design, where more heritable phenotypes show greater similarity between monozygotic (MZ) twins than dizygotic (DZ) twins. MZ twin networks can be simulated by networks with the same genome (and therefore, parameters), while DZ twins can be simulated by networks that share on average 50% of the gene variants in their genomes (see Thomas et al., 2016, for further details). Heritability of behavior and brain structure can then be simulated by comparing the respective correlations between MZ networks versus DZ networks.

SES can plausibly be implemented in several ways (Thomas, Forrester & Ronald, 2013): it might influence how a network is constructed (equivalent to prenatal effects on brain development); it might influence the information on which the network is trained (equivalent to differences in levels of cognitive stimulation during post-natal development); or it might influence both factors. In the following simulations, we evaluated a model that implemented SES as differences in the richness of the training set.

An ANN trained with backpropagation has very limited biological plausibility. We should therefore be clear what are our key assumptions in relating measures of network structure to measures of brain structure. They are as follows: (1) neuron number is fixed so that changes in structure reflect changes in connectivity; (2) structural measures that increase over development (cortical surface area, white matter) reflect increases in connection strength, while structural measures that decrease over development (cortical thickness, grey matter) reflect reductions in connection number; (3) connection strength increases can only be experience dependent; (4) connection strength decreases can be experience dependent (training reduces some connections), intrinsic (weight decay), or both (an intrinsic pruning process operates depending on connection strengths which in turn are influenced by experience); (5) connection number is intrinsic (growth) or an interaction with experience (pruning); (6) we did not include an assumption that connection growth might be partly experience / environment dependent, nor that there might be intrinsic contributions to connection strengthening (e.g., myelination occurring through maturation).

The adequacy of the model in capturing the patterns of empirical data will serve as a test of these assumptions.

Method

The following simulations use a base model taken from the field of language development, addressed to the domain of English past-tense formation. Here, the model was employed in an illustrative setting, intended only as an example of a developmental system applied to the problem of extracting the latent structure of a cognitive domain through exposure to a variable training environment. The intention was to capture qualitative characteristics of the empirical data rather than to exactly calibrate variances from genetic and environmental sources to fit empirically observed estimates of heritability in certain populations. In that capacity, the past tense accuracy of the networks was taken as a metric of behavioral development, and of intelligent behavior more widely (that is, of the type measured by cognitive ability tests). However, the base model has been used to specifically simulate data on the influence of SES on children's past-tense acquisition (Thomas et al., 2013). Full details of the current simulation can be found in Thomas (2016).

Network architecture: The basic model was a 3-layer backpropagation network, with 57 input and 62 outputs. The process of network growth was not modeled, only the outcome of this process. The number and size of initial connections was influenced by several factors, including number of weight layers, sparseness of connectivity, and range of initial random variation. Connection pruning occurred after a specified training epoch, and removed any connections below a specified threshold with a specified probability. Each of these three parameters was free to vary between individuals. Pruning onset varied between 0 epochs and 1000 epochs, where 1000 epochs was full lifetime (median value 100 epochs); pruning threshold varied between a magnitude of 0.1 and 1.5 (median 0.5); pruning probability varied between 0 and 1 (median 0.05) per pattern presentation. Overall, fourteen neurocomputational parameters were free to vary between individuals. These were: the architecture (fully connected or three-layer), number of hidden units, sparseness of connectivity, sigmoid activation function temperature, activation noise added to unit net inputs, nearest neighbor output threshold, learning rate, backpropagation error measure (root mean square or cross entropy), momentum, initial weight variance, weight decay, pruning onset epoch, pruning threshold, and pruning probability (see Thomas, 2016, for parameter specifications, and range of values, for the GWEW condition).

Training set: The training set comprised 508 artificial monosyllabic verbs, constructed using consonant–vowel templates and the phoneme set of English. Phonemes were represented over 19 binary articulatory features. The verbs conformed to the past-tense patterns observed in English,

with 410 regular verbs (forming the past tense via the *+ed* rule) and 98 irregular verbs of three types, no-change, vowel-change, and arbitrary (see Thomas et al., 2016, for more details). Training used pattern presentation in random order without replacement.

Implementation of SES differences: Each simulated child was raised in a family with a given level of language stimulation, taken to be correlated to the family's SES (Hart & Risley, 1995). A family quotient parameter was sampled uniformly between the range 0 and 1. This proportion was applied as a one-time filter on the full training set. A network raised in a family with a family quotient of 0.75 would be exposed to a training set with around 75% of the training patterns. With a range between 0 and 1, networks could in principle be exposed to very few training patterns (see Thomas, 2016, for discussion).

Implementation of genetic differences: Differences in learning ability arose from the net effect of small variations in all the neurocomputational parameters, under a polygenic model of intelligence (Thomas, 2018). For this simulation, all variation in these parameters was considered to be under genetic control. There was a random association of family quotient to genotype, that is, we did not simulate gene-environment correlations.

Simulation design: A population of 1000 networks was created in sets of pairs, either MZ or DZ twins. Each network was trained for 1000 epochs. Performance on the training set (regular and irregular verbs) and two network measures, total number of connections and magnitude of connections, were assessed across training.

Results

Developmental changes in behavior: Figure 3 shows the monotonic improvement in accuracy in regular and irregular (vowel-change) verbs across training, averaged across the whole population (Table 1, #1).

Developmental changes in brain structure: Figure 4 plots the change in the magnitude of connections (gradually increasing) and the total number of connections (a non-linear decline) across training, averaged across the whole population. The plot captures the increase and decrease of different structural measures (Table 1, #2 and #3).

SES effects on behavior: The behavioral scores of the networks were split by their SES (upper quartile, family quotients >.75, lower quartile family quotients <.25). At each measurement point, the population distribution in accuracy values was used to convert accuracy to IQ scores, by deriving the population mean and standard deviation and transforming these to a mean of 100 and standard deviation of 15. Figure 5 plots developmental trajectories of IQs split by upper, lower and middle two quartiles. The plot captures a widening gap between the groups (Table 1, #4). In the simulation, this is the result of non-linear developmental trajectories, whereby the lower SES groups show earlier plateauing of performance.

SES effects on brain development: Figure 6 shows a scatter plot of each network's connection magnitude against SES (family quotient value), after 100 epochs of training. The simulations demonstrate a reliable association of SES to network structure. The pattern of a small effect size and non-linear relationship capture that shown in Noble et al.'s (2015) cortical surface area data, with larger reductions in area at the lowest SES levels (Table 1, #5).

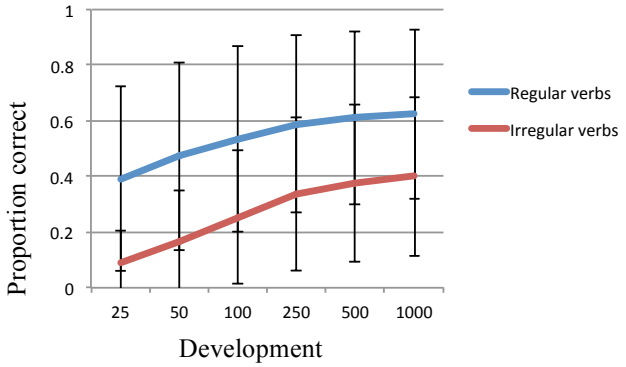

Figure 3: Average population development for two behaviors, regular verb and irregular verb performance. (Error bars show standard deviations)

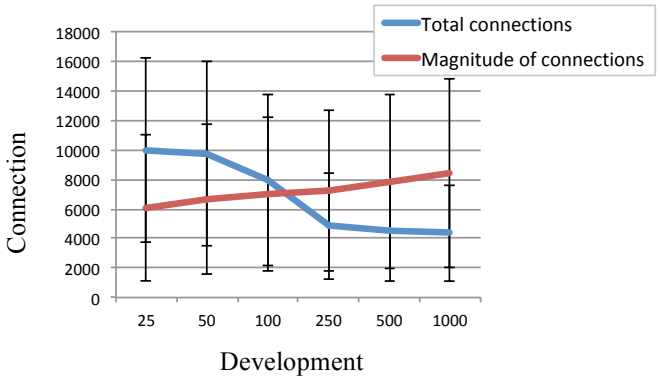

Figure 4: Average population changes in connection magnitude and number over development. (Error bars show standard deviations)

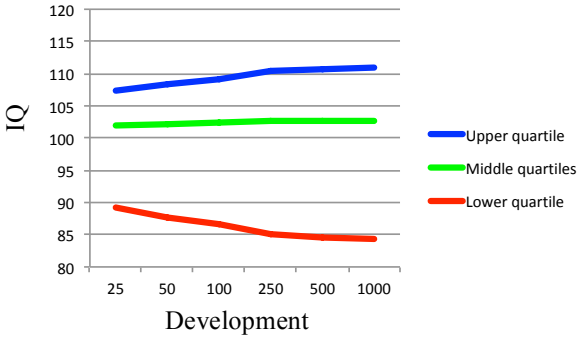

Figure 5: Development of behavior split by SES quartile.

Figure 7 separates the networks into the upper quartile and lower quartile according to SES and plots change in total number of connections across development (for simplicity, linking two points in training, epochs 25 and

250). There was no reliable main effect of SES on connection total (p=.547), but a reliable interaction, whereby connection total reduced more quickly in the lower SES quartile (F(1,498)=15.42, p<.001, η_p^2=.030). This occurred because lower SES networks received less stimulation, causing less strengthening of connections, and in turn greater vulnerability to later pruning processes. The result captures Piccolo et al.'s (2016) observation that cortex thins more quickly in children from a lower SES background, without overall differences in cortical thickness between groups (Table 1, #6).

Figure 8 plots the equivalent simulation data for connection magnitude, split by SES quartile. The model shows a main effect of SES, with smaller magnitudes in low SES networks (F(1,498)=13.33, p<.001, η_p^2=.026), but also an interaction, where magnitude in low SES networks improves much more slowly ((F(1,498)=150.88, p<.001, η_p^2=.233). The first effect captures the smaller cortical surface area observed by Piccolo et al. (2016) for lower SES children, but the interaction does not accord with the empirical data – SES does not modify rate of change of cortical surface area (Table 1, #7, not captured).

Brain structure mediates relationship of SES to behavior: Noble et al. (2015) found that cortical surface area mediated the relationship between SES and behavior but thickness did not. In the model, we observed increasing correlations between SES, connection magnitude, and behavior across training, such that a mediation effect was detectable by the end of training. Figure 9 shows that connection magnitude mediated associations between SES and regular verb performance (β=0.05, t(998)=8.44, p<.001, CI [.04; .07]). The Sobel test was significant, confirming partial mediation (Sobel-z=7.98, p<.001). Per Noble et al.'s findings, the analogue of thickness, connection number, did not show the mediation effect. This is because in the model, the correlation of SES to connection number did not reach significance (Table 1, #8).

Heritability of individual differences: at 100 epochs, the correlations between twin pairs were as follows: Regular verb performance: MZ=.99, DZ=.61; irregular verb (vowel change) performance: MZ=.97, DZ=.49; connection magnitude: MZ=1.00, DZ=.44; connection total: MZ=1.00, DZ=.33. Where MZ correlations are higher than DZ correlations, this implies genetic influence. The difference between the correlations can be used to estimate the heritability of the phenotype. Under an additive model, the respective heritabilities are .76, .97, 1.12, and 1.34 (that the latter values exceed 1 shows that the genetic effects violate an additive model and there are dominance effects operating). These values are higher than observed for behavior and measures of brain structure (Plomin et al., 2013). The simulations included no measurement error, which would appear as an environmental effect unique to each individual. Nevertheless, these high estimates of heritability imply the assumption that all neurocomputational parameter variation is under genetic control is not plausible, and that the environment contributes to variation in parameters (perhaps during prenatal brain development). However, the observed high heritabilities meant that effects of SES on brain and behavior were successfully simulated against a background of strong genetic influence on both measures (Table 1, #9).

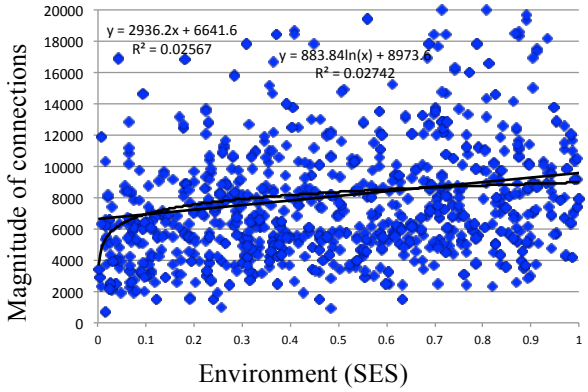

Figure 6: Connection magnitude versus SES

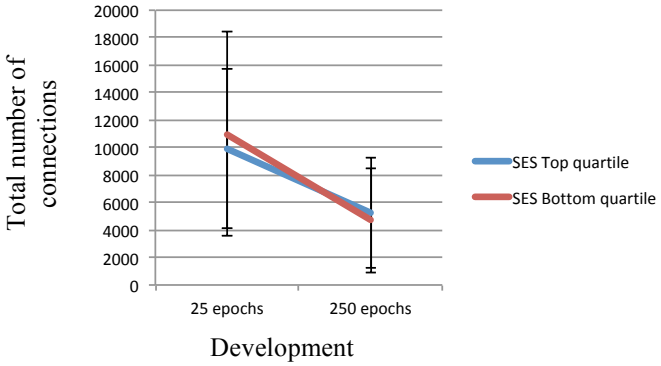

Figure 7: Change in number of connections across development, split by SES. (Error bars = STD)

Estimates of heritability were also observed to differ between upper and lower SES quartiles, with the lower SES quartile showing reduced heritability as the impoverished training set – rather than the neurocomputational parameters – became the limiting factor on performance. For example, for irregular verbs at 100 epochs, the upper quartile showed MZ correlation of .97, DZ .35, while in the lower quartile, these values were .95 and .60. The reduced gap between MZ and DZ correlations shows reduced genetic influence in the low SES group (Table 1 #10).

Relation of intelligence to brain structure: The 'ability' of each network was assessed based on its behavior. We chose to assess this based on irregular (vowel-change) verb performance at an early point in development (50 epochs), which gave good sensitivity to discriminate between individuals. At 100 epochs, the correlation of ability with total connections was .352, and with magnitude was .371. This captures the empirical observation of the small correlation between brain size and intelligence (Table 1, #11).

Based on the ability measure, we derived upper quartiles (top 25%) and lower quartiles (bottom 25%) of ability. Figure 10 shows the change in total number of connections between two points in development, epoch 25 and epoch 250. At epoch 25, high ability networks had reliably more connections ($t(458)=8.74$, $p<.001$, Cohen's $d=.81$). We did not simulate the growth of connectivity, only the outcome of this process. The higher peak captures the outcome of putative faster thickening of cortex across development for children with higher IQs (Shaw et al., 2006). Across development, connection number fell reliably more quickly in high ability networks than low ability networks ($F(1,458)=31.60$, $p<.001$, $\eta_p^2=.065$). The faster fall is a side effect of the higher peak – the greater ability arises from the greater computational power of having a larger network, while larger networks experience faster pruning. The result captures the observation by Shaw et al. (2006) that cortex thins more quickly in children with higher IQ (Table 1, #12).

Discussion

The model was successful in qualitatively capturing 11 of 12 target phenomena linking SES, IQ, brain development and behavioral development. The model used simple error-driven backpropagation networks, where connection strengths are altered to improve performance. Links to brain structure were established by adding a pruning process that, after a certain point early in development, removes unused connections. Measures of network connectivity gave analogous fits to brain structure measures that either show increases with age (white matter, cortical surface area) or decreases (gray matter, cortical thickness). The match of simulation and empirical data supports the view that these brain measures represent the results of experience-dependent strengthening of connectivity combined with intrinsic processes for connectivity growth and loss, where connectivity loss is dependent on the extent to which previous experience has strengthened connections.

The successful simulation of SES patterns in behavior and brain support the view that a key element of these effects is the level of cognitive stimulation. However, this is unlikely to be the full effect, and other environmental influences on prenatal and postnatal development undoubtedly contribute (see, e.g., Betancourt et al., 2016, for SES-related gray matter differences observed in babies at 1 month of age, where experience-dependent effects have had little time to act). Extension of the model presented here is necessary to explore the possibility that environmental effects on brain growth may interact with, and indeed may be correlated with, differences in cognitive stimulation.

The model failed in two regards. First, it did not capture the observed absence of SES effects in the rate of change of cortical surface area (Piccolo et al., 2016). The model did not show enough strengthening of connectivity across development in the low SES group. This implies that one of the assumptions of the model – that connection strength increases can only be experience dependent – is incorrect, and that there is a maturational contribution to connectivity increases (such as myelination). Second, its estimates of heritability were too high for individual differences in behavior and brain. In part, this is due to the absence of measure error in the simulations. But, consistent with above comments, it also demonstrates another initial assumption of the model is incorrect, that neurocomputational parameters are solely under genetic influence.

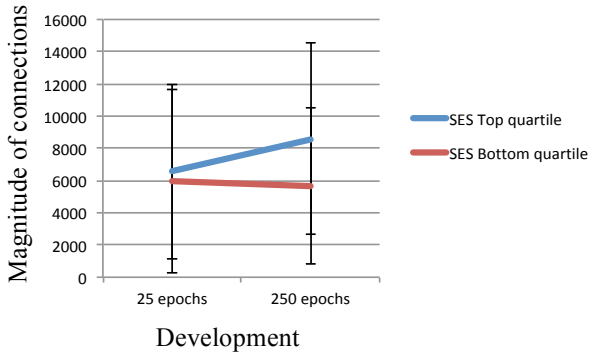

Figure 8: Change in magnitude of connections across development, split by SES. (Error bars = STD)

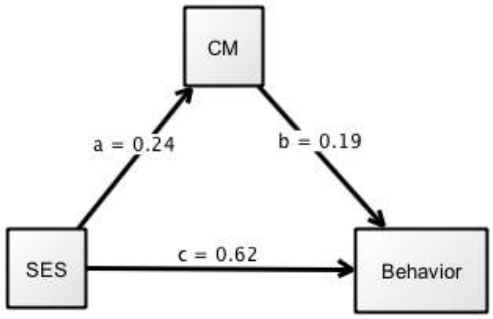

Figure 9: Partial mediation between connection magnitude (CM), SES and behavior (regular verb accuracy)

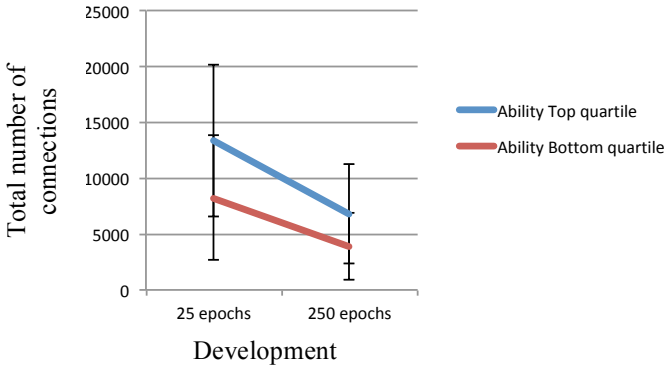

Figure 10: Change in number of connections across development, split by behavioral ability. (Error bars = STD)

A future extension of the model should investigate environmental influences on specifying network parameters, such as initial network growth. It should also be noted that the model set out only to simulate qualitative patterns, not to calibrate against precise ranges of genetic or environmental

variation, or to capture particular population mean levels of behavior at a given point in development. Some assumptions could be questioned, such as the extreme deprivation implied by training sets that could vary down to including no patterns.

Implementation of a mechanistic model provides the benefit that it can reconcile apparent paradoxes in the empirical literature. Why are high IQs associated with having a bigger brain (as if more neural resources were better for cognition) but also associated with faster gray matter loss and cortical thinning (as if fewer resources were better)? The answer is that the network size is driving ability (so more is always better), but that a higher peak of network size is then associated with faster connectivity loss during pruning of unused resources (in the manner that higher mountain peaks have steeper sides). How can faster cortical thinning be simultaneously associated with higher IQ and lower SES (which is associated with *lower* IQ)? The answer is that in the higher ability networks, there are more spare resources to be lost during pruning so thinning is faster; in low SES networks, the small training set (equivalent to lower cognitive stimulation) produces less strengthening of connectivity so that connections are more vulnerable to loss when pruning starts, leading once more to faster thinning. In other words, rate of change of structure isn't a direct marker of ability; ability is delivered by the full computational properties of the network and its developmental origins, not proxy measures like cortical thickness.

The model presented here is highly simplified, employing a single artificial network with very restricted biological plausibility. The range of the phenomena that the model captures probably reflects the fact that the existing observations we have on behavior, brain structure, and SES give limited insight into the detailed neural processes underlying behavior, development, and environmental influences. Nevertheless, we argue here for the importance of building multi-scale models that integrate individual differences within a developmental framework, and which can therefore evaluate causal mechanisms linking SES, brain and behavior. With causal, mechanistic accounts in hand, we are better able to consider interventions to ameliorate the impact of poverty and deprivation on children's development. The results here point to the importance of cognitive stimulation, and encourage interventions that seek to enrich that stimulation for children from poor backgrounds.

Working memory for object concepts relies on both linguistic and simulation information

Abstract

The linguistic-simulation approach to cognition predicts that language can enable more efficient conceptual processing than sensorimotor-affective simulations of concepts. We proposed that this has implications for working memory, whereby use of linguistic labels enables more efficient representation of concepts in a limited-capacity store than representation via full sensorimotor simulation. In two pre-registered experiments, we asked participants to remember sequences of real-world objects, and used articulatory suppression to selectively block access to linguistic information, which we predicted would impair accuracy and latency of performance in an object memory recognition task. We found that blocking access to language at encoding impaired memory performance, but blocking access at retrieval unexpectedly facilitated speed of responding. These results suggest that working memory for object concepts normally relies on language but people can flexibly adapt their memory strategies when language is unavailable. Moreover, our data suggest that a sequence of up to 10 object concepts can be held in working memory when relying on sensorimotor information alone, but this capacity increases when linguistic labels are available.

Keywords: working memory; concepts; linguistic information; simulation; embodied cognition

Introduction

Although traditionally conceptual representations were considered amodal and removed from perceptual experience (Tranel, Damasio & Damasio, 1997), more recent evidence suggest that concepts are grounded in sensorimotor and linguistic experience (Barsalou et al., 2008; Connell & Lynott, 2014; Vigliocco et al., 2009). Simulated representations engage the neural subsystems involved in sensorimotor, affective, introspective, and other situated experiences of a concept. For example, the concept *"dog"* includes its visual shape and colour, the action and feel of patting its fur, the sound of its bark, walking it on a leash, and the positive feelings towards a pet. The neural activation patterns involved in processing these experiences can later be partially re-activated (i.e., *simulated*) to represent a concept. Linguistic representations, on the other hand, comprise word (and phrase) labels associated with these sensorimotor-affective simulations, and the distributional patterns between them (statistical co-occurrences of words in language). For instance, seeing a terrier or hearing a bark will activate the label "dog", and words that frequently appear in similar contexts, like "tail" or "leash". These two components are interrelated and mutually supportive, and recent theories argue that both are intrinsic to conceptual representation (Connell & Lynott, 2014; Louwerse, 2011). That is, linguistic labels are part of concepts and conceptual processing uses simulation and linguistic information to varying extents depending on task demands, available resources, and other factors (Connell, 2018; Connell & Lynott, 2014).

The role of simulation and linguistic components in cognition is illustrated by a range of empirical evidence. Neuroimaging research has shown that processing of action words (e.g. "pick", "kick") activates body part-specific motor areas (Hauk, Johnsrude, & Pulvermüller, 2004). Critically, processing of such words is selectively impaired in patients with neurodegeneration of the motor system – Parkinson's disease (Boulenger et al., 2008). Behavioural experiments also show evidence for use of simulations: for example, people were faster to recognise a horizontally-oriented nail after reading "He pounded the nail into the wall" than "He pounded the nail into the floor" (Stanfield & Zwaan, 2001). Participants were also quicker to make a size judgment of manipulable objects than when the objects were too big to be physically manipulated (Connell, Lynott, & Dreyer, 2012). As for the linguistic component, information from language alone is powerful enough to inform responses across diverse conceptual tasks. Evidence comes from a range of paradigms, including property verification and generation (Louwerse & Connell, 2011; Santos et al., 2011), spatial iconicity judgements (Louwerse & Jeuniaux, 2010) and spatial cuing of attention (Goodhew, McGaw, & Kidd, 2014). Frequency of words co-occurring in the same context can predict how easily they are understood as a novel conceptual combination (Connell & Lynott, 2013). These findings show that both sensorimotor and linguistic information is functionally important to conceptual processing.

Much evidence for the linguistic component centres on the usefulness of distributional information (i.e., co-occurrence relationships between words/phrases) in cognition. However, that is not its full role. Language is a unique human characteristic which allows us to communicate something in the past, future, or hypothetical existence (Barsalou, 2005), and allows us to concisely name a complex multimodal experience. The idea that language is beneficial for our cognitive processing has been around for a while (e.g.: Paivio, 1971), but recent theories have developed the role of linguistic labels in a number of new directions (e.g., Borghi et al., 2018; Connell, 2018; Lupyan, 2012). Most relevant to our present purposes, Connell and Lynott (2014) propose that having labels for concepts enables a process of *linguistic bootstrapping*, whereby words and phrases act as *linguistic placeholders* in an ongoing representation when there are insufficient resources to maintain a sensorimotor simulation in full. These linguistic placeholders can later be fleshed out into a simulation again at any time if

resources become available. To date, the linguistic bootstrapping hypothesis has remained theoretical and has not been tested directly but there is indirect support for the idea in the wider literature. Working memory (WM) is necessarily limited in capacity – there are only so many concepts that can be maintained and manipulated at once – and recent evidence does suggest that linguistic information is more economical in representation (i.e., occupies less "space" in working memory) than sensory information (Langerock, Vergauwe, & Barrouillet, 2014). Further, explicitly labelling simple visual stimuli seems to increase memory capacity (Zormpa et al., 2018). It is possible that when working memory capacity is strained to its limit, as when trying to maintain a representation of numerous concepts, a linguistic label could deputise for its referent sensorimotor information (e.g., word "dog" replaces simulation of *dog*) to free up space.

It is currently unknown how many concepts (i.e., representations of real-world objects, events, and situations, such as *dog*, *running*, or *holiday*) can be maintained in working memory at once. Research on memory from the linguistic-simulation perspective concentrated on the role of sensorimotor simulation in memory (Dutriaux, Dahiez, & Gyselinck, 2018; Vermeulen et al., 2013) rather than the interplay of simulated and linguistic information in capacity limits. Working memory research has established a central capacity limit of 4 items (Cowan, 2010), but research informing this has used simple, artificial stimuli (e.g., feature conjunctions such as *red triangle*; random word pairs such as *desk-ball*). Such stimuli do not generalise to naturalistic, real-world concepts that comprise rich sensorimotor and linguistic information from long-term memory, and that are typically represented in broader situated simulations where concepts to reinforce and cue one another (e.g., a *dog* that is *running* with a *ball*). Baddeley's (2000) episodic buffer, a finite-capacity buffer that allows information from long-term memory to be integrated and manipulated goes some way to address these issues. For instance, participants remember sequences of words better when they are presented in meaningful sentences (i.e., that exploit interconnections between words) than in unstructured lists, which Baddeley and colleagues attribute to long-term knowledge retrieved to support representations in the episodic buffer. Nonetheless, not much is known about the role of simulated and linguistic information in representing concepts in working memory.

The current study

Our aim was to examine the role of linguistic and simulation components in working memory for real-world object concepts. In two pre-registered experiments, we presented ecologically valid sequences of object pictures (e.g., ingredients for a novel recipe) in a nonverbal paradigm, and tested recognition memory by asking participants to select the previously-presented objects from arrays of distractors. Critically, participants performed articulatory suppression (repeating aloud "the") during item encoding and/or retrieval to block access to linguistic information. Articulatory suppression has been widely used in WM research (Baddeley, 1992), where it has been shown to interfere with verbal encoding but to have little effect on general processing in the central executive (e.g., De Rammelaere, Stuyven, & Vandierendonck, 2001; Jaroslawska et al., 2018). We used a no-suppression condition as a baseline instead of an alternative suppression task, such as spatial tapping or visual interference, because such tasks would have interfered with the sensorimotor representation of concepts and therefore could not provide a useful control in our experiment. Thus, we expected the articulatory suppression task to block participants' access to the linguistic component of their conceptual representations.

We hypothesised that storage of object concepts in working memory will normally rely on language (i.e., linguistic placeholders), and that speed and accuracy of performance will be impaired when access to language is blocked. We expected performance to be best with no articulatory suppression at either encoding or retrieval, when participants are free to use both linguistic and sensorimotor information. We expected performance to be worst with articulatory suppression at retrieval only, when participants can employ linguistic placeholders to encode more objects, but lose access to those objects at retrieval when access to linguistic information is blocked. We planned to estimate working memory capacity for sensorimotor representations of concepts by calculating the average number of objects correctly retrieved with articulatory suppression at both encoding and retrieval (i.e., when linguistic information was unavailable).

Experiment 1

In this first experiment (pre-registration, data, analysis code, and full results are available as supplemental materials at https://osf.io/acv3m/?view_only=c1799106289a4063abf2eaa490eae009), we presented six objects per sequence, based on estimates from Langerock et al. (2014) that only 2-3 complex representations can be maintained in the episodic buffer. Participants viewed images of objects in each sequence one at a time during the encoding stage, and then had to select an alternative image of each target object from an array of distractors during the retrieval stage. Articulatory suppression took place half the time at encoding (to block access to object labels and prevent the use of linguistic placeholders when storing objects in WM) and half the time at retrieval (to block access to linguistic placeholders stored in WM).

Method

Participants Thirty-two native speakers of English (27 females; mean age = 21.2 years, *SD* = 3.2 years) were recruited from Lancaster University, for which they received course credit or a payment of £3.50. One participant was replaced due to a procedural error during testing.

The sample size was determined using sequential hypothesis testing with Bayes Factors (Schönbrodt et al., 2017). We stopped at the minimum sample size $N = 32$ when the Step 3 models for accuracy and Response Time (RT) cleared the specified threshold of evidence $BF_{10} < 0.2$. (model details in Design & Analysis section, full statistics in the Results section).

Materials Test items comprised of 72 target objects, divided into 12 sequences, each designed to be an ecologically valid

order of objects that would be plausibly used in a real-world setting, such as ingredients used in the process of making a cake, or a set of tools used in order to hang a picture. Each sequence therefore consisted of 6 target objects for study during the encoding stage, and each target object was assigned five distractor items for display in an object array during the retrieval (testing) stage. Five distractor objects were selected from the same category (e.g., food items, clothing) of which three were chosen based on colour, shape or function of the target object. Target and distractor items could all be plausibly used in a particular sequence (e.g. recipe) so that the task maintained ecological validity, and it would not be obvious which item in the array was the correct one.

To ensure the order of objects within each sequence was ecologically valid, we asked 9 naïve participants (who did not take part in the experiment) to rank-order the items according to how they are used in a given context. We used mean rank per object to finalise each sequence. For example: in the scenario *Tools for hanging a picture on the wall*, participants decided on the following order: *spirit level*, *drill*, *screw plug*, *screw*, *screwdriver*, *picture frame.*

We sourced photographic images for all objects from license-free online resources and edited them to appear on a uniform transparent background. To ensure that participants were tested on memory for object concepts, and not perceptual matching of a specific image, we prepared two different images for each target object: one for study during encoding and one for display in the distractor array during retrieval (e.g., showing an object from a different perspective or in a different colour). Images were scaled to 840 pixels along the longest dimension for objects presented during the encoding stage, and 470 pixels along the longest dimension for objects (targets and distractors) presented in the object arrays during retrieval. This resulted in a total of 504 object images: 72 target objects presented at encoding, 72 target objects presented at retrieval, and 360 distractor objects presented at retrieval. Figure 1 shows sample stimuli.

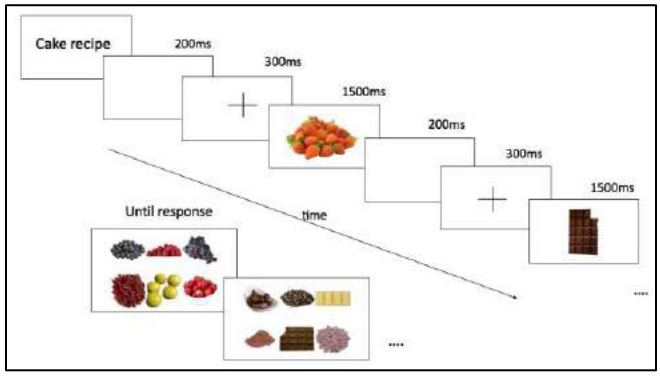

Figure 1: Diagram showing trial sequence and example stimuli at encoding and retrieval stages.

Procedure Participants were tested individually. After signing the consent form, the experimenter explained and demonstrated articulatory suppression, asking the participant to practice it. Once the participant confirmed that they understood and could perform articulatory suppression correctly, they sat in front of a computer, provided demographic information and proceeded to instructions. Participants were told they would see a sequence of everyday objects appear one by one onscreen, and their task was to remember the objects; later, they would see groups of objects onscreen and they should click on the object that belongs to the sequence they had been asked to remember. Participants then commenced a practice sequence without any articulatory suppression at encoding or retrieval. When the participant confirmed that they understood the task and were happy to continue, they were instructed on the articulatory suppression condition for both encoding and retrieval (i.e. when to start and stop) and commenced the experimental trials. Articulatory suppression was manipulated between participants at encoding and within participants at retrieval. The order of retrieval conditions was counterbalanced, and six sequences were presented in a randomised order within each condition. Experiment presentation was controlled by PsychoPy software (version 1.84.1; Peirce, 2009).

In the encoding stage, target objects were presented individually in a sequence (see Figure 1 for display times). Each sequence was preceded by a label (e.g. "cake recipe"). Once a full sequence of six target objects had been presented, participants saw a "wait" screen of 3 asterisks ("***") for 10 seconds before the retrieval stage began. In the articulatory suppression condition at encoding, participants repeated "the" aloud until this wait screen timed out. In the retrieval stage, participants saw a 2×3 array of six objects (one target object and five distractors) in random locations within the array (see Figure 1). Response times were measured from the onset of the array display until the participant clicked on an object using the mouse. After the retrieval of all six target objects had been tested, a message on the screen asked participants to press space when they were ready to proceed to the next object sequence.

After completing encoding and retrieval of six sequences, participants were instructed to take a self-paced break. They were then asked to switch to the counterbalanced articulatory suppression condition at retrieval (articulatory suppression at encoding remained constant). Participants then completed encoding and retrieval for six further object sequences.

Design and Analysis We analysed accuracy (dummy coded: incorrect = 0, correct = 1) with a mixed-effects hierarchical logistic regression (binomial, logit link). Step 1 entered participants and items as crossed random effects, where items were defined as objects nested within sequences. Step 2 added encoding and retrieval as fixed effects (no articulatory suppression = 0, articulatory suppression = 1). Step 3 added the interaction of encoding and retrieval as a fixed effect. We ran Bayesian model comparisons between steps, with Bayes Factors (BF) calculated via Bayesian Information Criteria (Wagenmakers, 2007). Similarly, we analysed RT for correct responses in a mixed-effects linear regression with the same effects and model comparisons as above. All analyses were run in R software (lme4 package, R version 3.4.1, 2017).

Results and Discussion

No trials were excluded on the basis of accuracy results[1]. For analysis of correct RTs, one trial was excluded as a motor error (faster than 300ms), and 27 trials were removed as outliers more than 3 standard deviations from the individual participant's mean (total 0.015% data removed).

Accuracy Bayesian model comparison showed equivocal evidence for Step 2 over Step 1, BF_{10} = 1.58; the data *very* weakly favoured the model containing articulatory suppression as fixed effects at encoding and retrieval over a model containing only random effects. There was strong evidence at Step 3 *against* the effect of the encoding-retrieval interaction on accuracy, BF_{10} = 0.02: the data were 47 times more likely under the Step 2 model without the interaction than the Step 3 model with the interaction.

We used the coefficients in Step 3 model to estimate the marginal accuracy for each condition of encoding × retrieval articulatory suppression (see Table 1). As predicted, accuracy was best in the no-suppression/no-suppression condition (no articulatory suppression at encoding or retrieval), with participants correctly recognising 5.6 out of 6 objects per sequence on average. However, accuracy was worst in the suppression/suppression condition: object memory was least accurate when language access was blocked at both encoding and retrieval (5.0 objects per sequence).

Finally, in an exploratory analysis not specified in the pre-registration, we examined the individual coefficients in the most likely model of fixed effects (i.e., Step 2)[2]. Articulatory suppression at encoding had a negative effect on response accuracy, beta = -0.567, *SE* = 0.275, *z* = -2.06, *p* = .039, as did articulatory suppression at retrieval, beta = -0.436, *SE* = 0.121, *z* = -3.59, *p* < .001. That is, as we predicted, removing access to language impaired object memory accuracy. When access to labels was blocked at the point of *encoding* objects, people were 76% more likely to make an error when later asked to recognise the object. Independently, when access to labels was blocked at the point of *retrieving* objects, people were 55% more likely to make an error. However, the inconsistency between equivocal Bayesian model comparison and significant regression parameters for Step 2 suggests that these effects should be treated cautiously.

Response Times Model comparisons showed very strong evidence at Step 2 for the effects of articulatory suppression at encoding and retrieval, BF_{10} = 1808.04. However, there was strong evidence at Step 3 *against* the effect of the encoding-retrieval interaction on RT, BF_{10} = 0.03: the data were 33 times more likely under the Step 2 model without the interaction than the Step 3 model with the interaction.

We took the coefficients in the Step 3 model to estimate the marginal mean RT for each condition of encoding × retrieval articulatory suppression (see Table 1). Against our expectations, recognition of target objects was best (fastest) in the no-suppression/suppression condition (language available at encoding but not at retrieval), and worst (slowest) in the suppression/no-suppression condition (language available at retrieval but not at encoding). People had most difficulty recognising the objects when language was blocked at the point of encoding but was available at retrieval.

We report an exploratory analysis of the coefficients in the most likely model of fixed effects (i.e., Step 2). As expected, articulatory suppression at encoding increased RT, beta = 408.57, *SE* = 172.32, *t*(31.99) = 2.371, *p* = .024. However, articulatory suppression at retrieval unexpectedly *reduced* RT, beta = -219.57, *SE* = 43.85, *t*(1770.74) = -5.007, *p* < .001). Closer examination of RT and accuracy suggested that this pattern was due to a speed-accuracy trade-off rather than facilitation of memory. When participants were asked to perform articulatory suppression at retrieval, response times were faster, but this was accompanied by lower accuracy, relative to no-suppression conditions (see Table 1). We discuss possible reasons for this trade-off below.

Summary Overall, the results support the hypothesis that memory for object concepts normally relies on language. Blocking language access when encoding a real-world object sequence affected memory: speed and accuracy were both impaired relative to no suppression. This is consistent with the idea that object concept is stored in WM via sensorimotor simulation *and* its linguistic label, and memory is impaired when only sensorimotor simulation is available.

However, blocking access to language while retrieving objects had unexpected effects. Rather than straightforward impairment, there was a speed-accuracy trade-off (low RT and accuracy), suggesting that articulatory suppression at retrieval caused participants to adopt an alternative, heuristic strategy that led to fast but inaccurate responding. Thus, the hypothesis that memory performance would be worst in the no-suppression/suppression condition was not supported. This may be because participants knew, before they studied the object sequence, whether they would perform articulatory suppression at retrieval. Knowing that language would be unavailable during retrieval could have led participants to strategically rely on sensorimotor information even when they had language access at encoding. Another possibility is that performance was subject to ceiling effects. When language was not available, participants correctly recognised 5.0 items per sequence on average, indicating that they were able to represent five object concepts in working memory from sensorimotor simulation alone (more than the suggested episodic buffer capacity of 2-3 items, Langerock et al., 2014). Thus, working memory capacity may not have been under particular strain, and participants did not have to replace some of the sensorimotor information with linguistic placeholders to remember the full sequence. We examine these possibilities in the next experiment.

[1] Exclusion criteria detailed in pre-registration

[2] All coefficients for all models available in supplemental materials

Table 1: Marginal accuracy (%) from logistic mixed effect regression, and marginal mean RT (ms, with standard errors in parentheses) from linear mixed effect regression, for each articulatory suppression condition in Experiments 1 and 2.

	Retrieval			
	No suppression		Suppression	
Encoding	%	RT (SE)	%	RT (SE)
Experiment 1				
No suppression	92.9	2499 (137)	89.6	2288 (138)
Suppression	88.3	2916 (138)	82.7	2687 (139)
Experiment 2				
No suppression	92.0	2786 (144)	90.2	2635 (144)
Suppression	83.4	2854 (141)	82.7	2675 (141)

Experiment 2

In our second experiment (pre-registration, data, analysis code, and full results are available as supplemental materials at https://osf.io/acv3m/?view_only=c1799106289a4063abf2eaa490eae009), we presented 12 objects per sequence rather than 6, and made methodological improvements to the design. Our hypotheses remained the same.

Method

Participants As in Experiment 1, we used Bayesian sequential hypothesis testing to determine sample size. Bayes Factors for Step 3 cleared the evidence threshold for the null at *N*min = 32 for both RT (BF_{10} = 0.02) and accuracy BF_{10} = 0.03). However, sequential analysis plots for the Step 2 model (the best-fitting model in Experiment 1) suggested that the level of evidence was still unstable for RT (i.e., BFs fluctuating between evidence for the null and the alternative, and equivocal evidence). We tested additional participants until it stabilised at *N* = 44. We therefore report results for 44 participants (33 female; mean age = 20.3 years, *SD* = 5.4). All other BF inferences and parameter estimates were consistent between *N* = 32 and *N* = 44 (full data and statistics in supplementals). Three participants were replaced due to failure to follow instructions.

Materials and procedure We used materials and procedure from Experiment 1 with the following methodological changes: to reduce the risk of ceiling effects, we paired sequences from Experiment 1, which resulted in six lists of 12 items each. Instead of a label for each list, participants were given brief information about the context (e.g.: "*You are making dinner and need to remember your shopping list for a meal and tea. Press space to proceed to the list of ingredients.*"), to provide a real-life, ecologically valid situation.

To prevent participants' knowledge of the articulatory suppression condition from affecting their encoding strategies, we altered the presentation of retrieval conditions. Instead of verbal instructions on articulatory suppression at the start of the experiment, participants saw an image of a mouth on the screen indicating the start of articulatory suppression, and the same image crossed out to indicate no articulatory suppression, before the encoding and retrieval stages on each trial. We then randomised the order of lists across retrieval conditions, so that participants did not know whether the trial involved articulatory suppression until encoding was complete. We also altered some of the distractors (N = 8; 0.015% of all items) to ensure that the target items were not easy to guess without relying on memory.

The experimental design remained the same (i.e., articulatory suppression manipulated between participants at encoding and within participants at retrieval).

We changed the "wait" screen to reduce the possibility of participants relying on perceptual matching (instead of memory for object concepts). Rather than passively looking at the screen, participants had to click on 4 dots appearing in random points on the screen to "calibrate the mouse". Additionally, object presentation time during encoding was prolonged to 2000ms, to give participants more time to encode the concept.

Results and Discussion

No trials were excluded on the basis of accuracy results. For RT analysis of correct responses, 31 trials (0.012% of data) were removed as being more than 3 SDs above the individual participant's mean.

Accuracy Bayesian model comparison showed strong evidence *against* Step 2 over Step 1, BF_{10} = 0.017; the data were 57 times more likely under the Step 1 model containing only random effects than a model containing articulatory suppression as fixed effects at encoding and retrieval. There was also strong evidence at Step 3 *against* the effect of the encoding-retrieval interaction on accuracy, BF_{10} = 0.025: the data were 40 times more likely under the Step 2 model with no interaction than the Step 3 model with the interaction.

We then used the coefficients in the Step 3 model to estimate the marginal accuracy for each encoding × retrieval articulatory suppression condition (see Table 1). As in Experiment 1, accuracy was best in the no-suppression/no-suppression condition (no articulatory suppression in either encoding or retrieval), with participants correctly recognising 11.0 out of 12 objects per sequence on average. However, accuracy was worst in the suppression/suppression condition (9.9 objects remembered). Object memory was least accurate when access to language was blocked at both encoding and retrieval, in line with Experiment 1 but not our predictions.

Although the BFs showed evidence against both models, we ran an exploratory analysis of the individual coefficients in the Step 2 model to make a comparison with Experiment 1. Articulatory suppression at encoding had a negative effect on response accuracy, beta = -0.736, *SE* = 0.273, *z* = -2.69, *p* = .007. As predicted, and replicating Experiment 1, removing access to language impaired object memory accuracy: when access to labels was blocked at encoding, people were 109% more likely to make an error when later attempting to recognise the object. Unlike Experiment 1, articulatory suppression at retrieval had little effect, beta = -0.117, *SE* = 0.100, *z* = -1.17, *p* = .243, decreasing the probability of a correct response by only 12%. However, the NHST effect of articulatory suppression at encoding was not consistent with the Bayesian model comparison at Step 2 (which added encoding and retrieval effects simultaneously), and so should be treated cautiously.

Reaction Time Bayesian model comparison showed equivocal evidence for Step 2 over Step 1, $BF_{10} = 0.61$. As in Experiment 1, there was strong evidence at Step 3 *against* the effect of the encoding-retrieval interaction, $BF_{10} = 0.02$.

We used the coefficients in the Step 3 model to estimate the marginal mean RT for each condition of encoding × retrieval articulatory suppression (see Table 1). Against our predictions, but in line with Experiment 1, recognition was best (fastest) in the no-suppression/suppression condition (language available at encoding but not retrieval), and worst (slowest) in the suppression/no-suppression condition (language available at retrieval but not encoding). People had most difficulty remembering objects when language was blocked at the point of encoding but was available at retrieval.

We report an exploratory analysis of the most likely model of fixed effects (Step 2). Articulatory suppression at encoding had no effect on speed of recognition, unlike Experiment 1, beta = 54.22, SE = 149.60, $t(43.68) = 0.36$, $p = .719$. Against our expectations but in line with Experiment 1, articulatory suppression at retrieval *reduced* RT, beta = -164.91, SE = 43.26, $t(2430.48) = -3.81$, $p < .001$. People were *faster* to recognise target objects if language was blocked at retrieval. Closer examination of RT and accuracy suggested that this may be due to a speed-accuracy trade-off, as in Experiment 1. Faster RTs due to articulatory suppression at retrieval were accompanied by a trend towards poorer accuracy, relative to no-suppression conditions (see Table 1).

Summary The results were broadly in line with Experiment 1 and support the hypothesis that memory for object concepts typically relies on language. Blocking language access while encoding a real-world object sequence impaired performance in terms of accuracy (but not latency), in line with the idea that an object concept is typically stored in WM via sensorimotor simulation *and* its linguistic label, and when only sensorimotor simulation is available, memory is adversely affected.

However, blocking language access while retrieving objects from working memory resulted in faster speed of responding that was not completely eliminated by methodological changes. These results suggest that participants adopted a heuristic strategy for responding while performing articulatory suppression at retrieval. For instance, participants may have adopted a satisficing approach to selecting the target object, based on a rapid assessment of superficial sensorimotor similarity between a concept in WM and the objects in the array, to compensate for lack of access to linguistic information. Alternatively, perhaps the articulatory suppression task itself made participants want to get through the task faster, which resulted in emphasis on speed at the cost of accuracy. We plan to follow up these possibilities in future work.

General Discussion

The study is the first to take a linguistic-sensorimotor approach to working memory. We used real-world object sequences to account for the complex nature of naturalistic concepts that can draw upon information in long-term memory, and an articulatory suppression task to investigate the role of linguistic labels in working memory for such objects. We found that blocking language access at encoding impairs memory performance (poorer speed and accuracy in Experiment 1; poorer accuracy in Experiment 2), whereas blocking access to language during retrieval leads to an apparent speed-accuracy trade-off (faster speed and poorer accuracy in Experiment 1; faster speed in Experiment 2).

The results support the sensorimotor-linguistic theories of conceptual processing that argue the importance of language in conceptual representation (Connell, 2018; Louwerse, 2011), and the linguistic bootstrapping hypothesis that proposes word labels act as placeholders in mental representations when resources are insufficient to maintain a full simulation (Connell & Lynott, 2014). When language is available, people encode objects in WM with linguistic labels and sensorimotor simulations, and when storage is at capacity, the linguistic placeholder can free up resources by allowing to drop a simulation. Experiment 2 results suggest that linguistic bootstrapping allows people to remember one extra concept in a sequence of 12 (11 rather than 10).

We expected memory performance to be impaired the most when participants could use linguistic bootstrapping at encoding but had no access to object labels at retrieval (no-suppression/suppression condition). This effect did not appear. Instead, when language access was blocked at retrieval, participants adopted an alternative, heuristic strategy to compensate for it, which resulted in a trade-off between speed and accuracy. Participants may have relied on an incomplete sensorimotor simulation in working memory (e.g., only the shape or the colour of the target object), which allowed them to respond quickly, but not always correctly.

The results highlight the importance of language in working memory performance for real-world object sequences. We plan to explore encoding and retrieval processes in more detail by testing complex stimuli in sequences of varying lengths and under time constraints.

Abstract

Young children are selective in deciding whom to help (i.e., they preferentially assist and share resources with prosocial versus antisocial others; Hamlin, Wynn, Bloom, & Mahajan, 2011; Vaish, Carpenter, & Tomasello, 2010) but are they also selective in deciding *how* to offer help? Here we show two to five-year-olds (N = 32; mean: 42.41 months; range 27-68 months) characters who are distressed for different reasons: they are hurt, bored, or sad. Children of all ages tried to help the agent but the selectivity of children's responses varied with age and condition; in particular, children's responses to boredom and sadness became increasingly differentiated with age.

Keywords: helping, empathy, social cognition, theory of mind, preschoolers, toddlers

Introduction

One of the more charming characteristics of young children is that they try to help others, even at ages when they themselves need help with almost every aspect of daily life. Toddlers who struggle to put on their own socks will open doors and pick up objects for others (Warneken & Tomasello, 2006; 2007), point to show others the location of hidden objects (Liszkowski, Carpenter, Striano, & Tomasello, 2006), hug and pat distressed peers (Friedman, Zahn-Waxler, & Radke-Yarrow, 1982), and try to understand the causes of others' distress (Knafo, Zahn-Waxler, Van Hulle, Robinson, & Rhee 2008; Zahn-Waxler, Radke-Yarrow, Wagner, & Chapman 1992; Zahn-Waxler, Robinson, & Emde 1992). Children's empathetic and prosocial behavior increases between two and four years of age (Knafo et al., 2008; Volbrecht, Lemery-Chalfant, Aksan, Zahn-Waxler, & Goldsmith, 2004; Zahn-Walxer, et al., 1992). This is arguably mediated by broad changes in their theory of mind (Miller, Eisenberg, Fabes, & Shell, 1996; Wellman, Cross, & Watson, 2001), specific changes in their emotion understanding and emotion regulation (Denham, 1998; Eisenberg, Spinrad, & Sadovsky, 2006), and increased socialization towards prosocial behaviors (Hoffman, 2000).

But the selectivity of children's helping behavior also increases over development (Hay & Cook, 2007; Hay, 1994) -- and even the youngest children do not help others indiscriminately. Toddlers preferentially help prosocial versus antisocial others (Behne, Carpenter, Call, & Tomasello, 2005; Dunfield & Kuhlmeier, 2010; Hamlin, et. al., 2011; Vaish, et al., 2010). By three, children consider others' past contributions to shared goals (Baumard Mascaro, & Chevallier, 2012) and history of reciprocity in deciding how to allocate resources (Olson & Spelke, 2008). Four and five-year-olds evaluate relative ability in deciding how to divide labor to achieve cooperative and prosocial goals (Magid, DePascale, & Schulz, 2018). By five and six, children's attempts to inform others take into account the learners' prior knowledge, past mistakes, and goals (Gweon, Shafto, & Schulz, 2014; Ronfard, Was, & Harris, 2016), the transparency and availability of information (Clegg & Legare, 2016; Ronfard, Was, & Harris, 2016), and the relative costs and benefits of information to the learner (Bridgers, Jara-Ettinger, & Gweon, 2016; Gweon & Schulz, 2019).

Thus, children's helping behavior is sophisticated in many respects. However, toddlers and young preschoolers are more likely to share resources or provide help with instrumental goals than offer comfort (Dunfield, Kuhlmeier, O'Connell, & Kelley, 2011; Newton, Thompson, & Goodman, 2016; Svetlova, Nichols, & Brownell, 2010). Similar results have been found in four and five-year-olds: they are more likely to help achieve goals than to share, and are least likely to try to offer soothing, encouragement or solace (Thompson & Newton, 2013).

Because very young children are adept at inferring both others' desires (e.g., Meltzoff, Gopnik, & Repacholi, 1999) and the goals of their failed intentional actions (e.g., Meltzoff, 1999), it may be relatively easy for young children to know what resources to offer and what actions to take. By contrast, it may be difficult for children to know what constitutes a helpful response to someone's emotional distress. Even as adults, we may understand perfectly well that someone is disappointed, agitated, or distraught and still find ourselves at a loss as to how to help them.

However, even if children do not know how best to intervene, there is reason to think that they may be attuned even to relatively fine-grained distinctions among emotions.

Within hours of birth, newborns respond differently to distinct emotional expressions (Field, Woodson, Greenberg, & Cohen, 1982) and by seven months, babies distinguish emotions cross-modally and within valence (e.g., generating distinct responses to anger and fear; matching happy faces to happy voices and interested faces to interested ones; Serrano, Iglesias, & Loeches, 1992; Walker-Andrews, 1998; see also Soken & Pick, 1999; Soderstrom, Reimchen, Sauter, & Morgan, 2017). Older infants map positively valenced emotions to the achievement of goals (Skerry & Spelke, 2014), and make nuanced distinctions among emotional expressions and connect them to their probable eliciting causes (Wu, Muentener, & Schulz, 2018).

Nonetheless, children's ability to categorize emotions (Widen & Russell, 2008; 2010), and their understanding of the way past experiences and social contexts shape the experience and expression of emotions (Pons, Harris, & de Rosnay, 2004), undergo considerable development between preschool and middle childhood. Emotion regulation in particular is relatively protracted (Pons et al., 2004), and this may apply to the ability to regulate other's emotions as well as one own. Moreover, perhaps the most common way to try to regulate someone else's negative emotions is to talk to them, thus offering comfort might place high verbal demands on children. The infrequency with which young children offer comfort may reflect limitations on their fluency, not their insight or compassion. In the current study, we remove linguistic demands by giving children a choice of objects that might be helpful, allowing us to ask whether children can calibrate their responses to the particular nature of others' distress.

Here we focus on two to four-year-olds because we know children in this age range can use social and moral evaluation to decide *whom* to help (Behne et al., 2005; Dunfield & Kuhlmeier, 2010; Vaish et al., 2010; Baumard, et al., 2012; Olson & Spelke, 2008) but the degree to which they use social cognition to make distinctions about *how* to help remains an open question. We show children characters who are upset for one of three reasons: they have scraped their knee and are hurt, there is nothing to do and they are bored, or their parent has left them at daycare and they are sad. In all cases, children are given a choice of three candidate offerings: a Band-Aid, a novel electronic toy, or the victim's favorite stuffed animal. We selected these pairings because both the emotional states and the stimuli should be familiar to children in this age range and yet the complexity of the inferences required to intervene upon the emotional states might differ across categories. In particular, children's tendency to choose an intervention might be related to the intuitive likelihood that the intervention would successfully change the agent's state.

Children have abundant experience with minor scrapes and bumps (Fearon, McGrath, & Achat, 1996), and in the United States, "booboos" are reliably linked with Band-Aids. Crying in response to a minor injury is an ambiguous response with respect to the extent to which it reflects a physiological response to pain or an emotional response to the fear associated with the pain, but in either case, from the perspective of a child, a Band-Aid may seem to solve the underlying problem. By contrast, there is no single canonical response to either boredom or sadness; intervening on these emotional states requires both understanding why the person feels as she does and understanding the role that the various choices may play in changing this state. Nonetheless, the link between boredom and novelty is arguably almost as straightforward as the link between booboos and Band-Aids: Children themselves respond to novelty with interest (Berlyne, 1950; Hutt, 1970) and providing something that is interesting effectively solves the problem of being bored. However, the distress of an agent who is sad about a separation is more complex. Children commonly regulate their sadness at separation from attachment figures with transitional objects (Kopp, 1989; Winnicott, 1986). Critically however, the intervention serves to regulate the distressed emotion rather than to resolve it (i.e., the only intervention that really solves sadness at separation from a loved one is for the loved one to return). Thus, although pilot data suggests that adults would offer Band-Aids, novel toys, and favorite stuffed animals in response to pain, boredom, and sadness respectively, children might well find some of these mappings easier than others.

Of course, if children offer anything at all to an agent who is upset, they are providing an empathetic, prosocial response, and any well-intentioned intervention may be effective even if it is not directly connected to the underlying concern. Band-Aids can alleviate boredom and sadness; novel toys can distract from sadness and pain, and stuffed animals can help with both pain and boredom. Perhaps more critically, engagement, attention, and sympathetic concern may go a long way towards resolving distress, independent of the degree to which any given intervention is specifically tailored to the source of the recipient's woes.

Nonetheless, commonsense suggests that some of these offerings are more likely to be effective in some contexts than others, and the early sophistication of children's helping behavior may relate to sensitivity to the contents of others' minds and overall social acuity. Thus, here we ask whether two to four-year-olds offer emotional comfort indiscriminately or whether they are sensitive to how different interventions might best alleviate different kinds of emotional distress.

Experiment

Participants

Thirty-two children (M = 42.41 months, range: 27-68 months) were recruited from an urban children's museum. Six children failed a practice trial but excluding them from the analysis made no difference to the results. Five additional children were recruited but excluded from analysis due to incomplete participation (N = 1), parental interference (N = 2), and incomplete consent forms (N = 2).

While most of the children were white and middle class, a range of ethnicities and socioeconomic backgrounds reflecting the diversity of the local population (47% European American, 24% African American, 9% Asian, 17% Latino, 4% two or more races) and the museum population (29% of museum attendees receive free or discounted admission) were represented.

Materials

In the practice trial an Ernie puppet from Sesame Street and two toys (a squishy ball and a plastic strawberry) were used. The test trial materials included six Paw Patrol Band-Aids each depicting a different or different set of characters from the children's series; six unique toys that lit-up, made funny sounds, and/or spun; and six unique stuffed animals. The materials were arranged on a plastic tray so that one material of each of the three kinds was placed on the tray (left/right/middle arrangement counterbalanced); children were presented with a different set of three items on each trial. (See Figure 1 for example presentation set). We also used six pairs of hand puppets; each pair had a parent and a child puppet. Stickers and a sticker "bookmark" were used to keep the children on task. See Figure 1 for examples of the stimuli.

Figure 1: Examples of the puppets (left) and the toy, stuffed animal, and Band-Aid (right)

Procedure

Children were tested individually in a private testing room. Children participated in a practice trial and six test trials, two of each kind (Hurt, Bored, and Sad). Sessions began with the experimenter explaining the task: "We're going to do six puppet stories okay? After each one, you get to put a sticker on this bookmark. Once we finish all six stories, you get to take the bookmark home. Does that sound good? Great! Before we start, we're going to do a practice story."

Practice Trial: The experimenter brought out the Ernie puppet and said, "This is my friend Ernie. He's really hungry. He hasn't eaten all day." Then the experimenter introduced the tray with the squishy toy and the strawberry. "Here we have a squishy toy and a strawberry. Which one of these things do you want to give him to make him feel better?" Choosing the correct option, the strawberry was met with positive feedback (Ernie said "thank you" and pretended to eat the strawberry "mm, mm, mm"); choosing the incorrect option was met with neutral feedback ("thank you"). Regardless of whether children passed the training trial, they continued onto the test trials.

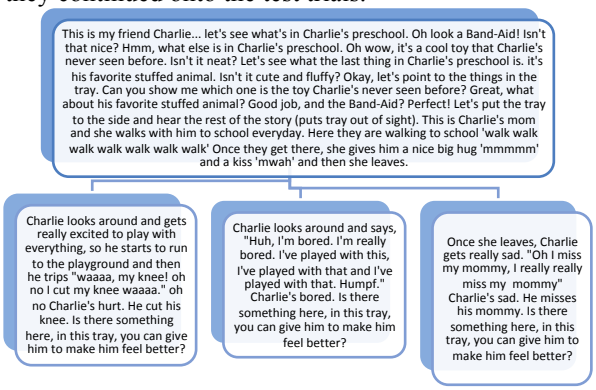

Figure 2: Example of the script and the three scenarios.

Test Trial Each test trial began with the introduction of the child puppet and three things in his preschool: a new toy that the puppet had never seen before, the puppet's favorite stuffed animal, and a Band-Aid. The child was given each item one at a time and told to place the item in the tray once they were done looking at it. Children were allowed to play for as long as they liked to minimize the chance that children would choose an item just to play more with it.
Children heard a core story and one of three possible endings: Hurt, Bored, and Sad. In the Hurt condition, the child puppet tripped and hurt his knee; in the Bored condition, the puppet got bored; in the Sad condition, the puppet got sad because he misses his mom. Participants were prompted to pick an item from the tray that would make the child puppet feel better. (See Figure 2 for an example.) Children received neutral feedback ("thank you" or "thanks for helping"); then a new pair of puppets and a new tray with three different items, one of each kind, was introduced. The scenarios were presented in random order for the first three trials and this order was repeated for the last three trials.

Results

Children were counted as performing correctly if they chose the Band-Aid for the Hurt scenarios, the new toy for the Bored scenarios, and the stuffed animal for the Sad scenarios. There was no effect of order on children's performance (Kruskal-Wallis rank sum test, $p = .44$).

Children had a choice of three items on each of the six trials. They received one point for each correct choice. Overall, children performed above chance (mean = 3.5; one-sample t-test, $p < .0001$). Only one child (the oldest) performed at ceiling but nine of the thirty-two children (28%) answered five of the six questions correctly ($p < .0001$ by binomial test). There was an effect of age on children's overall score ($r^2 = 0.15$, $p < .0001$; see Figure 3); older children performed better, and as clear in Figure 4, the effect was driven primarily by improvement in the Sad condition.

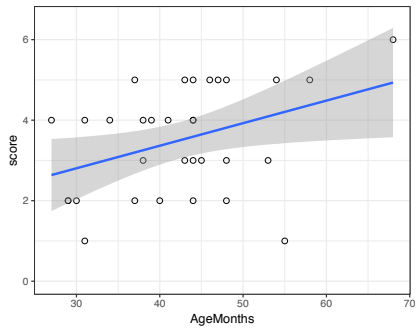

Figure 3: Children's overall score as a function of age

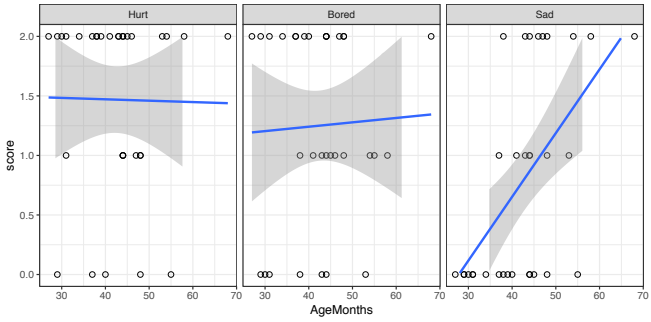

Figure 4: Children's responses by age and condition

The kind of scenario affected children's score (Test of Equal Proportions, $p < .001$); thus we used pairwise comparisons to look within each scenario at children's performance. Children performed better in both the Hurt and Bored conditions than in the Sad condition (Hurt versus Sad; $p < .001$; Bored vs. Sad, , $p < .05$; see Figure 5); children's performance in the Hurt and Bored conditions did not differ from each other (Hurt vs. Bored; $p = .26$). Within each condition, children performed above chance in both the Hurt ($p < .0001$ by Test of Equal Proportions) and Bored conditions ($p < .0001$); but their scores in the Sad condition were not significantly different from chance ($p = 0.78$).

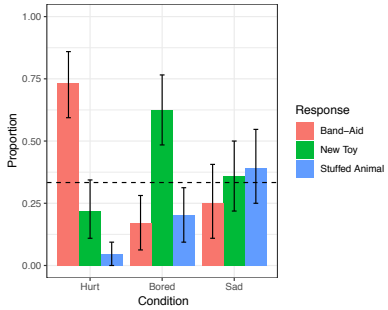

Figure 5: Children's choice of each of the three responses by condition

Discussion

Above all, these results suggest that, at least in simple forced choice contexts with low verbal demands, very young children's helping behavior is not restricted to resource sharing or assisting with functional, goal-directed actions; children seek to help relieve others' distress and do so in ways that are responsive to distinct sources of negative affect. Although children's ability to calibrate their response to the emotional state improved over development, even children as young as two and three distinguished upset due to pain and upset due to boredom and generated distinct, appropriate responses.

As predicted however, children had more difficulty knowing how to respond to distress due to a separation. We hypothesized that this might be because the impact of the intervention on the outcome was more uncertain. None of the candidate options would directly remove the source of distress; the best children could do would be to offer something that would help moderate it. There are possibilities however. Children may simply have preferred the fun toy to the stuffed animal – inflating their performance in the Bored condition and impairing it in the Sad condition. We think this interpretation is unlikely however, given both the method and results: We intentionally allowed children to play with each item to satiation in advance to wash out any differential stimuli effects, and children had no difficulty overcoming any preference for the toy in the Hurt condition.

Alternatively, young children might genuinely believe that the other options (toys or Band-Aids) were more likely to provide comfort than the stuffed animal – and indeed, at least for some children, in some contexts, this might be correct. Indeed, emotion regulation is challenging because there are no determinate rules: what works one time might not work the next, and what works for one person might not work for another. Nonetheless, within a given culture and context, there is a probabilistic relationship between certain responses and outcomes, and the current results suggest that children begin to learn these relations over the preschool years. Future research might extend this study to older children to see if their responses are adult-like or even provide children with the option to not help the puppet. Future research might also look at children's sensitivity to culturally specific, or family specific, dimensions of emotion regulation to look at how socialization affects children's responses.

Overall however, these results suggest that children's empathetic responses are not monolithic. With apologies to Tolstoy, even two-year-olds seem to recognize that every unhappy puppet is unhappy in its own way – and they offer solace accordingly.

Abstract

Transfer learning is fundamental for intelligence; agents expected to operate in novel and unfamiliar environments must be able to transfer previously learned knowledge to new domains or problems. However, knowledge transfer manifests at different levels of representation. The underlying computational mechanisms in support of different types of transfer learning remain unclear. In this paper, we approach the transfer learning challenge by decomposing the underlying computational mechanisms involved in bottom-up associative learning and top-down causal schema induction. We adopt a Bayesian framework to model causal theory induction and use the inferred causal theory to transfer *abstract* knowledge between similar environments. Specifically, we train a simulated agent to discover and transfer useful relational and abstract knowledge by interactively exploring the problem space and extracting relations from observed low-level attributes. A set of hierarchical causal schema is constructed to determine task structure. Our agent combines causal theories and associative learning to select a sequence of actions most likely to accomplish the task. To evaluate the proposed framework, we compare performances of the simulated agent with human performance in the OpenLock environment, a virtual "escape room" with a complex hierarchy that requires agents to reason about causal structures governing the system. While the simulated agent requires more attempts than human participants, the qualitative trends of transfer in the learning situations are similar between humans and our trained agent. These findings suggest human causal learning in complex, unfamiliar situations may rely on the synergy between bottom-up associative learning and top-down schema reasoning.

Introduction

The human capacity for inferring causal relations in unfamiliar environments is a hallmark of human intelligence (Mackie, 1974) that is often taken for granted in daily life. An illustrative example is that of the escape room—a prevalent social activity where groups of people inside of a locked room work together to complete sub-goals (puzzles) to achieve the goal—escape from the room. In order to succeed, teams must: (i) identify goal-relevant entities in the environment among distractors, (ii) develop a causal model for individual sub-goals, and (iii) interact with scene components to refine entity- and goal-based hypotheses. In this paper, we propose that inference in scenarios like the one above depends on two critical learning components. First, attributes relevant to candidate causal hypotheses are learned by interacting with entities in the scene, and second, causal hypotheses are refined based on newly encoded attribute-based knowledge.

It is worth noting that the above approach is generally inconsistent with early studies on causal learning in psychological research (Holyoak & Cheng, 2011). Early studies primarily focused on animal learning and conditioning experimental paradigms, framing causal understanding as learned stimulus-response relationships attained primarily through observation (*e.g.*, Shanks and Dickinson (1988)). Given associative weights on cue-effect links, the Rescorla-Wagner model was often utilized to explain how humans (and non-humans) construct expectations based on the co-occurrence of perceptual stimuli (Rescorla & Wagner, 1972). However, the knowledge that people have about causal mechanisms in the distal world has been shown to extend beyond the covariation between observed (perceptual) variables. For instance, adults interact with dynamic physical scenarios in ways that maximize information relevant to their causal hypotheses (Bramley, Gerstenberg, Tenenbaum, & Gureckis, 2018), and even infants test their beliefs about the physical characteristics of objects through exploration and experimentation (Stahl & Feigenson, 2015).

Contrary to the associative account, researchers have demonstrated that human learning and reasoning in novel (causal) environments rely heavily on the discovery of abstract causal structure (Waldmann & Holyoak, 1992) and strength (Cheng, 1997) rather than purely associative (statistical) dependencies. More recently, the integration of causal graphical models and Bayesian statistical inference (*i.e.*, Bayes nets) has provided a general representational framework for how this structure and strength is learned and transferred to novel situations (Griffiths & Tenenbaum, 2005, 2009; Tenenbaum, Griffiths, & Kemp, 2006; Bramley, Lagnado, & Speekenbrink, 2015; Bramley, Dayan, Griffiths, & Lagnado, 2017; Edmonds et al., 2018; Holyoak & Cheng, 2011). Under this framework, causal knowledge plays an essential role in constructing a flexible model of the world in which environmental states represent some status in the world, and connections between states imply the strength of a causal relationship.

We propose that creative discovery in novel domains relies on both causal structure *and* associations. Knowledge of causal structure enables agents to simulate how interventions will influence the environmental state, and without associations to guide exploration, the number of causal hypotheses to consider becomes intractable. For problem domains where the number of possible interventions is particularly high, the need for associative "guidance" can drastically improve decision-making. To solve this problem, we propose a computational model that integrates two learning mecha-

nisms: (i) a bottom-up process that determines which object attributes are causally relevant, and (ii) a top-down process that learns which abstract causal structures accomplish a task. The outcomes of actions are used to update the causal hypothesis space, and simulated agents learn a dynamics model capable of solving a challenging task.

We implement the proposed model in a virtual "escape room" environment where agents (human and artificial) are trapped in a room containing a single locked door and a set of conspicuous levers. The door of this room will unlock after the agent has interacted with the levers in a specific sequence. An agent placed in such a room may begin to randomly push or pull on the levers and revise their theory about the door's locking mechanism based on observed changes. Once an agent discovers a single solution, they are placed back into the same room and tasked with finding the next solution. The agent "escapes" from a room after finding *all* of the solutions which can be used to unlock the door.

After escaping from a room, agents are placed in a similar room but with newly positioned levers. Although the levers are in different positions, the new room is governed by the same abstract rules as the last (unknown to the agent). Thus, the agent's task is to identify the role of each lever in a new room. If the agent makes use of some knowledge from previous trials, we expect to observe fewer attempts in solving the problem. Because these rules are abstract descriptions of the latent state of the escape room, we refer to the underlying theory as a causal schema (*i.e.*, a conceptual organization of events identified as cause and effect; Heider, 1958). Once learned, this schema enables agents to transfer between different arrangements of levers in the room. The present work models the causal learning process from a hierarchical Bayesian perspective and makes three major contributions:

1. Utilizes a bottom-up associative learning paradigm to determine which attributes of the scene contribute to causal relations.
2. Utilizes a top-down causal schema model of the generalized operation of the environment to quickly adapt to similar but new scenarios.
3. Leverages causal hypotheses to learn a world model capable of transferring knowledge between seemingly dissimilar but structurally and causally equivalent environments.

The remainder of the paper is structured as follows. First, the OpenLock environment and experimental procedure are described, followed by an analysis of human performance from Edmonds et al. (2018). Next, components of the proposed model are described and corresponding results are provided. Finally, the paper concludes with a discussion of results and directions for future work.

Experiment: OpenLock Task

Participants

A total of 160 undergraduate students (114 female; mean age= 21.6) from the University of California, Los Angeles (UCLA) Department of Psychology subject pool and were compensated with course credit for their participation.

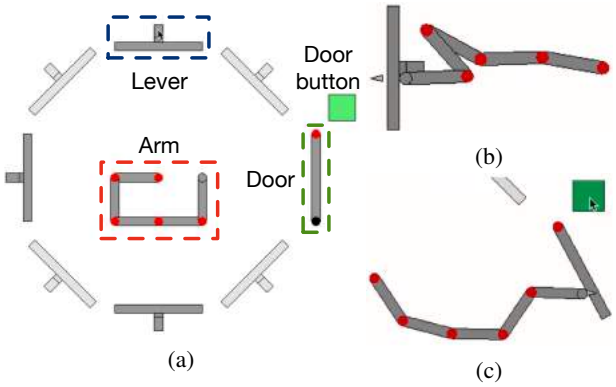

Figure 1: (a) Initial configuration of the room containing three active levers. All levers begin pulled toward the robot arm located at the center of the display. The arm interacts with levers by pushing/pulling them outward/inward. Only push actions are needed to unlock the door in each room (unknown to agents). White levers never move; this information is not explicitly stated. Once the door is unlocked, the green button can be clicked to command the arm to push the door open. The black circle located opposite the door's red hinge represents the door lock indicator (present if locked, absent if unlocked). (b) Pushing on a lever. (c) Opening the door by clicking the green button.

Materials and Procedure

In this section, we outline the OpenLock task, initially presented in Edmonds et al., 2018. In the task, agents are required to "escape" from a virtual room by unlocking and opening a door. The door unlocks after manipulating the levers in a particular sequence (see Figure 1). Each room consists of seven levers surrounding a robotic arm that can *push* or *pull* on each lever. While a subset of the levers is always involved in the locking mechanism (*i.e.*, active levers; colored grey), other levers are not causally relevant (*i.e.*, inactive levers; colored white). Agents observe the color of the levers and are expected to *learn* that grey levers–but not white levers–are always part of solutions in each room. Importantly, agents are tasked with finding *all* possible solutions for opening the door within a room. Participants are explicitly told that their goal is to open the door and are informed of how many solutions they have remaining in this room.[1]

The mechanics underlying the environment obey one of two causal schemas: Common Cause (CC) and Common Effect (CE) (see Figure 2). Requiring agents to find all solutions within a specific room ensures that agents abstract CC or CE schema structures. While a single solution corresponds to a single causal chain, a schema relies on nodes that are shared between multiple chains. Agents operate under a movement-limit constraint, where only three movements can be used to either (i) *push* or *pull* on levers (active or inactive), or (ii) *push* open the door. This constraint was placed on the agent to confine the search depth of possible solutions. After three movements, the episode terminates and the environment re-

Figure 2: Common Cause (CC) and Common Effect (CE) structures used in the OpenLock task, in which L_i indicates a lever in the scene, and D indicates the effect of opening the door. In (a) CC3 and (b) CE3 condition, both include three causal cues but with different causal structures.

sets, regardless of the outcome. Agents also operate under a limited number of episodes (30) in a particular room, regardless of whether all solutions are found. We denote three movements as an *attempt* and each room as a *trial*. After completing a trial, agents move to a new trial (*i.e.*, room) with the same underlying causal schema but a different lever arrangement. This setup ensures that agents do not overfit their understanding of the environment to a single trial; *i.e.*, if agents are forming a useful abstraction, the knowledge they acquired in previous trials should aid in their ability to find all solutions in new trials. Note that in a 3-lever room, an optimal agent should produce both solutions within 3 attempts. One attempt may be used to identify the role of the observed levers in the abstract structure, and the remaining attempts are used for each solution.

Human Results

The analyses reported herein expand on previous behavioral findings by examining the number of attempts needed to find *each* solution rather than accumulating *all* solutions (see Human Data, Edmonds et al., 2018). The purpose of this exploration was to tease apart the separate learning components involved in the OpenLock task. Participants who failed to find all solutions in the allotted maximum number of attempts in *any* trial were removed from the analysis (24 participants removed from each condition). Eighty human participants were assigned to each condition (CC and CE).

We first examined whether the number of attempts needed to find each solution varied across trials. The behavioral data from each experimental condition is depicted in Figure 4. For participants who trained under a Common Cause (CC) schema, attempts needed to find the *first* solution decreased significantly following both the first trial ($t(55) = 6.80; p < .001$) and second trial ($t(55) = 2.52; p = .02$). First solution attempts also showed a marginal decrease following the fifth trial ($t(55) = 1.99; p = .051$). For the *second* solution, the number of attempts needed decreased significantly following the first trial only ($t(55) = 4.40; p < .001$). A similar trend was observed for participants assigned to the Common Effect (CE) condition—attempts needed to find the *first* solution decreased following the first trial ($t(55) = 5.30; p < .001$) and third trial ($t(55) = 2.19; p = .03$), and attempts needed to find the *second* solution decreased following the first trial only ($t(55) = 2.36; p = .02$).

The human results demonstrate that regardless of which causal schema participants trained with, significant learning appeared to occur in the early trials for both the *first* and *second* solution. However, the learning rate for the *first* solution was much faster, and the learning rate for the *second* solution was relatively less pronounced. In the next sections, we describe our computational approach and report whether it can account for human performance.

Model Details

We begin by describing our agent's process for combining top-down (abstract) causal knowledge with bottom-up (associative) attribute knowledge. The agent decides which action to perform by (i) computing the posterior probability of each candidate causal chain and (ii) making a selection using the computed posterior and a model-based planner.

Causal Theory Induction: To explain trends in human performance, we follow a Bayesian account of how hierarchical causal theories can be induced from data (Griffiths & Tenenbaum, 2005, 2009; Tenenbaum et al., 2006). The key insight in this framework is that hierarchy enables abstraction, and theories provide general background knowledge about a task or environment at the highest level. Theories consist of principles; for example, an analysis of evolutionary traits between species can be represented with a taxonomic tree and mutation processes (example from Tenenbaum et al. (2006)). Principles lead to structure; for example, a tree describing how primates evolved and split into species over time. Finally, structure leads to data; such as shared genes among primates.

The goal of this work is to model a human decision-making process where agents are required to learn *transferable* knowledge between different yet similar environments. We approach the problem from the perspective of *active* causal theory learning, where we expect an agent endowed with no information to learn the underlying abstract mechanics and commonalities between environments through interaction. This approach naturally places the focus of the learning task on how the agent decides the best action to take next and how to effectively integrate the results into the agent's model of the world.

In this work, we adhere to two general principles of learning: (i) *causal relations induce state changes in the environment, and non-causal relations do not* (referred to as our bottom-up β theory), and (ii) *causal structures that have previously been useful may be useful in the future* (referred to as our top-down γ theory). Specifically, the environment provides a set of attributes, such as position and color, and our agent learns which attributes are associated with levers that induce state changes in the environment. Our agent also learns a distribution over abstract causal structures (*i.e.*, schemas) that provide generalized notions of task structure.

We define a causal chain hypothesis space, Ω_C, over possible causal chains, $c \in \Omega_C$. Figure 3b shows the structure of the causal chain. Each chain is defined by a tuple of subchains $c = (c_0, \ldots, c_k)$, where each subchain is defined as a tuple $c_i = (a_i, s_i, cr_i^a, cr_i^s)$. Each a_i represents an action node that the agent can intervene on (execute), and the space of actions, Ω_A, consists of pushing and pulling on every lever and

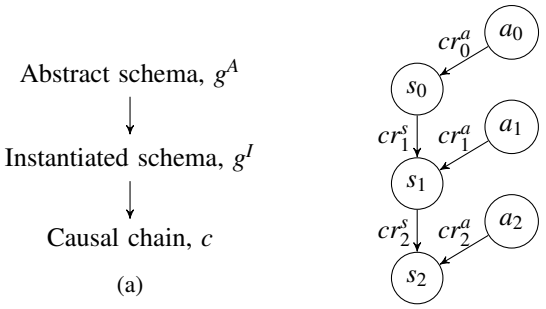

Figure 3: (a) An illustration of hierarchical structure of the model. A bottom-up associative learning theory, β, and a top-down causal theory, γ, serve as priors for the rest of the model. The model makes decisions at the causal chain resolution. (b) Atomic causal chain. The chain is composed by a set of sub-chains, c_i, where each c_i is defined by: (i) a_i, an action node that can be intervened upon by the agent, (ii) s_i, a state node capturing the time-invariant *attributes* and time-varying *fluents* of the object, (iii) cr_i^a, the causal relation between a_i and s_i, and (iv) cr_i^s, the causal relation between s_i and s_{i-1}.

pushing on the door. Each s_i represents a state node. The state node is defined as a tuple, $s_i = (\phi_i, f_i)$, where ϕ_i is a vector of time-invariant *attributes* and f_i is a vector of time-varying *fluents*. The state node is influenced by taking action a_i according to the causal relation cr_i^a and may be affected by a previous state node through the causal relation cr_i^s. For instance, in Figure 1a and Figure 3b, the action *push* for the leftmost lever may transition the lever from the fluent *pulled* to *pushed* through cr_0^a, which in turn transitions the uppermost lever from *locked* to *unlocked* according to cr_1^s.

The space of attributes is denoted as Ω_ϕ, consisting of position and color. The space of fluents, Ω_F, consists of binary values for lever status (*pushed* or *pulled*) and lever lock status (*locked* or *unlocked*). The space of states is defined as $\Omega_S = \Omega_\phi \times \Omega_F$. The space of causal relations is defined as $\Omega_{CR} = \Omega_F \times \Omega_F$, capturing the possibly binary transitions between previous fluent values and the next fluent values.

We assume agents can directly intervene on (*i.e.*, control) *actions*, but cannot directly intervene on *fluents*. This distinction adds significantly more complexity to the causal chain hypothesis space but means that we do not assume the effects of actions, nor do we assume an agent can directly intervene on the value of a particular fluent. We assume that an agent can execute any action within the action space (through an intervention on the action node in the causal chain), but how that action affects the state of the world must be learned (*i.e.*, the effects of the actions are learned).

Decomposing states into time-invariant *attributes* and time-varying *fluents* aids in the computational complexity of learning and inference; our agent assumes attributes cannot be changed by actions or other states. In addition, because the attributes are time-invariant, attributes offer a grounding upon which the agent can learn knowledge, regardless of the executed action sequence or lever configuration. In contrast, the fluents are time-varying and include the latent state of the lever's internal locking mechanism; *i.e.*, *locked* or *unlocked*. The agent learns how to influence these latent states through observational cues about which attributes are associated with a particular fluent. Attributes are defined by low-level features of an object, *e.g.*, position, color, shape, orientation, *etc.*. These low-level attributes provide general background knowledge about how specific objects change under certain actions (for instance, which levers can be pushed or pulled).

A background theory encodes general knowledge that can be used to induce or evaluate a structural representation. We use two background theories—one for bottom-up features, denoted β, to learn beliefs about which attributes of objects indicate the object can be interacted with to produce a causal effect. This low-level knowledge about object attributes and their propensity to be involved in causal relationships provides information to transfer between similar but different environments governed by common underlying dynamics. The second background theory provides a top-down abstraction, denoted γ, that assumes tasks have similar causal structure across slightly different environments; *i.e.*, changes in the observable environment do not alter the underlying causal structure of a task.

Attribute Learning: Attributes provide time-invariant properties of an object. Categories of objects often share common attributes; *e.g.*, all cups share a common shape, all stop signs are red, *etc.*. However, objects in a category may vary in their physical form but share common functionality; for instance, light switches come in a number of shapes and sizes, but all examples share a common mechanism to transit between states.

We learn which attributes are relevant to our causal hypotheses via a Bayesian learning process, based on our assumption that causal relationships induce state changes. Therefore, an object changing states under an action indicates that the object's attributes may be related to a causal relationship. These attributes provide generalization clues for the agent, such as insights into which low-level attributes indicate that the corresponding object is part of a solution. This knowledge is invariant across trials and causal schemas.

The agent's belief in an attribute being causal is modelled with a multinomial distribution $\text{Mult}(\theta)$ parameterized by θ. The posterior distribution of θ given observed data $\mathbf{X}$ and the bottom-up theory β follows a Dirichlet distribution: $p(\theta|\mathbf{X};\beta) = \text{Dir}(\alpha')$, where α' is given by a maximum a posteriori (MAP).

Attributes are learned in two different time scales: a global timescale to learn attributes across all trials (between trials) and a local timescale to learn attributes specific to this trial (within trials). This separation allows the agent to adapt quickly to trial-specific knowledge while maintaining a global understanding across all trials. In each timescale, we perform this attribute learning in the following steps: (i) draw a sample (produce an observation by selecting an intervention and observing the result), (ii) accept the sample if the environment changed state in any way (*i.e.*, there was an effect from the intervention), and (iii) increase α of each attribute's Dirichlet distribution according to observed outcome.

A Dirichlet distribution, $\text{Dir}(\alpha^G)$, is used to model the posterior of the global attribute distribution. After finishing a

trial, the agent's global Dirichlet parameters, α^G, are updated to incorporate the observed data within a trial.

For each trial, we initialize the parameters of the local attribute Dirichlet distribution, $\text{Dir}(\alpha^L)$, with a scaled sample from the global Dirichlet, $\alpha^L = k\theta$, where $\theta \sim \text{Dir}(\alpha^G)$. This scaling factor k reduces the variance and enables fast adaptation of the agent's local attribute beliefs. In our experiments, we set k to initialize the local Dirichlet to have $\alpha^L \in [1, 10]$.

We introduce an additional variable, ρ to represent a casual event according to our background theory β; *i.e.*, that causal events induce state changes in the environment. We use a local prior over attributes as our bottom-up associative learning theory. We compute the likelihood that the attributes of a particular chain c are causally relevant given a background theory β as:

$$p(\rho|c;\beta) = \prod_{c_i \in c} p(\rho_i|c_i;\beta), \tag{1}$$

where $p(\rho_i|c_i;\beta)$ is computed as

$$p(\rho_i|c_i;\beta) \propto \prod_{\substack{\phi_{ij} \in s_i \\ s_i \in c_i}} p(\rho_i|\phi_{ij};\beta) \tag{2}$$

where ϕ_{ij} is the j-th attribute from the i-th subchain. The term $p(\rho_i|\phi_{ij};\beta)$ represents the probability that attribute ϕ_{ij} adheres to the background theory β. Here, β represents the probability that attribute ϕ_{ij} is associated with objects that induce state changes. Note that $p(\rho_i|\phi_{ij};\beta)$ is parameterized by a sample from the local attribute Dirichlet distribution. After finishing an attempt, we update the parameters α^L of the local distribution to incorporate the outcome of the attempt and resample θ.

Recall our associative theory: causal relationships induce state changes in the environment; practically, $p(\rho_i|\phi_{ij};\beta)$ represents the probability that attribute ϕ_{ij} is associated with objects that produce state changes, under the assumption these attributes are independently associated with causal events. In our domain, an agent using this theory should learn that grey levers are involved in causal events and white levers are not. Additionally, the agent should initially believe that position is an important attribute for detecting causal relationships. However, as the agent observes multiple configurations of levers with different positions of grey levers, every position will be involved in causal events, and therefore this belief should approach the uniform distribution.

This bottom-up inference enables agents to leverage low-level associative information about causal relationships. We then transfer this belief between trials, thereby enabling our agent to leverage the knowledge acquired in one trial to transfer to the next trial. The agent updates its belief regarding which attributes it believes are causal after each attempt.

Abstract Schema Learning: Learning attributes that correspond to causal cues is critical for an agent expected to learn how an environment operates. However, many environments share common high-level abstract causal structures. For instance, switches come in all different shapes and sizes tailored to specific tasks—from a light switch to a circuit breaker to a railroad switch. Each of these domain-specific mechanisms share a common abstract functionality—changing the state of some object from one discrete state to another.

We propose a model to learn abstract structural models that can be used to instantiate domain-specific models to achieve a task in an environment. This abstract knowledge is assumed to be useful across domains, and agents may acquire a collection of useful abstract models of different functionality. Our model considers learning abstract knowledge as a form of model selection, where the agent hypothesizes a space of potential abstract structures and updates the beliefs in those abstract structures based on its experience in the environment.

More specifically, we consider an abstract causal schema, g^A, from a hypothesis space of abstract schemas, Ω_{G^A}, to be a structural description of some causal relationships (see Figure 2). The space Ω_{G^A} is enumerated in this work; *i.e.*, all possible structural combinations of $N = 2$ trajectories (*i.e.*, causal chains) with length $K = 3$ are considered (since there are two solutions and three actions per attempt). We introduce a prior over abstract schemas, $p(g^A;\gamma)$, that is a multinomial distribution parameterized using a sample from the abstract schema Dirichlet distribution, $\text{Dir}(\alpha^A)$. After completing a trial, the abstract schema that encodes the solutions found in this trial receives a parameter update in the Dirichlet distribution—*i.e.*, an increase to the solution abstract schema's α^A.

These abstract structures are not bound to any particular instantiation of attributes, states, or actions. Instead, they encode common structural properties under varying instantiations—knowledge that may be useful when an observational setting is changed. In our task, abstract schemas encode the abstract structures, some of which are useful for solving OpenLock (*i.e.*, CC or CE), and we should expect agents to have a biased prior towards these structures.

Next, we consider an instantiated schema, g^I, to be a composition of causal chains, $c \in \Omega_C$. Instantiated schemas share the same structure as abstract schemas, but contain specific assignments for each a_i, s_i, cr_i^a, and cr_i^s of each subchain in the schema. We compute the belief in an instantiated schema g^I according to the hierarchical structure in Figure 3a:

$$p(g^I|do(q);\gamma) = \sum_{g^A \in \Omega_{G^A}} p(g^I|g^A, do(q))p(g^A;\gamma), \tag{3}$$

where $do(q)$ represents an intervention where the agent performs q—the solutions found thus far, a set of action sequences $q = \{A_0, A_1, \ldots, A_n\}$, where A_i is an action sequence. The $do()$ operator is the intervention operation presented by Pearl (2009), which allows the agent to bias its top-down inference towards instantiated schemas that contain solutions already found. Next, we compute the top-down belief in a causal chain by summing over instantiated schemas that contain the chain:

$$p(c|do(q);\gamma) = \sum_{g^I \in \Omega_{G^I}} p(c|g^I, do(q))p(g^I|do(q);\gamma). \tag{4}$$

These terms enable top-down inference on which chain is most likely to adhere to instantiated schemas that reflect abstract causal structures that have been useful in the past.

Learning which abstract schemas were successful in previous trials can be leveraged when the agent faces a new room configuration with the same underlying abstract mechanism governing the lock.

Intervention Selection: We formulate our intervention selection as a combination of the top-down and bottom-up causal chain beliefs, and we consider our learning mechanisms, γ and β, to be independent. We compute the posterior of the chain based on our top-down belief and bottom-up likelihood, assuming a uniform prior $p(\rho)$:

$$p(c|\rho, do(q); \gamma, \beta) \propto p(c|do(q); \gamma) p(\rho|c; \beta). \quad (5)$$

Our agent maintains an explicit notion of the goal of the task—to open the door. Human participants were also told the precise goal of the task. Thus, we frame our intervention selection process as a form of model-based planning. Our agent seeks to infer the causal chain most likely to achieve the goal—opening the door—given the agent's current model of the environment. The agent's model of the environment comes from two forms of learning: bottom-up associative attribute learning and top-down abstract schema learning.

We define a target goal of our planner as a particular state of the environment, denoted s^*. Given a target goal our agent models its current state as a tuple of (n, q), where n represents the number of solutions remaining, and q the set of solutions already executed. The agent seeks to execute a causal chain c in the hopes of transitioning n to $n-1$. The agent replans after every attempt until it finds all solutions the room; *i.e.*, when $n = 0$. Thus, our final planning objective at time t is to pick the causal chain with the maximal posterior subject to the constraints that the chain contains the target goal state s^* (*i.e.*, the door being *pushed*) and is not in the agent's set of solutions executed q:

$$c_t^* = \arg\max_{c \in \Omega_C} p(c|\rho, do(q); \gamma, \beta) \quad \text{s.t. } s^* \in c \wedge c \notin q, \quad (6)$$

where $p(c|\rho, do(q); \gamma, \beta)$ is defined in Equation 5. This state definition matches information provided to human participants and places the focus of our planner on achieving task-level goals.

Among the chains that satisfy the constraints, we rely on our chain posterior to capture which chains are causally plausible. The posterior combines the top-down structural knowledge with the bottom-up attribute knowledge. This combination is powerful for two reasons: (i) bottom-up knowledge biases beliefs towards structures that contain attributes that have been present in causal events in the past, and (ii) top-down knowledge allows the agent to bias beliefs towards structures that have been useful in the past.

Model Results

We train our agent in the same fashion as humans; specifically, we allow the agent to complete 80 trials in CC and CE escape rooms (same number as human participants). The agent is also limited to 3 actions in an attempt and 30 attempts within a trial. Any agent that did not complete all trials was removed from the study (same as human participant data—no agents were removed from the CC condition; 7 agents were removed from the CE condition).

Figure 4 compares human and model performance. The model shows a similar trend as humans but with slightly worse performance in each trial[2]. For the agent assigned to the CC condition, the number of attempts needed to find the *first* solution decreased significantly following the first trial ($t(79) = 8.09; p < .001$) and second trial ($t(79) = 4.04; p < .001$). The CE agent required less attempts to find the *first* solution following the first trial only ($t(72) = 6.23; p < .001$). Decreases in first and second solution attempts were not significant between the remaining trials.

These results demonstrate that our model is roughly capable of capturing learning rates of human participants but does not capture all significant changes in the number of attempts needed: *e.g.*, in both the CC and CE conditions, the number of attempts needed by participants to find the *second* solution consistently decreased following the first trial. However, our model overall effectively captures general trends in human performance: the number of attempts needed to find *all* solutions matches well to humans and decreases near-monotonically, albeit at a lesser rate.

[2]Example solution executions for human participants and the model can be viewed at `https://vimeo.com/334518941`

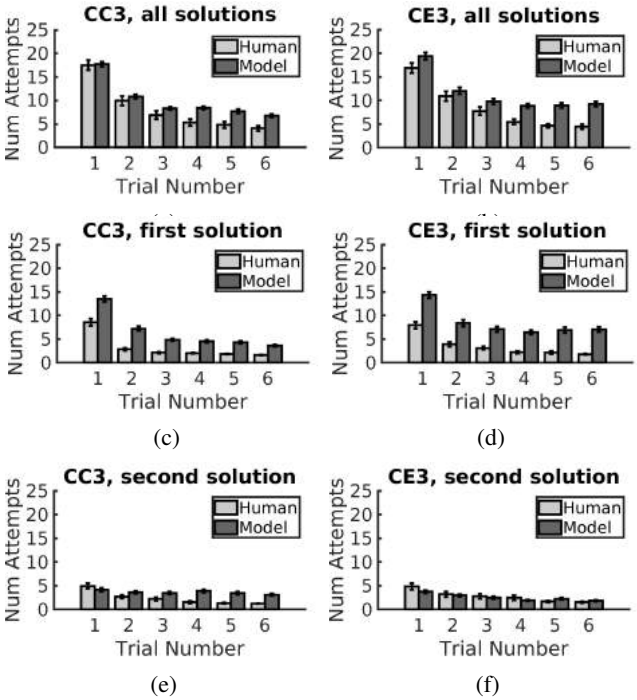

Figure 4: Comparison of human and model results for the common-cause CC3 condition and the common-effect CE3 condition. (a) and (b) compare the total number of attempts to find all solutions; (c) and (d) compare the number of attempts to find the *first* solution; (e) and (f) compare the number of attempts to find the *second* solution.

Conclusion

In this work, we showcase a hierarchical model based on associative learning and schema reasoning. Our model integrates two learning mechanisms: (i) a bottom-up theory that learns which attributes have causal associations in the environment, and (ii) a top-down theory that learns useful abstract structures in the environment. Our agent chooses an intervention based on the posterior of causal chains and updates its model using the observed outcome of the intervention. Model results show that our hybrid agent is able to capture general trends observed in human participants and captures some of the statistical significance observed in human performance. These results suggest that human causal learning may consist of a mechanism that combines bottom-up associative learning with top-down reasoning about causal structure.

The underlying computational framework presented here is broadly applicable outside of the OpenLock environment; it can be applied to any reinforcement learning environment where: (i) underlying dynamics are constrained by some causal structure; (ii) interactive elements have observable features which signal causal relevance; and (iii) physical locations of key elements change over time. In the future, we hope to expand our model to account for more extreme observational changes. For example, what if levers could suddenly be rotated instead of pushed/pulled? What if new colors were introduced which provided further cues about causal relevance? And what if the environment began operating in a probabilistic fashion where levers may fail to actuate properly? Future behavioral and computational work should examine how these processes integrate in more complex scenarios that provide a closer approximation to the real world.

Discussion

What other theories may be useful for learning causal relationships? The background theories presented here—namely that causal relationships induce state changes and abstract causal knowledge can be reused—provide reasonable background theories. However, other background theories may also be appealing. For instance, Pearl (2009) defines a stricter definition of causal relations based on whether or not a causal relation is *identifiable* in a directed acyclic graph.

How can hypothesis space enumeration be avoided? The spaces of Ω_{g^A} and Ω_{g^I} are enumerated in this work. Hypothesis space enumeration can quickly become intractable as problems increase in size. While this work used a fixed, fully enumerated hypothesis space, future work will include examining how sampling-based approaches to iterative generate causal hypotheses (*e.g.*, see Bramley et al. (2017)).

What are the other possibilities of bottom-up associative criteria? Our method treats low-level attributes as the criteria for our bottom-up associative learning. However, other possibilities are equally valid. For instance, a modeler could pair attributes with specific actions and learn distributions of causal effects over this pairing. This decision ultimately comes down to the resolution of the problem being considered and what is appropriate to correctly model the problem.

How is this work connected to reinforcement learning (RL)? The model-based planner is closely related to model-based RL. Our problem setting could be cast in terms of a 0-1 reward function—the agent receives a reward of 1 if the door is opened, and 0 otherwise. However, model-based RL typically assumes a world model is provided, but our agent iteratively updates its conception of world dynamics through associative learning and schema reasoning.

Moral Reasoning with Multiple Effects: Justification and Moral Responsibility for Side Effects

Neele Engelmann (neele.engelmann@uni-goettingen.de)
Michael R. Waldmann (michael.waldmann@bio.uni-goettingen.de)
Department of Psychology, University of Göttingen, Germany

Abstract

Many actions have both an intended primary effect and unintended, but foreseen side effects. In two experiments we investigated how people morally evaluate such situations. While a negative side effect was held constant across conditions in Experiment 1, we varied features of the positive primary effect. We found that judgments of moral justification of actions were sensitive to the numerical ratios of helped versus harmed entities as well as to the kind of state change that was induced by an agent's action (saving entities from harm versus improving their status quo). Judgments of moral responsibility for side effects were only sensitive to the latter manipulation. In Experiment 2, we found initial support for a subjective utilitarian explanation of the moral justification judgments.

Keywords: Moral Reasoning, Causal Reasoning

Introduction

Research on moral judgments often probes people's intuitions about moral dilemmas. One of the most famous and well-studied dilemmas is the so-called trolley problem (Foot, 1967). In the side effect variant of trolley dilemmas, agents have a choice between letting a runaway trolley kill several people or an action that redirects the trolley to a different track where it would kill fewer people. The primary question in these studies is typically whether it is morally permissible to act. Many factors have been identified that influence people's intuition about this question (for an overview see Waldmann, Nagel, & Wiegmann, 2012).

The two dominant normative ethical approaches, utilitarianism and nonconsequentialism, largely agree in this situation. According to utilitarian recommendations, the action should be performed whenever its positive consequences outweigh the negative effects. Nonconsequentialist theories, such as the *Doctrine of Double Effect* (DDE, see Mikhail, 2011), arrive at similar conclusions for this case. The focus of the DDE and nonconsequentialism in general lies on the causal structure mediating acts and outcomes. In the side effect variant of the trolley dilemma, acting is considered permissible because the negative effect is not an intended means, but merely a foreseen side effect, and is not out of proportion to the positive effect. Psychological research on the side effect dilemma has shown that subjects indeed take the alternative outcomes into account when assessing the action's permissibility (e.g., Mikhail, 2011; Cohen & Ahn, 2016).

Evaluating Actions and their Side Effects

The focus of research on trolley dilemmas is on how people evaluate the permissibility of an action that causes two outcomes. All theories assume that in the side effect dilemma, both outcomes are compared and affect the moral evaluation, but little is known about the functional form of this comparison. A typical claim is that harming is permissible if the good outweighs the bad, but it is unclear whether this decision is just based on a simple categorical decision about which value is larger, or whether gradual differences between outcome values affect the decision. Few studies have systematically manipulated the numbers of victims that are saved or harmed in moral dilemmas (but see Cohen & Ahn, 2016; Waldmann & Wiegmann, 2012).

Cohen and Ahn (2016) postulate a subjective utilitarian analysis. For each item or set of items (e.g., 5 people) subjects provided an estimate of their personal value. The personal values were affected by the type of item and their number, although the number turned out to have a relatively small effect. These estimates of the personal values were then used to predict subjects' judgments about choice situations in which one set of items is about to be destroyed (or killed) when no action is taken but saved when the agent acts, which in turn would destroy (kill) a second set of items. According to the categorical utilitarian decision strategy, the action is chosen that saves items with the higher personal value. The model also predicts reaction times: Given that the comparison is typically influenced by uncertainty, a faster reaction time is predicted when the difference between values becomes larger.

One key goal of our project is to provide further tests of the subjective utilitarian model. A salient problem of the current version of the model is that it lacks generality. Its predictions are based on the personal values of the items involved in the outcomes but this model neglects that actions cause transitions between states. An evaluation of an action thus needs to take into account the values of the states of the items in the presence versus the absence of the action. Cohen and Ahn (2016) did not consider how subjects assess the personal values of the items in their destroyed or dead states, probably because this was the standard state in the absence of an action across all item sets. However, actions can also improve the state of items that otherwise would be in a normal state, or they could be saved from a disease that would harm, but not kill them. To provide a full utilitarian account of how outcomes of actions should be evaluated we suggest that people compute contrasts between the personal values of the outcomes in the presence versus the absence of the target action. We will also argue that sometimes more than two states need to be considered. We will present an experiment that presents a wider range of actions, which allows us to test our subjective utilitarian model against theories that are not sensitive to different types of states in the presence and absence of the

target action.

A further focus of our study is to investigate how the relation between the number of people that are positively or negatively affected by the action influences the degree to which people find the action morally justifiable and the agent morally responsible for the outcomes, especially the negative side effect. We systematically manipulated the numbers involving the positive primary effect while holding the negative side effect constant (see also Waldmann & Wiegmann, 2012, for a similar design but different tasks). For example, in one of our experimental conditions, ten members of a tribe are harmed by an action that would save a varying number of members of a different tribe. According to Cohen and Ahn's (2016) model, an act involving a negative side effect should lead to faster reaction times the more entities are helped compared to harmed. If reaction times indicate certainty about an act's permissibility, one can also derive from this theory the prediction that justification ratings should be affected in a similar manner.

One limitation of trolley studies is that so far they have focused on a particular type of situation in which the primary goal is to save victims that otherwise would be killed. It may well be that acts that lead to negative side effects are only considered justified when the primary effect targets entities that, prior to the intervention, are threatened to be harmed. The primary effect may be less effective as a justification when the act is supererogatory and just improves the states of entities that prior to the act are in a normal state. For example, instead of saving varying numbers of victims from grave harm, the people may be fine prior to the act, with the act just improving their health and living conditions. The theory proposed by Cohen and Ahn (2016) does not make predictions here because it only takes into account the personal values of the entities in their intact state. We will in Experiment 2 test a modified account that postulates that subjects take into account personal values of states in both the presence and the absence of an action. This account makes predictions for the difference between saving entities or improving their states.

Another limitation of the typical trolley dilemma studies is that they have focused on situations in which saving and harming are causally achieved by redirecting a harmful entity (the runaway trolley). In order to widen the range of studied dilemmas and to be able to manipulate the prior state of the entities involved in the primary goal, we tested a different causal structure in which a helpful act rather than a threat was redirected (see also Ritov & Baron, 1999; Bartels & Medin, 2007). For example, in the condition involving two tribes, a dam may be opened that redirects water from one tribe to the other. Redirecting might save tribe members from a negative state or improve their normal situation.

Finally, a limitation of previous research is that the test question typically focuses only on the act leading to two outcomes. We are also interested in how people evaluate the two outcomes individually. We therefore added as test questions requests to judge moral responsibility for the negative side effect. Our goal was to test whether these judgments are also influenced by the value of the primary effect (e.g., number of victims). If subjects just focus on the side effect, the primary effect should not have an influence. However, if the status quo or the number of affected entities are used as exonerating factors, their impact should also be seen in moral responsibility ratings for the side effect.

Together, these manipulations and the studied judgments widen the focus of previous work on people's moral intuitions about cases with multiple effects. The aim of the first experiment was to test whether the relation between primary and side effect of an action influences moral justification assessments. Moreover we were interested in whether the primary effect influences moral responsibility assessments for a bad side effect. We tested whether these two types of moral queries are affected by the kind and number of entities that are potentially harmed or saved, and by their state change due to a possible intervention. Experiment 2 inquires to what extent the results of Experiment 1 can be explained by a subjective-utilitarian framework.

Experiment 1

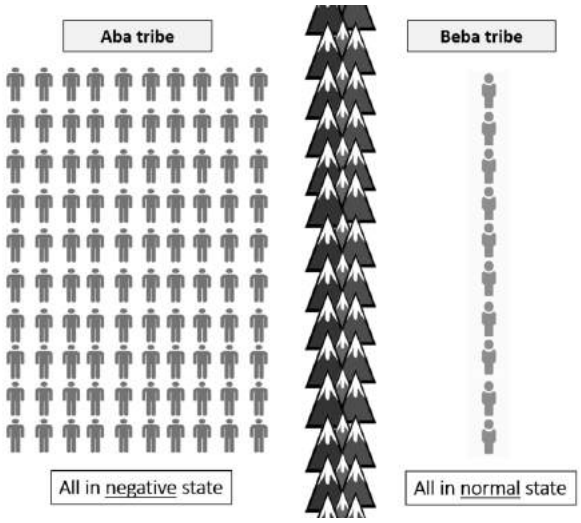
We constructed three scenarios in which an agent decides to perform an action with a positive, intended primary effect and a negative, unintended (but foreseen) side effect. The negative side effect was held constant across conditions and always consisted in killing 10 entities (people, animals, or plants). We varied whether 1, 5, 20 or 100 entities benefitted from the action. Furthermore, we manipulated whether these entities were in a negative or a neutral state prior to the action. In the situations in which the entities were in a negative state, they would have died without the agent's action; in the contrasted normal state condition, the action would merely cause additional benefit (e.g., people improving their living conditions or plants growing better).

Design, Material and Procedure[1] 450 participants were recruited via the UK based platform Prolific Academics for a compensation of £0.25 (£6 per hour). Inclusion criteria were a minimum age of 18 years, English as a first language, a study approval rate on the platform of at least 90%, and not having participated in previous studies with similar material. Participants were randomly allocated to one of 24 conditions (primary effect: saving vs. improving; number of helped entities: 1 vs. 5 vs. 20 vs. 100; affected entities: people vs. animals vs. plants). Here is an example vignette from the *saving* conditions. The example describes a condition in which 100 people are saved by the action, who otherwise would die:

Suzy is the prime minister of Tolosia, a mountainous country with many distant and small villages. The villages are populated by different indigenous tribes. She is authorised to make all decisions about the country's welfare that she deems appropriate. One day, she learns that a mountain village has

[1]The full material and data for both experiments are available under `https://osf.io/jcux6/`

suffered from an ongoing drought that left its inhabitants, the Aba tribe, in poor health due to lack of water. Exactly 100 people belong to the Aba tribe, all of whom are in critical condition and will die if nothing is done. Suzy could order to open a dam that would redirect a mountain river towards the Aba tribe. With a quick water supply, the 100 members of the Aba tribe could recover. However, the redirection of the river could also cause a lack of water in another mountain village, home to the Beba tribe, causing its 10 members to die of thirst within a few days. All of the 10 members of the Beba tribe are fine at the moment. Since both mountain villages are inaccessible to any means of transport, redirecting the river is the only currently available measure to influence the well-being of the two tribes. Here is a schematic representation of the two tribes and the current state of their members:



Suzy is aware of all the facts. She wants the 100 members of the Aba tribe to recover, but also not to cause any harm to the 10 members of the Beba tribe. She decides to open the dam and redirect the mountain river. All of the 100 members of the Aba tribe recover. However, all of the 10 members of the Beba tribe die within a few days.

The figure was followed by the instruction: "Here is a schematic representation of the tribes and their state after the river has been redirected" along with the same figure as above in which the lower labels now read "all in normal state" for the Aba tribe and "all dead" for the Beba tribe. In the corresponding *improving* condition, the vignette stated that the Aba tribe could vastly improve their health and lifespan with an extra water supply (no threat by a drought was mentioned). In the subsequent test phase participants were asked to rate the extent to which they saw the agent's action as morally justified ("To what extent was Suzy's action morally justified ?"). The moral responsibility question focused on the side effect ("To what extent is Suzy morally responsible for the members of the Beba tribe dying?"). As a control, we also asked about the primary goal ("To what extent is Suzy morally responsible for the members of the Aba tribe improving their health?"). Ratings were given on a 10-point Likert scale with the endpoints labelled "not at all" (1) and "fully" (10). Justification and responsibility questions were presented on two separate pages, with page order counterbalanced between participants; order of the two responsibility questions within the respective page was randomized. Subsequently, two manipulation check questions assessed whether people had correctly understood how many entities were harmed and helped in the scenario.

Results and Discussion 18 participants were excluded for failing at least one of the manipulation check questions, leaving data of 432 participants for the analysis (mean age = 34.4, SD = 11.93). We conducted a 2 (primary effect) x 3 (entity) x 4 (numbers) x 2 (test question order) ANOVA for each of the three dependent variables. Since our study is partly exploratory, we used a conservative significance threshold that takes into account the number of tests in the models (here: $p<.003$). Results for the 432 valid subjects can be seen in Figure 1.

Moral justification ratings were higher the more entities were helped compared to harmed, $F_{(3,\,384)} = 8.81$, $p<.001$, $\eta^2 = .06$. Additionally, a large effect was obtained between the conditions saving and improving, $F_{(1,384)} = 130.74$, $p<.001$, $\eta^2 = .25$. The interaction was not significant (p=.37). Participants gave the highest justification ratings when the primary effect was an instance of saving and more entities were saved than killed.

Post hoc tests (Newman-Keuls) for the saving condition revealed that the case in which only one entity was saved as a primary effect was judged significantly less morally justified than the cases in which twenty or a hundred entities were saved. The other cases did not differ significantly from each other. In the *improving* condition, post hoc tests showed no significant differences.

There was also a main effect of vignette. Subjects considered the action as most morally justified when the affected entities were plants (M = 5.23, SD = 2.6), followed by animals (M = 4.41, SD = 2.52), and people (M = 3.84, SD = 2.77), $F_{(2,384)} = 14.39$, $p<.001$, $\eta^2 = .07$. A possible reason for this ordering might be that harming people may be seen as a harsher moral violation than harming plants and therefore less justifiable by good effects. Animals seem to be in the middle.

Additionally, a small unexpected order effect was found. Ratings were slightly higher when the moral justification question was presented after the moral responsibility questions (M = 4.88, SD = 2.71) compared to before (M = 4.12, SD = 2.62), $F_{(1,384)} = 12.51$, $p<.001$, $\eta^2 = .03$.

Moral responsibility ratings for the negative side effect were generally high, but not detectably influenced by the number of helped entities, $F_{(3,384)} = 0.35$, $p = .79$ (see Fig. 1). However, the ratings were lower when the action's primary effect was an instance of saving (M = 8.09, SD = 2.23) rather than improving (M = 9.12, SD = 1.59), $F_{(1,384)} = 33.51$, $p<.001$, $\eta^2 = .08$. The interaction was not significant (p=.61). *Moral responsibility ratings* for the positive primary effect were

high (M = 8.23, SD = 2.31) and not influenced by any manipulation.

In sum, the moral justification ratings of the action were sensitive to the relation between the primary and the side effect. The more entities were helped as a primary effect, the more justified the action was judged. This pattern shows that moral justification is a continuous quantity that is sensitive to the relative size of the outcomes. A novel result concerns the comparison between different status quos, which generated the largest effect. If entities are saved from a threat, the action was seen as substantially more justified than when the primary goal is just to improve states starting from a neutral state.

The fact that subjects took into account both the primary and the side effect in their justification judgments is predicted by both nonconsequentialist and utilitarian accounts. However, the specific theory proposed by Cohen and Ahn (2016) does not predict the largest effect in our experiment: Subjects clearly differentiated between saving entities versus improving their state. Simply using assessments of personal values of the entities does not predict these effects without taking into account the personal values of the states of the entities in the absence of the action. We will test a modified model that is sensitive to state changes in Experiment 2.

An interesting unexpected finding was that moral responsibility ratings proved insensitive to the number of helped entities, but were reduced when the action's primary effect was an instance of saving rather than improving. This latter effect makes it unlikely that the lack of an effect of number is due to a ceiling effect. A possible interpretation of this pattern may be that subjects tried to focus on the side effect alone but were influenced by features of the primary effect that have a large impact on justification, such as the status quo, rather than only a small effect, such as the numbers.[2]

Experiment 2

The aim of the second experiment is to investigate to what extent the effects observed in Experiment 1 could be explained by a a variant of a subjective utilitarian theory that in crucial aspects differs from the one proposed by Cohen and Ahn (2016). Cohen and Ahn (2016) modeled choices as decisions based on the personal values of the entities involved in the alternative outcomes. For example, the task in their second study was to choose which of two sets of items should be saved and which destroyed in a dilemma. The model claims that the differences between the personal values of the two sets of items predict judgments. The focus on the personal values of the items seems appropriate here because all actions represented a choice between leaving the items intact or destroying (or killing) them. This restriction of the task allowed Cohen and Ahn (2016) to focus on the personal values of the affected items. However, the model is a too restrictive as a general model of moral reasoning. We suggest that the focus should be on actions, which can cause transitions between various states, not only between the states dead and alive or intact and destroyed. For example, in our Experiment 1 we presented cases in which actions improved states of entities that prior to the intervention were in a normal state.

To overcome the limitations of the model proposed by Cohen and Ahn (2016), we here propose a variant of a subjective utilitarian theory that focuses on actions and models them as state changes. When people evaluate an action, they should be sensitive to both the outcomes in the presence of the action but also to what happens in the absence of the action. For example, an action that improves the state of an entity can be represented as the difference between the personal values of the improved state and the normal state prior to the action. More complex state transitions are conceivable, and in fact in Experiment 1 we presented scenarios in which the entities shifted between four possible states (normal, threatened, improved, dead). In the present study we collected assessments of personal values of all the entities for these four states and used these assessments to predict the justification judgments obtained in Experiment 1.

Figure 2 shows how we adapted our model to the cover stories in Experiment 1. In the example in Figure 2, 100 people are under the threat of dying prior to any action. In the absence of an action (i.e., omission) they would die, which is modeled here as the contrast of the personal values between death and a critical state (second component of Figure 2a). In the presence of the action, the people in critical state would be shifted into a normal, healthy state, here represented as the difference between the personal values of a critical versus a normal state (first component of Figure 2a). The overall utility of saving the people is modeled as the sum of these contrasts because the action both prevents the people from being killed and puts them from a critical into a healthy state. Thus, the representation of the saving action considers both the effects of the potential action and of its omission. In the case of improving (not depicted), the model simplifies to a contrast between the values of the improved versus the normal states. The second component in the equation in Figure 2a would amount to 0 in this case because there is no threat to the normal state. Finally, Figure 2b shows how we model the total utility of the action in a scenario with multiple effects: It is the sum of the median utilities of the primary effect (saving) and the harmful side effect (killing 10 people).

Design, Material and Procedure The design of our basic value estimation task largely follows the methodology described in Cohen and Ahn (2016) but assesses a wider range of possible states of entities. Like Cohen and Ahn (2016), we tested the influence of the numbers of entities (1 vs. 5 vs. 10 vs. 20 vs. 100) on personal value assessments in

[2] In this experiment, moral justification was assessed globally (i.e., for a whole action), while responsibility was assessed separately for the single effects. One might worry that this does not allow us to tell whether the differences between the two judgments are driven by the type of judgment or by the focus of the question on global or separate outcomes. We therefore conducted a follow-up study in which we fully crossed these two factors. We found that the type of judgment seems to be the driving factor. The study is available online along with materials and data.

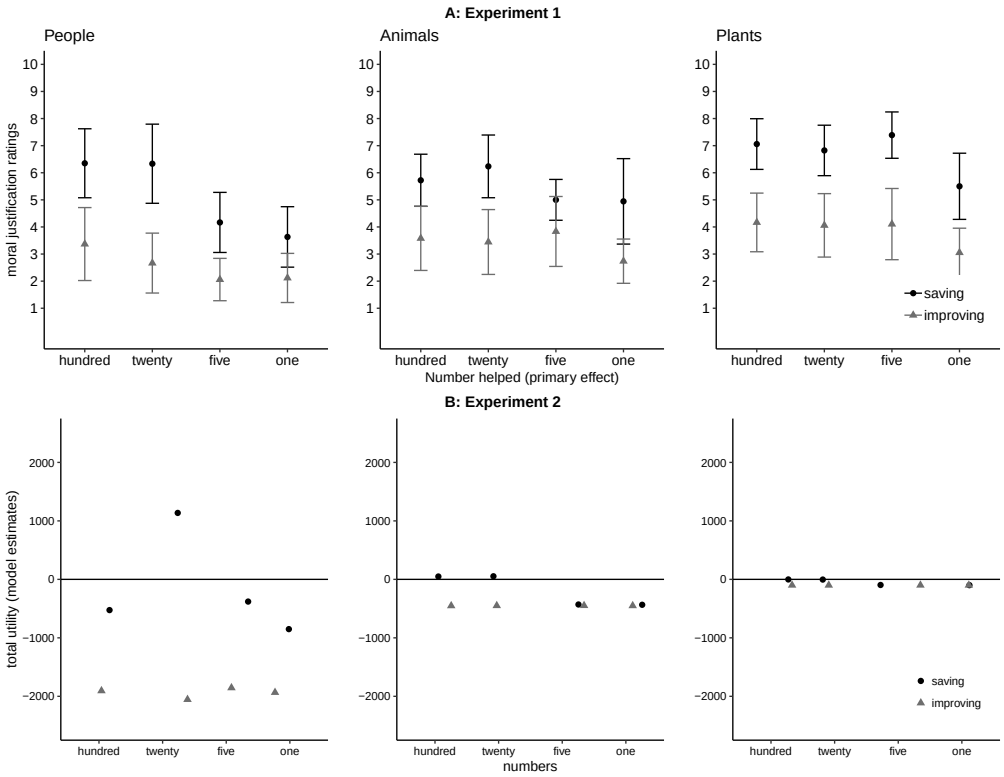


Figure 1: A: Means and 95% confidence intervals for moral justification ratings in Experiment 1, B: Total utility estimates generated by our model in Experiment 2.

separate experimental groups to avoid demand characteristics (i.e., participants feeling pressured to assign exactly five times the value of one entity to a group of five of the same entities). Within each group, we presented instances of people, fish and roses, each of them in all of the states that were described in Experiment 1 (normal vs. threatened vs. improved vs. dead). Thus, each participant judged 12 stimuli, in randomised order.[3] Like Cohen and Ahn, we presented people with a measuring standard to calibrate their value estimates. They were told that "one healthy chimpanzee" should be taken to have a value of 1000. If they valued any item half (or twice or any other ratio) as much as one healthy chimpanzee, they should assign the corresponding value to the item (e.g., a value of 500 if they value an item half as much as the chimpanzee). Participants were further instructed that "personal value" does not necessarily correspond to monetary value and that they should judge the entities' value in their *current* state. 250 participants (mean age = 36.6, SD = 13.5, 67% female, 32% male, 1% other) were recruited on Prolific Academics and completed the survey for a compensation of £0.40 (£6 per hour). Inclusion criteria were identical to Experiment 1, and not having participated in Experiment 1.

Results and Discussion To test our model, we used the value estimates of the four states of the entities to generate predictions for the justification assessments. Following the rationale outlined in Figure 2 we generated predictions for all 24 experimental conditions.The results are shown in Figure 1B. The total utilities overall capture the patterns found in Experiment 1, even though the maximal range of values was much wider for people cases compared to animals and plants (see Fig. 1A). Most importantly, the total utility estimates reflected the differences between improving versus saving, at least for people (Kruskal-Wallis $\chi^2 = 6.14$, $p = .01$) and animals (Kruskal-Wallis $\chi^2 = 6.14$, $p = .01$)[4]. In both cases the total utility for saving was larger than for improving, which mirrors the effects in Experiment 1. The corresponding effect for plants was not significant when correcting for multiple testing. Moreover, we did not find significant effects for the manipulation of the number of the affected entities for either people, animals or plants. But note that this effect was fairly small in Experiment 1 (and also in Cohen & Ahn, 2016). Also, this factor was the only one manipulated between subjects, which may have led to reduced sensitivity to this factor.

As an overall test of the fit of our model to the data of Experiment 1, we conducted a linear regression analysis with to-

[3] With the exception of the "10 entities" condition, which referred to the constant side effect. Here, we only needed estimations of each set of entities in their normal and dead states since the side effect entities never were in other states.

[4] We used again a conservative significance threshold that takes into account that we tested each factor separately for each entity category (here: $p < .017$).

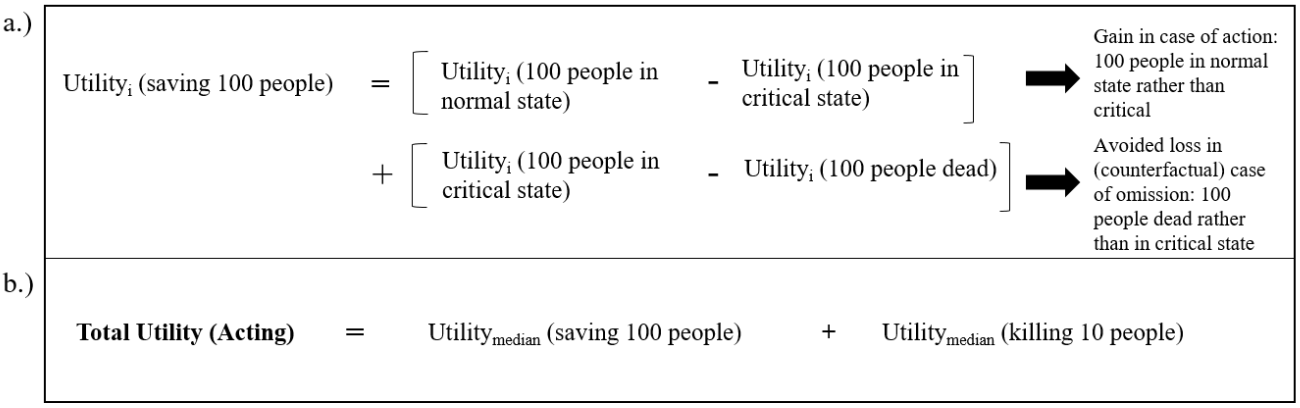

Figure 2: Rationale of our calculation of an action's total utility, spelled out for the example of the *saving 100 people* scenario. See text for explanation.

tal utilities estimated by our model as the predictor and mean moral justification ratings obtained in Experiment 1 as the criterion. The model fit the data well and explained a substantial amount of variance in the criterion, $F_{(1,22)} = 16.31$, $p<.001$, $R^2 = .43$, $RMSE = 1.14$.

General Discussion

The main goal of our study was to provide more fine-grained evidence on how moral judgments are influenced by characteristics of multiple effects of an action in dilemma situations. Experiment 1 showed that judgments of moral justification for the agent's action increased with more favourable ratios of helped compared to harmed entities, but were even more influenced by the change of state that was induced by the agent's action (saving vs. improving). Moral responsibility judgments for the negative side effect were only affected by the latter manipulation but not by the number of affected entities.

In Experiment 2 we tested a novel subjective utilitarian model that goes beyond previous proposals. Whereas Cohen and Ahn (2016) claimed that moral decisions are based on the personal values of the affected entities in their healthy or intact states, we argued that this assumption restricts their model to a small set of situations in which actions destroy or kill entities. Our goal was to propose a model that is more general. A basic assumption of our model is that actions can be modelled as state changes and that moral judgments are sensitive to both the states that entities are in prior and following a target action. This model allowed us to not only model cases of killing and saving but also, for example, cases of improvement.

Although our results in Experiment 2 showed that the new model explains a substantial amount of variance, it does not capture all effects. One reason for this may have been the necessary differences in the designs of Experiments 1 and 2. But there may be other reasons: For example, to demonstrate the increase of expressiveness of our model, we suggested a model for the cover stories of Experiment 1 that captures transitions between the four possible states mentioned there. Given that utility measurements are unreliable and influenced by additional factors, making the model more complex will certainly reduce its fit to the data.

Future research will also have to investigate whether there are alternative models that may also capture the results. As in the case of improving, we could, for example, generally use a more basic utilitarian model that only compares the two states in the presence versus absence of the action (e.g., dead vs. alive in the case of saving). Future research will need to test in greater detail the assumptions entering the different variants of the model.

We labeled our model "subjective utilitarian" because it was inspired by the theory of Cohen and Ahn (2016). However, we mentioned in the introduction that both utilitarian and nonconsequentalist theories predict that in side effect dilemmas the outcomes should be compared. Thus, our model may also be viewed as a component of a nonconsequentialist account. One possible way to test the two alternative theoretical possibilities is to take a closer look at the assumption that actions can be modeled as state changes. This assumption embodies the utilitarian claim that it is only the outcomes that matter, not the type of action leading to the outcomes. We suspect, however, that the type of action and the type of causal relations leading to the changes may also matter (see Kamm, 2007; Waldmann, Wiegmann, & Nagel, 2017). Future research will have to further explore these issues.

Acknowledgements

We thank Alex Wiegmann for helpful discussions about our utility model.

Abstract

Modern deep neural networks require a tremendous amount of data to train, often needing hundreds or thousands of labeled examples to learn an effective representation. For these networks to work with less data, more structure must be built into their architectures or learned from previous experience. The learned weights of convolutional neural networks (CNNs) trained on large datasets for object recognition contain a substantial amount of structure. These representations have parallels to simple cells in the primary visual cortex, where receptive fields are smooth and contain many regularities. Incorporating smoothness constraints over the kernel weights of modern CNN architectures is a promising way to improve their sample complexity. We propose a smooth kernel regularizer that encourages spatial correlations in convolution kernel weights. The correlation parameters of this regularizer are learned from previous experience, yielding a method with a hierarchical Bayesian interpretation. We show that our correlated regularizer can help constrain models for visual recognition, improving over an L2 regularization baseline.

Keywords: convolutional neural networks; regularization; model priors; visual recognition

Introduction

Convolutional neural networks (CNNs) are powerful feed-forward architectures inspired by mammalian visual processing capable of learning complex visual representations from raw image data (LeCun et al., 2015). These networks achieve human-level performance in some visual recognition tasks; however, their performance often comes at the cost of hundreds or thousands of labelled examples. In contrast, children can learn to recognize new concepts from just one or a few examples (Bloom, 2000; Xu & Tenenbaum, 2007), evidencing the use of rich structural constraints (Lake et al., 2017). By enforcing structure on neural networks to account for the regularities of visual data, it may be possible to substantially reduce the number of training examples they need to generalize. In this paper, we introduce a soft architectural constraint for CNNs that encourages smooth, correlated structure on their convolution kernels through transfer learning.[1] We see this as an important step towards a general, off-the-shelf CNN regularizer that operates independently of previous experience.

The basis for our constraint is the idea that the weights of a convolutional kernel should in general be well-structured and smooth. The weight kernels of CNNs that have been trained on the large-scale ImageNet object recognition task contain a substantial amount of structure. These kernels have parallels to simple cells in primary visual cortex, where smooth receptive fields implement bandpass oriented filters of various scale (Jones & Palmer, 1987).

(a) VGG16 layer-1 kernels

(b) i.i.d. Gaussian (L2-reg) (c) correlated Gaussian (SK-reg)

Figure 1: Kernel priors for VGG16. The layer-1 convolution kernels of VGG16, shown in (a), possess considerable correlation structure. An i.i.d. Gaussian prior that has been fit to the VGG layer-1 kernels, samples from which are shown in (b), captures little of the structure in these kernels. A correlated multivariate Gaussian prior, samples from which are shown in (c), captures the correlation structure of these kernels well.

The consistencies of visual receptive fields are explained by the regularities of image data. Locations within the kernel window have parallels to locations in image space, and images are generally smooth (Li, 2009). Consequently, smooth, structured receptive fields are necessary to capture important visual features like edges. In landmark work, Hubel & Wiesel (1962) discovered edge-detecting features in the primary visual cortex of cat. Since then, the community has successfully modeled receptive fields in early areas of mammalian visual cortex using Gabor kernels (Jones & Palmer, 1987). These kernels are smooth and contain many spatial correlations. In later stages of visual processing, locations of kernel space continue to parallel image space; however, inputs to these kernels are visual features, such as edges. Like earlier layers, these layers also benefit from smooth, structured kernels that capture correlations across the input space. Geisler et al. (2001) showed that human contour perception–an important component of object recognition–is well-explained by a model of edge co-occurrences, suggesting that correlated receptive fields are useful in higher layers of processing as well.

Despite the clear advantages of structured receptive fields, constraints placed on the convolution kernels of CNNs are typically chosen to be as general as possible, with neglect of this structure. L2 regularization–the standard soft constraint applied to kernel weights, which is interpreted as a zero-mean, independent identically distributed (i.i.d.) Gaussian prior–treats each weight as an independent random variable, with no correlations between weights expected a priori. Fig. 1 shows the layer-1 convolutional kernels of VGG16, a ConvNet trained on the large-scale ImageNet object recognition task (Simonyan & Zisserman, 2015). Fig. 1b shows some samples from an i.i.d. Gaussian prior, the equivalent of L2 regularization. Clearly, this prior captures little of the correlation structure possessed by the kernels.

A simple and logical extension of the i.i.d. Gaussian prior is a correlated multivariate Gaussian prior, which is capable of capturing some of the covariance structure in the convolution kernels. Fig. 1c shows some samples from a correlated Gaussian prior that has been fit to the VGG16 kernels. This prior provides a much better model of the kernel distribution. In this paper, we perform a series of controlled CNN learning experiments using a smooth kernel regularizer–which we denote "SK-reg"–based on a correlated Gaussian prior. The correlation parameters of this prior are obtained by fitting a Gaussian to the learned kernels from previous experience. We compare SK-reg to standard L2 regularization in two object recognition use cases: one with simple silhouette images, and another with Tiny ImageNet natural images. In the condition of limited training data, SK-reg yields improved generalization performance.

Background

Our goal in this paper is to introduce new a priori structure into CNN receptive fields to account for the regularities of image data and help reduce the sample complexity of these models. Previous methods from this literature often require a fixed model architecture that cannot be adjusted from task to task. In contrast, our method enforces structure via a statistical prior over receptive field weights, allowing for flexible architecture adaption to the task at hand. Nevertheless, in this section we review the most common approaches to structured vision models.

A popular method to enforce structure on visual recognition models is to apply a fixed, pre-specified representation. In computational vision, models of image recognition consist of a hierarchy of transformations motivated by principles from neuroscience and signal processing (e.g., Serre et al., 2007; Bruna & Mallat, 2013). These models are effective at extracting important statistical features from natural images, and they have been shown to provide a useful image representation for SVMs, logistic regression and other "shallow" classifiers when applied to recognition tasks with limited training data. Unlike CNNs, the kernel parameters of these models are not learned by gradient descent. As result, these features may not be well-adapted to the specific task at hand.

In machine learning, it is commonplace to use the features from CNNs trained on large object recognition datasets as a generic image representation for novel vision tasks (Donahue et al., 2014; Razavian et al., 2014). Due to the large variety of training examples that these CNNs receive, the learned features of these networks provide an effective representation for a range of new recognition tasks. Some *meta-learning* algorithms use a similar form of feature transfer, where a feature representation is first learned via a series of classification episodes, each with a different support set of classes (e.g., Vinyals et al., 2016). As with pre-specified feature models, the representations of these feature transfer models are fixed for the new task; thus, performance on the new task may be sub-optimal.

Beyond fixed feature representations, other approaches use a pre-trained CNN as an initialization point for a new network, following with a fine-tuning phase where network weights are further optimized for a new task via gradient descent (e.g., Girshick et al., 2014; Girshick, 2015). By adapting the CNN representation to the new task, this approach often enables better performance than fixed feature methods; however, when the scale of the required adaptation is large and the training data is limited, fine-tuning can be difficult. Finn et al. (2017) proposed a modification of the pre-train/fine-tune paradigm called model-agnostic meta-learning (MAML) that enables flexible adaptation in the fine-tuning phase when the training data is limited. During pre-training (or *meta-learning*), MAML optimizes for a representation that can be easily adapted to a new learning task in a later phase. Although effective for many use cases, this approach is unlikely to generalize well when the type of adaptation required differs significantly from the adaptations seen in the meta-learning episodes. A shared concern for all pre-train/fine-tune methods is that they require a fixed model architecture between the pre-train and fine-tune phases.

The objective of our method is distinct from those of fixed feature representations and pre-train/fine-tune algorithms. In this paper, we study the structure in the learned parameters of vision models, with the aim of extracting general structural principles that can be incorporated into new models across a broad range of learning tasks. SK-reg serves as a parameter prior over the convolution kernels of CNNs and has a theoretical foundation in Bayesian parameter estimation. This approach facilitates a CNN architecture and representation that is adapted to the specific task at hand, yet that possesses adequate structure to account for the regularities of image data. The SK-reg prior is learned from previous experience, yielding an interpretation of our algorithm as a method for hierarchical Bayesian inference.

Independently of our work, Atanov et al. (2019) developed the *deep weight prior*, an algorithm to learn and apply a CNN kernel prior in a Bayesian framework. Unlike our prior, which is parameterized by a simple multivariate Gaussian, the deep weight prior uses a sophisticated density estimator parameterized by a neural network to model the learned kernels of previously-trained CNNs. The application of this prior to new learning tasks requires variational inference with a well-calibrated variational distribution. Our goal with SK-reg differs in that we aim to provide an interpretable, generalizable prior for CNN weight kernels that can be applied to existing CNN training algorithms with little modification.

Bayesian interpretation of regularization

From the perspective of Bayesian parameter estimation, the L2 regularization objective can be interpreted as performing *maximum a-posteriori* inference over CNN parameters with a zero-mean, i.i.d. Gaussian prior. Here, we review this connection, and we discuss the extension to SK-reg.

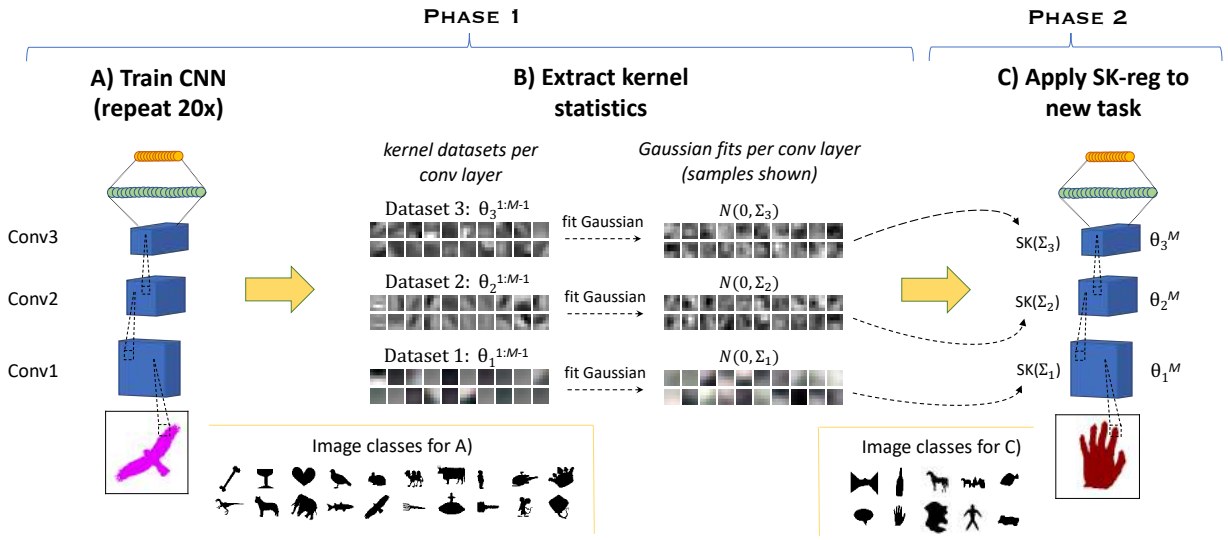

Figure 2: SK-reg workflow. A) First, a CNN is trained repeatedly (20x) on an object recognition task. B) Next, the learned parameters of each CNN are studied and statistics are extracted. For each convolution layer, kernels from the multiple CNNs are consolidated, yielding a kernel dataset for the layer. A multivariate Gaussian is fit to each kernel dataset. C) SK-reg is applied to a fresh CNN trained on a new learning task with limited training data (possibly with a different architecture or numbers of kernels), using the resulting Gaussians from each layer.

L2 regularization. Assume we have a dataset $X = \{x_1,...,x_N\}$ and $Y = \{y_1,...,y_N\}$ consisting of N images x_i and N class labels y_i. Let θ define the parameters of the CNN that we wish to estimate. The L2 regularization objective is stated as follows:

$$\tilde{\theta} = \arg\max_{\theta} \log p(Y \mid \theta; X) - \lambda * \theta^T \theta. \quad (1)$$

Here, the first term of our objective is our prediction accuracy (classification log-likelihood), and the second term is our L2 regularization penalty.

From a Bayesian perspective, this objective can be thought of as finding the *maximum a-posteriori* (MAP) estimate of the network parameter posterior $p(\theta \mid Y; X) \propto p(Y \mid \theta; X) * p(\theta)$, leading to the optimization problem

$$\tilde{\theta} = \arg\max_{\theta} \log p(Y \mid \theta; X) + \log p(\theta). \quad (2)$$

To make the connection with L2 regularization, we assume a zero-mean, i.i.d Gaussian prior over the parameters θ of a weight kernel, written as

$$p(\theta) = \frac{1}{Z} \exp\Big(-\frac{1}{2\sigma^2}\theta^T\theta\Big). \quad (3)$$

With this prior, Eq. 2 becomes

$$\tilde{\theta} = \arg\max_{\theta} \log p(Y \mid \theta; X) - \frac{1}{2\sigma^2}\theta^T\theta,$$

which is the L2 objective of Eq. 1, with $\lambda = \frac{1}{2\sigma^2}$.

SK regularization. The key idea behind SK-reg is to extend the L2 Gaussian prior to include a non-diagonal covariance matrix; i.e., to add correlation. In the case of SK-reg, the prior over kernel weights θ of Eq. 3 becomes

$$p(\theta) = \frac{1}{Z} \exp\Big(-\frac{1}{2}\theta^T\Sigma^{-1}\theta\Big)$$

for some covariance matrix Σ, and the new objective is written

$$\tilde{\theta} = \arg\max_{\theta} \log p(Y \mid \theta; X) - \lambda * \theta^T\Sigma^{-1}\theta. \quad (4)$$

Hierarchical Bayes. When Σ is learned from previous experience, SK-reg can be interpreted as approximate inference in a hierarchical Bayesian model. The SK regularizer for a CNN with C layers, $\boldsymbol{\Sigma} = \{\Sigma_1,\ldots,\Sigma_C\}$, assumes a unique zero-mean Gaussian prior $\mathcal{N}(\theta_i; 0, \Sigma_i)$ over the weight kernels for each convolutional layer, $\boldsymbol{\theta} = \{\theta_1,\ldots,\theta_C\}$. Due to the regularities of the visual world, it is plausible that effective general priors exist for each layer of visual processing. In this paper, transfer learning is used to fit the prior covariances $\boldsymbol{\Sigma}$ from previous datasets $X^{1:M-1}$ and $Y^{1:M-1}$, which informs the solution for a new problem X^M and Y^M, yielding the hierarchical Bayesian interpretation depicted in Fig. 3. Task-specific

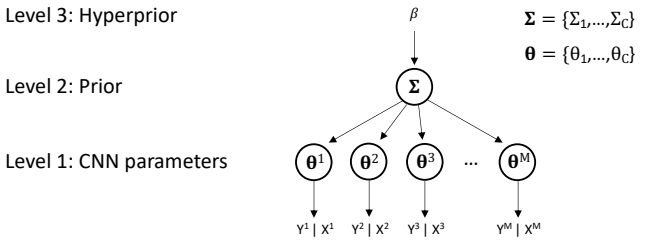

Figure 3: A hierarchical Bayesian interpretation of SK-reg. A point estimate of prior parameters $\boldsymbol{\Sigma}$ is first computed with MAP estimation. Next, this prior is applied to estimate CNN parameters $\boldsymbol{\theta}^j$ in a new task.

CNN parameters $\boldsymbol{\theta}^{1:M}$ are drawn from a common $\boldsymbol{\Sigma}$, and $\boldsymbol{\Sigma}$ has a hyperprior specified by β. Ideal inference would compute $p(Y^M|Y^{1:M-1};X^{1:M})$, marginalizing over $\boldsymbol{\theta}^{1:M}$ and $\boldsymbol{\Sigma}$.

We propose a very simple empirical Bayes procedure for learning the kernel regularizer in Eq. 4 from data. First, $M-1$ CNNs are fit independently to the datasets $X^{1:M-1}$ and $Y^{1:M-1}$ using standard methods, in this case optimizing Eq. 1 to get point estimates $\tilde{\boldsymbol{\theta}}^{1:M-1}$. Second, a point estimate $\tilde{\boldsymbol{\Sigma}}$ is computed by maximizing $p(\boldsymbol{\Sigma}|\tilde{\boldsymbol{\theta}}^{1:M-1};\beta)$, which is a simple regularized covariance estimator. Last, for a new task M with training data X^M and Y^M, a CNN with parameters $\boldsymbol{\theta}^M$ is trained with the SK-reg objective (Eq. 4), with $\boldsymbol{\Sigma}=\tilde{\boldsymbol{\Sigma}}$.

This procedure can be compared with the hierarchical Bayesian interpretation of MAML (Grant et al., 2018). Unlike MAML, our method allows flexibility to use different architectures for different datasets/episodes, and the optimizer for $\boldsymbol{\theta}^M$ is run to convergence rather than just a few steps.

Experiments

We evaluate our approach within a set of controlled visual learning environments. SK-reg parameters Σ_i for each convolution layer θ_i are determined by fitting a Gaussian to the kernels acquired from an earlier learning phase. We divide our learning tasks into two unique phases, applying the same CNN architecture in each case. We note that our approach does not require a fixed CNN architecture across these two phases; the number of feature maps in each layer may be easily adjusted. A depiction of the two learning phases is given in Fig. 2.

Phase 1. The goal of phase 1 is to extract general principles about the structure of learned convolution kernels by training an array of CNNs and collecting statistics about the resulting kernels. In this phase, we train a CNN architecture to classify objects using a sufficiently large training set with numerous examples per object class. Training is repeated multiple times with unique random seeds, and the learned convolution kernels are stored for each run. During this phase, standard L2 regularization is applied to enforce a minimal constraint on each layer's weights (optimization problem of Eq. 1). After training, the convolution kernels from each run are consolidated, holding each layer separate. A multivariate Gaussian is fit to the centered kernel dataset of each layer, yielding a distribution $N(0,\Sigma_i)$ for each convolution layer i. To ensure the stability of the covariance estimators, we apply shrinkage to each covariance estimate, mixing the empirical covariance with an identity matrix of equal dimensionality. This can be interpreted as a hyperprior $p(\boldsymbol{\Sigma};\beta)$ (Fig. 3) that favors small correlations. The optimal mixing parameter is determined via cross-validation.

Phase 2. In phase 2, we test the aptitude of SK-reg on a new visual recognition task, applying the covariance matrices Σ_i obtained from phase 1 to regularize each convolution layer i in a freshly-trained CNN (optimization problem of Eq. 4). In order to adequately test the generalization capability of our algorithm, we use a new set of classes that differ from the phase 1 classes in substantial ways, and we provide just a few training examples from each class. Performance of SK-reg is compared against standard L2 regularization.

Figure 4: Exemplars of the phase 1 silhouette object classes.

Table 1: CNN architecture. Layer hyperparameters include window size, stride, feature count, and regularization weight (λ). Dropout is applied after the last pooling layer and the fully-connected layer with rates 0.2 and 0.5, respectively.

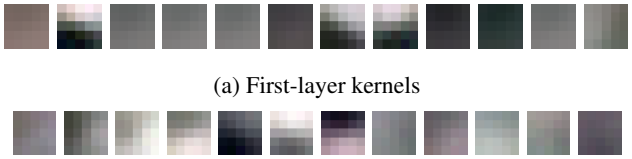
Silhouettes

As a preliminary use case, we train our network using the binary shape image dataset developed at Brown University[2], henceforth denoted "Silhouettes." Silhouette images are binary masks that depict the structural form of various object classes. Simple shape-based stimuli such as these provide a controlled learning environment for studying the inductive biases of CNNs (Feinman & Lake, 2018). We select a set of 20 well-structured silhouette classes for phase 1, and a set of 10 unique, well-structured classes for phase 2 that differ from phase 1 in their consistency and form. The images are padded to a fixed size of 200×200.

During phase 1, we train our network to perform 20-way object classification. Exemplars of the phase 1 classes are shown in Fig. 4. The number of examples varies for each class, ranging from 12 to 49 with a mean of 24. Class weighting is used to remedy class imbalances. To add complexity to the silhouette images, colors are assigned randomly to each silhouette before training. During training, random translations, rotations and horizontal flips are applied at each training epoch to improve generalization performance.

We use a CNN architecture with 3 convolution layers, each followed by a max pooling layer (see Table 1). Hyperparameters including convolution window size, pool size, and filter counts were selected via randomized grid-search, using a validation set with examples from each class to score candidate values. A rectified linear unit (ReLU) nonlinearity is applied to the output of each convolution layer, as well as to the

[2]The binary shape dataset is available in the "Databases" section at `http://vision.lems.brown.edu`



(a) First-layer kernels

(b) Gaussian samples

Figure 5: Learned first-layer kernels vs. Gaussian samples. (a) depicts some of the learned first-layer kernels acquired from phase 1 silhouette training. For comparison, (b) shows a few samples from a multivariate Gaussian that was fit to the first-layer kernel dataset.

fully-connected layer. The network is trained 20 times using the Adam optimizer, each time with a unique random initialization. It achieves an average validation accuracy of 97.7% across the 20 trials, indicating substantial generalization.

Following the completion of phase 1 training, a kernel dataset is obtained for each convolution layer by consolidating the learned kernels for that layer from the 20 trials. Covariance matrices Σ_i for each layer i are obtained by fitting a multivariate Gaussian to the layer's kernel dataset. For a first-layer convolution with window size $K \times K$, this Gaussian has dimensionality $3K^2$, equal to the window area times RGB depth. We model the input channels as separate variables in layer 1 because these channels have a consistent interpretation as the RGB color channels of the input image. For remaining convolution layers, where the interpretation of input channels may vary from case to case, we treat each input channel as an independent sample from a Gaussian with dimensionality K^2. The kernel datasets for each layer are centered to ensure zero mean, typically requiring only a small perturbation vector.

To ensure that our multivariate Gaussians model the kernel data well, we computed the cross-validated log-likelihoods of this estimator on each layer's kernel dataset and compared them to those of an i.i.d. Gaussian estimator fit to the same data. The multivariate Gaussian achieved an average score of 358.5, 413.3 and 828.1 for convolution layers 1, 2 and 3, respectively. In comparison, the i.i.d. Gaussian achieved an average score of 144.4, 289.6 and 621.9 for the same layers. These results confirm that our multivariate Gaussian provides an improved model of the kernel data. Some examples of the first-layer convolution kernels are shown in Fig. 5 alongside samples from our multivariate Gaussian that was fit to the first-layer kernel dataset. The samples appear structurally consistent with our phase 1 kernels.

In phase 2, we train our CNN on a new 10-way classification task, providing the network with just 3 examples per class for gradient descent training and 3 examples per class for validation. Colors are again added at random to each silhouette in the dataset. The network is initialized randomly, and we apply SK-reg to the convolution kernels of each layer during training using the covariance matrices obtained in phase 1. Our validation set is used to track and save the best model over the course of the training epochs (early stopping). A holdout set with 6 examples per class is used to assess the final performance of the model. A depiction of the train, validation and test sets used for phase 2 is given in Fig. 6. The validation and test images have been shifted, translated and flipped to make for a more challenging generalization test. Similar to phase 1, random shifts, rotations and horizontal flips are applied to the training images at each training epoch. As a baseline, we also train our CNN using standard L2 regularization.

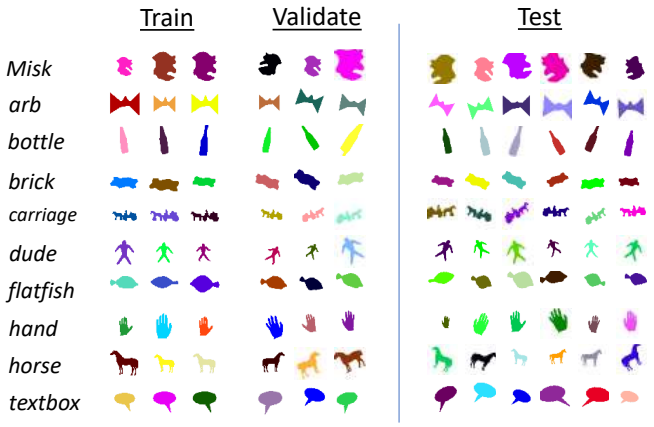


Figure 6: Silhouettes phase 2 datasets. 3 examples per class are provided in both the train and validation sets. A holdout test set with 6 examples per class is used to evaluate final model performance.

Method	λ	Cross-entropy	Accuracy
L2	0.214	2.000 (+/- 0.033)	0.530 (+/- 0.013)
SK	0.129	0.597 (+/- 0.172)	0.821 (+/- 0.056)

Table 2: Silhouettes phase 2 results. For each regularization method, the optimal regularization weight λ was selected via grid-search. Results show the average cross-entropy and classification accuracy achieved on the holdout test set over 10 phase 2 training runs.

The regularization weight λ is an important hyperparameter of both SK and L2 regularization. Before performing the phase 2 training assessment, we use a validated grid search to select the optimal λ for each regularization method, applying our train/validate sets.[3] The same weight λ is applied to each convolution layer, as done in phase 1.

Results. With our optimal λ values selected, we trained our CNN on the 10-way phase 2 classification task of Fig. 6, comparing SK regularization to a baseline L2 regularization model. Average results for the two models collected over 10 training runs are presented in Table 2. Average test accuracy is improved by roughly 55% with the addition of SK reg, a substantial performance boost from 53.0% correct to 82.1% correct. Clearly, a priori structure is beneficial to generalization in this use case. An inspection of the learned kernels confirms that SK-reg encourages the structure we expect; these

[3]To yield interpretable λ values that can be compared between the SK and L2 cases, we normalize each covariance matrix to unit determinant by applying a scaling factor c, such that $\det(c\Sigma) = \det(I)$.

kernels look visually similar to samples from the Gaussian (e.g. Fig. 5).

Tiny ImageNet

Our silhouette experiment demonstrates the effectiveness of SK-reg when the parameters of the regularizer are determined from the structure of CNNs trained on a similar image domain. However, it remains unclear whether these regularization parameters can generalize to novel image domains. Due to the nature of the silhouette images, the silhouette recognition task encourages representations with properties that are desirable for object recognition tasks in general. Categorizing silhouettes requires forming a rich representation of shape, and shape perception is critical to object recognition. Therefore, this family of representation may be useful in a variety of object recognition tasks.

To test whether our kernel priors obtained from silhouette training generalize to a novel domain, we applied SK-reg to a simplified version of the Tiny ImageNet visual recognition challenge, using covariance parameters fitted to silhouette-trained CNNs. Tiny ImageNet images were up-sampled with bilinear interpolation from their original size of 64×64 to mirror the Silhouette size 200×200. We selected 10 well-structured ImageNet classes that contain properties consistent with the silhouette images.[4] We performed 10-way image classification with these classes, using the same CNN architecture from Table 1 and applying the SK-reg soft constraint. The network is provided 10 images per class for training and 10 per class for validation. Because of the increased complexity of the Tiny ImageNet data, a larger number of examples per class is merited to achieve good generalization performance. A holdout test set with 20 images per class is used to evaluate performance. Fig. 7 shows a breakdown of the train, validate and test sets.

A few modifications were made to account for the new image data. First, we modified the phase 1 silhouette training used to acquire our covariance parameters, this time applying random colors to both the foreground and background of each silhouette. Previously, each silhouette overlaid a strictly white background. Consequently, the edge detectors of the learned CNNs would be unlikely to generalize to novel color gradients. Second, we added additional regularization to our covariance estimators to avoid over-fitting and help improve the generalization capability of the resulting kernel priors. Due to the nature of the phase 2 task in this experiment, and the extent to which the images differ from phase 1, additional regularization was necessary to ensure that our kernel priors could generalize. Specifically, we applied L1-regularized inverse covariance estimation (Friedman et al., 2008) to estimate each Σ_i, which can be interpreted as a hyperprior $p(\mathbf{\Sigma}; \beta)$ (Fig. 3) that favors a sparse inverse covariance (Lake & Tenenbaum, 2010).

Similar to the silhouettes experiment, the validation set is used to select weighting hyperparameter λ and to track the best model over the course of learning. As a baseline, we again compared SK-reg to a λ-optimized L2 regularizer.

[4] Desirable classes have a uniform, centralized object with consistent shape properties and a distinct background.

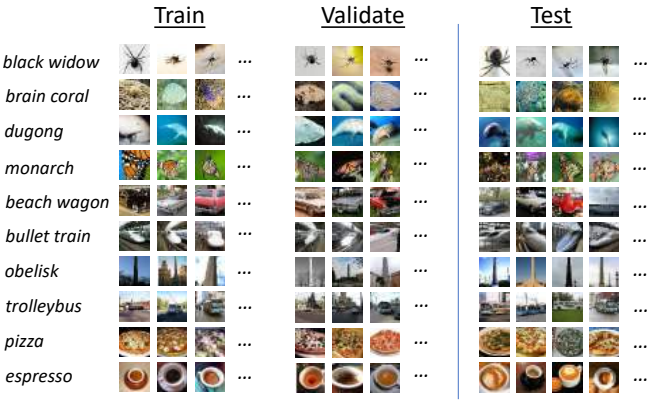

Figure 7: Tiny ImageNet datasets. 10 classes were selected to form a 10-way classification task. The train and validate sets each contain 10 examples per class. The holdout test set contains 20 examples per class.

Method	λ	Cross-entropy	Accuracy
L2	0.450	1.073 (+/- 0.102)	0.700 (+/- 0.030)
SK	0.450	0.956 (+/- 0.180)	0.776 (+/- 0.035)

Table 3: Tiny ImageNet SK-reg and L2 results. Table shows the average cross-entropy and classification accuracy achieved on the holdout test set over 10 training runs.

Results. SK-reg improved the average holdout performance received from 10 training runs as compared to an L2 baseline, both in accuracy and cross-entropy. Results for each regularization method, as well as their optimal λ values, are reported in Table 3. An improvement of 8% in test accuracy suggests that some of the structure captured by our kernel prior is useful even in a very distinct image domain. The complexity of natural images like ImageNet is vast in comparison to simple binary shape masks; nonetheless, our prior from phase 1 silhouette training is able to influence ImageNet learning in a manner that is beneficial to generalization.

Discussion

Using a set of controlled visual learning experiments, our work in this paper demonstrates the potential of structured receptive field priors in CNN learning tasks. Due to the properties of image data, smooth, structured receptive fields have many desirable properties for visual recognition models. In our experiments, we have shown that a simple multivariate Gaussian model can effectively capture some of the structure in the learned receptive fields of CNNs trained on simple object recognition tasks. Samples from the fitted Gaussians are visually consistent with learned receptive fields, and when applied as a model prior for new learning tasks, these Gaussians can help a CNN generalize in conditions of limited training data. We demonstrated our new regularization method in two simple use cases. Our silhouettes experiment shows that,

when the parameters of SK-reg are determined from CNNs trained on a similar image domain to that of the new task, the performance increase that results in the new task can be quite substantial–as large as 55% over an L2 baseline. Our Tiny ImageNet experiment demonstrates that SK-reg is capable of encoding generalizable structural principles about the correlations in receptive fields; the statistics of learned parameters in one domain can be useful in a completely new domain with substantial differences.

The Gaussians that we fit to kernel data in phase 1 of our experiments could be overfit to the CNN training runs. We have discussed the application of sparse inverse covariance (precision) estimation as one approach to reduce over-fitting. In future work, we would like to explore a Gaussian model with graphical connectivity that is specified by a 2D grid MRF. Model fitting would consist of optimizing the non-zero precision matrix values subject to this pre-specified sparsity. The grid MRF model is enticing for its potential to serve as a general "smoothness" prior for CNN receptive fields. Ultimately, we hope to develop a general-purpose kernel regularizer that does not depend on transfer learning.

Although a Gaussian can model some kernel families sufficiently, other families would give it a difficult time. The first-layer kernels of AlexNet–which are 11×11 and are visually similar to Gabor wavelets and derivative kernels–are not well-modeled by a multivariate Gaussian. A more sophisticated prior is needed to model kernels of this size effectively. In future work, we hope to investigate more complex families of priors that can capture the regularities of filters such as Gabors and derivatives. Nevertheless, a simple Gaussian estimator works well for smaller kernels, and in the literature, it has been shown that architectures with a hierarchy of smaller convolutions followed by nonlinearities can achieve equal (and often better) performance as those will fewer, larger kernels (Simonyan & Zisserman, 2015). Thus, the ready-made Gaussian regularizer we introduced here can be used in many applications.

Abstract

The semantics of spatial terms has attracted substantial attention in the cognitive sciences, revealing both compelling similarities and striking differences across languages. However, much of the evidence regarding cross-linguistic variation pertains to fine-grained comparisons between individual lexical items, while cross-linguistic similarities are found in more coarse-grained studies of the conceptual space underlying semantic systems. We seek to bridge this gap, moving beyond the semantics of individual terms to ask what the comparison of spatial semantic systems may reveal about the conceptualization of locations in English and Mandarin Chinese and about the nature of potential universals in this domain. We subjected descriptions of 116 spatial scenes to multidimensional scaling analyses in order to reveal the structures of the underlying conceptual spaces in each language. In addition to revealing overlaps and divergences in the conceptualization of space in English and Mandarin, our results suggest a difference in complexity, whereby Mandarin terms are accommodated by a lower-dimensional similarity space than are English terms.

Keywords: spatial semantics; universals; cross-linguistic variation

Introduction

All peoples, in all languages, have occasion to talk about the locations of objects in their environments – environments which are fundamentally similar. Despite this, the vocabularies of space differ strikingly across languages, fueling interest in spatial semantics across the cognitive sciences. Most notably, scholars have observed that both the number and the nature of the contrasts that are encoded vary markedly from language to language (Bowerman 1996; Bowerman & Choi 2001; Feist 2000; Gentner & Bowerman 2009; Landau & Jackendoff 1993), with the result that "translation equivalents" for spatial terms can be quite different in meaning (Feist 2013; Trujillo 1995).

As a case in point, the range of spatial configurations that can be described using the English preposition *on* is divided amongst three prepositions – *op, aan*, and *om* – in Dutch (Gentner & Bowerman 2009); Dutch thus routinely encodes distinctions that are optional in English. More strikingly, even the dimensions of contrast encoded in spatial semantic systems may vary across languages: whereas English encodes a distinction between containment and support, Korean encodes a distinction between tight and loose fit (Bowerman & Choi 2001) that neutralizes the containment/support contrast.

Tempering these findings of variation is an overall structuring of the semantic domain of topological relations which appears to be shared cross-linguistically. For example, despite finding evidence of a "fractionated picture of overlapping contrasts" (Levinson & Wilkins 2006, p. 520) which echoes the variation briefly reviewed above, Levinson and Wilkins argue that the extensional ranges of the adpositions in the dozen languages they studied suggest a common underlying conceptual space. This is consistent with earlier findings suggesting that topological notions may be organized in a coherent conceptual space characterized by a small set of "attractors" – groups of situations that are likely to be lexicalized in similar ways across languages (Levinson & Meira 2003), including "ATTACHMENT", "IN", and "ON-TOP". Thus, while the semantics of individual spatial terms in different languages may differ from one another, the underlying conceptual components that make them up are argued to be drawn from a common set. This conclusion is supported by the work of Feist (2008), who found that the extensional ranges of spatial terms across a sample of 24 languages could be accommodated by a two-dimensional similarity space, with one dimension encoding the degree to which the reference object constrains the location of the located object, while the second dimension encodes the relative vertical positions of the two objects. Taken together, these studies in semantic typology suggest that the cross-linguistic variation that has often been noted is overlaid upon a common conceptual core.

The stark contrast between the word-level evidence of cross-linguistic variation and the system-level evidence of a common conceptual core raises many questions regarding the conceptualization of space. Is cross-linguistic variation limited to fine-grained details of lexical encoding, leaving a substantial universal conceptual basis intact? This would suggest that, while languages vary in the contrasts they mark, each structures its semantic system around fundamentally the same topological concepts. Or is the fine-grained cross-linguistic variation evidence of deeper differences in the nature of the topological concepts underlying the meanings of spatial terms? This would suggest that the system-level similarities that have been observed are in fact quite abstract, with variation arising within the set of topological concepts upon which the meanings of lexical items are based.

Zhang, Segalowitz, and Gatbonton (2011) began to address questions such as these, asking whether Mandarin Chinese and English differ with respect to the conceptual specification of containment and support rather than merely in the mapping of these two concepts onto spatial lexemes. They had speakers describe a set of 116 line drawings depicting a range of topological relations in order to examine the lexicalization

of containment and support in the two languages. Each of the elicited spatial terms was classified as encoding containment, support, or "other concepts", and the extensions of containment-encoding and support-encoding lexemes in the two languages were compared. They found that approximately half of the pictures were categorized similarly at this broad level of detail (either as examples of containment or as examples of support) by speakers of the two languages, representing a large overlap in how the concepts of containment and support may be represented in English and in Mandarin. However, Zhang and her colleagues also noted differences in the uses of containment-encoding and support-encoding adpositions: Mandarin speakers described a larger proportion of the pictures using support-encoding lexical items than using containment-encoding lexical items, while English speakers evidenced the opposite pattern. Much of this difference could be accounted for via a difference in the encoding of partial inclusion and of part-whole relations: these relations tended to be described using support-encoding adpositions in Mandarin, but containment-encoding adpositions in English. This pattern of results suggests cross-linguistic differences in the boundaries separating the two conceptual categories, despite overlap in their cores, thus situating variation as a lexicalization phenomenon, rather than as evidence that the conceptual systems – and the topological concepts themselves – differ.

In a similar vein, Johannes and her colleagues asked whether the cores of lexicalized containment and support concepts were similar across languages (Johannes et al. 2015; Landau et al. 2017). They asked speakers to describe scenes predefined as representing subtypes of containment or support, then examined the rate of use of the Basic Locative Construction[1] for each subtype. For both concepts, they found that the rate of use of this construction was highest for a similar range of subtypes across the languages sampled, suggesting that these subtypes may constitute universal conceptual cores for containment and support.

Before we can conclude that the conceptual cores are indeed universal, however, we need to take a closer look at the extensions of containment- and support-encoding spatial terms as a source of evidence for the underlying structures of the concepts, without prejudging the status of either the adpositions or the scenes as exemplars of containment or support. In their study, Zhang et al (2011) classified each adposition *a priori* as encoding support, containment, or "other concepts"; they then used this classification to explore the kinds of situations that will be encoded as either containment or support in Mandarin and in English. In so doing, they neutralized fine-grained contrasts marked by the lexical items in the two languages, in essence positing that coherent, unified concepts of support and containment are encoded in English and Mandarin. In a parallel fashion, Johannes and her colleagues (2015; Landau et al. 2017) classified the scenes used in their studies as exemplars of either containment or support. In addition, they limited the scope of their study to variation in the use of BE *in/on* (and its translation equivalents), leaving fine-grained semantic contrasts unexplored. This methodology likewise assumes the existence of coherent, unified concepts of support and containment. Such unified concepts, however, cannot be assumed. As a case in point, the coherence of support as a universally salient concept has been contradicted by cross-linguistic evidence, with support relations clustering with two different groups of scenes in Levinson and Meira's (2003) analysis. In abstracting away from the semantic richness of the spatial adpositions and the complexity of the scenes, these studies may have inadvertently introduced a universal structure to the systems rather than objectively testing for its presence. In this paper, we reintroduce the semantic richness of the spatial terms while removing the *a priori* categorization of the scenes and adpositions in order to better assess the degree of similarity between the Mandarin and the English spatial semantic systems.

Spatial semantics in paradigmatic perspective

In order to better understand the comparison between the Mandarin spatial descriptors and the English ones, we shift the focus of our attention from the spatial terms as exemplars of abstract concepts to the spatial terms as indicators of linguistically-relevant degrees of similarity amongst spatial scenes (cf., Croft 2010; Feist 2008; Levinson & Meira 2003). Because words name categories, when speakers use a single word to describe two scenes, they are relying on a perceived similarity between the scenes that enables the sameness of description. Conversely, when two scenes are described using different words, speakers are highlighting differences between the scenes.

We can examine the patterns of similarity that underlie a language's semantic system via statistical techniques such as multidimensional scaling (MDS). MDS uses the co-occurrence of lexical items and pictures to construct a similarity space in which the placement of each picture is a function of the extent to which the lexical items used to describe it overlap with the lexical items used to describe each of the other pictures in the set. For example, consider the two pictures in Figure 1. If one speaker described the apple as *in* the bowl and the boat as *in* the water, this would provide evidence that the two scenes are similar, and should be placed close together in the similarity space. However, if another speaker instead described the boat as *on* the water, this would temper that judgment of similarity, and result in some distance between the two pictures. By adding in evidence from multiple speakers, a fuller picture may emerge of the extent to which each pair of pictures is treated as similar by speakers of a language.

[1] Although Levinson and Meira (2003, p. 486) define this construction as "answers to *where* questions", Johannes and her colleagues limited their investigation to BE *in/on* (and its equivalent in the other languages studied).

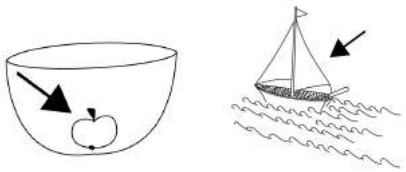

Figure 1: Two spatial scenes (from Bowerman & Pederson 1992b)

The output of multidimensional scaling is a similarity space reflecting this evidence, in which the placement of points (each representing a picture in the set) is a function of the overlap between the set of spatial terms used to describe that picture and the sets of spatial terms used to describe all the other pictures under study. The more shared spatial terms in the elicited descriptions for a pair of pictures, the closer the pictures will be in the final similarity space (see Croft 2010; Croft & Poole 2008; Feist 2008; Levinson & Meira 2003). Hence, the similarity space presents a visual representation of the conceptual space underlying the uses of the spatial terms.

To assess the adequacy of the account of the patterns in the data provided by the similarity space, we can examine both the percent correct classification, indicating the proportion of the pictures in the solution that are placed correctly relative to the elicited naming patterns, and the aggregate proportional reduction of error (APRE), indicating the extent to which the resulting solution improves upon a solution which places all of the pictures in a single category (see Croft & Poole 2008; Poole 2000, 2005 for further discussion). The APRE is measured on a scale from 0-1, with higher values indicating fewer errors in the model.

With a cross-linguistic data set, MDS returns a representation of a space upon which all the languages in the set may be overlaid such that the distinctions marked in each language isolate contiguous sets of points (Croft & Poole 2008; Feist 2008); the fewer that are miscategorized, the better the solution. As such, MDS provides a means by which we may identify potential universals underlying the semantic systems of a varied set of languages (Feist 2008; Levinson & Meira 2003). In the current study, we use MDS to construct separate similarity spaces for a set of simple spatial scenes as described by speakers of Mandarin and by speakers of English. With single-language data sets such as these, the conceptual space that MDS returns is one that only respects the distinctions marked in that language, thus providing a representation of the similarities amongst the pictures in the set as encoded in the naming patterns of the language under study. Comparison of the conceptual spaces resulting from separate MDS analyses, thus, gives a novel view into the fine-grained differences in the contrasts marked within the semantic systems of the examined languages, thus enabling a richer comparison than has been possible in previous work.

Method

The Corpus We used the 5800 picture descriptions (2900 descriptions from each language) collected by Zhang et al. (2011). The descriptions were elicited using 116 simple line drawings: 65 pictures from Bowerman and Pederson's (1992b) Topological Relations Picture Series (pictures 18, 20, 24, 33, 47, and 59 were excluded; see Zhang 2013) and an additional 51 developed by Zhang (2013). Each drawing depicts two objects – one highlighted in yellow, and one in black and white – in a simple spatial relation, with the names of the objects printed below the picture (in English or in Mandarin, as appropriate). The pictures depicted a range of topological relations; example pictures are shown in Figure 1. The pictures were printed two to a page, vertically aligned**.**

The set of pictures was described by 25 native speakers of English living in Montreal, Canada, and 25 native speakers of Mandarin living in Harbin, China. All speakers reported themselves either to be monolingual, or to have only limited knowledge of a second language. The pictures were presented in random order, and participants were asked to describe for each the location of the yellow object with respect to the black and white one.

Analysis In order to be able to compare the structuring of space in the two languages, the English and Mandarin descriptions were analyzed separately. We used Poole's Optimal Classification nonparametric unfolding algorithm (Poole 2000, 2005; see also Croft 2010; Feist 2008) to perform MDS analyses of the two sets of descriptions.

Our procedure was as follows. First, we identified the spatial terms used in each of the elicited descriptions. Because our aim was to analyze spatial term usage at a fine level of detail, we considered each adpositional expression to be a separate spatial term, hence *in* was separate from *inside; on,* from *on top*. This resulted in identification of 36 spatial terms in Mandarin and 38 in English. Next, we constructed two matrices – one for each language – with the 116 pictures defining the rows and with the elicited spatial terms defining the columns. Within each matrix, we then filled in each cell to indicate whether the spatial term heading the column had been used by any participant to describe the picture heading the row (cf., Feist 2008). These matrices were then input into the Optimal Classification algorithm as implemented within the R programming environment.

Results

We look first at the results for each language separately, beginning with English. Next, we turn to the comparison between the English solution spaces and the Mandarin ones.

English The lowest dimensional fit that provided a high rate of correct classification and a substantial improvement over a null model (i.e., one in which all the pictures are in a single category) was the two-dimensional solution, with 97.7% correct classification and an APRE of .765. The conceptual space associated with this solution is presented in Figure 2.

A close examination of Figure 2 reveals that the dimensions in the solution space readily admit of semantic interpretation. The x-axis, anchored by pictures of a ball underneath an upside-down bowl (and, hence, located at its

interior) [picture number 110] and of a muscle in a leg [83] on the left end, and by pictures of a city at the shore of an ocean [109] and of a rope wound around a tree stump [43] on the right, corresponds to a continuum between interior location and surface contact. The y-axis, on the other hand, is anchored by pictures of a dog resting beside a dog house [6] and of a garden on the bank of a river [108] on the upper end, and by pictures of a gate in a fence [136] and of a muscle in a leg [83] at the lower. This axis thus corresponds to variation in the amount of control that the ground exerts over the figure. Along the y-axis we also see variation in the alienability of the objects (i.e., the extent to which the relation between them is inherent to their nature [Strazny 2005]), with more alienable connections (including tree/house [49] and garden/river [108]) anchoring the upper end of the dimension, and more inalienable connections (including muscle/leg [83] and gate/fence [136]) anchoring the lower end.

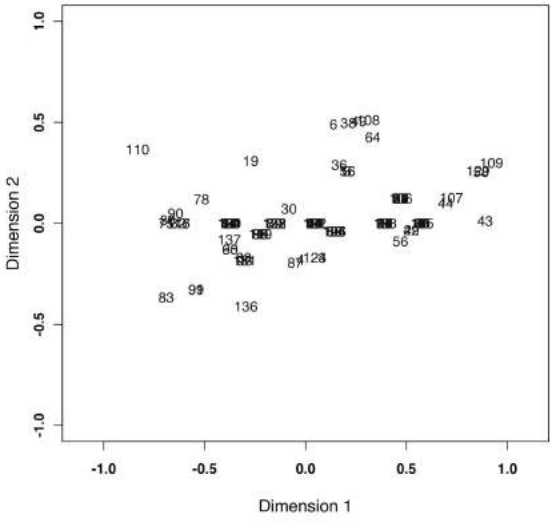

Figure 2: 2-dimensional solution for English. Each number represents one picture in the set.

The addition of more dimensions improved the fit and, even more so, the APRE. The analysis in four dimensions provided the best fit, with 99.5% correct classification, and an APRE of .947 (see Tables 1 and 2).

Mandarin The lowest dimensional fit that provided a high rate of correct classification and a substantial improvement over a null model was again the two-dimensional solution, with 98.8% correct classification and an APRE of .889. The conceptual space associated with this solution is presented in Figure 3.

A close examination of the solution space reveals that the dimension located along the x-axis encodes a continuum between interior location and surface contact. This dimension is anchored at the left end by pictures of a ball underneath an upside-down bowl [110], of a circle surrounded by a rectangle [91], and of a house surrounded by a fence [60], and at the right end by pictures of a garden on the bank of a river [108], of a city on the shore of an ocean [109], of a crease in a pair of pants [86], and of a tree at the top of a hill [65]. The y-axis, on the other hand, encodes variation in the alienability of the two objects. This axis is anchored at the upper end by alienable pairs such as a ball underneath an upside-down bowl [110], a ball under a chair [16], and a garden on the bank of a river [108]; the axis is anchored at the lower end by inalienable pairs such as a curve in a road [88], a tree growing at the top of a hill [65], and a bump in a road [123].

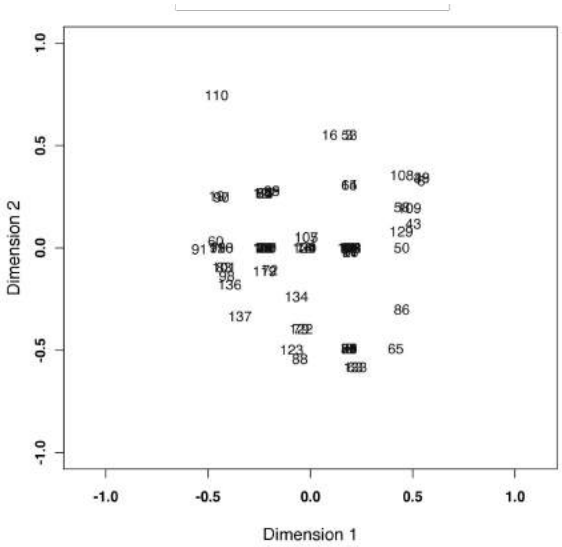

Figure 3: 2-dimensional solution for Mandarin. Each number represents one picture in the set.

The analysis in three dimensions provided the best fit, with 99.4% correct classification, and an APRE of .947, while the gains associated with a higher dimensional fit were more modest (see Tables 1 and 2).

Comparing the solution spaces

There are a number of ways in which we can compare the structurings of the spatial semantic domain in English and Mandarin. At a broad level, we can ask whether the two languages differ in the complexity of the structure of the domain, whereas at a more fine-grained level we can ask whether – and how – conceptual distinctions differ across the two languages.

Turning first to the question of complexity, we compared the two languages with respect to the adequacy of the similarity spaces produced by the MDS analyses. Despite the fact that the two languages yielded comparable numbers of spatial terms (36 in Mandarin; 38 in English), we observed that the Mandarin data was better accommodated at all dimensionalities than was the English data, for both measures of fitness. Table 1 shows the correct classification rates at one, two, three, and four dimensions for both languages. Although the adequacy of the solutions for the two languages was comparable, we note that the Mandarin solution correctly classified a slightly higher proportion of the pictures than did

the English solution at each of the four levels of dimensionality considered. This pattern is replicated for the other fitness statistic, the APRE, for which the differences in adequacy between the Mandarin solutions and the English ones are more pronounced.

Table 1: Correct classification rates for four MDS solutions in both languages

	Mandarin	English
1 dimension	96.4%	95.5%
2 dimensions	98.8%	97.7%
3 dimensions	99.4%	98.6%
4 dimensions	99.7%	99.5%

Table 2: APRE for four MDS solutions in both languages

	Mandarin	English
1 dimension	.659	.551
2 dimensions	.889	.765
3 dimensions	.947	.864
4 dimensions	.976	.947

Pushing this observation farther, we found that the optimal solution in Mandarin was achieved with fewer dimensions than in English, underscoring differences between the two languages in the degree of complexity encoded in topological spatial terms and hinting at differences between the two languages in the semantic structuring of this domain. Notably, the fitness statistics for the three-dimensional Mandarin solution and the four-dimensional English solution were almost identical (99.4% and 99.5% correct classification, respectively, and APREs of .947).

Looking more closely at the placements of the individual pictures, we can ask whether the semantic structurings associated with the two languages differ at a finer-grained conceptual level. To do this, we compared the one-. two-, and three-dimensional semantic spaces across the two languages, asking in each case whether the placements of the pictures along each dimension correlated across the two languages.

We looked first at the one-dimensional solutions, which correctly classified a substantial proportion of the pictures for each language, but presented a relatively modest improvement over a null model. Our analysis revealed a substantial overlap in the placement of pictures along the one-dimensional solution (r = .68, p < .0001), suggesting significant similarity in the ways in which English and Mandarin group situation types in the spatial domain.

In both languages, we observed that the lowest dimensional solution that provided both a high rate of correct classification and a substantial improvement over a null model was the two-dimensional solution, so a comparison of the two-dimensional solutions will be especially important to our understanding of cross-linguistic variation in this domain. At first blush, the English and Mandarin two-dimensional solutions share many similarities: both include one dimension that encodes a continuum between inclusion and surface contact and one dimension that encodes the alienability of the figure-ground relation. However, a closer look reveals that these similarities are but part of the story, co-existing with important differences in the details of the solution spaces.

We consider first the details of the continuum between interior and surface contact. While the English and Mandarin continua overlap, reflected in high correlation between the coordinates along this dimension across the two languages (r = .75, p < .0001), we noted important differences in the placements of many of the pictures in our set. First, we observed that some pictures, such as the crease in pants [86] and the light bulb in a socket [133], are located toward the surface contact end of Mandarin's Dimension 1 but more centrally in the English solution space. In addition, many examples of three-dimensional full inclusion (e.g., an apple in a bowl [2] and a fish in a fishbowl [32]) can be found towards the center of the expanse of Mandarin's Dimension 1, but farther towards the inclusion end of Dimension 1 in English. Looking more closely, we observed that the sets of pictures anchoring the inclusion end of Dimension 1 differed between the two languages: in English, this dimension is anchored by examples of three-dimensional inclusion such as a ball underneath an upside-down bowl [110] and of a muscle in a leg [83], whereas in Mandarin this dimension is anchored by examples of two-dimensional inclusion such as a circle surrounded by a rectangle [91] and a house surrounded by a fence [60]. Whereas all these scenes could be classified as "containment" (cf., Johannes et al. 2015; Landau et al. 2017), these differences suggest that even though both Mandarin and English draw upon a contrast between inclusion and surface contact, the Mandarin system privileges two-dimensional over three-dimensional inclusion, whereas the English system privileges three-dimensional over two-dimensional inclusion. In addition, this dimension is far more spread out in English than in Mandarin, suggesting not only differences in the nature of the inclusion concept, but also differences in the linguistically-relevant degree of similarity amongst the pictures along this dimension.

Turning to the second dimension, we noted less overlap in the semantic interpretation (above), reflected in weaker correlation between the coordinates along this dimension across the two languages (r = .36, p < .0001). Furthermore, whereas this dimension encodes alienability in both solution spaces, this factor is connected to the amount of control exerted by the ground in English, but not in Mandarin. This suggests that control may play a larger role in the semantics of English spatial terms than in the semantics of the Mandarin terms. In addition, this data suggests that the closeness of the relation between two objects may be more likely to be independently assessed and taken into account for speakers of Mandarin than for speakers of English.

Finally, we compared the three-dimensional solutions, which improved substantially beyond the two-dimensional solution in English, but less so in Mandarin. Just as the gains in moving from two dimensions to three differed in the two

languages, we also observed that the placements of the pictures were less congruent in the three-dimensional solutions (dimension 1: $r = .60$, $p < .0001$; dimension 2: $r = .37$, $p < .0001$; dimension 3: $r = .28$, $p = .0023$) than what had been observed for the two-dimensional solutions. This decrement in congruence suggests greater differences between the two semantic systems become evident at more fine-grained levels of analysis.

Conclusions

Our study extends the evidence regarding cross-linguistic variation in the semantics of spatial terms beyond comparisons of the meanings of individual terms by comparing and contrasting the conceptual spaces underlying the semantics of spatial terms in English and in Mandarin. Whereas our findings reinforce the conclusion from past work (i.e., Feist 2008; Levinson & Meira 2003; Levinson & Wilkins 2006) that the conceptual spaces underlying spatial relational inventories are subject to similar factors across languages, this similarity is tempered by evidence that both the factors and the conceptual spaces themselves differ in subtle ways across languages.

We consider first the findings regarding the spatial semantic systems in the two languages. Our Mandarin data was accommodated with fewer dimensions than was our English data, suggesting that the semantic complexity of spatial relational systems varies cross-linguistically. Furthermore, whereas the optimal scaling solution in Mandarin drew upon two dimensions, echoing Feist's (2008) optimal solution for a cross-linguistic dataset, the optimal solution for our English dataset required additional dimensions. This may indicate that each language elaborates on and, hence, may add complexity beyond a universal conceptual core. Thus, while this conceptual core may provide a skeletal structure for how humans think and talk about spatial location (cf., Feist 2008; Levinson & Meira 2003), it markedly underspecifies what we need to encode in order to effectively function in a spatial world.

The strongest correlation between the solution spaces for the two languages involved Dimension 1 of the two-dimensional solutions, which encoded a continuum between interior location and surface contact. In addition to reflecting the importance of the distinction between containment and support (cf., Zhang 2013), this dimension echoes continua that have emerged from other cross-linguistic studies of the semantics of spatial terms, including Bowerman and Pederson's (1992a; see also Bowerman & Choi 2001) similarity gradient and the dimension corresponding to location control in Feist's (2008) MDS analysis. However, whereas Feist's (2008) MDS solution conflated location control and the interior-surface continuum, suggesting that the two may often be inseparable, the English solution reported here separates the two as individual dimensions. This suggests that, whereas both factors are important cross-linguistically and are related, individual languages will make use of different options regarding the extent to which factors are separated in their semantic systems.

Our findings further suggest that cross-linguistic variation may extend beyond fine-grained details of lexical encoding into the nature of the topological concepts themselves. As in the work of Johannes and her colleagues (2015; Landau et al. 2017), our findings underscore the importance of containment and support concepts in the semantics of topological terms. However, a close examination of the continuum between interior and surface contact in the solution spaces for English and Mandarin revealed that the distribution of inclusion scenes differs considerably across the two languages, suggesting differences in the underlying containment concepts. In English, we observed that scenes in which the ground surrounded the figure in three dimensions were placed farther toward the interior end of the continuum than were scenes in which the ground surrounded the figure in two dimensions, suggesting that three-dimensional inclusion is more prototypical than is two-dimensional inclusion in this language. In contrast, in Mandarin we observed the opposite pattern, suggesting that two-dimensional inclusion constitutes a better example of the concept than does three-dimensional inclusion in this language. While inclusion played an important role in structuring spatial semantics in each case, the conceptual cores around which the inclusion concepts were structured differed. Thus, cross-linguistic differences lie not only in the ways terms are distributed relative to a conceptual distinction, but also in the kinds of scenes considered to be best examples of the anchoring conceptual categories.

Whereas MDS allows visualization of the conceptual space underlying semantic systems, it does not afford a picture of the meanings of the lexical items themselves, nor does it afford a close look at the encoding possibilities for individual spatial scenes. The lower correlations observed between the dimensions of the three-dimensional solutions suggest that important cross-linguistic differences may only become evident when viewed at this fine-grained level of analysis. In future work, we will complement the current analysis with analyses focused on these two aspects of spatial semantics. To better understand the detailed ways in which the lexical items relate to one another, we will examine frequencies of use of each term for each picture – i.e., the behavioral profiles (Gries 2010) of each of the elicited terms. To better understand variation in the codability of the scenes, we will assess the breadth of descriptions elicited by each scene. Taken in combination with the current study, these analyses will afford a better understanding of the ways in which individual lexemes fit together to create a semantic system.

Taken together, the current results present a rich picture of the interplay between universals and variation in the semantics of spatial terms. While languages may draw upon a common set of concepts to structure meanings in this domain, these concepts may in fact be quite underspecified. As a result, the variation in meaning that has been observed across languages may be indicative of variation in the ways in which the universal conceptual core has been developed in each language in order to produce a useful set of concepts for communication.

Abstract

This study utilises an experiment famous in quantum physics, the Stern-Gerlach experiment, to inform the structure of an experimental protocol from which a quantum cognitive decision model can be developed. The 'quantumness' of this model is tested by computing a discrete quasi-probabilistic Wigner function. Based on theory from quantum physics, our hypothesis is that the Stern-Gerlach protocol will admit negative values in the Wigner function, thus signalling that the cognitive decision model is quantum. A crowdsourced experiment of two images was used to collect decisions around three questions related to image trustworthiness. The resultant data was used to instantiate the quantum model and compute the Wigner function. Negative values in the Wigner functions of both images were encountered, thus substantiating our hypothesis. Findings also revealed that the quantum cognitive model was a more accurate predictor of decisions when compared to predictions computed using Bayes' rule.

Keywords: quantum cognition; decision-making; complex Hilbert space; binary response; cognitive modelling

Introduction

A generally accepted notion is that we can approximately access cognitive states through questioning and observation, and whilst this measurement is not deemed to be perfect, it is a standard means of experimental practice in the psychological discipline. This notion relies on the fact that these internal states hold distinct values and by measuring them, we are merely attempting to record what is already there. Often, probabilistic outcomes of these measures appear to be illogical and do not follow the laws of classical probability, for example, cognitive biases identified in decision-making (Tversky & Kahneman, 1974). Quantum cognition has emerged as an alternative means of analysing probabilistic outcomes that do not follow these classical laws. Its potential derives from an alternative probability which has successfully been used to address human decision making considered paradoxical, generate non-reductive understandings of human conceptual processing, and provide new understandings of perception and human memory (Bruza, Wang, & Busemeyer, 2015; Busemeyer & Bruza, 2012). The present paper extends current approaches to quantum modelling by means of two new aspects: 1) the Stern-Gerlach experiment, to inform an experimental protocol from which a complex Hilbert space model can be constructed and 2) the discrete Wigner function to perform a check on 'quantumness' of cognitive systems being modelled.

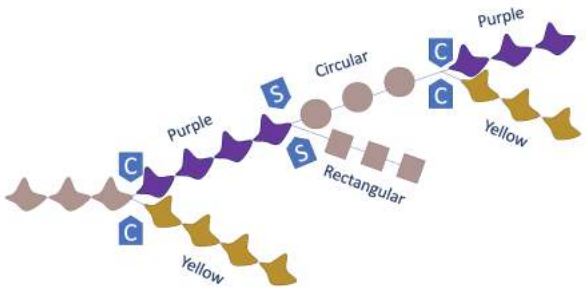

Figure 1: S.G. Setup using colour-type measurements (C) and shape-type measurements (S) in place of spin measurements at different orientations.

The Stern-Gerlach Experiment

The Stern-Gerlach (S.G.) experiment (Sakurai & Commins, 1995) takes a beam of particles (for example, silver atoms) and observes their spin using a device that creates an electromagnetic field (S.G. device). This device can be placed at different orientations to observe spins at associated orientations. Due to the fact that a particle's spin is a complex concept to describe, we will substitute this property with colour and shape in our description of the S.G. experiment in the interests of clarity. For the following, we will describe the experiment as having two orientations of S.G. devices: one oriented one way to measure one type of spin (we will call this a 'colour-type' measure differentiating purple from yellow), and another oriented orthogonal to the first to measure a second type of spin (we will call this a 'shape-type' measure differentiating circular from rectangular). Each enable measurement of separate aspects of the same object (two orientations of spin, or colour and shape in our analogy).

The experiment involves a beam of atoms hitting an S.G. device which splits it into two separate beams: one purple beam and another yellow beam. A second S.G. device of the same orientation as the first (colour-type) is placed in the path of the purple beam. This time, the beam does not split, and

only one beam of purple atoms come out, as one would expect (i.e. we assume no yellow atoms to have entered it due to the separation performed by the first S.G. device). We then place a shape-type S.G. device in-between the two colour-type S.G. devices, which splits the first purple beam into circular and rectangular atoms before hitting the second colour-type device (see figure 1).

In a classical system, we would expect only one beam to emit from the second colour-type device, as, again, we would assume that only purple atoms were sent that way from the first device. A quantum system, however, does not work in this way. In a quantum system, the second colour-type device will emit two beams after the original beam of purple atoms has passed through the shape-type device, as illustrated in figure 1. This is because the shape-type measurement has destroyed the first measurement of colour, essentially resetting it. This can only happen if a particle's properties are not simply observed in a predefined definite state, but are determined at the point of measurement.

A Cognitive Analogue

This concept can be applied to cognitive measures, however, in a slightly more complex way. Due to the potential of memory effects inherent in repeating a question in a string of only three total questions, we utilise a more complex version of the S.G. experiment, where a third question is introduced. The general concept, however, remains the same. When one considers a question or makes a decision, they may simply be accessing an internal state predetermined by a range of variables such as past experience, knowledge, predisposition, values, what they had for lunch that day, etc. On the other hand, they may be creating the state only at the point of measurement (i.e. considering a question or making a decision). To place this in the context of the S.G. experiment, consider three questions asked after presentation of an image: Do you feel a sense of trust when viewing this (T), do you feel that the person in this image is attractive (A), and do you feel that the image may have been manipulated (M). Taking a classical position, one could describe this system in the following way: A person views an image and this event interacts with internal variables to create a variety of probable judgments of this image, including judgments of trust, attractiveness and manipulation. A person then considers the sequential questions of trust, attractiveness and manipulation, each time taking an internal measurement of the predefined values that each of these hold in the person's internal state. On the contrary, taking a quantum position would instead describe no definite judgments to be formed at the point of viewing the image, but only at the point of considering each question. This view would also posit that each question would destroy the measurement of the prior question, in the same way the shape-type S.G. device did in our above example.

This article presents an experimental protocol that is analogous to the S.G. experiment in order to derive a quantum model of decision making. For this purpose a complex Hilbert space is used.

Derivation of a Quantum Model of Decision Making from the S.G. device

As described above, the basic idea behind the model is to translate the S.G. device into cognitive science by way of analogy; human subjects correspond to silver atoms and questions correspond to S.G. devices. As a running example we will use an image trustworthiness task whereby subjects are asked whether they trust (T) an image, whether they find the subject of the image attractive (A) and whether they deem the image to be manipulated (M) e.g., photoshopped. The particular order of questions is determined by the order of the devices in the S.G. device as depicted in figure 2.

The derivation of the quantum model corresponding to the S.G. device comprises two steps: In the first step, a complex Hilbert space model with states and operators is constructed. In the second step, a criterion for checking the 'quantumness' of the model is applied by using a discrete Wigner function.

The cognitive decision space is modelled by means of a complex Hilbert space model (HSM), i.e., a complex vector space, equipped with an inner product with a positive definite metric (Sakurai & Commins, 1995). Any yes/no outcome of a specific question X, is denoted by a ket $|X,\pm\rangle$ using the Dirac notation, where +/- respectively denotes a yes/no outcome :

$$|X\rangle = \alpha|X,+\rangle + \beta|X,-\rangle, \qquad \alpha,\beta \in \mathbb{C}$$

in which $|\alpha|^2$ and $|\beta|^2$, based on the Born rule, give the probability of observing the positive and negative answers. In addition, outcomes are orthogonal, $\langle X,\pm|X,\mp\rangle = 0$ and probabilities are normalized, $|\alpha|^2 + |\beta|^2 = 1$. Also, an observable is defined as a Hermitian operator. Without going into the technical details, a Hermitian operator $\hat{A}$ is a special type of matrix where the eigenstates correspond to outcomes that are observed, and the corresponding eigenvalue relates to the probability of observing that outcome. The Pauli matrices σ_i, $i = 1,2,3$,

$$\sigma_x = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}, \quad \sigma_y = \begin{pmatrix} 0 & -i \\ i & 0 \end{pmatrix}, \quad \sigma_z = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix},$$

along with the identity matrix $I_{2\times 2}$, form an orthogonal basis for the complex Hilbert space of all 2×2 matrices. As a consequence, any operator such as $\hat{A}$ can be expressed by $\hat{A} = a_0 I + \sum_{i=1}^{3} a_i \sigma_i$, in which $a_i \in \mathbb{R}$ with $i = 0,1,2,3$.

Steps to construct a complex HSM Based on the preceding formalism, the following steps are used to derive the quantum model from the S.G. depicted in figure 2:

1) A quantum state is defined by the first question T based on relative frequencies of yes/no outcomes sampled from the experimental data, $|T\rangle = \sqrt{P_t(+)}|T,+\rangle + \sqrt{P_t(-)}|T,-\rangle$, in which $P_t(+)$ and $P_t(-)$ are respectively probability of finding positive and negative responses to the question T. Also, we can consistently define the projection or filtering-type quantum cognitive operator $\hat{\pi}_t(\pm) = |T,\pm\rangle\langle T,\pm|$, so that $P_t(\pm) = \langle T|\hat{\pi}_t(\pm)|T\rangle$. The filtering-type operators $\hat{\pi}_t(\pm)$ satisfy the completeness relation, $\hat{\pi}_t^{\dagger}(+)\hat{\pi}_t(+) + \hat{\pi}_t^{\dagger}(-)\hat{\pi}_t(-) = I_{2\times 2}$,

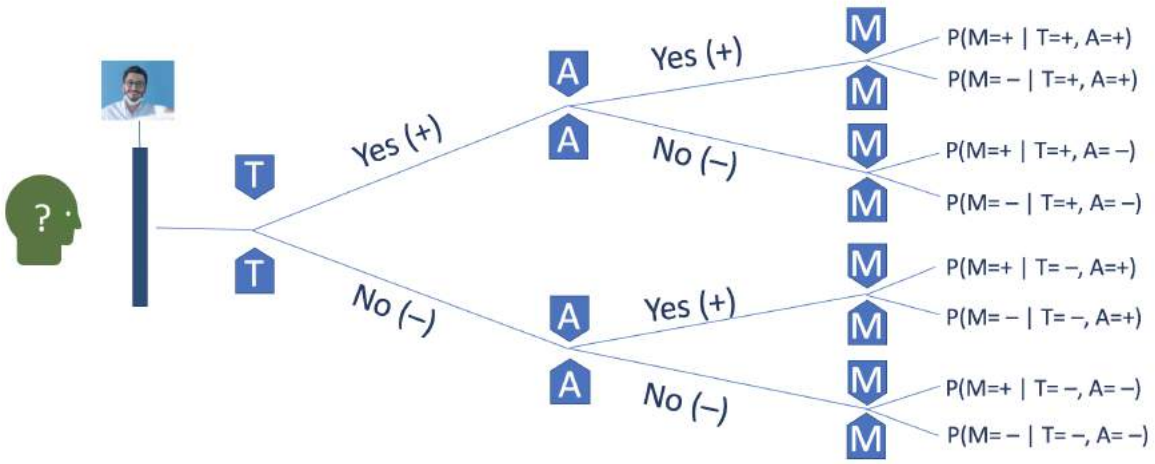

Figure 2: A cognitive analogue to a S.G. experiment where Trustworthiness (T) is asked first, followed by Attractiveness (A), then Manipulated (M).

and the operator $\hat{T}$ is defined as : $\hat{T} = \hat{\pi}_t(+) - \hat{\pi}_t(-) = \sigma_z$, where σ_z is the Pauli matrix in direction z.

2) In the second step, we obtain the probability of finding positive and negative responses to the second question A through the first question T. Hence, we can define the cognitive state regarding a decision of attractiveness A in the basis of the state of trustfulness T, i.e., $|A,+\rangle = \cos\frac{\theta_a}{2}|T,+\rangle + \sin\frac{\theta_a}{2}|T,-\rangle$ and $|A,-\rangle = \sin\frac{\theta_a}{2}|T,+\rangle - \cos\frac{\theta_a}{2}|T,-\rangle$. The filtering-type measurement operators $\pi_a(\pm)$ can be written as follows:

$$\hat{\pi}_a(\pm) = \frac{1}{2}\Big[I_{2\times 2} \pm \sin\theta_a\sigma_x \pm \cos\theta_a\sigma_z\Big].$$

Hence, the operator $\hat{A}$ is given by

$$\hat{A} = \begin{bmatrix} \cos\theta_a & \sin\theta_a \\ \sin\theta_a & -\cos\theta_a \end{bmatrix} \tag{1}$$

in which θ_a characterizes a specific direction, which can be computed from the experimental data. By applying the Born rule, the conditional probabilities can be computed. For example,

$$P(A=+|T=+) = |\pi_a(+)\pi_t(+)|T\rangle|^2 = P_t(+)\cos^2\frac{\theta_a}{2}, \tag{2}$$

3) A similar method to step 2) derives another filtering-type operator corresponding to the third question M,

$$\hat{\pi}_m(\pm) = \frac{1}{2}\Big[I_{2\times 2} \pm \sin\theta_m\cos\phi_m\sigma_x \pm \sin\theta_m\sin\phi_m\sigma_y \pm \cos\theta_m\sigma_z\Big]$$

in which θ_m can be obtained, despite of the fact that we must have extra information for acquiring ϕ_m. Note that the states of third question M are defined as follows:

$$\begin{aligned} |M,+\rangle &= \cos\frac{\theta_m}{2}|T,+\rangle + e^{i\phi_m}\sin\frac{\theta_m}{2}|T,-\rangle, \\ |M,-\rangle &= e^{-i\phi_m}\sin\frac{\theta_m}{2}|T,+\rangle + \cos\frac{\theta_m}{2}|T,-\rangle. \end{aligned}$$

4) In the last step, probabilities of the third question M are computed based in light of the outcomes from the second question A:

$$\begin{aligned} &P(M=+|A=+,T=+) = |\pi_m(+)\pi_a(+)\pi_t(+)|T\rangle|^2 \\ &= P_t(+)\cos^2\tfrac{\theta_a}{2}(+)\Big(\cos^2\tfrac{\theta_a}{2}\cos^2\tfrac{\theta_m}{2} + \sin^2\tfrac{\theta_a}{2}\sin^2\tfrac{\theta_m}{2} \\ &+\tfrac{1}{2}\sin\theta_a\sin\theta_m\cos\phi_m\Big). \end{aligned} \tag{3}$$

By using the previous equations, values of ϕ_m can be computed.

Determining quantumness using the discrete Wigner distribution When we construct the Hilbert space structure of the cognitive state and associated operators, we can examine the quantumness of the cognitive state. Quantum physics has a range of criteria for this. In this article we will employ one such criterium, namely the negative discrete Wigner function, where the negativity of the function can be interpreted as a signature of quantum interference. In order to explain the discrete Wigner function, the continuous Wigner function is first introduced. For a continuous phase space (q,p), the continuous Wigner distribution is defined by

$$W_\Psi(q,p) = \frac{1}{2\pi}\int_{-\infty}^{\infty} dx\langle q - \frac{x}{2}|x\rangle\langle x|q+\frac{x}{2}\rangle e^{ipx}. \tag{4}$$

Therefore, the expectation value of an arbitrary operator $\hat{X}$, by using the Wigner distribution, is given by

$$\langle\hat{X}\rangle = Tr[\hat{\rho}\hat{X}] = \int\int dx\,dp W(x,p)\tilde{X}(x,p), \tag{5}$$

in which $\tilde{X}(x,p)$ is the average of a physical quantity over the phase space. Assuming two arbitrary states $|\psi_a\rangle$ and $|\psi_b\rangle$, it can be verified that:

$$|\langle\psi_a|\psi_b\rangle|^2 = Tr[\hat{\rho}_a\hat{\rho}_b] = \int dx\,dp W_{\psi_a}(x,p)W_{\psi_b}(x,p). \tag{6}$$

If we consider a situation in which two states are orthogonal, i.e.,

$$\int dx\,dp W_{\psi_a}(x,p)W_{\psi_b}(x,p) = 0, \tag{7}$$

at least in part of the region in phase space, one of the above mentioned Wigner distributions has to be negative. The values in Wigner distributions still sum to 1 even when values happen to be negative, which is why Wigner distributions are termed "quasi-probability" distributions. The negativeness of the Wigner distribution can be the result of the following two facts: Firstly, the accessibility of information for a system described by the quantum formalism is when the system is described by classical probability (Goh et al., 2018; Vourdas, 2019). Secondly, the negativeness can be interpreted as quantum contextuality (Huang, Yu, & Zhang, n.d.; Raussendorf, Browne, Delfosse, Okay, & Bermejo-Vega, 2017; Kocia & Love, 2017).

The binary nature of the responses implies a discrete, rather than continuous phase space. We apply a generalized version of the continuous Wigner function (Wootters, 1987). In fact, by defining a geometrical structure on the discrete phase space, such as parallel line, *etc.*, and using a Finite Field $\mathcal{F}_n$, a discrete Wigner distribution can be defined (Gibbons, Hoffman, & Wootters, 2004; Galvao, 2005; Di Matteo, Sánchez-Soto, Leuchs, & Grassl, 2017).

Due to the fact that we have binary responses, the discrete phase space occupies a 2×2 array of points where q runs along the horizontal axis and p runs along the vertical axis, as shown in figure 3. We place the origin, $(q,p) = (0,0)$, at the lower left-hand corner. We define a line λ in the 2×2 phase space as the set of two points satisfying an equation of the form $aq + bp = c$, where a, b, and c are elements of $\mathbb{Z}_2$ ($\mathbb{Z}_2$ constraints numbers to binary 0s and 1s) where a and b cannot both equal zero. It has the following conditions: (i) given any two distinct points, exactly one line contains both points;(ii) given a point α, if a line λ does not contain α, there is exactly one line parallel to λ that does contain it (iii) two lines that are not parallel intersect in exactly one point. In the preceding conditions, two lines can be considered parallel if they can be represented by equations having the same values for a and b but different values for c. In the case of a binary response, therefore, a line connecting $(0,0)$ and $(0,1)$ is parallel with the line that connects $(1,0)$ and $(1,1)$. Moreover, two equations $p+q=0$ and $p+q=1$, with $p,q \in \mathbb{Z}_2$, give the lines connecting points $(1,0)$ and $(0,1)$ and the parallel line connecting $(0,0)$ and $(1,1)$. Finally, the line $(0,0)$ and $(1,0)$ is parallel with the line $(0,1)$ and $(1,1)$. Figure 3 demonstrates these striations in (1), (2), and (3) respectively. Note that the lines drawn in (2) are technically parallel based on the equation described above. As is the case in the continuous phase space, the integral of the Wigner function over the strip of phase space bounded by the lines $aq+bp=c_1$ and $aq+bp=c_2$ is the probability that the operator $a\hat{q}+b\hat{p}$ will take a value between c_1 and c_2 (Wootters, 1987), the discrete Wigner function has to satisfy the following equation:

$$Tr\left(|\alpha_{i,j}\rangle\langle\alpha_{i,j}|\rho\right) = \sum_{\alpha \in \lambda_{i,j}} W_\alpha, \tag{8}$$

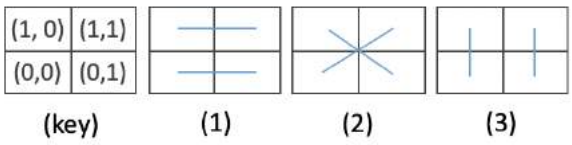

Figure 3: The striations of the 2×2 phase space. Each point occupies a quadrant.

in which ρ is density matrix,

$$\hat{\rho} = \frac{1}{2}\left(I + \vec{r}\cdot\sigma\right) = \frac{1}{2}\begin{pmatrix} 1+r_z & r_x - ir_y \\ r_x + ir_y & 1-r_z \end{pmatrix}. \tag{9}$$

and $|\alpha_{i,j}\rangle$ are three mutually unbiased bases for a two-dimensional Hilbert space, with the following property:

$$|\langle\alpha_{i,j}|\alpha_{k,l}\rangle|^2 = \frac{1}{2} \text{ if } i \neq k, \tag{10}$$

where $i = 1,2,3$ indexes the mutually unbiased bases and $j = 1,2$ indexes the basis vector in each mutually unbiased bases, with the following condition $\langle\alpha_{i,j}|\alpha_{i,k}\rangle|^2 = \delta_{j,k}$. Naturally, we can consider a one-to-one map between Pauli matrices σ_i and striations S_i.

Experiment

Participants

Participants consisted of 300 members of the crowdsourcing platform Prolific, 187 of which were male, 110 female, and 3 who preferred not to disclose their gender. Participants were over 18 years and from a variety of countries across North America (39.7%), Europe (32.3%), UK (22.9%), Australiasia (4.0%) Middle East (0.7%) and Asia (0.3%). Participants were randomly assigned to one of 4 conditions, each with 75 participants. All participants had been verified as proficient in English by Prolific. Remuneration was in the form of a small payment (£.23), as per Prolific convention, and an informed consent page was presented to participants prior to commencement.

Materials

Questions asked were as follows: While viewing, did you feel a sense of trust? (T), Did you feel that this person was attractive? (A), and Did you feel that this image may have been photoshopped? (M). Question orders were *TAM* and *TMA* for each image. Questions were selected based on the likelihood that the operators associated with these variables would be non-commutative. In other words, we were expecting some order effects between variables/operators, meaning that they are not entirely independent of one another. For example, we expect the probabilities associated with the question of attractiveness (A, given T) and the probabilities associated with the question of manipulated (M, given T & A) to be different if the order of A and M were to be reversed (i.e., TMA, with $M|T$, and $A|T$ & M). The image stimuli used to gather ratings of the above dimensions are shown in Figure 4.

(a) Image 1: Unedited.

(b) Image 2: Edited.

Figure 4: Image Stimuli

(A)

P(T=+)	P(A |T=+)	P(M |A,T=+)
P(T=+)=0.85	P(A=+|T=+)=0.69	P(M=+| A=+,T=+)=0.29
		P(M=-| A=+,T=+)=0.40
	P(A=-|T=+)=0.16	P(M=+| A=-,T=+)=0.10
		P(M=-| A=-,T=-)=0.05

(B)

P(T=+)	P(M |T=+)	P(A |M,T=+)
P(T=+)=0.77	P(M=+|T=+)=0.32	P(A=+| M=+,T=+)=0.24
		P(A=-| M=+,T=+)=0.08
	P(M=-|T=+)=0.45	P(A=+| M=-,T=+)=0.37
		P(A=-| M=-,T=+)=0.08

Figure 5: Table (A) and (B) correspond to Image 1 (unedited). Probabilities relating to the first question (T) are depicted in the first columns; the second column states conditional probabilities of the second question given first one, i.e., $P(A = \pm|T = +)$ in Table (A) and $P(M = \pm|T = +)$ in Table (B); the third column indicates conditional probabilities of the third question given the first and second questions.

Design

Each image was presented with two question orders, creating a between subjects design with four conditions. The dependant variables were ratings of trustworthiness, attractiveness and image manipulation.

Procedure

In all conditions, participants completed an online experiment by first perusing a short description on the Prolific site, if deciding to continue, they then clicked a link to the project page which begins with short instructions and a link to the consent form to read before continuing. The design of the experiment was aimed at accessing fast intuitive responses, rather than responses based on analytical thinking, as this was believed to be analogous to the short distances between measurement devices in the S.G. experiment (i.e. fast measurements restricting interacting influences). To this end, instructions included a notice to look out for a button popping up for some participants that afforded a bonus (distraction to assign less cognitive resources to the decision task), questions were asked with emotive wording (to help prompt intuitive thinking), and both image display and questions included a time limit (2 seconds for the image and 4 seconds for each question). Participants could only view one question at a time, with each subsequent question hidden until an answer had been given for the preceding one. Lastly, participants were asked to provide one or two words to describe their first impressions of what they saw, as well as a confidence rating for their combined judgments, and were asked their gender and the country they resided in.

(A)

P(T=+)	P(A |T=+)	P(M |A,T=+)
P(T=+)=0.85	P(A=+|T=+)=0.69	P(M=+| A=+,T=+)=0.29
		P(M=-| A=+,T=+)=0.40
	P(A=-|T=+)=0.16	P(M=+| A=-,T=+)=0.10
		P(M=-| A=-,T=-)=0.05

(B)

P(T=+)	P(M |T=+)	P(A |M,T=+)
P(T=+)=0.77	P(M=+|T=+)=0.32	P(A=+| M=+,T=+)=0.24
		P(A=-| M=+,T=+)=0.08
	P(M=-|T=+)=0.45	P(A=+| M=-,T=+)=0.37
		P(A=-| M=-,T=+)=0.08

Figure 6: Table (A) and (B) correspond to Image 2 (edited). Probabilities relating to the first question (T) are depicted in the first columns; the second column states conditional probabilities of the second question given first one,i.e., $P(A = \pm|T = +)$ in Table (A) and $P(M = \pm|T = +)$ in Table (B); the third column indicates conditional probabilities of the third question given the first and second questions.

Results

Based on the probabilities shown in Table 5 (A), (B) and Table 6 (A), (B), the cognitive states associated with the first question T are given by:

$$|T_1\rangle = \sqrt{0.85}|T_1,+\rangle + \sqrt{0.15}|T_1,-\rangle, \quad (11)$$

$$|T_2\rangle = \sqrt{0.59}|T_2,+\rangle + \sqrt{0.31}|T_2,-\rangle. \quad (12)$$

where the subscripts respectively denote the unedited and edited images.

According to probabilities in the second column in Table 5 (A), (B) and also by using the equation (2), the angles between operator $\hat{T}$ and $\hat{A}$, as well as $\hat{T}$ and $\hat{M}$, are respectively given by $\theta_a^{(1)} = 51.42$ and $\theta_m^{(1)} = 99.79$ for the unedited image. By using the same method, in the second column of Table 6 (A), (B), the angles between the operators $\hat{T}$ and $\hat{A}$, as well as $\hat{T}$ and $\hat{M}$, are obtained respectively by $\theta_a^{(2)} = 71.20$ and $\theta_m^{(2)} = 87.70$ for the edited image. By using equation (3) together with the third column of Table 5 (A), (B) and Table 6

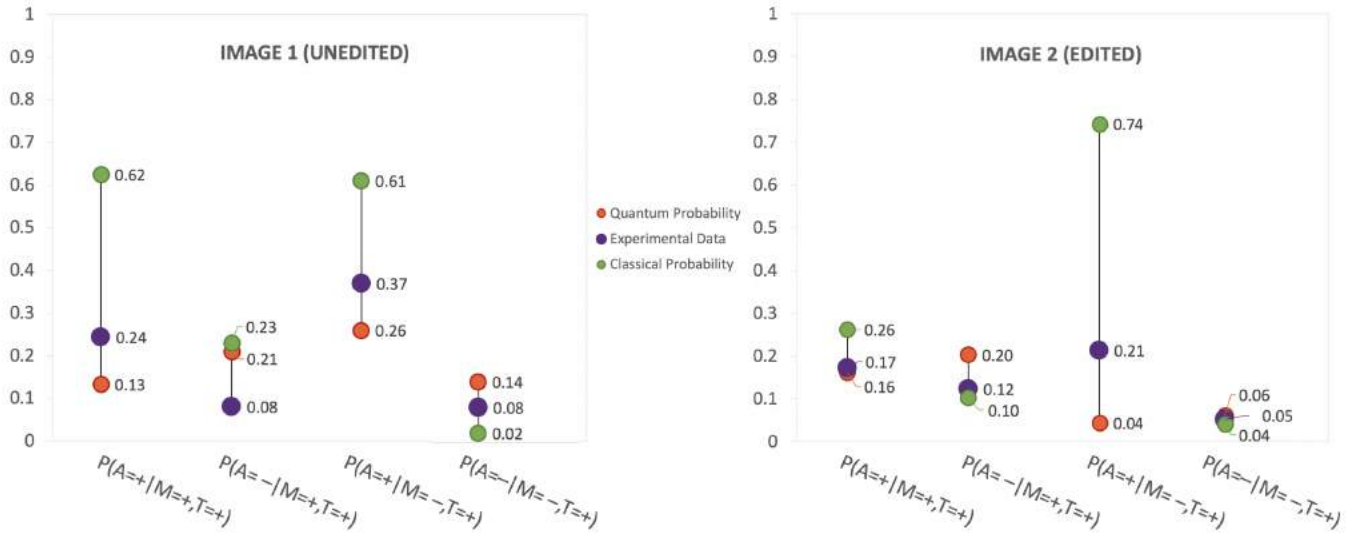

Figure 7: Comparison of actual probabilities (Experimental Data) of the third question Attractiveness (A) to predicted probabilities computed by the Born rule (Quantum Probabilities) and Bayes' rule (Classical Probabilities).

(A), (B), we obtain respectively $\phi_m^{(1)} = 85.99$ and $\phi_m^{(2)} = 85.30$ for the unedited and edited images.

Comparison of prediction of decision: quantum probabilities vs. classical probabilities For the prediction comparison, we consider a new situation in which the the order of questions is altered. According to operators $\hat{A}$ and $\hat{M}$ and new preparation state $|T\rangle$, we obtain the probability of positive and negative answers and compare them with the experimental data. Indeed, as defined in equation (3), the phase interference ϕ_m appears in the probability of the third question. The predictions of the quantum model are compared to classical probabilities in the following way: The cognitive S.G. device depicted in Figure 2 can be modelled by using the chain rule: $P(T,A,M) = P(T)P(A|T)P(M|A,T)$. The three distributions on the RHS are empirically collected from the S.G. device. Similarly, in the new situation the order of the A and M magnets are reversed so the chain rule is written out as follows: $P(T,M,A) = P(T)P(M|T)P(A|M,T)$. Therefore,

$$P(M|A,T) = \frac{P(M|T)P(A|M,T)}{P(A|T)} \quad (13)$$

$$P(A|M,T) = \frac{P(A|T)P(M|A,T)}{P(M|T)} \quad (14)$$

The LHS of both equations constitute predictions based on classical probability theory. As evidenced by Figure 7 (A) and (B), the predicted results calculated based on the HSM are generally closer to the actual probabilities than the classical predictions. Figure 7 compares results of probabilities of the decision regarding manipulation given attractiveness and trustworthiness, for the unedited and edited images respectively.

Wigner functions for both images By using equation (9):

$$r_x = 2\sqrt{P_t(+)\left(1-P_t(+)\right)},\ r_y = 0,\ r_z = 2P_t(+)-1,$$

The discrete Wigner distribution that is obtained is the following:

$$W = \frac{1}{4}\begin{pmatrix} 1+r_x+r_z & 1-r_x+r_z \\ 1-r_x-r_z & 1+r_x-r_z \end{pmatrix} \quad (15)$$

Therefore, the Wigner distributions for both unedited (W_1) and edited (W_2) images are given as follows:

$$W_1 = \begin{pmatrix} 0.63 & 0.13 \\ -0.13 & 0.36 \end{pmatrix}, \quad W_2 = \begin{pmatrix} 0.53 & 0.03 \\ -0.03 & 0.47 \end{pmatrix} \quad (16)$$

Discussion

The Wigner function of both images showed negative values. Therefore, the cognitive analogue of the S.G. experiment that produces quantum models in physics, also produces a quantum model for cognitive decision making.

It is known from physics that negative values in the Wigner function are a consequence of quantum interference effects. The negative values are a consequence of the fact that once a particle has passed through a magnet its polarization (either + or -) is not retained when it arrives at the next magnet. This is a consequence of the the fact that a particle is always in a superposed state each time it interacts with a magnet. As a result of the interaction, a particular polarization will be observed. In terms of the cognitive analogue depicted in Figure 2, the preceding can be translated as follows: Even though a subject has already decided that they trust (T=+) the image and have deemed the face to be attractive (A=+), when they are presented with the decision about whether the image is manipulated, at that decision point they are necessarily superposed with respect to trust and attractiveness. This can only occur when the decision perspectives are incompatible. Incompatibility is indeed present in the HSM as the operators corresponding to decisions of trustworthiness $\hat{T},\hat{A},\hat{M}$ do not pair-wise mutually commute: $[\hat{T},\hat{A}] \neq 0$, $[\hat{T},\hat{M}] \neq 0$, $[\hat{A},\hat{M}] \neq 0$.

Incompatibility generates interference effects which gen-

erate probabilities of outcomes, that is they are fundamentally different from standard probabilistic models (Bruza et al., 2015). As stated above, the cognitive S.G. device depicted in Figure 2 can be modelled by using the chain rule: $P(T,A,M) = P(T)P(A|T)P(M|A,T)$. This expresses that the underlying probabilistic model of the device is simply the joint probability distribution $P(T,A,M)$. The critical point is that the structure of the event space underpinning $P(T,A,M)$ assumes that the variables are *jointly* measurable, e.g., the subject can simultaneously access information regarding the attractiveness of the face and whether the image is manipulated. The previously mentioned incompatibility in the HSM $[\hat{A},\hat{M}] \neq 0$ implies that this assumption does not hold. Consequently, the subject cannot cognitively form the joint distribution $P(T,A,M)$. In short, the HSM provides a probabilistic framework which does not rely on the assumption that variables are jointly measurable. This has been one of the key features of quantum models of cognition (Busemeyer & Bruza, 2012).

The use of three operators is crucial in the derivation of the two-dimensional Hilbert space because three operators necessarily entail that a *complex* Hilbert space must be used. The use of less than three operators necessarily implies that the cognitive decision model can be expressed as a real-valued Hilbert space, which has been the practice thus far in quantum cognition research. The significance of this difference lies in the complex phase factor $\exp(i\phi_m)$ which cannot be derived unless there are three operators. We speculate that it is this phase factor which generates the interference effects for the Wigner function to go negative and hence become quantum. To the best of our knowledge, this study is the first to: a) develop a specialised protocol to genuinely exploit the complex Hilbert space by constructing three operators and states, and b) utilise the Wigner function to determine the quantumness of a cognitive state.

Moreover, this determination is straightforward and does not suffer from the challenges and controversies associated with using contextuality to determine whether the cognitive system is quantum-like (Dzhafarov, Kujala, Cervantes, Zhang, & Jones, 2016; Bruza & Fell, 2018).

Conclusions and future work

This article has demonstrated the specification and validation of a quantum decision model by employing an experimental protocol derived from quantum physics. The protocol involved three binary decisions in a forced choice design. Future studies may investigate the measurement of decisions by asking binary questions of any number of points within a spectrum of responses by extending the quantum model described in this paper.

Abstract

The use of abstract higher-level knowledge (overhypotheses) allows humans to learn quickly from sparse data, and make predictions in new situations. Previous research has suggested that humans may be the only species capable of abstract knowledge formation, but this remains controversial, and there is also mixed evidence for when this ability emerges over human development. Kemp et al. (2007) proposed a computational model of overhypothesis formation from sparse data. We provide the first direct test of this model: an ecologically valid paradigm for testing two species, capuchin monkeys (Sapajus spp.) and 4-5-year-old human children. We compared performance to predictions made by models with and without the capacity to learn overhypotheses. Children's choices were consistent with the overhypothesis model predictions, whereas monkeys performed at chance level.

Keywords: Overhypotheses, abstraction, generalization, animal cognition, computational modeling, cognitive development

Introduction

For long-lived species that exploit a complex environment it might be beneficial to transfer adaptive behavior across situations, through the formation of abstract generalizations. For example, if a primate learns that one tree grows figs, a second papaya and a third nuts, at a more abstract level she is also exposed to the regularity: "Trees carry a uniform fruit type". Learning this abstraction would make just one bite of fruit from a new tree sufficient to decide whether or not continued foraging in this tree would be beneficial.

In the developmental literature the term 'overhypotheses' (Goodman, 1955) describes such higher-order generalizations at an abstract level that inform inferences about more specific hypotheses (Kemp, Perfors, & Tenenbaum, 2007). Kemp et al. (2007) developed a computational model that suggested that, in principle, overhypotheses can be learned quickly from sparse data and used to make wide-ranging predictions in new situations.

Evidence for a possible early emergence of this ability during human infancy comes from a study using looking-time methodology. Dewar and Xu (2010) presented 9-month-olds with sampled evidence supporting the overhypothesis that containers are filled with objects of the same shape. In a test situation, infants looked longer when two differently shaped objects were drawn from the same container, contradicting this overhypothesis, than when two uniformly shaped objects were sampled.

Despite this evidence for early overhypothesis formation, other methods show contrasting results. A common method to assess understanding of the abstract concepts "same" and "different" is the relational matching-to-sample (RMTS) task. Here, participants are presented with an example stimulus pair (either two of the same or two different items) as well as two test pairs, and must select the pair with the matching abstract relation to the example. Hochmann et al. (2017) showed that children begin to succeed in a 2-item RMTS task by the age of 5 but not earlier (see Kotovsky & Gentner, 1996 for a similar result). However, labeling the relations verbally enables children to succeed in the RMTS task as early as age 2 (Christie & Gentner, 2014).

In contrast, in an anticipatory looking time procedure, Hochmann, Carey and Mehler (2018) showed that 7 and 12-month-olds were sensitive to the abstract relation of same but not different. Similarly, 18- to 30-month-old children correctly selected either a matching or a dissimilar pair of objects following evidence that their relation was causally relevant (Walker & Gopnik, 2014).

In addition, only a few non-human species master the RMTS task, usually after lengthy training regimes (e.g. Truppa, Mortari, Garofoli, Privitera, & Visalberghi, 2011; see also Smirnova, Zorina, Obozova & Wasserman (2015)), and often only with multi-stimulus arrays instead of stimulus pairs (see Wasserman & Young, 2010 for a review; the latter also helping 3-year-olds succeed, Hochmann et al., 2017). As a result, some have suggested that the RMTS task can be solved by perceptual processes alone, and that abstract knowledge is a uniquely human capability (Penn, Holyoak, & Povinelli, 2008; Vonk, 2015). In a different set of tasks, chimpanzees and bonobos have been suggested to use relative spatial relations such as "top" or "middle" to find hidden food rewards (Haun & Call, 2009; Christie, Gentner, Call & Haun, 2016). However, it is not clear whether searching based on relative rather than absolute

[*] Equal contribution

spatial relations represents the same kind of abstract knowledge as concepts such as "same" and "different". In summary, the question of whether abstract knowledge formation is an evolutionary primitive, shared with other species and emerging early in human development, or a recently-evolved, late-developing skill, is complicated by considerable methodological differences between the tasks used across ages and species. Further, as in other areas of cognitive development, there is something of a dissociation between looking time results that suggest an early-emerging conceptual competence, and later emerging success on choice-based measures by older children. One concern is that successful discrimination in infant looking time tasks may not require the same kind of conceptual competence as paradigms requiring participants to use their knowledge to make a choice (e.g., Hood, 2004).

We therefore designed a task that could be used across species, to examine abstract knowledge formation in an ethologically valid context without extensive training or explanation, based on the original idea of overhypothesis formation by Goodman (1955). Importantly this allowed us to test a theoretical computational model for how limited data can be sufficient for overhypothesis formation in this task (Kemp et al., 2007). Similar to Dewar and Xu's (2010) infant looking time study, we adapted Goodman's thought experiment, in which bags of marbles can be either uniform or mixed in color, to create a choice paradigm suitable for older children and capuchin monkeys. We presented sampled evidence from three containers either supporting the overhypothesis that rewards are sorted by their *size* or by their *type*. At test, participants were presented with two new containers and one example item from each: a small, high-valued reward from A and a large, low-valued reward from B (Figure 1). Participants then chose between two covert samples from these new containers. Differential choice between conditions—namely, choosing A to obtain a high-valued option in the type condition, but choosing B to obtain a large item in the size condition—would reflect sensitivity to the overhypotheses governing object sorting.

Computational Model

Probabilistic hierarchical Bayesian models have frequently been proposed as computational models of children's rapid early learning (Kemp et al., 2007; Tenenbaum, Kemp, Griffiths, & Goodman, 2011). They demonstrate how, in principle, knowledge can be acquired at multiple levels of abstraction simultaneously, after only seeing small amounts of data. Kemp et al. (2007) show how more abstract hypotheses can constrain the hypothesis space at lower levels, leading to rapid inferences when encountering new but related situations. Due to the interdependence of concrete observations and higher-order concepts, these models do not exhibit the tension between low-level and higher-level learning often discussed in the animal literature. However, while the Kemp et al. model has successfully characterized existing findings in the developmental literature, the model's predictions have not been directly empirically tested in children or animals.

Here, we extended the Kemp et al. (2007) model with a rational choice rule, allowing us to directly compare the model's predictions for which test container (A or B) learners should choose to receive a reward from with new empirical data. We infer the relative utilities of the different reward types, based on the participants' choices in preference testing, following the inverse preference model developed by Lucas et al. (2014).

Model Overview.

Figure 1 provides an overview of both our task and of the computational model. In this model, items are sampled from evidence containers, each of which has a distribution of items with different features (i.e., item type and size). These distributions capture a first level of abstract knowledge (level 1), describing the kinds of items likely to be found in this specific container. Simultaneously, the model also represents a more abstract level of knowledge (level 2), which describes the probability distribution over containers—the extent to which containers in general tend to be mixed or uniform, and the distribution of features across containers. Using this hierarchical structure, the model captures how specific observations of samples from individual containers can be used to simultaneously infer parameters at multiple levels of abstraction.

Learning Overhypotheses.

As in Kemp et al., (2007) we use a Dirichlet-multinomial model (Gelman, Carlin, Stern & Rubin, 2003). The individual sees evidence items $\boldsymbol{y^i}$ with d feature dimensions (in our case d = 2: the item's type and size), sampled from each evidence container i. We assume that items are drawn randomly and independently from each container and that the item's type is determined independently of its size. The item types (sizes) are sampled from $\boldsymbol{y_d^i} \sim$ Multinomial ($\boldsymbol{\theta_d^i}$), the distribution over item types (sizes) in that container. Each container's distribution over item types (sizes), $\boldsymbol{\theta_d^i}$, is in turn sampled from a Dirichlet distribution, parameterized by a scalar α_d and a vector $\boldsymbol{\beta_d}$, $\boldsymbol{\theta_d^i} \sim$ Dirichlet(α_d, $\boldsymbol{\beta_d}$). These hyperparameters characterize the overhypothesis across containers. α_d parameterizes the extent to which items in each container are uniform in type (size). $\boldsymbol{\beta_d}$ represents the type (size) distribution across the entire set of containers. α_d is in turn sampled from an exponential distribution, $\alpha_d \sim$ Exponential(1), and $\boldsymbol{\beta_d}$ from a symmetric Dirichlet distribution, $\boldsymbol{\beta_d} \sim$ Dirichlet(1).

To model overhypothesis formation, we infer $p(\alpha_d, \boldsymbol{\beta}_d | \boldsymbol{Y_d})$ (referred to as $p(\alpha, \boldsymbol{\beta} | \boldsymbol{Y})$ for simplicity below), the posterior distribution over (α, $\boldsymbol{\beta}$), given the observed items $\boldsymbol{y^i}$, drawn from the N evidence containers,

$$p(\alpha, \boldsymbol{\beta} | \boldsymbol{Y}) \propto \int \prod_{i=1}^{N} p(\boldsymbol{y^i} | \boldsymbol{\theta^i}) \boldsymbol{p}(\boldsymbol{\theta^i} | \alpha, \boldsymbol{\beta}) p(\alpha) p(\boldsymbol{\beta}) \, d\theta \qquad (1)$$

estimated using the Metropolis-Hastings algorithm. Here we used 5 chains with 2000 samples and a burn in of 1000.

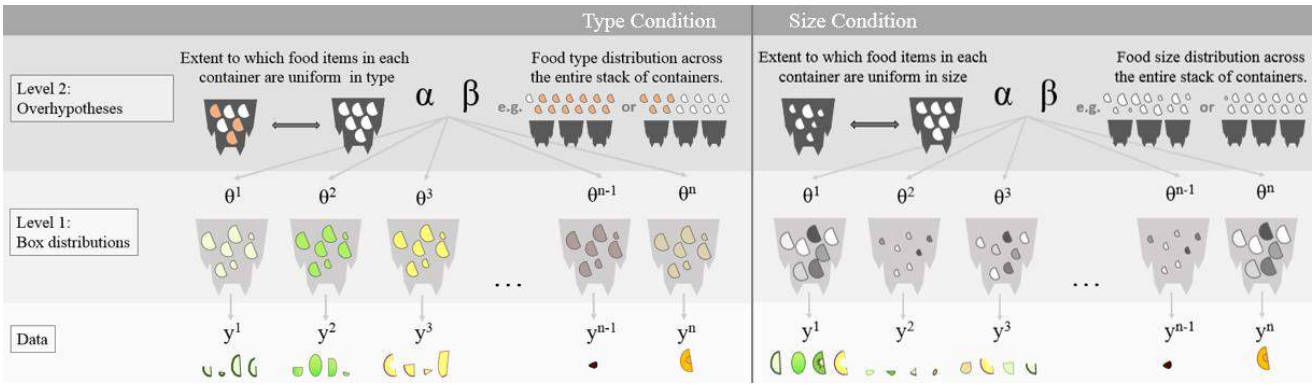

Figure 1: Hierarchical Bayesian model of overhypothesis formation. The parameters α and **β** describe an overhypothesis at the second level of abstraction: α represents the extent to which containers in general tend to be uniform for a given feature dimension, and **β** captures the feature variability across all containers. Feature distributions of a specific container ($\boldsymbol{\theta}^{\mathbf{i}}$, Level 1 abstraction), are constrained by overhypotheses at Level 2, and in turn constrain the items $\boldsymbol{y}^{\boldsymbol{i}}$ sampled from that container.

Predicting the content of the test buckets

We would like to predict the type (size) of the j^{th} (unseen) sample from the new test container *i+1*, given already known samples from this test container, -j (everything not j), and the overhypotheses inferred from the evidence containers. For a Dirichlet-Multinomial distribution, $p(y_j^{i+1} | \boldsymbol{y}_{-\boldsymbol{j}}^{\boldsymbol{i+1}}, \alpha, \boldsymbol{\beta})$, the posterior predictive distribution for the type (size) of the next item in the container, given the previously seen items and the hyperparameters $\alpha, \boldsymbol{\beta}$, has a simple closed form solution. Marginalizing over $p(\alpha, \boldsymbol{\beta}|\boldsymbol{Y})$, the posterior distribution over possible values of α and **β**, estimated from the evidence containers give us,

$$p(y_j^{i+1} | \boldsymbol{y}_{-\boldsymbol{j}}^{\boldsymbol{i+1}}) = \iint p(y_j^{i+1} | \boldsymbol{y}_{-\boldsymbol{j}}^{\boldsymbol{i+1}}, \alpha, \boldsymbol{\beta}) p(\alpha, \boldsymbol{\beta}|\boldsymbol{Y})\, d\alpha, d\boldsymbol{\beta} \qquad (2)$$

Approximated by averaging $p(y_j^{i+1} | \boldsymbol{y}_{-\boldsymbol{j}}^{\boldsymbol{i+1}}, \alpha, \boldsymbol{\beta})$ across sampled values of $p(\alpha, \boldsymbol{\beta}|\boldsymbol{Y})$.

Predicting choice of test item

Given the distribution over possible next items from each test container, we would like to predict the learner's choices. We assume that learners are choosing which box to take the next item from based on the expected utility of the next item from each container. As in Lucas et al. (2014), we assume that the utility of an item *x* is just the product of the utility of its individual features. For simplicity we assume that utility scales linearly with item size, s_x, so that the utility of item *x*, is $u_x = s_x \cdot \delta_{t_x}$, where δ_{t_x} is the learner's utility for one unit of item type t_x. The utility of a container is calculated by summing the utilities of each possible item, weighted by its probability of being the next item. As in previous work, we assume that learners become exponentially more likely to choose a container *i* as its expected utility increases.

$$P(c = i|u) = \frac{e^{u_i}}{\sum_j e^{u_j}} \qquad (3)$$

Inferring reward utilities.

To compute the relative utilities of the different reward items, prior to the main experiment, we conducted a series of preference tests, where participants chose which of two reward items they wanted. For simplicity, we only included the categorical item types high, medium and low-value. Comparisons included choices between different item types of fixed size, between different sizes of the same type, as well as mixed comparisons between large items of low value and small items of high value.

Following the preference inference model described in Lucas et al. (2014), we assume that learners choose items based on their relative utilities as in equation 3. We infer item type utilities **u** from learner's choices **c,** separately for each species, by computing the posterior probability $p(u|c) \propto p(c|u)p(\boldsymbol{u})$, estimated using the Metropolis-Hastings algorithm. Following Lucas et al. (2014), we assume that the type preferences **δ** are normally distributed, with $\mu = 0$, and variance $\sigma^2 = 2$ (however the inferred preferences are robust to different values of σ^2). Here we used one chain with 10000 samples and a burn in of 500.

Model Predictions.

Using this approach, we inferred strong preferences for high vs low value items for both species (children: Δ0.62; monkeys: Δ1.19). We used each species item utilities, separately inferred from their preference task data, to make *a priori* choice predictions for our experiment. Model predictions based on Level 2 abstraction (abstraction across containers) make clear contrasting choice predictions between the size and type conditions for both species after only one trial (one set of 3 evidences containers; Figure 2a). Predictions across subsequent trials, after seeing up to 6 sets of evidence containers get asymptotically more extreme (Figure 2b). In contrast, for a lesioned model capable of only Level 1 abstraction, and thus not learning from the evidence containers, the test container with the small, high value item is the preferred choice independent of condition.

Experiment 1: Abstraction across containers

Methods

Participants. Participants were 80 4- to 5- year-old children (M age = 4.9 yrs, 50% female), recruited at two local museums in Toronto, Canada. Eight additional children were excluded from analysis because they ended the game early (n = 5) or due to experimenter error (n=3). Seventeen brown capuchin monkeys (*Sapajus spp.*, M age = 6.5 yrs, 29% female) completed a preparatory food preference testing. Due to motivation decline only 11 monkeys finished the main study and are included in the data analysis.

Materials & Procedure. For the monkeys, nine different types of food items (divided into 3 categories: high, medium and low value) and 5 item sizes were used. Rewards for children were stickers picturing either animals (high value) or simple shapes (low value). Size was manipulated by the number of stickers on a strip, varying from 1 to 5. To encourage consistent sticker preferences across children, they were given the task of filling in a zoo map with as many animals as possible, making animal stickers more valuable than shape stickers. Prior to the main experiment, both species received preference testing, details of this procedure are given below. All sessions were video recorded.

Main Experiment. For both species the procedure in each trial was very similar. The experimenter successively sampled four example items from each of 3 evidence containers into transparent cups (monkeys), or onto metal frames (children), starting always on the left side. Depending on the condition, the items from one container were either all of the same type but of varying sizes (type condition) or all identical in size but different in type (size condition, see Figure 1). During the sampling, the experimenter closed her eyes and kept her head upright to create the illusion of random sampling.

Subsequently, two new test containers were brought forward, with the other containers and their evidence still in view of the participants off to the side. The experimenter first simultaneously sampled one evidence item from each test container. This was always a small, high-valued reward from container A and a large, low-valued reward from container B (item types counterbalanced). The experimenter then sampled another item from each container simultaneously, this time keeping the reward items hidden in her closed hands. The closed hands were extended towards the participants so that they could indicate their choice by reaching towards one of the hands. Participants were rewarded with the chosen item. Reward items were chosen to be in line with the condition overhypothesis (i.e., of the expected type or size), at least of medium value in the size condition, and otherwise randomly sampled.

For monkeys, the experimenter crossed her hands in half of the trials (a procedure they are familiar with) to ensure they tracked the hidden sample in the experimenter's hand and were not just pointing towards the sampled items. For children, hands were never crossed. In comparison to the monkeys, children's pointing was not restricted by a choice panel and thus they were able to clearly indicate a specific hand rather than only a side (unlike the monkeys children also had no prior experience with this procedure and showed confusion about the hands crossing in a pilot study).

Due to the small available sample, monkeys experienced both conditions, size and type, in a within-subject ABAB design, with the first condition counterbalanced across monkeys. Here, two different kinds of containers, bags and boxes (counterbalanced), were used, so that any overhypothesis could be tied to a specific kind of container. Monkeys received 16 sessions with 3 trials each, with 4 sessions per block. Children were tested in a between-subject design to allow us to test them in a single session in a science museum. and thus only presented with one container type (boxes). They received one session of 6 trials. Importantly, as for the monkeys, they did not receive any explicit instruction concerning the abstract rules governing the reward distribution.

Reward Preference Testing. Prior to the main experiment, we conducted preference testing to ensure that participants preferred bigger over smaller (size comparisons) and high over low-value rewards (type comparisons). Further small, high-value items were compared to large, low-value items (mixed comparisons). Monkeys received 9 kinds of size comparisons, one for each food type. There were also 6 kinds of type and mixed comparisons respectively, as each of the three high-value items was compared to two low-value items. Finally, the least liked high-value item was compared to all 3 medium valued items to ensure a clear preference. Monkeys received 10 trials for each of the 24 comparisons, presented over 24 sessions. Food items were presented in a covered forced choice procedure, where the monkeys first saw the food on the experimenter's palms and then had to choose between her closed fists.

Children first received a warm-up of 3 trials in which they were familiarized with the closed-hands choice procedure. Due to the constraints of museum testing, children were presented with a reduced preference procedure of two preference trials each for the type and size comparisons. A subset of n=58 children also received two mixed trials. Following preference testing, for the main experiment, novel stickers were used, and children were asked to find a lot of animals for a new, blank zoo map.

Results

Reward Preference Testing. In the type comparisons, both species significantly preferred high-value items over equally sized low-value alternatives (Capuchins: M = 0.86, SD = 0.12, $t(16)=11.78$, $p<0.001$; Children: (M = 0.94, SD = 0.18, $t(79) = 22.33$, $p < 0.001$). Capuchins further preferred the least liked high value item over equally sized pieces of medium-valued foods (M = 0.89, SD = 0.06, $t(16)=25.07$, $p<0.001$). Both groups also significantly preferred large over small items (Capuchins: M = 0.83, SD = 0.06, $t(16)=23.96$, $p<0.001$; Children: M = 0.83, SD = 0.32, $t(79) = 9.11$, $p < 0.001$). In the mixed comparisons

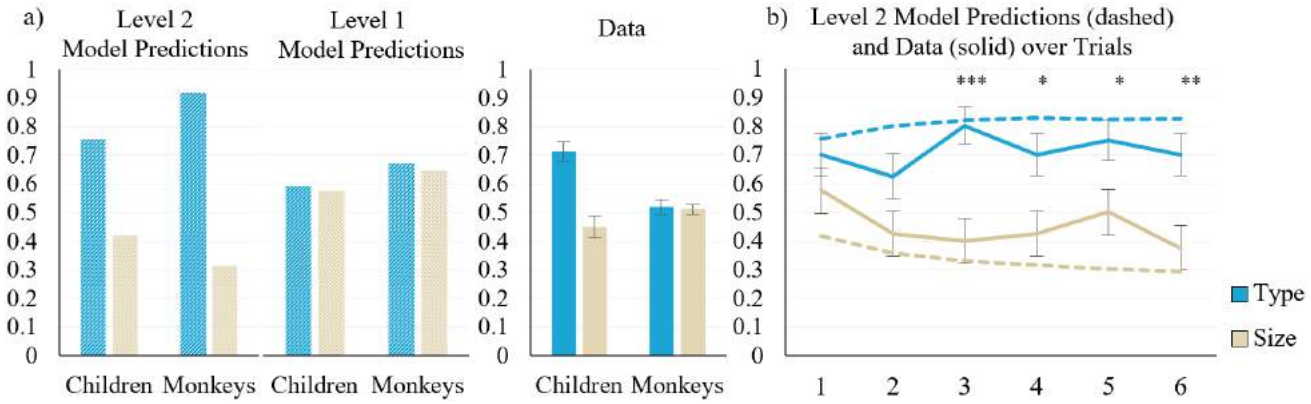

Figure 2: a) Model Predictions for a learner capable of Level 2 or Level 1 abstraction and empirical results (mean across trials ± SE) for the choice for the sample from the box with the small, high-valued example item for capuchin monkeys and children. Model predictions are shown for one trial with 3 evidence boxes. b) Children's level 2 model predictions and data (M ± SE) over the course of six trials. Significant differences between the size and the type condition are indicated.

both groups expressed a significant preference for the small, high-valued items over the big, low-value option (Capuchins: M=0.96, SD = 0.04, t(16) = 48.52, p <0.001; Children: (M = 0.92, SD = 0.21, t(57) = 15.68, p < 0.001). Further, no difference in performance was found between the choice presentation with crossed and straight hands.

Main Experiment. Monkeys were equally likely to choose the sample from the container with the small high-value example in both conditions (paired t(10)= 0.27, p = 0.79), and chose at chance level (12/24 trials) between the two hidden samples (type: M = 12.45, SD = 1.37, t(10) = 1.10, p = 0.30; size: M = 12.27, SD = 1.95, t(10) = 0.46, p = 0.65).

Unlike the preference testing, multiple monkeys expressed a bias regarding the side of their chosen reward sample or the side of the container (7/11 monkeys chose either a consistent hand-side or a consistent container-side in more than 80% of trials). They did not reach more frequently to the side of the small, high-valued sample (M = 0.52). There was no improvement from the first block to the second in either condition (type: M_{first} = 0.52, M_{second} = 0.52; size: M_{first} = 0.51, M_{second} = 0.51).

Children chose the sample from the container with the small, high-value example item more often in the type condition than the size condition, t(77.50) = -5.18, p < 0.001. When compared to chance (3/6 trials), only the choices in the type condition were significantly different (type: M = 4.28, SD = 1.41, t(39) = 5.70, p < 0.001; size: M = 2.7, SD = 1.30, t(39) = -1.45, p = 0.15).

The Level 2 models for both species predict a clear distinction between both conditions in the tendency to choose the item from the container with the small, high-value example item (Figure 2). Choice predictions are stronger for monkeys as the inferred utilities for low and high-value items based on their reward preferences are more extreme. When compared to the empirical data, the monkey's chance level performance is in stark contrast to the predictions of a model that learns overhypotheses, using item utilities inferred from the monkey's food preferences. For children the level 2 overhypothesis model predictions qualitatively fit the data well and the trajectory across trials shows a similar trend for both data and model predictions.

Discussion

As predicted by the model fit separately to their preference data, children made different choices in the size and type conditions despite the evidence from the test containers being the same in both cases, suggesting that they formed overhypotheses. However, their performance only differed significantly from chance in the type condition, which could suggest that they are only capable of forming abstract rules about certain reward properties. Alternatively, children might have a strong prior towards sorting by type, which is possibly more common in children's experience, or the two features might have had an unequal salience based on pre-existing preferences or the task description (see also Kemp et al., 2007 for discussion of the 'shape bias' in word learning). However, children did show a preference for larger items when presented with a simple choice in the preference test, suggesting they attended to this dimension. Interestingly, the overhypothesis model fit to children's preferences also predicted a smaller distinction from chance in the size condition, suggesting that this result may nonetheless be consistent with the overhypotheses. Future work could try to increase sample size or change utilities to differentiate lack of attention to the size dimension from a smaller predicted difference in utility between containers.

The monkeys' performance suggests that they were not able to form overhypotheses about the food distribution pattern across containers. Their failure on the second level of abstraction could be due to a failure to form abstractions about containers in general (Level 2 overhypotheses), or based on the inability to infer the content distributions of each evidence container (Level 1 overhypotheses) based on the sampled evidence. However, as with any negative result from a complex task, there could be other limiting factors, specifically the sampling procedure required sustained attention and inhibition skills which could be an impeding factor for the performance of monkeys (Tecwyn, Denison,

Messer, & Buchsbaum, 2017), a point we will return to in the general discussion.

Experiment 2: Abstraction within a container

To test the hypothesis that monkeys did not form Level 1 generalizations about the contents of the containers in experiment 1 (precluding generalization over containers – Level 2), we conducted a second experiment, with reduced task demands. Here, we presented subjects with only two containers from which we sampled four evidence items each. Now, the choice items were sampled directly from these containers, so that no generalization to new containers (Level 2) was required. However, participants would still have to form Level 1 generalizations to choose successfully.

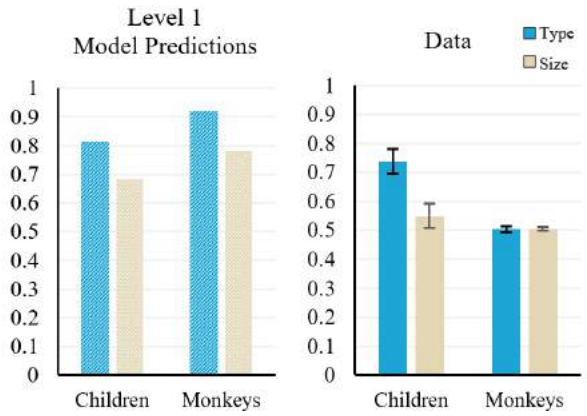

Figure 3: Model predictions (left) and empirical data (right, M ± SE) for the correct choices of children and monkeys in the type (high-value item) and size (large item) condition.

Methods

Participants. Participants were 47 4- to 5- year-old children recruited at two local museums in Toronto (M age = 5.0 yrs, 50% female, n= 24 in type condition, n= 23 size condition). Two additional children were excluded because they ended the game early or due to experimenter error. The total sample of capuchin monkeys (*Sapajus spp.*) consisted of 13 individuals. Ten had previously completed Experiment 1. Out of the 13 subjects, 11 participated in both conditions whereas two participated only in one of the conditions.

Design and Procedure. All sessions were video recorded. The procedure was similar to Experiment 1. This time only two containers were presented on the table and four items were sampled from each successively. Subsequently, the experimenter extracted the two choice items directly from these containers, kept them hidden in her hand and requested the participant to choose. In the size condition, the same four types of rewards, two low- and two high-value, were drawn from both containers in a randomized order whereby one container only yielded small (size 1) and the other one only big (size 5) items. The reward was identical to one of the four types previously drawn from the container. In the type condition, items of the same type in the sizes 1, 2, 4 and 5 were drawn from the container. Thereby one container offered only low-valued and the other only high-valued items. The reward was a randomly sized piece of the expected type for this container. Monkeys received 3 sessions of 8 trials each per condition with order of condition counterbalanced. Children received one session of 6 trials in a between-subject design beginning with a preference testing of two size and two type comparisons.

Results and Discussion

Children performed significantly above chance (3/6 trials) in the type condition ($M = 4.42$, $SD = 1.28$, $t(23) = 5.41$, $p < 0.001$) but not in the size condition ($M= 3.30$, $SD = 1.22$, $t(23) = 1.19$, $p = 0.25$). Monkeys performed at chance level (12/24 trials) in both conditions (type: $M = 12.09$, $SD = 0.94$, $t(10) = 0.32$, $p = 0.76$; size: $M = 12.09$, $SD = 0.54$, $t(10) = 0.56$, $p = 0.59$). The choice predictions of models based on the inferred feature distribution in each container (Level 1 abstraction) showed a clear tendency to choose the next item from the container with high-value items in the type condition and from the container with large items in the size condition. The strong type preferences of both species, lead to a greater predicted container preference in the type condition. Whereas the monkeys performed at chance level in both conditions, children's performance resembled the model prediction in both conditions, showing strong performance in the type condition whereas choices in the size condition were at chance. This suggests that children are able to form abstractions at both levels whereas capuchin monkeys in our study were unable to engage in any level of abstraction, though we emphasize that the reasons for this failure remain ambiguous (lack of ability or task demands).

General Discussion

We presented two studies testing abstraction, and the predictions of the Kemp et al. (2007) overhypothesis model, using a choice paradigm in children and capuchin monkeys. Across both experiments, none of the capuchin monkeys showed the pattern predicted for a learner capable of forming overhypotheses along the item size or type dimensions. In contrast, children treated the same evidence differently when they had previously experienced that items were sorted by size or type. Their performance was well characterized by a hierarchical Bayesian model, fit to their actual reward preferences. They showed a significant difference between conditions after just a few trials.

The model predictions based on capuchin's preferences support that the presented evidence was sufficient for the formation of overhypotheses, but the monkeys did not show this ability in this paradigm. The monkeys' results are in line with low success rates achieved after long training regimes in previous studies on abstract concept formation and analogical reasoning in capuchins (Flemming, 2011; Kennedy & Fragaszy, 2008; Truppa et al., 2011). We can also rule out some other possible explanations for their failure. Monkeys did not show a preference for the side exhibiting the small, high-value item (showing some

understanding of the procedure: they were not simply trying to acquire the samples). No individual monkey showed a difference between conditions, and the sample was sufficient to detect significant food preferences, suggesting that this was also not a sample size limitation.

Still, it remains possible that other tasks demands masked monkeys' abstract reasoning abilities. Monkeys and apes can infer a hidden item sampled from a clear population (Tecwyn et al., 2017; Eckert, Rakoczy, & Call, 2017; Rakoczy et al., 2014). However, apes' ability to make inferences about hidden populations based on visible samples (as in this study) was recently shown to be more limited (Eckert, Rakoczy, & Call, 2017). Future work will explore abstract reasoning with reduced task demands, e.g. by allowing the subjects to sample items themselves. Nevertheless, the approach taken here, in which subjects do not need to be trained to make arbitrary judgements about abstract relations but simply need to secure the best rewards, is a promising avenue for future research.

The findings from 4-5 year-olds are in line with infants' performance in causal learning and looking time procedures but stand in contrast to children's limited spontaneous use of abstract concepts in RMTS tasks (Hochmann et al., 2017), perhaps due to a reduced need for training. This approach could be extended to toddlers to bridge the gap across ontogeny.

In summary, we conducted the first direct test of the hierarchical Bayesian approach described by Kemp et al. (2007) in children and animals, and extended it to make choice predictions based on item utilities. We have shown that it is a promising model for how children are able to form generalizations from sparse evidence. We suggest that further application of computational models to empirical data of overhypothesis formation is desirable to understand its development over early childhood, and to further understanding possible species differences.

Individual differences in fluency with idea generation predict children's beliefs in their own free will

Abstract

The ability to imagine alternative possibilities plays a crucial role in everyday cognitive functioning beginning in early childhood. Across two studies, we ask whether individual differences in young children's (Mean Age = 5.01; SD = 0.78 Range = 2) fluency in generating alternative possibilities relates to a particular type of social-cognitive counterfactual judgment, namely children's belief in the possibility to "act otherwise" when actions go against stated strong desires (i.e. "free will"). We found that the fluency of generating ideas was a consistent individual difference that held regardless of domain. We also found that individual children's fluency predicted judgments of free will for themselves (Study 2) but not for others (Study 1). Our findings raise new questions about how counterfactual thinking enables children to overcome psychological barriers to self-control, and how stimulating the imagination facilitates developing cognitions that rely on it.

Keywords: counterfactual thinking, free will, social cognition, modal cognition

Introduction

The ability to imagine alternative possibilities is ubiquitous in human cognition. Broadly, it is invoked in all types of modal thinking: how we imagine counterfactually what could have been in the past, hypothetically what might be in the future, and normatively what should or ought to be (Lewis, 1973; Balke & Pearl, 1994; Woodward & Hitchcock, 2003). Imagining possibilities is a critical cognitive skill underlying our memory for past events (Schacter et al., 2015), ability to plan for the future (Baumeister, Vohs, & Oettingen, 2016), our moral judgments (Phillips & Cushman, 2017; Phillips, Luguri, & Knobe, 2015), and our causal cognition (Engle & Walker, 2018). Moreover, this type of thinking is governed by a common cognitive and neural architecture (De Brigard et al., 2013). Recently, researchers have claimed that it plays a role in a host of psychological processes that develop in early childhood, including future thinking (Atance & Meltzoff, 2005), causal inference (Walker & Gopnik, 2013; Engle & Walker, 2018), imaginary play (Taylor et al, 2018; Weisberg & Sobel, 2012), self-regulation (White et al., 2017), and social and moral judgment (Kushnir, 2018).

Separate from this, there has been a long research tradition focused on ability to imagine alternative possibilities as a stable individual difference, relating it to differences in creativity and intelligence. Most of this work utilizes a classic method developed by Guilford (1967) in which people are asked to generate many unique alternative possible uses for a common object (e.g. a tissue). Conservatively, these tasks capture individual differences in verbal fluency, performance on these "idea generation" paradigms also relates to individual differences in creativity and intelligence (Wallach & Kogan, 1965; Nusbaum & Silva, 2011). There is recent evidence that modified versions of tasks such as Gilford's capture stable individual differences in children as well, even when controlling for age and verbal IQ (Taylor et al., 2018).

To date, however, no studies have linked individual differences in "idea generation", either in adults or children, to the types of cognitions that have been hypothesized to rely on modal thinking. Here we explore one such link: we examine whether individual differences in the ability to generate alternative ideas relate to a particular social-cognitive skill that relies on counterfactual thinking – children's judgment of their own and others' freedom of choice.

Counterfactual thinking has been argued to be the basis of folk intuitions of freedom of choice (i.e. "free will", Alquist et al., 2015; Nichols, 2011). Studies show that when adults make free will judgments, they consider whether or not there were alternative choices available (Feldman, Baumeister, & Wong, 2014). Children's early developing intuitions about free will are also based on the ability to represent alternative possibilities. For example, infants are more impatient with an agent when the agent is unwilling to act (they understand that a possible alternative is available) than when the agent is unable to act (they understand that no possible alternative is available, Behne et al., 2005). Preschoolers can answer explicit questions about whether an agent can and can't do otherwise when actions are possible, impossible, or limited by social and moral considerations (Nichols, 2004; Schult & Wellman, 1977; Shtulman & Phillips, 2008). As part of this ability, children generate explanations about what alternative actions are available if an agent chooses to "do otherwise."

Children's beliefs about free will also undergo important developmental changes, changes that may be linked to their counterfactual thinking. For example, 6-year-olds are more likely to endorse the free will to act against desires than 4-year-olds (Kushnir et al., 2015). Furthermore, older children

are more likely than younger children to endorse the freedom to act against moral and social norms (Chernyak et al., 2013; Chernyak, Kushnir, & Wellman, 2010). Moreover, younger children have difficulty distinguishing improbable from impermissible events more generally (Lane et al., 2016; Shtulman & Carey, 2007; Shtulman & Phillips, 2008). Together these studies suggest that a domain-general cognitive mechanism is responsible for the developmental shift.

One intriguing possibility is that the ability to *fluently generate ideas* about possible alternative actions underlies children's judgments of free will. That is, in order to make judgments of free will (or possibility more generally) children are attempting to imagine any situations in which an action could be different, and, if they can think of one or more such situations readily and easily, they answer in the affirmative. For example, a child may be able to easily imagine how yummy crackers could be inedible for all sorts of reasons, thus they answer that one can choose not to eat them. Anecdotally, this hypothesis has some support from the post-hoc justifications that children come up with following the initial yes/no judgment. The large majority of their justifications are imagined alternative scenarios (i.e. "because some crackers aren't good for you" Kushnir et al, 2015). Under this model, individual differences in free will judgments should relate to individual differences with a facility for idea generation.

To test this, we conducted two studies using the third person (Study 1) and first-person (Study 2) versions of the free will questions from Kushnir et al. (2015). Overall, we hypothesized that children's free will judgments would replicate prior work, such that there would be some variability in children's free will beliefs, and also age-related changes. Like prior work, we expect lower free will beliefs (and more variability) for first-person question (Study 2) than for third-person (Study 1).

We also measured children's ability to generate alternative possibilities using a battery of idea generation tasks. Our tasks had a structure modeled after standard creativity task (e.g. "uncommon uses task" Milgram & Milgram, 1976; Wallach & Kogan, 1965) with some notable differences. First, we scored children on idea fluency only. That is, we did not compare each idea to the sample-wide list of ideas to score its originality. Fluency was captured by coding for number of unique ideas listed a child gives for a particular question.

Second, we asked children to list as many alternative possibilities they could think of in each of three different domains – Physical, Fantastical, and Social/Psychological. The Physical question was adapted from Guilford (1967) and asked about alternative uses for a tissue. The Fantastical questions were adapted from Taylor et al. (2018) asking children to imagine what the world would be like if certain laws of our world were changed (ability to walk on walls, people have tails). We added to these our own set of Social/Psychological questions which asked children to come up with ways to help a sad friend feel better (social) or make themselves feel better when they are sad (psychological).

Including a range of idea generation tasks across these domains allowed us to explore the generality of the relationships: we were able to check whether children who generate a lot of ideas in one domain also do so in others. Moreover, Since children's free will beliefs are part of their developing social-cognition, our addition of questions which explore children's social and psychological idea generation allowed us to check whether social/psychological ideas are specifically related to free will beliefs over and above other types of ideas.

Study 1

Method

Participants A total of 43 4–6-year-olds (M_{age} = 5.07, SD_{age} = 0.80, N_{female} = 23) were recruited at a science museum in a small city in the northeastern United States.

Procedure Children were interviewed individually in a quiet room at a museum. The procedure began with the free will questions, adapted from Kushnir et al. (2015). Two Action questions (one about food and one about activity) asked children to judge whether an agent could "choose to" act against or whether they "have to" act in accordance with the stated desire (e.g. "Even though she does not like the cracker, can she just *choose to* eat the cracker or does she *have to not* eat the cracker?"). Two Inhibition questions (one about food and one about activity) asked children to judge whether an agent could choose to *not* act (i.e. inhibit action) or whether they have to act on a stated strong desire (e.g. "Even though she wants to know about the box, can she just *choose not to* look into the box or does she *have to* look into the box"). Note that the free will questions offer children a forced choice between a stated action (e.g. eating a yummy cookie) and a general possibility of acting otherwise without explicitly stating any alternative actions. Question order was counterbalanced. Order of the options within the question ("choose to" vs "have to") was counterbalanced. There were also two Control questions, Simple free action (e.g. "Can she step off a chair?") and Physically Impossible action (e.g. "Can she run through a wall?"). The majority of children (86%) answered these control questions correctly, ensuring children understood and could follow the form of the target questions about acting against desires.

After the free will questions, children completed the idea generation task battery. This began with a warm-up question about uncommon uses for a pen ("Besides [drawing/writing] can you think of some things to do with [pen]?") that was used to familiarize children with the question format and idea probes ("what else?"). Following the warm-up, the idea generation task battery consisted of three question types in a latin-square counterbalanced order:

Physical (one, Gilford 1967): Children were asked for the common use of, and then ideas for uncommon uses of, a tissue ("Can you think of some things you can do with it besides [common use]?").

Fantastical (two, Taylor et al, 2018): Children were asked to "imagine what if we all woke up tomorrow and every person [had a tail/could walk on walls]. What would the world be like if we all [had tails/could walk on walls]?"

Social/Psychological (one third-person, one first-person). Children were asked to think of ways to make a friend /themselves happy when the friend/they themselves are sad. (e.g. "Imagine that one day [your friend/you] [was/are] very sad and didn't want to play at all. What things could you do to make [your friend/yourself] feel better and want to play again?).

For each question, children were encouraged using the probe "what else?" to keep generating ideas until they chose to stop (e.g. saying they had no more ideas). Children also participated in a storytelling task at the end of the procedure, but those results are not reported here.

Coding For the free will task, children received a score of 0-2 for each story type, Action and Inhibition (2 meaning they said "choose to" for both food and activity questions). Two coders independently scored each response. A Cohen's k indicated agreement between the two coders for each question (κs > .83, *ps* < .0005). Discrepancies were resolved through discussion.

For the idea generation tasks, the number of unique responses were recorded for each question. Uniqueness was defined as any difference from previous responses (e.g. "we could wag our tails" versus "we could bounce on our tails"). Two coders were trained on the coding scheme. A Cohen's k indicated agreement between the two coders for each question (κs > .867, *ps* < .0005). Discrepancies were resolved through discussion.

Results

Free Will A repeated measures ANCOVA with Question Type (Action vs Inhibition) as a within-groups factor and age as a covariate found a marginal main effect of Question Type ($F(1) = 3.17$, $p = .083$) and a marginal age effect ($F(1) = 3.097$, $p = .086$) and no interaction. Replicating past work, children's free will scores were higher for Action ($M = 1.45$, $SD = 0.78$) than in Inhibition ($M = 1.13$, $SD = 0.82$; $t(39) = 2.177$, $p = .036$). In addition, scores were significantly above chance for Action ($t(39) = 3.636$, $p = .001$) but not Inhibition ($t(41) = .927$, $p = .359$). We found a significant positive correlation between age and Inhibition score ($r = .376$, $p = .014$), but not age and Action score ($r = .088$, $p = .590$).

Idea Generation Table 1 shows the descriptive statistics for each idea generation task as well as the correlations between them. The results point to group-level and individual consistency across domains. On the group level, a repeated measures ANCOVA with Question Type (Physical vs Fantastical_Tails vs Fantastical_Walls vs Social vs Psychological vs Total) and age as a covariate found no effect of Question Type ($F(1) = 2.58$, $p = .117$), no effect of age ($F(1)=.013$, $p = .911$), and no interaction. Also, the number of unique ideas generated was positively correlated across domains (*ps* < .05); children who generated more in one domain tending to generate more in another.

Relationship between Free will beliefs and Fluency Children received a score of 0-4 for total free will judgments (combined Action and Inhibition scores). Total free will score did not significantly correlate with any of the idea generation scores separately or total idea generation score (see Table 1).

Table 1: Relationships between idea generation questions across domains in Study 1. Relationship between idea generation and third-person free will judgments included in final row.

	Physical	Fantastical Tails	Fantastical Walls	Soc/Psych third-person	Soc/psych first-person	Total number of ideas generated
Physical ($M = 4.73$, $SD = 4.62$)	-	.500**	.571***	.728***	.382*	
Fantastical Tails ($M = 4.70$, $SD = 5.06$)	-	-	.367*	.365*	.645***	
Fantastical Walls ($M = 4.28$, $SD = 3.83$)	-	-	-	.410**	.374*	
Social/psychological third-person ($M = 4.29$, $SD = 5.44$)	-	-	-	-	.420**	
Social/psychological first-person ($M = 2.79$, $SD = 2.55$)	-	-	-	-	-	
Third-person Free Will	.075	.037	.144	-.112	-.060	.032

*p<.05; **p<.01, ***p<.001

Discussion

In this study, we examined children's third-person free will judgments, children's ability to fluently generate alternative possibilities, and the relationship between two. Patterns of children's free will judgment by age and type of question (action vs inhibition) mirrored past work. Children generated an average of 4-5 ideas per domain (with the exception of first-person social/psychological ideas). Idea generation was consistent across Physical, Fantastical, and Social/Psychological domains, both at the group level and at the individual level. Our findings of cross-domain consistency in idea generation suggest that these tasks, if properly validated (e.g. by controlling for verbal IQ, see Taylor et al, 2018), could be used to measure fluency in children.

We did not find significant relationships between idea generation scores and third-person free will judgments. One reason could be that there was not enough variability in free will judgments, which were relatively high in this study even for the youngest children.

More substantively, taking this third-person view may facilitate children's reasoning about possible actions in itself, and thus our third-person task may not be demanding enough to demonstrate the role of individual differences. Recent work has shown that, like adults, children are subject to such "psychological distance" effects when reasoning about possibility, choice, and future desires (Bowman-Smith, Shtulman & Friedman, 2018; Lee & Atance, 2016; Kushnir et al, 2015). Relatedly, taking a third-personal view on actions can facilitate higher-cognitions required for immediate (White & Carlson, 2015) and future-oriented (Atance, Louw & Clayton, 2015) self-regulation. In Study 2 we explore whether fluency has more predictive power in explaining individual differences in children's beliefs about their ability to act against and inhibit desires which they have expressed for themselves, rather than those given for another person.

Study 2

Method

Participants A total of 28 4-6-year-olds (M_{age} = 4.93, SD_{age} = 0.77, N_{female} = 19) were recruited at a science museum in a small city in the northeastern United States. Data collection is still ongoing and preliminary results are reported.

Procedure Children were interviewed individually in a quiet room at a museum. The procedure consisted of the first-person free will questions followed by the idea generation task battery in a counterbalanced order.

The free will task was similar to Study 1, but the questions first asked children to think of their own desires (e.g. "think of a [food you really like]/[something you really like to do]" and then referenced the child's response rather than the desires of someone else (e.g. "If *you* really wanted to [eat/do X], could *you* just choose to…"). Question order was counterbalanced. Order of the answer choices within the question ("choose to" vs "have to") was counterbalanced. The two Control questions had the same form as in Study 1. A majority of responses to these control questions (82%) were correct. A Cohen's k indicated agreement between the two coders for each question (κs > .82, *ps* < .0005). Disagreements were resolved through discussion.

After the free will questions, children completed the idea generation task battery, exactly as in Study 1. Coding followed the same procedure as in Study 1. Two coders were trained on the coding scheme. A Cohen's k indicated agreement between the two coders for each question (κs > .815, *ps* < .0005). Disagreements were resolved through discussion.

Results

Free Will A repeated measures ANCOVA with Question Type (Action vs Inhibition) as a within-subjects factor and age as a covariate found no effect of question type ($F(1)$ = .151, p = .701), no effect of age ($F(1)$ = .151, p = .701), and no interaction. In addition to not being different from each other or correlated with age, children's free will scores were significantly below chance for Action (M = 0.64, SD = 0.70; $t(25)$ = -2.132, p = .043) but not Inhibition (M = 0.96, SD = 0.89; $t(25)$ = -.225; p = .824). We further confirmed that rates of "choose to" responses were low by comparing to responses in Study 1. T-tests of overall "choose to" scores showed that they were significantly lower in Study 2 than in Study 1 (Study 1: M = 2.58, SD = 1.299, Study 2, M = 1.60, SD = 1.354; $t(63)$ = 2.897, p = .005).

Idea Generation Table 2 shows the descriptive statistics for each idea generation task as well as the correlations between them. As in Study 1, the results point to group-level and individual consistency across domains. On the group level, a repeated measures ANCOVA with Question Type (Physical vs Fantastical_Tails vs Fantastical_Walls vs Social vs Psychological vs Total) and age as a covariate found no effect of Question Type ($F(1)$ = .137, p = .715), no effect of age ($F(1)$ = 2.450, p = .132), and no interaction. Also, we found correlations between the tasks, not all approached significance. However, a 2 (Study: Study 1 vs Study 2, between subjects) x 6 (Question: Physical vs Fantastical_Tails vs Fantastical_Walls vs Social vs Psychological vs Total, within subjects) ANCOVA controlling for age revealed a marginal effect of Study ($F(1)$ = 3.157, p = .081), no main effect of Question ($F(1)$ = 1.778, p = .187), and no interaction.

Relationship between Free will beliefs and Fluency Children received a score of 0-4 for total free will judgments. Total free will score was significantly correlated with the number of ideas generated in the Fantastical Tails task (r = .493, p = .020). Total free will score was also significantly correlated with the number of ideas generated across all tasks (r = .428, p = .047). (see Table 2).

Discussion

In this study, we examined children's first-person free will judgments, children's fluency with generating alternative possibilities, and the relationship between the two. Children's first-person free will judgments were lower and more variable than children's third-person free will judgments, replicating past findings and supporting the idea that psychological distance facilitates children's ability to think about alternative possible actions.

As in Study 1, idea generation was consistent across Physical, Fantastical, and Social/Psychological domains at the group level and to a large extent at the individual level. Though our second sample was smaller, we again found reliable individual differences in counterfactual fluency using this measure.

Importantly, children's fluency predicted their judgments that they could possibly choose to act against their own most and least desired foods and activities. This relationship suggests that facility in generating multiple alternative possibilities might contribute to children's free will beliefs. Implications of this are discussed further below.

General Discussion

In this project, we examined whether individual differences in the ability to generate multiple alterative possibilities in an idea generation task relate to children's first-person or third-person free will judgments. We conducted two studies that measured a child's third-person or first-person free will judgments and their ability to fluently generate alternative possibilities. Overall, we found consistency in children's fluency across domains and we found that children's first-person free will judgments relate to overall fluency across domains and fluency within one of the fantasy domains.

Children's first-person free will judgments were also related specifically to one of our fantasy idea-generation tasks – imagining a world where everyone has tails. It is worth noting that we did not find comparable correlations between free will beliefs and social-psychological idea generation (e.g. ideas for making a friend happy when she is sad). This suggestive result (based as it is on a small sample) requires further study, but parallels links found in recent work by White et al. (2017) showing that pretending to be a superhero or other fantasy character has advantages for self-regulation. Together with this work, our results raise interesting questions about whether fantasy or pretense, rather than general theory-of mind abilities, might present unique advantages to children's developing ability to overcome struggles of will power and self-control.

Evidence of our hypothesized relationship between children's first-person free will judgments and their overall fluency is both correlational and preliminary, thus examining causal links is question for future research. Establishing causal links will have implications for understanding the mechanisms by which children's imaginations help them overcome psychological barriers in their self-beliefs.

One potential mechanism is a direct pathway from idea generation to judgments of choice and possibility. To explore this further would require experimentally limiting or enhancing idea generation in children and then exploring downstream effects on free will judgments. Other potential causal mechanisms are more indirect, via a third factor (or set of factors) that is responsible for both imaginative idea generation and judgments of free will. Language development is one candidate causal influence on both;

Table 2: Relationships between idea generation questions across domains in Study 2. Relationship between idea generation and first-person free will judgments included in final row.

	Physical	Fantastical Tails	Fantastical Walls	Soc/Psych third-person	Soc/psych first-person	Total number of ideas generated

$^{+}$p<.1, *p<.05; **p<.01, ***p<.001

ideational fluency is known to be correlated with verbal ability, a fact which is supported in our study by intercorrelations between ability to generate ideas across physical, fantastical, and social/psychological domains. Social-cognitive skills are also correlated with language development (e.g. Astington & Jenkins, 1999; Carlson & Moses, 20001). Additional work is needed to investigate what influence, if any, developing verbal abilities have on the link between the two.

Perhaps a more interesting possibility is that one specific aspect of language development, semantic fluency, plays an important causal role. Indeed, semantic fluency tasks which require a child to list as many examples from a category in a specified amount of time (Kave, Kigel, & Kocvha, 2008) bear a resemblance to idea generation tasks such as the UUT: both require the child to have enough knowledge to explore a space of possibilities within a specified category. But idea generation tasks also go beyond semantic fluency because they require extending and conceptually re-combining familiar ideas and concepts in novel ways (e.g. other uses for a tissue). Conceptual re-combination additionally require other cognitive facilities like cognitive flexibility and, in first-personal cases, knowledge that is episodic or autobiographical (Schacter & Addis, 2007). We therefore don't believe it is likely that semantic fluency alone explains the link between idea generation and free will judgments, but this is a question that is beyond the scope of our data to address.

Despite recent agreement that the ability to imagine alternative possibilities is an important cognitive skill, few studies have examined how individual differences in modal cognition play a role in the ordinary judgments that rely on it. Perhaps capturing these differences can help explain variability and developmental changes in judgments of possibility (Shtulman & Carey, 2007; Lane et al, 2016), episodic future thinking (Atance & Melzoff, 2005, Atance et al, 2015) and counterfactual/hypothetical reasoning (Beck, Robinson, Carroll & Apperly, 2006) and causal inference (Walker & Gopnik, 2014). The approach outlined here could also be used to explore whether cultivating an ease with imagining new ideas could help children master basic (but difficult) social, cognitive and self-regulatory tasks.

Acknowledgments

We would like to thank Aliza Adhami, Regina Longley, and Nicole Calautti for their help with data collection, coding, and analyses as research assistants. Also, we thank the families from the Ithaca community for participating in this project, and we thank the Ithaca Sciencenter for partnering with us for this study.

Children master the cardinal significance of counting after they learn to count

Abstract

Children learn the meaning of number words by going through a systematic set of stages of knowledge that culminates in their mastery of counting. Theoretical work has long suggested that children's acquisition of counting is not procedural, but semantic: all counters understand that counting computes cardinality. Yet, recent research has cast doubt on whether early counters truly understand the meaning of these words. Here we show that early counters also have an immature understanding of how one-to-one correspondence between an ordered list and a set of objects can be used to compute exact cardinality. Nonetheless, this understanding is improved when cues to quantity, such as size, are highlighted. Our results add to a growing body of work suggesting that counting is not a final stage in children's path to number, but a powerful tool that they can use to build and strengthen their intuitions about cardinalities.

Keywords: Cognitive development; number cognition; one-to-one correspondence.

Introduction

Children go through a systematic set of stages of knowledge when they learn number words and counting (Carey, 2009; Wynn, 1990; Fuson, 1988). First, children memorize the count list without knowing what these words mean (akin to learning a song like "eeny, meeny, miny, moe, …"), usually around the age of two. Children then slowly, but steadily, uncover the meaning of the words "one," "two," "three," and sometimes even "four," taking approximately six months to learn the meaning of each word. Children at these stages are called one-, two-, three-, and four-knowers, respectively, or subset-knowers collectively. After learning the meaning of the first three or four words, something clicks in children's minds. Rather than continuing to learn the meaning of number words one at a time, children suddenly, in what seems like a stroke of insight, grasp the logic of counting. Children at this stage, called *full counters*[1], can determine the size of any set (as long as they have memorized the count list up to that number). This last transition is a major milestone: the mastery of counting (Carey, 2009; Wynn, 1990; 1992; Piantadosi, Tenenbaum, & Goodman, 2012; Sarnecka & Lee, 2009; Lee & Sarnecka, 2010).

Theoretical work suggests that, in order to count correctly, children must understand five principles (Gelman & Gallistel, 1987). First, children must understand that any collection of objects can be counted (abstraction principle). To do so, objects must be placed in one-to-one correspondence with number words (one-to-one correspondence principle). The order in which the objects are counted is irrelevant (order irrelevance principle) but the order in which the number words are recited is not (stable order principle). When these steps are executed correctly, the word associated with the last object refers to the total number of objects in the set (the cardinal principle).

Research has long focused on the acquisition of the cardinal principle, as it is thought to be the key principle that marks the difference between children who can count, and children who cannot (Carey, 2009; Piantadosi, Tenenbaum, & Goodman, 2012). Yet, recent research has cast doubt on whether early counters have indeed grasped the conceptual logic of the cardinal principle. In a now classical study, Davidson, Eng, & Barner (2012) showed that children who had recently learned to count failed seemingly simple questions like determining whether "five" is more than "four." This work suggests that children's mastery of counting is a procedural milestone—learning to perform a complex set of rules in a systematic way—rather than a sematic milestone—learning that all number words refer to exact quantities and that counting computes a set's cardinality.

Nonetheless, if early counters are only missing the cardinal principle, they should understand how the rest of the principles combined can be used to determine a set's cardinality. Consider, for instance, watching an agent count two sets of objects. If the agent counts up to "six" in one set and up to "seven" in the second set, we can recognize that the second set has more objects because the set of words "one, two, …, seven" is larger than the set of words "one, two, …, six." Conceptually, this kind of inference only requires understanding that the objects were placed in one-to-one correspondence with the ordered list of number words. In practice, however, this type of inference is unavailable because it requires representing the list of words as a set of objects. However, if the objects were placed in one-to-one

[1] Full counters are classically called Cardinal Principle knowers (or CP-knowers for short; Carey, 2009; Lee & Sarnecka, 2010; Sarnecka & Lee, 2009; Piantadosi, Jara-Ettinger, & Gibson, 2014). Here we use a more neutral term that describes procedural competence without commitment to conceptual change because recent work suggests full counters may not know the cardinal principle yet (Davidson, Eng, & Barner, 2012; Jara-Ettinger, Piantadosi, Spelke, Levy, & Gibson, 2017).

correspondence with a visible set of objects, young counters may be able to perform these inferences.

Research into children's understanding of number principles suggests this may be the case. Three-year-olds understand that two small sets placed in one-to-one correspondence must be of equal size (Sophian, 1988; Gelman, 1982), and, at an earlier age, 18-month-olds preferentially look at counting events that follow one-to-one correspondence over events that do not (and this preference disappears when the agent uses novel words or beeps; Slaughter, Itakura, Kutsuki, & Siegal, 2011). At the same time, classical studies were performed with small sets that even infants can track, independent of their knowledge of number (Feigenson & Carey, 2003; Feigenson, Carey, & Hauser, 2002), and children's performance in other numerical tasks suggests that young children do not grasp the full significance of how one-to-one correspondence relates to exact number (Shipley & Shepperson, 1990; Izard, Streri, & Spelke, 2014).

Here we test if young counters can determine a set's cardinality by watching an agent apply all the counting principles using a list where the words are not names for cardinalities. We introduced participants to an ordered list of animals that someone used to count two sets of objects. Children could not see the two sets of objects, but they could see the agent placing them in one-to-one correspondence with the animal list in a stable order. If children understand the logic of these principles, they should be able to determine which of the two sets has more objects (as this only requires seeing on which set the counter reached an animal further along in the list). If, however, children are unable to identify which set has more objects, this would suggest that a robust understanding of how these counting principles help reveal exact cardinality emerges after children learn to count.

Experiment 1

In Experiment 1 participants watched an agent count two sets of hidden objects by placing them in one-to-one correspondence with an ordered list of animals (Figure 1a). Participants were then asked to determine which of the two boxes had more objects. Participants completed three trials. Two of these trials were controls to ensure that children understood that the agent was placing the animals in one-to-one correspondence with the objects. The first control trial contrasted two with three objects (such that, if children understand that the agent was placing the unobservable objects in one-to-one correspondence with the animals, they should identify the box with three objects by simply tracking the small quantities; Feigenson & Carey, 2003; Feigenson, Carey, & Hauser, 2002). The second control trial contrasted three with six objects (such that if children understand the one-to-one correspondence between objects and animals, they should identify the box with six objects by relying on their approximate number system; Xu & Spelke, 2000; Xu, 2003; Lipton & Spelke, 2003; Wood & Spelke, 2005). Finally, the critical trial contrasted six versus seven objects, which can only be solved if children understand how a proper application of counting principles reveals exact cardinality. Hypotheses, procedure, exclusion criteria, and analyses were pre-registered.

Methods

Participants. 60 full counters, as determined by the Give-N Task (Wynn, 1992; Carey, 2009, Sarnecka & Lee, 2009; Lee & Sarnecka, 2010) were recruited for this study (mean age: 4.88 years; range = 3.35-5.98). Twenty-nine additional children were recruited for the study, but not included because the experimenter determined they did not know how to count based on pre-registered criteria (n=16; see Procedure); because a coder blind to hypothesis determined that the participant did not know how to count (n=10; see Results) or because they declined to complete the study (n=3 participants; see Results).

Stimuli. The stimuli consisted of two bowls and ten bouncy balls for the Give-N task. For the animal task, the stimuli consisted of an ordered animal list, composed of eight animals ordered by size (Figure 1a), eight erasers, and three videos, each showing an agent counting objects in two opaque boxes using the ordered animal list.

Procedure.

Give-N Task. Children were presented with one bowl with ten bouncy ball and one empty bowl. The task always began with a request to move four bouncy balls from one bowl to the other. After each query, all bouncy balls were returned to the first bowl. If the child succeeded in this first trial, the next request was to move five bouncy balls. If the child failed, the next request was to move one bouncy ball. The task then followed a stair-cased procedure: children were asked to move *N+1* bouncy balls if they moved *N* bouncy balls correctly, and were asked to move *N-1* bouncy balls otherwise, with two exceptions: the same request was repeated when children failed at *N=1* and when they succeed at *N=8* (ensuring that moving all bouncy balls was never the correct answer).

Whenever children's error was off by (at most) two bouncy balls, the experimenter asked "Is that *N* bouncy balls? Can you count them for me please?" If the child recognized an error, the experimenter asked "Can you fix it so there are *N* bouncy balls in the bowl?" The experimenter recorded the original and the revised answers, and used the final answer to determine the next trial. Only participants who correctly moved four bouncy balls at least once proceeded to the one-to-one correspondence task (as determined in the pre-registration; although note that all participants who participated in the one-to-one correspondence were coded afterwards to test if they knew how to count; see Results).

Animal task. Participants were introduced to a non-numeric ordered list that consisted of eight animals ordered from left to right based on size (from smallest to largest; Figure 1a): ant, mouse, cat, pig, cow, bear, elephant, giraffe. Children were given a printed version of this list that they could consult at any time. To show how an agent would count using this list, the experimenter counted a line of four identical objects visible to the child using the list ("ant,

mouse, cat, pig"), and then counted a line of eight visible objects using the list ("ant, mouse, …, elephant, giraffe"). The experimenter counted out loud while using their finger to touch each item as they pronounced each animal name in the non-numeric ordered list and emphasized the final word. The experimenter then restated the final word of the count list (e.g., "there are giraffe objects"). After the warm-up, children completed three test trials (order counterbalanced across participants). In each trial, participants watched a video of an agent counting the objects in two boxes. The boxes were visible, but their contents were not. Immediately after counting the items in the box, the agent placed a picture of the corresponding animal on each box and then stated how many items were in the box using the non-numeric animal list. The animals were scaled by size on the printed list that children received, and on the pictures attached to the boxes (see below).

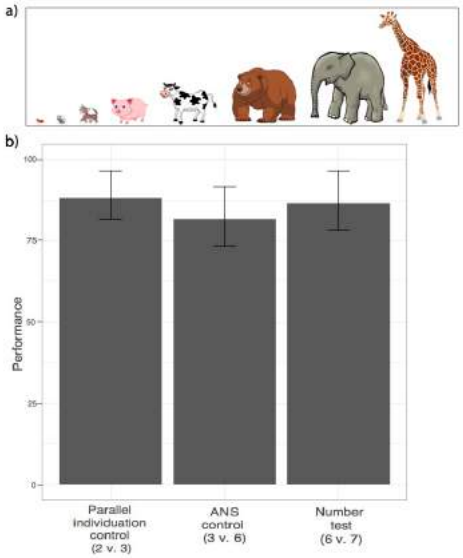

Figure 1. a) Animal list used in Experiment 1. b) Results from Experiment 1. The x axis shows the trial and the y axis shows the percentage of participants who correctly identified the box with more objects. Vertical lines show 95% bootstrapped confidence intervals. Overall, participants were able to identify which box had more objects in all three trials.

The three counterbalanced trials consisted of a 2 v. 3 trial, a 3 v. 6 trial, and a 6 v. 7 trial. In the 2 v. 3 trial the agent counted two objects in one box and then three objects in another box using the animal list (order in which boxes were counted counterbalanced). In the 3 v. 6 trial the agent counted three objects in one box and then the agent counted six objects in another box using the non-numeric ordered list (order counterbalanced). Finally, in the 6 v. 7 trial the agent counted six objects in one box and then seven objects in a second box using the non-numeric ordered list (order counterbalanced). The first two trials were control trials, as they could be solved by tracking number of words uttered via the parallel individuation system (2 v. 3 trial; Feigenson & Carey, 2003; Feigenson, Carey, & Hauser, 2002), or they could be distinguished through the approximate number system (3 v. 6 trial; Xu & Spelke, 2000; Xu, 2003; Lipton & Spelke, 2003; Wood & Spelke, 2005). The last trial (6 v. 7) was the critical one, as it can only be solved by understanding how the assignment of objects to animals reveals exact cardinality.

Trial order was counterbalanced across participants. In all videos, the agent counted out loud while using their finger to touch the inside of the box as they pronounced each animal name in the non-numeric ordered list. After each video, children were shown a picture of the two boxes, each labeled with the animal corresponding to the number of objects in the box, and they were asked which box has more blocks in it.

Results and Discussion

A coder blind to the experiment hypothesis coded whether children who participated in the one-to-one correspondence study knew how to count, based on their Give-N responses.

Participants who were not determined to be full counters by decision of a coder blind to hypothesis were excluded from the study and replaced (n = 10). An additional 3 participants were excluded and replaced because they did not want to complete the study.

Figure 1b shows the results from the experiment. Participants overwhelmingly succeeded in the 2 v. 3 and in the 3 v. 6 trials, showing that they understood the task. Of the 60 full counters included in the study, 88.3% (95% CI: 78.33-95.00; N=53 participants) correctly identified the box with more objects in the 2 versus 3 trial, and 81.7% of participants (N=49; 95% CI: 70.00-90.00) correctly identified the box with more objects in the 3 versus 6 trial.

Participants also succeeded in the critical 6 v. 7 trial. 86.6% of participants (N=52; 95% CI: 78.33-96.97) correctly identified the box with more objects in the 6 v. 7 trial. Together, these results suggest that children were able to understand that the number of recited animals revealed the quantity of objects in the set.

To test for any developmental change, we ran a mixed-effects logistic regression predicting children's response in the critical number trial (6 v. 7) as a function of age (as a continuous variable), with trial order as a random intercept. These results suggested that children's performance improved as a function of age ($\beta = 1.87$, $p < 0.01$; See Figure 2).

Children's ability to succeed in the 6 versus 7 trial of this experiment suggests that children understand how following the counting principles can reveal a set's cardinality. Critically, this understanding can happen without recognizing that the words themselves are names for different set sizes.

At the same time, it is possible that children's performance was facilitated by the use of an animal list ordered by size. Specifically, children may have simply followed a heuristic where they always pointed to the larger

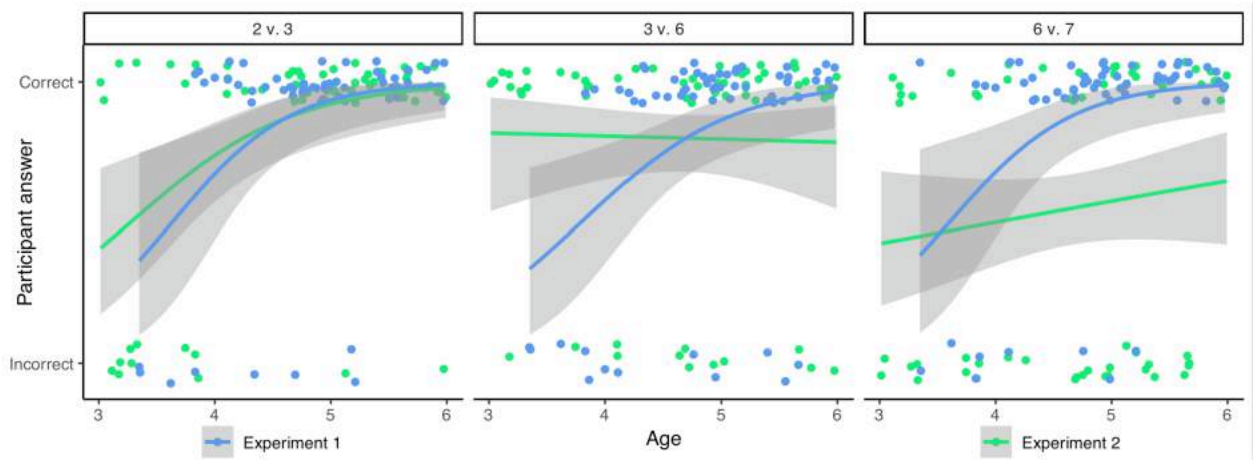

Figure 2. Participant responses in both experiments. Each dot represents a participant answer. The x-axis shows their age, and the y axis shows whether they identified the box with more objects. Data is minimally jittered on the y-axis for visibility purposes but was not jittered on the x-axis. Color indicates the experiment and the lines show logistic regressions.

animal without a deep understanding of how counting relates to cardinality. We test for this possibility in Experiment 2.

Experiment 2

Experiment 2 was conceptually identical to Experiment 1, with the difference that we used an animal list where the animals were no longer ordered on the basis of size, such that animals associated with larger quantities were not visually larger. Hypotheses, procedure, exclusion criteria, and analyses were pre-registered.

Methods

Participants. 60 full counters, as determined by the Give-N Task (Wynn, 1992; Carey, 2009, Sarnecka & Lee, 2009; Lee & Sarnecka, 2010) were recruited for this study (mean age: 4.67 years; range = 3.01-5.99). Nineteen additional children were recruited for the study, but not included because the experimenter determined they did not know how to count based on a pre-registered criterion (n=9; see Procedure); because a coder blind to hypothesis determined that the participant did not know how to count, as determined by a pre-registered coding procedure (n=8; see Results); or due to an error playing the experiment videos (n=2; see results).

Stimuli. Stimuli were identical to those in Experiment 1 with one exception. The counting list for this study consisted of eight different animals, ordered by color (Figure 3a).

Procedure. Methods for this study were identical to those from Experiment 1 with one exception. Instead of ordering the list by size, we now used a list of animals ordered by color (green, blue, purple, magenta, pink, red, orange, yellow): alligator, frog, octopus, butterfly, flamingo, lobster, fox, duck (Figure 3a). The size of the animals was matched on the printed list that children received and on the pictures attached to the boxes. Children completed the Give-N task, and the warm-up, as described in the previous experiment, using this new ordered list.

Children then completed the same three counterbalanced trials from Experiment 1: a 2 v. 3 trial, a 3 v. 6 trial, and a 6 v. 7 trial. After each video, children were shown a picture of the two boxes, each labeled with the animal corresponding to the number of objects in the box, and asked which box has more blocks in it.

Results and Discussion

Results were coded in the same way as Experiment 1. Eight participants were excluded from the study because they had not yet learned how to count. Two additional children were excluded because the experimental videos did not load properly.

Figure 3b shows the results from the experiment. Overall, participants succeeded in the two control trials, confirming that participants understood that the agent who counted was placing the objects in one-to-one correspondence with the animal list, and that the uttered animals revealed the number of objects in the set. Of the 60 full counters included in the study, 81.7% of participants (N=49; 95% CI: 71.67-91.67) correctly identified the box with more objects in the 2 v. 3 trial, and 80.0% of participants (N=48; 95% CI: 70.00-90.00) correctly identified the box with more objects in the 3 versus 6 trial. By contrast, only half of participants were now able to solve the critical 6 v. 7 trial. In this critical trial, only 55.0% of participants (N=33; 95% CI: 41.67-68.33) identified the box with seven objects.

To test for any developmental change, we ran a mixed-effects logistic regression predicting children's response in the critical number trial (6 v. 7) as a function of age (as a continuous variable), with trial order as a random intercept. These results suggested that children's performance did not improve as a function of age ($\beta = 0.3$; $p = 0.29$; See Figure 3).

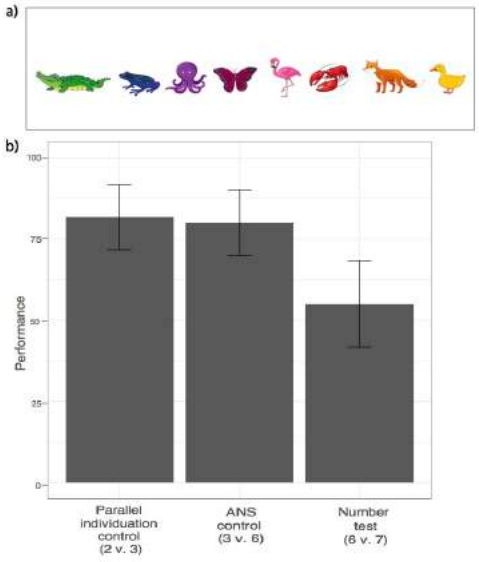

Figure 3. a) Animal list used in Experiment 2. b) Results from the experiment. The x axis shows the trial and the y axis shows the percentage of participants who correctly identified the box with more objects. Vertical lines show 95% bootstrapped confidence intervals. Overall, participants were able to identify box had more in the the 2 vs 3 and the 3 vs 6 trials. By contrast, only half of the participants succeeded in the critical 6 vs 7 trial.

These results conflict with those from Experiment 1, and they suggest that children did not recognize that the animal list could be used to determine exact cardinality. If they did, they could have solved the 6 v. 7 trial simply by consulting the list of animals and checking whether the set crocodile-lobster (six animals) was smaller or larger than the set alligator-fox (seven animals) were farther along the list. Note also that children always had a printed version of the list in front of them, and that pictures of the corresponding animals were placed in front of each box, minimizing concerns explainable by memory constraints.

These results suggest that children's success in Experiment 1 was supported by the use of animals ordered by size. Similarly, their overall failure in this experiment suggests that children understood that animals were being placed in one-to-one correspondence with the animal list, as they were able to solve the two control trials, but that they did not recognize that, through this process, children could determine the exact number of objects in the set.

General Discussion

Here we tested whether children who can count understand how the counting principles can be used to determine a set's exact cardinality, even without knowing the cardinal-principle—the understanding that the last word during counting refers to the size of the entire set. In Experiment 1 children watched an agent count the number of objects in two opaque boxes via one-to-one correspondence with a non-numerical animal list ordered by size (Figure 1a). Children were able to identify which box had more objects when the agent counted two objects in one box and three objects in the other, when the agent counted three objects in one box and six objects in the other, and when the agent counted six objects in one box and seven objects in the other (Figure 1b). Experiment 2 replicated this study using an animal list where the size of the animals was kept constant (Figure 3a). While children continued to successfully identify the larger set in the two control trials, their performance was drastically lower in the critical trial (Figure 3b).

Children's success in the two versus three trial, and in the three versus six trial in both experiments shows they understood that the number of words the agent uttered revealed the quantity of objects (Note also that children completed two warm-up trials where they saw the agent place two visible sets of objects in one-to-one correspondence with the animal list). However, success in these trials does not imply a mature understanding of how the counting procedure reveals exact cardinality. Past research has shown that children can distinguish between two and three sounds via the parallel individuation system (Feigenson & Carey, 2003; Feigenson, Carey, & Hauser, 2002) and that they can distinguish between three and six sounds via the approximate number system (Xu & Spelke, 2000; Xu, 2003; Lipton & Spelke, 2003; Wood & Spelke, 2005). By contrast, because children cannot perceptually distinguish between six and seven sounds, they could only solve this by understanding how the counting procedure reveals exact cardinality.

Critically, in our study, children did not need to understand the cardinal principle to succeed. If children recognized that the agent was placing the hidden objects in one-to-one correspondence with the animal list, they could have solved the task through at least two strategies. A first strategy is through awareness that, when counting principles are applied, later items reveal greater quantities. If children understood this, they would need to only find which animal comes later in the list to perform at ceiling. However, even if children did not recognize that later symbols in a count list reveal greater quantities, they could have solved the task through a second strategy: When the agent counted up to a certain animal, children could consult their list and see a set of animals that is numerically identical to the set of hidden objects (e.g., when the agent counted to butterfly in Experiment 1, children could see their list and recognize that the set of animals starting in crocodile and ending in butterfly is a set of the same size than the set of hidden objects that was counted). Through this strategy, children could recognize that one of the sets of animals is a subset of the other, making it trivial to identify which bowl had more objects.

The results from Experiment 1 are consistent with two possibilities. A first possibility is that children's ability to determine which of two sets had more objects improves when we the list includes a cue to number (by ordering the animal's based on size; Figure 1a). However, it is also possible that varying the size of the animals did not help children link the animal list to cardinalities. Instead, children may have simply selected the larger animal without conceptually understanding why this would be the correct answer. Note,

however, that children's performance in the 2 v. 3 and the 3 v. 6 trials was near-identical in Experiment 1 and Experiment 2. If children were simply pointing to the larger animal in Experiment 1, one might expect better performance relative to Experiment 2. In addition, older children were more likely to succeed in the 6 v.7 trial in Experiment 1. Intuitively, if children were relying on a size heuristic, younger children should have succeeded as well. Future work will test if this alternative can explain children's improved performance in Experiment 1.

In this study we recruited three-, four-, and five-year-olds and only tested children who were able to count. Because, in the US, children usually learn to count at around age four (Piantadosi, Jara-Ettinger, & Gibson, 2014; Wynn 1990, 1992), it is likely that most of our participants had just learned how to count. However, older participants are more likely to have known how to count for a longer time such that experience with counting and age were likely correlated in our sample. Thus, our finding that children improved in the 6 v. 7 trial in Experiment 1 does not reveal whether this improvement was due to age, or due to experience with counting. Future work will disambiguate between these possibilities.

Altogether, our results suggest that children who know how to count have yet to reach a mature understanding of how the counting principles reveal exact cardinalities. Our results add to a body of work that suggests that children's mastery of the counting procedure is not a final milestone in children's mastery of number words. Related work has also shown that young counters may also lack the cardinal principle (Davidson, Eng, & Barner, 2012; see introduction for review). Combined, this work suggests that when children learn to count, they master a set of procedural rules with only a partial understanding of how these rules relate to cardinality. Under this view, children's ability to count may be a building block towards their understanding of number words and cardinality rather than an endpoint. By learning to count, children may begin to notice a relationship between the set size and the final number word when counting, helping them realize that counting computes cardinality. Future work will test this hypothesis. What our findings do show, is that children's mastery of counting is an intermediate step in children's path to knowledge, and we add to a growing body of work suggesting that children's acquisition of procedural number knowledge may precede a mature understanding of the meaning of number words and counting (Jara-Ettinger, Piantadosi, Spelke, Levy, & Gibson, 2017; Davidson, Eng, & Barner, 2012; Cheung & LeCorre, 2015).

Toddlers recognize multiple polysemous meanings and use them to infer additional meanings

Abstract

Up to 80% of words have multiple, related meanings (polysemy), yet work on early word learning has almost uniformly assumed one-to-one mappings between form and meaning. Using a looking-while-listening procedure, we present the first evidence that toddlers (n=40) can recognize multiple meanings for common nouns, e.g., dog collar, shirt collar. In an English-meaning condition, toddlers were tested on their ability to recognize multiple English meanings for polysemous words such as cap (e.g., a baseball cap and a bottle cap). Another condition prompted toddlers with the same English words (e.g., cap), but target referents instead corresponded to the words polysemous extension in an unfamiliar language, (e.g., lid is a meaning for Spanishs cap, tapa). Toddlers looked to the correct targets above chance on both trial types, but with greater accuracy on English-meaning trials, demonstrating a recognition of familiar word-meaning pairs and an ability to infer potential new meanings.

Do Neural Language Representations Learn Physical Commonsense?

Maxwell Forbes†, Ari Holtzman†‡, and Yejin Choi†‡

Abstract

Humans understand language based on the rich background knowledge about how the physical world works, which in turn, allows us to reason about the physical world through language. In addition to the *properties* of objects (e.g., *boats require fuel*) and their *affordances*, i.e., the actions that are applicable to them (e.g., *boats can be driven*), we can also reason about *if–then* inferences between what properties of objects imply the kind of actions that are applicable to them (e.g., that *if we can drive something then it likely requires fuel*).

In this paper, we investigate the extent to which state-of-the-art neural language representations, trained on a vast amount of natural language text, demonstrate physical commonsense reasoning. While recent advancements of neural language models have demonstrated strong performance on various types of natural language inference tasks, our study based on a dataset of over 200k newly collected annotations suggests that neural language representations still only learn associations that are explicitly written down.[1]

Keywords: physical commonsense, natural language, neural networks, affordances

Introduction

Understanding everyday natural language communication requires a rich spectrum of physical commonsense knowledge. Consider the example dialog sketched in Figure 1. A simple observation that, *"The blender is broken again!"* triggers myriad pieces of implied understanding (e.g., that something which requires electricity will only work with a source of power). Such knowledge is rarely stated explicitly (Van Durme, 2010), and instead can be inferred on-the-fly as needed.

In this paper, we study physical commonsense knowledge underlying natural language understanding, organized as interactions among three distinct concepts: (i) objects, (ii) their attributes (properties), and (iii) the actions that can be applied to them (affordances) (Figure 1, bottom). The premise of our study is that language models trained on a sufficiently large amount of text can recover a great deal of physical commonsense knowledge about each of these concepts. However, aspects of this knowledge may only be implicit in natural language utterances. For example, answering a question from the Winograd Schema Challenge (Levesque, Davis, & Morgenstern, 2012)—"The trophy would not *fit* in the brown suitcase because it was too *big*. What was too big?"—implicitly requires the physical commonsense reasoning that *"in order to fit X in Y, X should be relatively smaller compared to Y"*, which essentially requires reasoning about the affordances of objects (fit X in Y) from their attributes (relative size of X and Y).

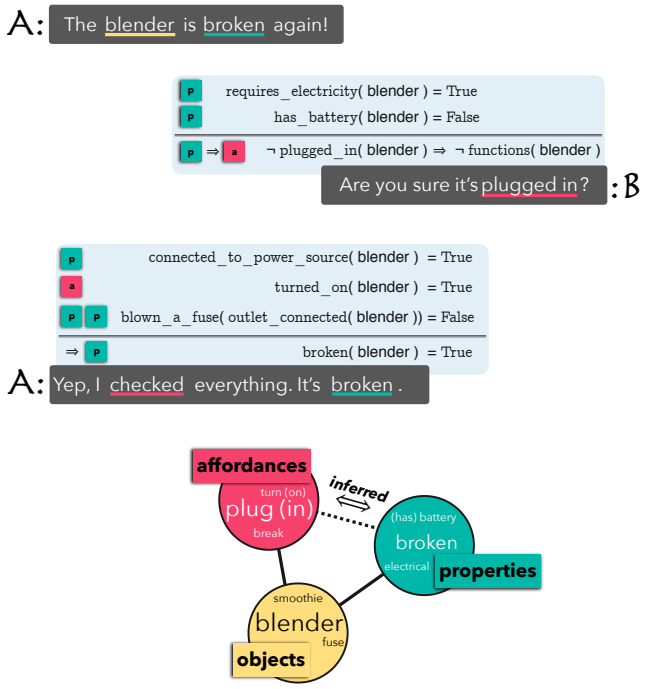

Figure 1: Natural language communication often requires reasoning about the affordances of objects (i.e., what actions are applicable to objects) from the properties of the objects (e.g., what are the size, weights, material of the objects) and vice versa. We study the extent to which neural networks trained on a large amount of text can recover various aspects of physical commonsense knowledge.

In this paper, we investigate the extent to which neural language models trained on a massive amount of text demonstrate various aspects of physical commonsense knowledge and reasoning. Our analysis includes word embeddings such as GloVe (Pennington, Socher, & Manning, 2014), as well as

[1] Visit `https://mbforbes.github.io/physical-commonsense` for our data, code, and more project information.

more recent contextualized representations like ELMo (Peters et al., 2018) and BERT (Devlin, Chang, Lee, & Toutanova, 2018). Such models are trained without supervision by exposing them to billions of words, and allowing them to extract patterns purely from token prediction tasks that can be derived directly from raw text. These language representation models have established unprecedented performance on a wide range of evaluations, including natural language inference and commonsense reasoning.

How much do these large, unsupervised models of language learn about physical commonsense knowledge? Some recent work has studied the capabilities of word embeddings to predict an object's properties (Rubinstein, Levi, Schwartz, & Rappoport, 2015; Lucy & Gauthier, 2017). Motivated by these efforts to understand language representations, we present several contributions. We contribute two datasets: the *abstract* dataset, a refreshed version of the McRate dataset (McRae, Cree, Seidenberg, & McNorgan, 2005), pruned and densely annotated to eliminate false negatives present in previous work; and the *situated dataset*, with annotations for objects' properties and affordances in real-world images sampled from the MS COCO dataset (Lin et al., 2014). As in previous work, we consider the prediction task of linking objects and their properties (O$\longleftrightarrow$P), but with our new situated dataset, we are also able to study the connection between objects and their affordances (O$\longleftrightarrow$A), as well as between affordances and properties (A$\longleftrightarrow$P). We also study the latest models from the natural language processing community (ELMo, BERT) using in-context word representations, and present results for all of our proposed datasets and tasks. Our analysis suggests that current neural language representations are proficient at guessing the affordances and properties of objects, but lack the ability to reason about the relationship between affordances and properties itself.

Characterizing Objects through Properties and Affordances

Properties

We use the term *properties* to refer to the static characteristics of objects. They encompass our commonsense understanding of what something is like. For example, we might say that an *apple* has the property of being *edible*, or that a *plant* is *stationary*.

As with McRae et al. (2005), properties capture the general perception of a thing. Exceptions naturally arise. For example, specific instances can violate the general properties of an object, such as the inediblilty of a rotten apple. Additionally, subtypes can diverge from the exemplar of a category, as with the Venus flytrap, a plant with the ability to move.

Affordances

We express an object's actions with verbs. One way to focus on understanding the actions of objects is to focus on their *affordances*. Coined by Gibson (1966), this term initially described animal-perceived uses for an object, but has since come to mean the perceived uses of an object in a given environment (Norman, 1988; Gaver, 1991).

Here, we take a simpler, human-centric definition. We consider an object's affordances to be, "what actions do humans take with an object?" For example, *boots* commonly afford *wear*, *kick off*, *lace up*, and *put on*.

Inference Between Affordances and Properties

Affordances and properties exhibit a surprising connection. As humans, we are able to infer many of an object's affordances based on its properties (A$\leftarrow$P). The same is also true in the reverse (A$\rightarrow$P).

Consider an exchange: *"You think you could fit that boulder in your truck?" "No way! That thing was so big you could go for a hike on it."* We might sketch out some of this information as:

$$\textit{fit } x \textit{ into } y \implies x <^{\text{size}} y$$
$$\text{hike(x)} \implies x \gg^{\text{size}} \textsc{Human}$$

While the above information only concerns a property's relative value (comparative size), all kinds of information traverse this edge implicitly:

*She **plugged in** her robot.*
$$\text{plug-in}(x) \implies \text{uses-electricity}(x)$$
*He **poured** coffee into the cup*
$$\text{pour-into}(x) \implies \text{holds-liquid}(x)$$
*It **shattered** on the floor.*
$$\text{shatter(x)} \implies \text{rigid}(x)$$

The implications ($\implies$) should be taken with a probabilistic grain of salt. However, they capture our intuitions about what we expect to be true. Wouldn't it be surprising to shatter something that isn't rigid, or plug-in something that doesn't take power?

Humans use the link between affordances and properties to recover information. Can machine learning models do the same? It is is difficult to model these implications based on text alone because there is no direct evidence for the implied information. Any implication that can be trivially understood by a person is precisely the kind of information left unsaid. Who would write, *"If I can walk inside my house, I know that my house is bigger than I am?"* Nevertheless, we naturally understand that: x *walk-inside* $y \implies x <^{\text{size}} y$.

Directly attacking the link between affordances and properties requires access to implications across the edges. Without such information, we can use objects as a proxy to understand how much modern neural networks know about this edge. For example, taking an object like *boots*, and using only its top affordances *wear*, *kick off*, and *lace up*, can we predict its properties?

Statistics

	Total	Statistics
Abstract		
Objects	514	411 train / 103 test
Properties	50	obj/prop: 60 median (3 min, 302 max) prop/obj: 8 median (1 min, 23 max)
Annotations	77,1000	3 anns/datum
Situated		
Objects	1,024	80 unique, split: 64 train / 16 test
Properties	50	
Affordances	3072	3 affordances / object (by design)
Annotations	156,672	3 anns/datum

Examples

Objects	Properties	Affordances
harmonica, van	*expensive, squishy*	*pick up, remove*
potato, shovel	*used as a tool for cooking*	*pet, talk to*
cat, bed	*decorative, fun*	*cook, throw out*

Table 1: Statistics and examples for the proposed abstract and situated datasets (based on (McRae et al., 2005) and (Lin et al., 2014)).

Experiments

Tasks

As shown at the bottom of Figure 1, our problem space naturally defines three edges in a graph. A property prediction task may attempt to produce the human-labeled set of properties given a new object (O→P) (Lucy & Gauthier, 2017). Predicting affordances can be done similarly: given a new object, can its top affordances be distinguished from others (O→A)? And finally, the troublesome but fertile edge between properties and affordances: can a model predict the set of properties compatible with an affordance (A→P)?

We frame each scenario as a series of joint reasoning tasks. Given two instances (e.g., an object and a property), a model must make a binary decision as to whether they are compatible. For example, predicting which properties out of a total of k are compatible with an object o will be set up as k compatibility tasks $(o, p_i) \rightarrow \{0, 1\}$. We denote the tasks as object-property (O⟷P), object-affordance (O⟷A), and affordance-property (A⟷P).

Data

To fuel experiments in these three tasks, we introduce two new datasets. The first we call the *abstract* dataset, which is a set of judgements elicited from only the name of the object (e.g., *wheelbarrow*) and property (e.g., *is an animal*). The second is the *situated* dataset, where properties and affordances are annotated on objects in the context of real-world pictures.[2]

Abstract Dataset Several lists of properties (McRae et al., 2005), categorization schemes (Devereux, Tyler, Geertzen, & Randall, 2014), and quantification layers (Herbelot & Vecchi, 2015) have been proposed. We take the set of objects and properties from McRae et al. and perform filtering and preprocessing similar to Lucy and Gauthier (2017). We also include the set of objects from the MS COCO dataset (Lin et al., 2014), collapse similar objects (e.g., many bird species) and add seven new properties (such as *man-made* and *squishy*). We end up with a set of 514 objects and 50 properties. We re-annotate all 25,700 object-property pairs to eliminate false negatives from the original McRae data collection process and provide labels for new entries. We annotate each pair three times for a total of 77,100 annotations, and keep only labels with $\geq 2/3$ agreement.

Situated Dataset We also annotate instances of objects situated in photographs. Images have the great advantage of resolving visual ambiguities of appearance, shape, and form. For example, a *bottle* has different properties if it is a glass beverage container or plastic shampoo tube. Only a few non-visual properties (e.g., *smelliness*) must then be inferred from the environment.

To build the an experimental situated testbed, we sample images from the MS COCO dataset (Lin et al., 2014). We constrain each image to have between three and seven objects to avoid scenes that are too sparse (often portraits) or dense (cluttered collections). We also ensure that we have at least five samples of each of the 80 unique object categories in the dataset. We end up with 1,024 objects across 220 images. We then annotate all 50 properties (introduced in the abstract dataset) for each object, annotating each three times for a total of 153,600 labels. We filter using the same scheme ($\geq 2/3$ agreement).

In addition to the properties, we also collect annotations of the affordances for all objects in the situated dataset. We allow annotators to choose from the 504 verbs from the imSitu dataset (Yatskar, Zettlemoyer, & Farhadi, 2016). We provide common variants of each verb that include particles, allowing annotations such as *pick up* and *throw out*. Annotators select the top three to five affordances that come to mind when they see the selected object in the context of its photograph. We again perform this annotation three times for each object, and aggregate the verbs chosen to pick the top three most common affordances for each object. We end up with a set of sparsely labeled affordances for each situated object. We perform balanced negative sampling by selecting $k = 3$ affordances for each datum and setting their labels to zero.

Detailed statistics and examples for both datasets are shown in Table 1.

[2]Annotations for both datasets are performed by workers on Amazon Mechanical Turk.

Table 2: Macro F1 scores per category (object, property, affordance) and micro F1 score (*μF1*) on both the abstract and situated test sets. Highest model values are bolded. Statistical significance (*sig*) is calculated with McNemar's test, comparing the best-scoring model (by *μF1*, denoted ←) with each other model. Stratified p-values are shown, with * for $p < 0.05$, ** for $p < 0.01$, and *** for $p < 0.001$. Human performance is estimated by 50 expert-annotated random samples from the test set (no McNemar's test).

Models

Word embeddings We consider four representations of the words involved in the tasks. Two of the representations are word embeddings. These map single words to vectors in $\mathbb{R}^d$. We use GloVe embeddings (Pennington et al., 2014) as they have proven effective at object-property tasks in the past (Lucy & Gauthier, 2017). We also use Dependency Based Word Embeddings (Levy & Goldberg, 2014), as they may more directly capture the relations between objects and their affordances. In both cases, $d = 300$, and we use the GloVe embedding variant with the largest amount of pretraining (840 billion words).

Contextualized representations The other two representations are ELMo (Peters et al., 2018) and BERT (Devlin et al., 2018), which are contextualized. These require full sentences (as opposed to single words) to compute a vector, but in turn produce results more specific to words' linguistic surroundings. For example, ELMo and BERT produce different representations for *book* in *"I read the book"* versus *"Please book the flight,"* while word embeddings have only a single representation.

To account for this, we generate sentences using the relevant objects, properties, and affordances for the task at hand. For example, to judge *accordion* and *squishy*, we would generate *"An accordion is squishy."*

For ELMo, we then take the final layer representations for the two compared words, each of which is a $d = 1024$ length vector. For BERT, we take the overall sentence representation and sum across the final four layers, which produces a single $d = 1024$ vector.

Finetuning Given the word representations above, we finetune each of the models by adding trainable multilayer perceptron (MLP) after the input representations. This allows models to learn interrelations between the two categories at hand, essentially calibrating the unsupervised representations into a compatibility function. We use a single hidden layer in the MLP, and train using mean squared error loss with L2 regularization.

To summarize, for two words (w_i, w_j) which can be written together in a sentence $s = w_1 ... w_n$, we have for a model m,

$$r(w_i, w_j) = \begin{cases} \langle m(w_i), m(w_j) \rangle & \text{if } m \in \{\text{GL., D.E.}\} \\ m^{-1}_{\{i,j\}}(s) & \text{if } m = \text{ELMO} \\ \sum_{\ell \in \{-4 ... -1\}} m^{\ell}(s) & \text{if } m = \text{BERT} \end{cases}$$

$$\hat{y}_{w_i,w_j} \propto \sigma(\mathbf{w_2^T} a(\mathbf{w_1^T} r(w_i, w_j) + \mathbf{b_1}) + \mathbf{b_2})$$

$$\mathcal{L}(w_i, w_j, y, \theta, \lambda) = (y - \hat{y}_{w_i,w_j})^2 + \lambda \|\theta\|_2^2$$

where $m(\cdot)_i^{\ell}$ is an embedding of the ith token in the layer ℓ, a is a nonlinear activation function, $y \in \{0, 1\}$ is the ground truth label, $\theta = \{\mathbf{w_1}, \mathbf{w_2}, \mathbf{b_1}, \mathbf{b_2}\}$ are trainable parameters, and λ is the regularization strength.

We optimize all models using gradient descent, and tune all hyperparameters using k-fold cross validation with $k = 5$.

Baselines We compare performance for these models against two simple approaches. The *random* baseline simply flips a coin for each compatibility decision. The *majority* baseline uses the per-class majority label for the training set, aggregating by property for the $O \longleftrightarrow P$ and $A \longleftrightarrow P$ tasks, and by affordance for the $O \longleftrightarrow A$ task.

Human performance Finally, we estimate human performance on this task. We sample 50 samples at random from the test set for each task, and have an expert annotate them. For fairness to the models, we do not show the expert the photographs or exact instance from which the situated examples are drawn.

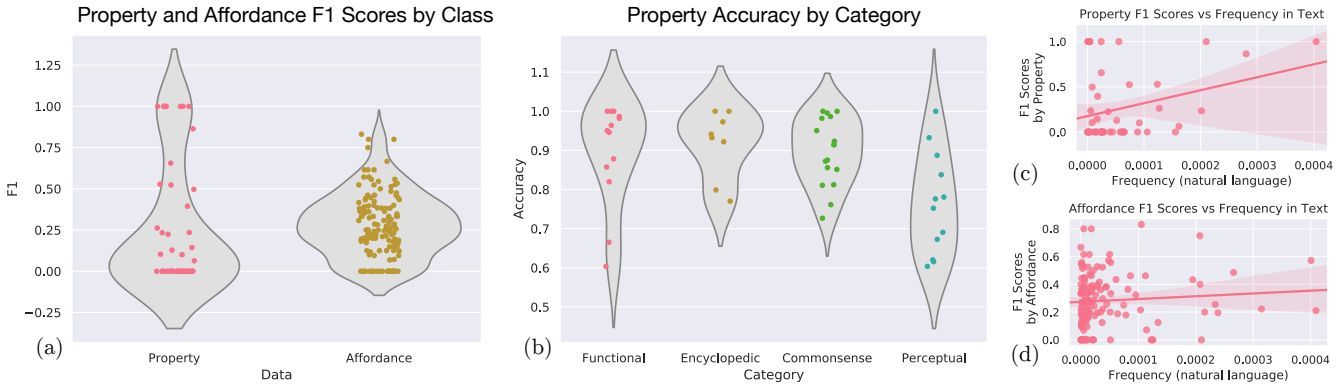

Figure 2: Detailed results of top performing model (ELMo) on the affordance-property compatibility task (A⟷P) in the situated dataset. (a) F1 scores are plotted per property (left) and affordance (right). (b) Properties are divided into four categories and plotted by accuracy. (c), (d) Both property and affordance F1 plotted against word frequency in natural language text.

Results

A summary of all model performances is shown in Table 2. Consistent with prior work that has studied object and property compatibility (Lucy & Gauthier, 2017), we find good but not perfect performance (close to 0.70 F1 scores) on the abstract dataset (task $O \longleftrightarrow P$). Models fare slightly worse on the situated $O \longleftrightarrow P$ task, with the best performance below 0.60 F1. This effect is consistent in the human expert scores as well. Though this dataset is larger, the introduction of context allows for greater variance in the properties of an object.

The object-affordance compatibility task ($O \longleftrightarrow A$) yields significantly higher numbers. Not only is this task statistically easier (as demonstrated by the strong majority baseline), but this edge is the only one directly observed in language. All models pretrained on text have been exposed to many instances of likely verbs for each object considered. In fact, all pretrained models perform in the same range as human ability, and there is no statistically significant difference between the models for this task.

However, all models struggle with the affordance-property task ($A \longleftrightarrow P$). The highest F1 scores are in the 0.30s, with the random baseline achieving the highest macro F1 score by property. While this task is also the most difficult for humans, their macro F1 scores for both affordances and properties are more than double that of the best performing models. We posit that the inference between affordances and properties requires multi-hop inference that is simply not present in the pretraining of large text-based models. We provide further analysis in the following section.

Analysis

Models achieve reasonable performance predicting the compatibility of both properties and affordances with objects. However, the task requiring inference between affordances and properties (A⟷P) confounds even the strongest models.

We explore this result through a detailed analysis of the top performing model. Figure 2 presents a breakdown of ELMo's results on the affordances-property compatibility task (A⟷P) on the situated dataset. From the leftmost graph (a), we observe that a per-property analysis shows a largely bimodal split between properties that are fully predicted (1.0 F1), and went completely unmodeled (0.0 F1). Affordances, on the other hand, lie more evenly across the F1 range. Because the task involved the compatibility between properties and affordances, mass for correct predictions must be shared between the two data groups. That so few properties achieved a high F1 score suggests that many affordances rely on only a few properties for accurate prediction.

We perform further analysis to investigate which kinds of properties yielded better affordance-property modeling. We categorize each property into four coarse classes: functional (e.g., *is used for cooking*), encyclopedic (e.g., *is an animal*), commonsense (e.g., *comes in pairs*), and perceptual (e.g., *is smooth*). Figure 2 (b) shows a breakdown of property performance grouped by these four categories. (Here, we plot accuracy instead of the sharper F1 metric to better illustrate the spread of performance.) Functional properties exhibit the highest performance. This makes intuitive since, because functional capabilities are directly tied to an object's affordances. In contrast, perceptual properties exhibit generally lower and inconsistent performance than other categories. We suspect that perceptual observations observed in text are not expressed with affordances, making this connection difficult for models. Largely perceptual features can be written about with simple verbs (*hear, see, feel*), giving them less implicit evidence than more nuanced properties. Finally, encyclopedic and commonsense properties fall somewhere in the middle. These properties, which involve an object's general characteristics (like *requires gasoline, lives in water,* or *has a peel*), correlate with a variety of verbs. But they may only be directly expressed at a distance from a verb, making the inference between them still challenging.

Our final analyses in Figure 2 (c) and (d) investigate

whether there is a link between the predictive power of the model and how often a word is used in text. We compute the frequencies of all affordances and properties occurring in natural language using the Google Web 1T corpus, an n-gram corpus computed from approximately one trillion words (Brants & Franz, 2006). Figure 2(c) plots the F1 score of properties against how frequently they appear in natural language; 2(d) plots the same for affordances. We include a best-fit line along with confidence intervals shown as one standard deviation of the data. We do not observe a statistical correlation between how much affordances and properties are written about, and how well neural models are able to connect their effects; a single confidence interval spans both positive and negative slopes. This lack of clear correlation is surprising, because large state-of-the-art neural textual models generally improve with repeated exposure to instances of words. Except for the three most common words measured by property F1 score, the rest of the data shows a strikingly uniform distribution of F1 scores for any choice of frequency in natural language. This suggests that current neural models are fundamentally limited in their capacity for physical reasoning, and that only new designs—not more data—can allow them to acquire this skill.

Discussion

Despite being able to associate a considerable range of information with the names of objects, neural models are not able to capture the more subtle interplay between affordances and properties. In some sense, this result is unsurprising. Collecting information around an object can be informed largely by the co-occurrence of words around that object's various mentions. Affordances that imply properties (and the reverse) are rarely mentioned together; their mutual connotation naturally renders joint expression redundant. Hence, priorless models that learn from statistical associations falter. Given the depth of the networks used in models such as ELMo and BERT, complex inter-parameter structure arises, but the latent semantic patterns that describe physical commonsense are much weaker than more superficial patterns that arise due to grammar or domain, making it difficult to capture.

This evidence feeds into theories of embodied cognition (Gover, 1996; Wilson, 2002), which suggest that the nature of human cognition depends strongly on the stimuli granted by physical experience. If this is so, then how is information encoded in our physical experience such that we can make predictions? If we assume a form of mental simulation, then what are the mental limits on its reliability? From an artificial intelligence perspective, the more interesting proof is in the principles of creating such a mental simulator. If we are to simulate human capacity for thought, how actually must we simulate elements of the physical world?

With the rise of physics engines, our ability to model physical inferences grows (Wu, Yildirim, Lim, Freeman, & Tenenbaum, 2015). However, while this may make us better at anticipating human predictions about physical situations through perceptual stimuli (Gerstenberg, Zhou, Smith, & Tenenbaum, 2017), there is still a long way to go before we understand the inferences that are being made through more symbolic stimuli, such as language. Exploring the mechanisms underlying this communication using an implicit shared world model will require us to either develop access to such a world model, or expose algorithms to predictions of that world model by directly querying humans. Bridging the inductive biases learned from simulation (Battaglia, Hamrick, & Tenenbaum, 2013) and those discovered by scientists (Lake, Linzen, & Baroni, 2019) to make inferences implicit in text will lead to a more cohesive model of commonsense physics. We expect such a model to bear great fruit in studies of communication rich with physical implications.

Continuous developmental change can explain discontinuities in word learning

Abstract

Cognitive development is often characterized in term of discontinuities, but these discontinuities can sometimes be apparent rather than actual and can arise from continuous developmental change. To explore this idea, we use as a case study the finding by Stager and Werker (1997) that children's early ability to distinguish similar sounds does not automatically translate into word learning skills. Early explanations proposed that children may not be able to encode subtle phonetic contrasts when learning novel word meanings, thus suggesting a discontinuous/stage-like pattern of development. However, later work has revealed (e.g., through using simpler testing methods) that children do encode such contrasts, thus favoring a continuous pattern of development. Here we propose a probabilistic model describing how development may proceed in a continuous fashion across the lifespan. The model accounts for previously documented facts and provides new predictions. We collected data from preschool children and adults, and we showed that the model can explain various patterns of learning both within the same age and across development. The findings suggest that major aspects of cognitive development that are typically thought of as discontinuities, may emerge from simpler, continuous mechanisms.

Keywords: word learning, cognitive development, computational modeling

Introduction

Cognitive development is sometimes characterized in terms of a succession of discontinuous stages (Piaget, 1954). Although intuitively appealing, stage theories can be challenging to integrate with theories of learning, which typically posit that knowledge and skills improve incrementally with experience. Indeed, one of the central challenges of cognitive development has been to explain transitions between stages which appear to be qualitatively different (Carey, 2009).

Nevertheless, at least in some cases, development may only appear to be stage-like. This appearance can be due, for example, to the use of a cognitively-demanding task which may mask learning, or to the use of statistical thresholding (in particular, p-value < 0.05) which can create a spurious dichotomy between success and failure in observing a given behavior. In such cases, positing discontinuous stages is unnecessary. Instead, a continuous model—involving similar representations across the lifespan—may provide a simpler and more transparent account of development.

We use a case study from word learning literature. Stager & Werker (1997) first showed that children's early ability to distinguish similar sounds does not automatically translate into word learning skills. Indeed, though infants around 14-month old can distinguish similar sound pairs such as "dih" and "bih", they appear to fail in mapping this pair to two different objects. Follow-up studies have focused on proposing possible explanations for this observed gap between speech perception and word learning (e.g., Fennell & Waxman, 2010; Hofer & Levy, 2017; Rost & McMurray, 2009; Stager & Werker, 1997).

By around 17 m.o, children succeed in the same task (Werker, Fennell, Corcoran, & Stager, 2002). How does development proceed? Early accounts assumed that children encode words in a binary way: they either fail or succeed in encoding the relevant phonetic details (simultaneously with the meanings). This account suggested a discontinuous/stage-like pattern of development whereby younger children fail to encode the contrastive phonetic detail, whereas older children succeed.

Subsequent findings have suggested otherwise. On the one hand, 14-month-olds—who typically fail in the original task—succeed when an easier testing method is used, even under the same learning conditions (Yoshida, Fennell, Swingley, & Werker, 2009). They also succeed when uncertainty is mitigated via disambiguating cues (e.g., Thiessen, 2007). On the other hand, adults show patterns of learning similar to those shown by 14-month-olds when the task is more challenging and when the similarity between words increases (Pajak, Creel, & Levy, 2016; White, Yee, Blumstein, & Morgan, 2013).

This pattern of evidence points towards another scenario, where the representations are encoded in a probabilistic (rather than binary) way, and where development is continuous, rather than stage-like (see also Swingley, 2007). On this account, correct representations are learned early in development, but these representations are encoded with higher uncertainty in younger children, leading to apparent failure in relatively demanding tasks. Development is a continuous process whereby the initial noisy representations become more precise. In addition, more precise representations are still imperfect: Even adults show low accuracy learning when the sound contrasts are subtle, e.g., non-native sounds (Pajak et al., 2016).

We provide an intuitive illustration of how such an account explains patterns of learning and development in Figure 1. We observe low accuracy in word learning when the perceptual distance between the labels is small relative to the uncertainty with which these labels are encoded. For example, in Stager and Werker's original experiment, children are supposed to associate label 1 ("bih") and label 2 ("dih") with object 1 and object 2, respectively. Though infants could learn that the label "bih" is a better match to object 1 than "dih", they could still judge the sound "dih" as a plausible instance of the label "bih", thanks to the relatively large uncertainty

of the encoding, and this confusion leads to "failure" in the recognition task. According to this account, accuracy in word learning improves if we increase either the perceptual distinctiveness of the stimuli (e.g., through using different-sounding labels) or the precision of the encoding itself (e.g., across development).

Building on this intuition, the current work proposes a probabilistic model, which we use to both account for previous experimental findings, and to make new predictions that have not been tested before. Using new data collected from both preschool children and adults, we show that the model can explain various patterns of learning both within the same age and across development.

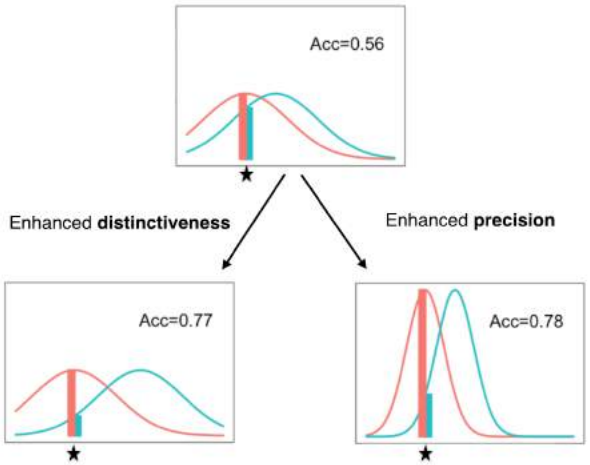

Figure 1: An illustration of the probabilistic/continuous account using simulated data. A word is represented with a distribution over the perceptual space (indicated in red or blue). When the uncertainty of the representation is large relative to the distance between the stimuli (top panel), an instance of the red category (indicated with a star) could also be a plausible instance of the green category, hence the low recognition accuracy score. The accuracy increases when the stimuli are less similar (left panel), or when the representations are more precise (right panel).

Model

Probabilistic structure

Our model consists of a set of variables describing the general process of spoken word recognition in a referential situation. These variables are related in a way that reflects the simple generative scenario represented graphically in Figure 2. When a speaker utters a sound in the presence of an object, the observer assumes that the object o activated the concept C in the speaker's mind. The concept prompted the corresponding label L. Finally, the label was physically instantiated by the sound s.

A similar probabilistic structure was used by Lewis & Frank (2013) to model concept learning, and by Hofer & Levy (2017) to model spoken word learning. However, the first study assumed that the sounds are heard unambiguously, and the second assumed the concepts are observed unambiguously. In our model, we assume that both labels and concepts are observed with a certain amount of perceptual noise, which we assume, for simplicity, is captured by a normal distribution:

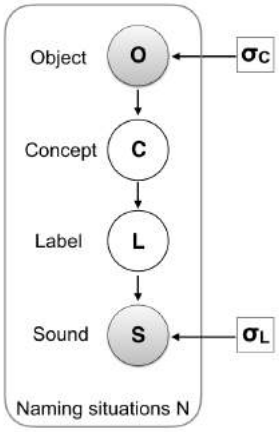

Figure 2: Graphical representation of our model. Circles indicate random variables (shading indicates observed variables). The squares indicate fixed model parameters.

$$p(o|C) \sim \mathcal{N}(\mu_C, \sigma_C^2)$$
$$p(s|L) \sim \mathcal{N}(\mu_L, \sigma_L^2)$$

Finally, we assume there to be one-to-one mappings between concepts and labels and that observers have successfully learned these mappings during the exposure phase:

$$P(L_i|C_j) = \begin{cases} 1 & \text{if } i = j \\ 0 & \text{otherwise} \end{cases}$$

Inference

The learner hears a sound s and has to decide which object o provides an optimal match to this sound. To this end, they must compute the probability $P(o|s)$ for all possible objects. This probability can be computed by summing over all possible concepts and labels:

$$P(o|s) = \sum_{C,L} P(o,C,L|s) \propto \sum_{C,L} P(o,C,L,s)$$

The joint probability $P(o,C,L,s)$ is obtained by factoring the Bayesian network in Figure 2:

$$P(o,C,L,s) = P(s|L)P(L|C)P(C|o)P(o)$$

which can be transformed using Bayes rule into:

$$P(o,C,L,s) = P(s|L)P(L|C)P(o|C)P(C)$$

Finally, assuming that the concepts' prior probability is uniformly distributed[1], we obtain the following expression, where all conditional dependencies are now well defined:

$$P(o|s) = \frac{\sum_{C,L} P(s|L)P(o|C)P(L|C)}{\sum_o \sum_{C,L} P(s|L)P(o|C)P(L|C)} \quad (1)$$

[1]This is a reasonable assumption in our particular case given the similarity of the concepts used in each naming situation in our experiment.

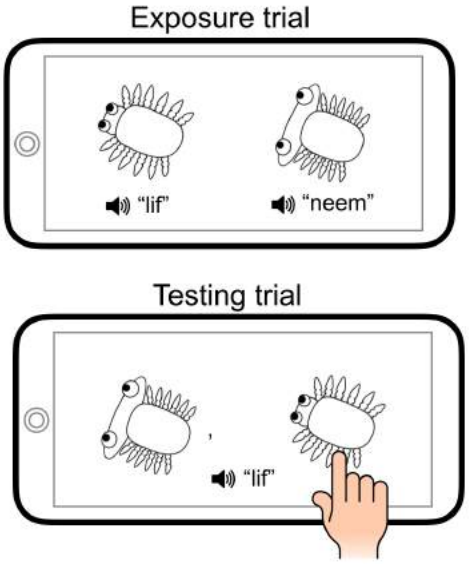

Figure 3: An overview of the task used in this study.

Task and model predictions

We use the model to predict performance in the word learning task introduced by Stager & Werker (1997), with a two-alternative forced choice as in Yoshida et al. (2009). In this task, participants are first exposed to the association between pairs of nonsense words (e.g., "lif"/"neem") and pairs of objects. The word-object associations are introduced sequentially. After this exposure phase, participants perform a series of test trials. In each of these trials, one of the two sounds is uttered (e.g., "lif") and participants choose the corresponding object from the two alternatives. An overview of the task is shown in Figure 3.

We used Equation 1 and the probability distributions defined above to obtain the exact analytical expression for the probability of accurate responses $p(o_T|s)$ (target object o_T given a sound s) in the simple case of two-alternative forced choice in the testing phase of our experimental task:

$$P(o_T|s) = \frac{1 + e^{-(\Delta s^2/2\sigma_L^2 + \Delta o^2/2\sigma_C^2)}}{1 + e^{-(\Delta s^2/2\sigma_L^2 + \Delta o^2/2\sigma_C^2)} + e^{-\Delta s^2/2\sigma_L^2} + e^{-\Delta o^2/2\sigma_C^2}} \quad (2)$$

Figure 4 show simulations of the predicted accuracy (Expression 2) as a function of the distinctiveness parameters (Δs and Δo) and the precision parameters, i.e., the variances of the distributions $p(s|L)$ and $p(o|C)$. To understand the qualitative behavior of the model, we assumed for simplicity that the precision parameter has similar values in both distributions, i.e., $\sigma = \sigma_C \approx \sigma_L$ (but we will allow those parameters to vary independently in the rest of the paper).

The simulations explain some previously documented facts, and make new predictions:

1) For fixed values of Δo and σ, the probability of accurate responses increases as a function of Δs. This pattern accounts for the fact that similar sounds are generally more challenging to learn than different sounds for both children (Stager & Werker, 1997) and adults (Pajak et al., 2016).

2) For fixed values of Δs and Δo, accuracy increases when the representational uncertainty (characterized with σ) decreases. This fact may explain development, i.e., younger children have noisier representations (see Swingley, 2007; Yoshida et al., 2009), which leads to lower word recognition accuracy, especially for similar-sounding words.

3) For fixed values of Δs and σ, accuracy increases with the visual distance between the semantic referents Δo. This is a new prediction that our model makes. Previous work studied the effect of several bottom-up and top-down properties in disambiguating similar sounding words (e.g., Fennell & Waxman, 2010; Rost & McMurray, 2009; Thiessen, 2007), but to our knowledge, no previous study in the literature tested the effect of the visual distance between the semantic referents.

Experiment

In this experiment, we tested participants in the word learning task introduced above (Figure 3). More precisely, we explored the predictions related to both distinctiveness and precision. Sound similarity (Δs) and object similarity (Δo) were varied simultaneously in a within-subject design. Two age groups (preschool children and adults) were tested on the same task to explore whether development can be characterized with the uncertainty parameters, σ_C and σ_L. The experiment, sample size, exclusion criteria and the model's main predictions were pre-registered.

Methods

Participants We planned to recruit a sample of $N = 60$ children ages 4-5 years from the Bing Nursery School on Stanford University's campus. Here we report data from $N = 55$ children. An additional $N = 35$ children participated but were removed from analyses because they were not above chance on the catch trials due to the challenging nature of our procedure (see below). We also collected a planned sample of $N = 100$ adult participants through Amazon Mechanical Turk. We planned to exclude data from participants who did not do well on the catch trials ($N = 26$) and from participants who were familiar with the non-English sound stimuli we used in the adult experiment ($N = 0$), yielding a final sample of $N = 74$.

Stimuli and similarity rating The sound stimuli were generated using the MBROLA Speech Synthesizer (Dutoit, Pagel, Pierret, Bataille, & Van der Vrecken, 1996). We generated three kinds of nonsense word pairs which varied in their degree of similarity to English speakers: 1) "different": "lif"/"neem" and "zem"/"doof", 2) "intermediate": "aka"/"ama" and "ada"/"aba", and 3) "similar" non-English minimal pairs: "ada"/"ad$^{\text{h}}$a" (in hindi) and "aʕa"/"a a" (in arabic).

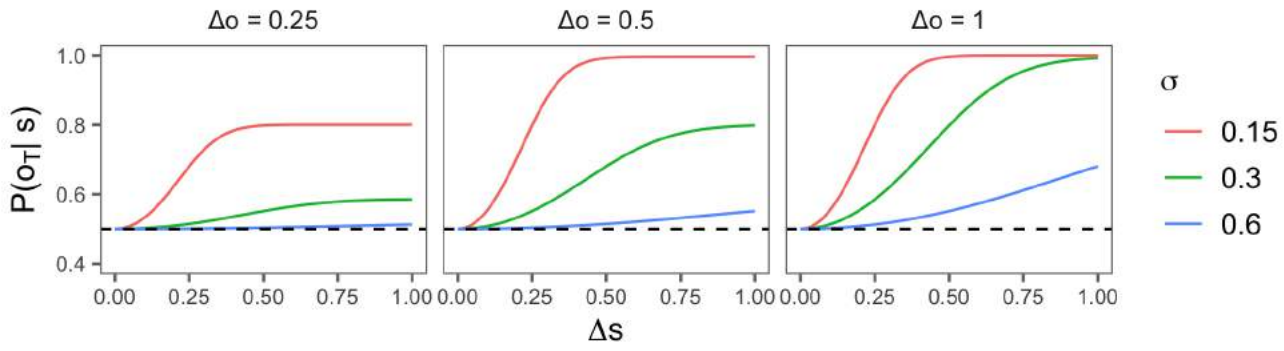

Figure 4: The predicted probability of accurate responses in the testing phase as a function of stimuli distinctiveness Δs and Δo and representation precision σ (for simplicity, we assume here that $\sigma{=}\sigma_C{=}\sigma_L$). Dashed line represents chance.

As for the objects, we used the Dynamic Stimuli javascript library[2] which allowed us to generate objects in four different categories: "tree", "bird", "bug", and "fish". These categories are supposed to be naturally occurring kinds that might be seen on an alien planet. In each category, we generated "different", "intermediate" and "similar" pairs by manipulating a continuous property controlling features of the category's shape (e.g, body stretch or head fatness).

In a separate survey, $N = 20$ participants recruited on Amazon Mechanical Turk evaluated the similarity of each sound and object pair on a 7-point scale. We scaled responses within the range [0,1]. Data are shown in Figure 5, for each stimulus group. These data will be used in the models as the perceptual distance of sound pairs (Δs) and object pairs (Δo).

Design Each age group saw only two of the three levels of similarity described in the previous sub-section: "different" vs. "intermediate" for preschoolers and "intermediate" vs. "similar" for adults. We made this choice in light of pilot studies showing that adults were at ceiling with "different" sounds/objects, and children were at chance with the "similar" sounds/objects. That said, this difference in the level of similarity is accounted for in the model by using the appropriate perceptual distance used in each age group (Figure 5).

To maximize our ability to measure subtle stimulus effects, the experiment was a 2x2 within-subjects factorial design with four conditions: high/low sound similarity crossed with high/low visual object similarity. Besides the 4 conditions, we also tested participants on a fifth catch condition which was similar in its structure to the other ones but was used only to select participants who were able to follow the instructions and show minimal learning.

Procedure Preschoolers were tested at the nursery school using a tablet, whereas adults used their own computers to complete the same experiment online. Participants were tested in a sequence of five conditions: the four experimental conditions plus the catch condition. In each condition, participants saw a first block of four exposure trials followed by four testing trials, and a second block of two exposure trials (for memory refreshment) followed by an additional four testing trials. The length of this procedure was demanding, especially for children, but we adopted a fully within-subjects design based on pilot testing that indicated that precision of measurement was critical for testing our experimental predictions.

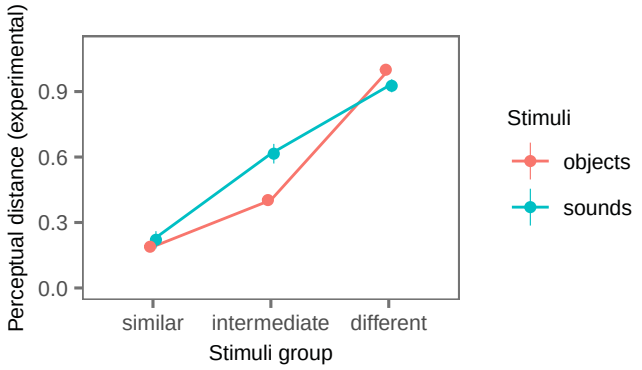

Figure 5: Distances for both sound and object pairs from an adult norming study. Data represent Likert values normalized to [0,1] interval. Error bars represent 95% confidence intervals.

In the exposure trials, participants saw two objects associated with their corresponding sounds. We presented the first object on the left side of the tablet's screen simultaneously with the corresponding sound. The second sound-object association followed on the other side of the screen after 500ms. For both objects, visual stimuli were present for the duration of the sound clip (800ms). In the testing trials, participants saw both objects simultaneously and heard only one sound. They completed the trial by selecting which of the two objects corresponded to the sound. The object-sound pairings were randomized across participants, as was the order of the conditions (except for the catch condition which was always placed in the middle of the testing sequence). We also randomized

the on-screen position (left vs. right) of the two pictures on each testing trial.

Results

We first analyzed the results using a mixed-effects logistic regression with sound distance, object distance and age group as fixed effects, and with a maximal random effects structure (allowing us to take into account the full nested structure of our data) (Barr, Levy, Scheepers, & Tily, 2013). We found main effects for all the fixed effects in the regression. For the sound distance, we obtained $\beta = 0.52$ ($p < 0.001$), replicating previous findings. For object distance, we found $\beta = 0.83$ ($p < 0.001$), and this finding confirms the new prediction of our model. Finally, for the age group, we obtained $\beta = 0.76$ ($p < 0.001$), showing that performance improves with age.

We next fit our model (using Equation 2) to the participants' responses in each age group using non-linear least-squares. The values of Δs and Δo were set based on data from the similarity judgment task (Figure 5). The model has two degrees of freedom for each group, i.e., σ_C and σ_L. We call it the double-variance model. Figure 6 (dashed lines) shows the predictions. The double-variance model captures the behavioral patterns in both age groups: starting from a low accuracy recognition when both the sound and object distances are small, the model correctly predicts an increase in accuracy when either the sound distance or the object distance increases. Further, accuracy is correctly predicted to be maximal when both the sound and object distances are high.

The values of the parameters were as follows. Children had a label-specific uncertainty of $\sigma_S = 0.83$ [0.64, 1.02][3], and a concept-specific uncertainty of $\sigma_C = 0.31$ [0.11, 0.51]. Adults had a label-specific uncertainty of $\sigma_S = 0.12$ [0.12, 0.13], and a concept-specific uncertainty of $\sigma_C = 0.17$ [0.16, 0.18]. As predicted, the uncertainty parameters were larger for children than they were for adults, showing that the probabilistic representations becomes more refined (that is, σ becomes smaller) across development. The developmental effect was more important for the label-specific uncertainty.

The double-variance model explained almost all the variance in the participants' mean responses. To investigate whether the model's strong predictive power was due to overfitting, we fit a simplified version with only one degree of freedom (i.e., a single variance common to both sounds and objects). This single-variance model also captured the main qualitative patterns and remained highly predictive ($R^2 = 0.95$). This result suggests that the explanatory power of the model is largely due to its structure, rather than its degrees of freedom.

General Discussion

This paper explored the idea that some seemingly stage-like patterns in cognitive development can be characterized in a

[3] All uncertainty intervals in this paper represent 95% Confidence Intervals.

continuous fashion. We used as a case study the seminal work of Stager & Werker (1997) showing a discrepancy between children's speech perception abilities and their word learning skills. While much of the previous investigation of this finding has been interested in the source of this discrepancy, here we have explored how it could arise from continuous developmental change in perceptual uncertainty.

Building on some previous discussions (e.g., Swingley, 2007; Yoshida et al., 2009), we proposed a model where perceptual stimuli are encoded probabilistically. We tested the model's predictions against data collected from preschool children and adults and we showed that developmental changes in word-object mappings can indeed be characterized as a continuous refinement (i.e., uncertainty reduction) in qualitatively similar representations across the life span.

The model made a new prediction which we tested experimentally: Learning similar words is not only modulated by the similarity of their phonological forms, but also by the visual similarity of their semantic referents. More generally, since visual similarity is an early organizing feature in the semantic domain (e.g., Wojcik & Saffran, 2013), our finding suggests that children may prioritize the acquisition of words that are quite distant in the semantic space. This suggestion is supported by recent findings based on the investigation of early vocabulary growth (Engelthaler & Hills, 2017; Sizemore, Karuza, Giusti, & Bassett, 2018).

One limitation of this work is that the model was fit to data from children at a relatively older age (4-5 years old) than what is typically studied in the literature (14-18 month-old). We selected this older age group to optimize the number and precision of the experimental measures (both are crucial to model fitting). Data collection involved presenting participants with several trials across four conditions in a between-subject design. It would have been challenging to obtain such measures with infants.

In sum, this paper proposes a model that accounts for the development of an important aspect of word learning. Our account suggests that the developmental data can be explained based on a continuous process operating over similar representations across development, suggesting developmental continuity. We used a case from word learning as an example, but the same idea might apply to other aspects of cognitive development that are typically thought of as stage-like (e.g., acquisition of a theory of mind). Computational models, such as the one proposed here, can help us investigate the extent to which such discontinuities emerge due to genuine qualitative changes and the extent to which they reflect the granularity of the researchers' own measurement tools.

Abstract

Human analogical ability involves the re-use of abstract, structured representations within and across domains. Here, we present a generative neural network that completes analogies in a 1D metric space, without explicit training on analogy. Our model integrates two key ideas. First, it operates over representations inspired by properties of the mammalian Entorhinal Cortex (EC), believed to extract low-dimensional representations of the environment from the transition probabilities between states. Second, we show that a neural network equipped with a simple predictive objective and highly general inductive bias can learn to utilize these EC-like codes to compute explicit, abstract relations between pairs of objects. The proposed inductive bias favors a latent code that consists of anti-correlated representations. The relational representations learned by the model can then be used to complete analogies involving the signed distance between novel input pairs (1:3 :: 5:? (7)), and extrapolate outside of the network's training domain. As a proof of principle, we extend the same architecture to more richly structured tree representations. We suggest that this combination of predictive, error-driven learning and simple inductive biases offers promise for deriving and utilizing the representations necessary for high-level cognitive functions, such as analogy.

Keywords: abstract structured representations; analogy; neural networks; predictive learning; relational reasoning;

Introduction

Analogy requires the flexible, yet orderly, transfer of abstract knowledge within and between domains. Although this transfer occasionally enables new theoretical insights (e.g., Rutherford's planetary model of atomic structure or the hydraulic model of blood circulation (Gentner, 1983)), it also provides critical support for basic cognitive functions, such as memory retrieval, categorization, and schema induction (Gick & Holyoak, 1983; Doumas, Hummel, & Sandhofer, 2008; Gentner & Forbus, 2011; Holyoak, 2012). Here, we test the idea that representations of abstract, structural relationships can be derived using simple forms of training. We evaluate whether these representations can, in turn, support higher-level functions such as analogical inference, without any explicit training on analogy itself.

Specifically, we test the idea that abstract, structured representations arise from learning systems that (a) exploit the vast amounts of observational data available to natural agents ((Rao & Ballard, 1999), O'Reilly, Wyatte, and Rohrlich, 2017) coupled with (b) particular inductive biases in the learning algorithm and network architecture.

We explore what particular input representations and model architectures enable the extraction and utilization of this relational knowledge. To do so, we focus on modeling signed distance relations in a 1-dimensional (1D) domain (e.g., analogies such as 1:3 :: 5:7), and conclude by extending the principles to analogies involving a simple family tree structure.

Throughout, we take inspiration from the representational properties of the mammalian Entorhinal Cortex (EC), believed to extract low-dimensional representations of the metric structure common across environments from the transition probabilities between states (Dayan, 1993; Gustafson & Daw, 2011; Stachenfeld, Botvinick, & Gershman, 2017). We then propose a learning procedure that combines error-driven learning and an inductive bias that naturally extracts explicit relational representations from pre-structured, EC-like representations of the current domain. We show that this combination of representation and model architecture can support analogical inference, and extrapolate well outside the network's training domain.

Methods

Input Representations We focus first on the 1D domain. What input representations enable relation learning that can support analogy (e.g., Figure 1A)? Here, we compare place codes, a successor representation (SR) of states, and lower dimensional representations generated by eigendecompositions of this SR matrix, truncated to 10, 5, or 2 components.

For the place code representation, locations are represented as 1xN one-hot vectors, each orthogonal to the others. This set of representations forms an nXn identity matrix (see Figure 1C, upper left panel), and thus lacks intrinsic structural

information about the domain. It is therefore, a priori, a poor candidate for discovering relational structure that could support analogy, which requires knowledge about structural equivalences (e.g., that the difference between 1-3 is the same as 5-7).

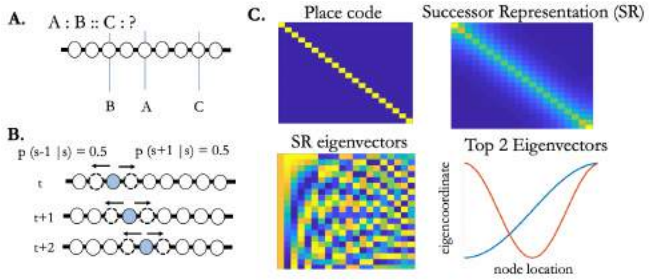

Figure 1: Schematic representation of the 1D domain. (A) depicts the task the network will perform: a signed distance analogy in 1D (here, 5:3 :: 8:?). (B). Following Stachenfeld et al. (2017), we use a random-walk transition matrix to compute the Successor Representation (SR), and derive a low-dimensional representation of the domain by computing the eigendecomposition of the SR. (C) The three forms of representations are compared as inputs to the network: place codes, the SR, and various number of eigenvectors of the SR.

We therefore extend the representation to carry information about the similarity structure of the dimension. To do so, we use the *successor representation* (SR) (Dayan, 1993). The SR is a predictive representation of possible future states, and thus carries information about the dimension's intrinsic structure. To illustrate, imagine, an animal navigating a linear track, with equal probability of moving to spatially adjacent states at successive time points (See Figure 1B). Experience along the track allows learning state-state transition probabilities. The SR encodes the likelihood of visiting a particular location s_i, given a trajectory initiated in a particular state s. The resulting nXn SR matrix is a collection of these conditional probabilities (See Figure 1C, upper right panel). The probability of visitation is high for neighboring states, but low for distant states. Although the SR has primarily been used in learning spatial structure, we take this approach to be representative of continuous dimensions, more broadly (e.g., *brightness*, *loudness*, *pitch*, etc., as well as semantic dimensions such as *animacy*, *size*, or *agreeableness*). The SR can be acquired using a temporal difference learning algorithm (Dayan, 1993). Here, however, we simply stipulate a transition matrix with equal probability of transitioning to adjacent states and a discounted value of future states of 0.9 (results are robust to this parameter). For the SR, the resulting input representation is an nXn matrix in which nearby states have similar representations.

Representing this similarity structure makes the SR a better candidate for analogical inference than a pure place code. However, it is still a high-dimensional representation that does not compactly encode variation along the dimension of interest. Critically, recent work has shown that a spectral representation of the SR provides an abstract, implicitly structured representation of the domain (Stachenfeld et al., 2017). Intriguingly, this spectral representation of the SR resembles the representational properties of grid-like cells in medial entorhinal cortex. Entorhinal cortex (EC) is believed to encode low-dimensional representations of the metric structure of the environment (Hafting et al., 2005; Gustafson and Daw, 2011; Stachenfeld et al., 2017). Here, we take grid-cells in EC to reflect a more general idea: the decomposition of transition probabilities into low-dimensional embeddings provides an abstract, implicitly structured representation of a domain. When domains share an underlying transition structure, these representations can be used to support analogies. To implement our 1D case, we follow Stachenfeld et al. (2017) and compute the eigendecomposition of the square (nXn) SR matrix. The eigenvalues (λ) are obtained solving $det(M-\lambda I)=0$, where M is the SR matrix, and I the identity matrix. We can obtain the corresponding eigenvector (U_i) for a particular eigenvalue (λ_i) by solving $MU_i = U_i\lambda_i$ for U_i. Finally, we encode each location in the native space using its eigencoordinates ($U\lambda$) (Figure 1C, lower left panel). We compare models trained on the top 10, top 5, top 2 highest eigenvalue eigenvectors (e.g., Figure 1C, lower right panel), and the neural network learns over these eigencoordinate representations, which implicitly encode the ordering and neighborhood relations among the locations. Finally, we include a scrambled version of the top 2 eigenvectors. This scrambled version removes the true similarity structure in the native space, and serves as a control to ensure that the neural network is not simply memorizing its inputs.

Model Architectures. We trained and tested networks on each of the input representations described above. Each network was constructed to take a pair of inputs (A and B — we refer to objects and relations, themselves, using non-italicized capitalized letters, and a model's representations of them using italicized lower-case (e.g., a and b)), and trained to predict each member of the pair from the other. We evaluated five competing model architectures, that we describe in detail below. In all models, representations of A converge on a common learned internal layer, which can then encode their relationship R. The ability to form a systematic, abstract relational encoding (r) is a primary focus of this paper. We evaluate the ability of r to support simple metric analogies by completing problems of the form A:B as C:? (e.g., 1:3 is to 5:?, answer: 7).

r is computed as,

$$r = f_\Theta(a,b)$$

where a and b are representations of the two input objects to be related, and Θ are the learned encoder parameters (by default, a one layer multiple layer perceptron (MLP) with 100 rectified linear units (RELU)) and (r) is the activation state across two linear nodes.

To train the model, the latent state r is composed with the object A representation (a) to predict B ($\hat{b}$), and composed with the object B representation (b) to predict A ($\hat{a}$).

$$\hat{a} = g_{\Phi}(r,b) \quad \hat{b} = g_{\Phi}(r,a)$$

where, $\hat{a}$ is the predicted version of a, g is the decoder function (a one layer MLP with 100 RELU units), with learned parameters Φ. r is $r = f_{\Theta}(a,b)$, as above, and b is the input representation of object B. Likewise for $\hat{b}$, *mutatis mutandis*.

The representations r , a , and b are thus arguments to functions parameterized by the encoder and decoder. Here, we control the selection and application of these arguments by hand, but not their values, therein focusing on the problem of representation learning.

Intuitively, the objective of the model is to learn a representation that enables transformation of the representation a to match representation b, and vice versa. The loss is the mean squared error of the reconstruction across both objects, and weights of the encoder (Θ) and decoder (Φ) are jointly updated using standard backpropagation (Rumelhart, Hinton, & Williams, 1985). We emphasize that the network is trained to minimize reconstruction error ($(a-\hat{a})^2 + (b-\hat{b})^2$), not to complete analogies.

Model architectures are shown in Figure 2. All 5 models consist of two linear nodes in the latent space (r), but differ in how they constrain the nodes in r to be used. For models 1 and 2, the same 2D vector of r is used in both $\hat{a} = g_{\Phi}(r,b)$ and $\hat{b} = g_{\Phi}(r,a)$. Model 2 differs from Model 1 only in allowing separate decoder parameters to be learned for $\hat{a} = g_{\Phi_a}(r,b)$ and $\hat{b} = g_{\Phi_b}(r,a)$. These models are free to learn how to use these nodes (r) to predict across a and b. By contrast, models 3, 4, and 5 specifically commit each of these two nodes to separately predicting a and b, which we refer to as r_a and r_b, respectively. That is, $\hat{a} = g_{\Phi}(r_a,b)$, and $\hat{b} = g_{\Phi}(r_b,a)$. Models 3, 4, and 5 all share decoder parameters across $\hat{a}$. and $\hat{b}$.

Models 4 and 5 involve chaining the two latent nodes in r (r_a and r_b), such that one of the components of the relational representation is a function of the other. The motivation for this chaining of latent nodes is as follows. Recall that activation in r_a encodes information necessary to transform b to a when passed through the decoder, and vice versa for r_b. Although the input representation may contain *implicit information* about the relationship between A and B, the encoder must extract this information and explicitly represent relational information in a low-dimensional form. Logically, in a metric space, how A relates to B cannot change without affecting how B relates to A – the two predictive tasks imposed on network. The chain weights in models 4 and 5 force such a bi-directional dependence in r (See Figure 2). While it is possible that an unconstrained neural network could learn the dependence between r_a and r_b, we find that, using the current objective, this does not occur reliably without imposing the constraint that $r_a = f_{\Theta}(a,b)$, and $r_b = r_a W + bias$.

Model 4 imposes the weakest version of this constraint, by allowing the weight W (that links r_a and r_b) to be randomly initialized. However, randomly initializing the chain weight fails to exploit all the world-structure that may be easily incorporated. Critically, the general relation between the components r_a and r_b should be anti-correlated (e.g., the "bigger" A is than B, the "smaller" B is than A). That is, r_a, r_b can be thought of as conjugate pairs (e.g., +-2). A prior that biases the network toward the discovery of this relational structure can easily be implemented by initializing W to -1. We refer to this architecture as the *conjugate symmetry prior*, as it favors extracting a representation in r that treats r_a and r_b as a conjugate pair, reflected about zero. Note that this was strictly an initialization, and that W was free to vary over training. Empirically, we find that it tends not to vary over the course of training when initialized to -1.

Analogy Evaluation. We address whether the trained networks can perform analogy as follows. First, two object representations (a and b) are passed to the network, and the resulting latent state (r) is computed, and manually clamped to use for analogical completion. Next, a third object representation (c) is passed directly to the decoder without modifying r. The decoder then generates the expected d ($\hat{d}$), given c and the latent state r that was previously computed from the ab pair, as $\hat{d} = g_{\Phi}(r,c)$. To quantify a network's analogical ability, we compute the cosine similarity between $\hat{d}$ and d, as well as the cosine similarity between d and three randomly chosen foils. If the correct mapping is more similar than all three incorrect mappings, the network is determined to have succeeded on that trial. Chance performance on this metric is thus 25%.

Our primary results involve a 1x80 space (Figure 3). We also explore 1x20, 1x40, and 1x160 spaces, and the ability to generalize between them (Figure 5). In all cases, we trained the model on 500 ab pairs from the same space, and held 100 unique pairs from that space out of training for model testing. The number of possible pairs varies by the size of the native space. For example, in the smallest space (1x20), there are 380 possible ab pairs, entailing that some were necessarily repeated in training. At the other extreme (1x160), there are 25,540 possible pairs, and only 500 were selected for training, meaning that the network only experienced 2% of the possible space of relation-tokens. We trained the network using batch sizes of 64 samples and the ADAM optimizer (with a constant learning rate of $3x10^{-4}$), implemented in Tensorflow. We trained all networks for a fixed number of 1000 batches. This was sufficient to observe reliable asymptotes in training loss. Unless otherwise indicated, we ran 50 replications of each network with random encoder and decoder weights and random samples from the training set, and plot the mean and 95% CI for each class of networks and input representations.

Results

Analogy Results Across Input Representations and Architectures. In the models explored here, we find that success on these analogies requires both a particular input representa-

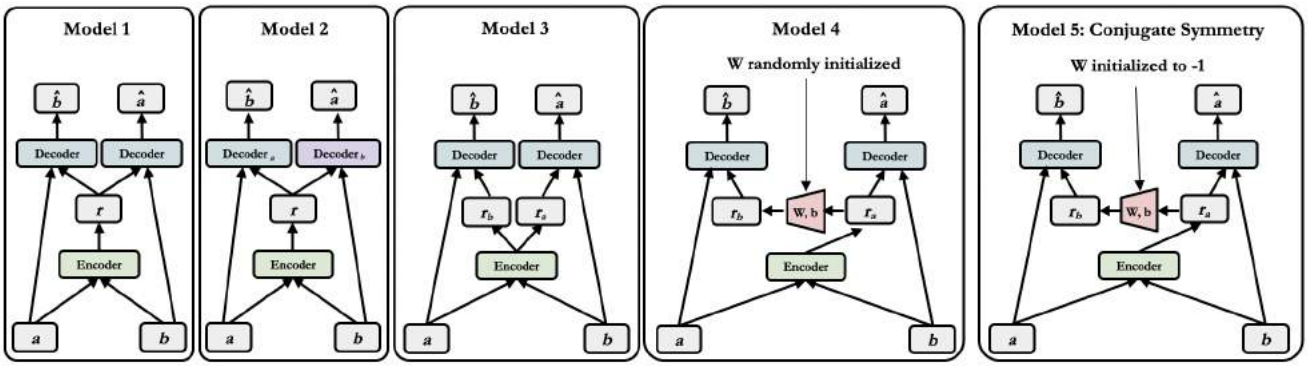

Figure 2: Schematic of model architectures. In each model, the encoder infers the relation r between a and b. The decoder predicts a given b and r, and predicts b given a and r. Gray boxes indicate activity vectors (inputs, outputs, or hidden states). Colored boxes indicate parameterized functions (linear layers or multilayer neural networks); boxes with the same name and color indicate shared parameters.

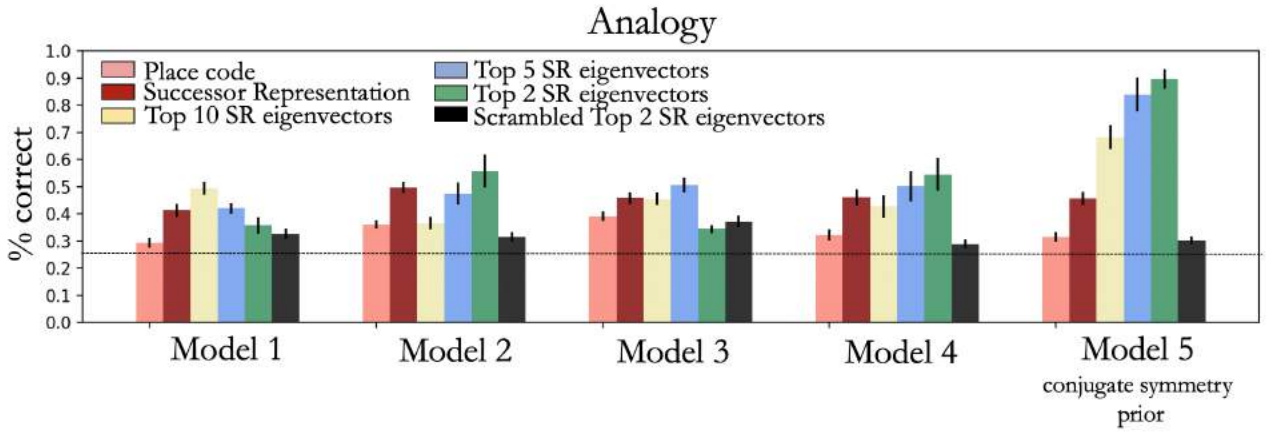

Figure 3: Analogy results for different model architectures. We see that only Model 5 (conjugate symmetry prior) trained on a low dimensional eigenrepresentation (e.g., 2 and 5) reliably learns relations enabling analogical completion.

tion and a particular architecture (See Figure 3.) Only models that integrate a low-dimensional eigenrepresentation of the SR (such as the top 2 or top 5 eigenvectors), and learn over this representation using a conjugate symmetry prior on the relational representation (Model 5) reliably complete analogies involving novel tokens (e.g., 1:3 :: 5: ? (7)). In the 1x80 space, this combination of architecture and top-2 eigenvectors averaged analogical performance of 90.5% across 50 iterations, well above a priori chance levels of 25%. Place codes, the full SR matrix, and scrambled eigenvectors never extracted relational representations that support analogical completion, regardless of architecture. Likewise, Models 1-4 did not reliably extract the appropriate relational structure, regardless of the input representation employed (i.e., even when the input representation was the top 2 or 5 eigenvectors).

Why is this particular combination of input representations and architectural biases important? The highest-eigenvalue eigenvectors carry implicit structural information about the dimension. In this 1D space, the 2nd eigenvector (Fiedler vector) here monotonically increases over the range of the domain, and is thus the closest approximation to a linear representation of the native space in the set of eigenvectors. (See Figure 1). In learning over these representations, Model 5 biases the network to represent the explicit bidirectional relation between a and b using anti-correlated conjugate pairs, reflecting the structure of the components of the relational representation (See Figure 4). This bias appears necessary for backpropagation to reliably learn suitable encoder and decoder parameters to support analogy, when using the transformational objective we employ, here (i.e., $\hat{a} = g_\Phi(R_a, b)$, and $\hat{b} = g_\Phi(R_b, a)$).

Figure 4 shows the latent representations in the two nodes of r for single, randomly chosen runs of all 5 models when trained on the top-2 eigenvectors. For Models 3-5, these

two nodes are functionally restricted, corresponding to r_a and r_b. Notably, we see that in Model 5, the latent activations (r_a, r_b) approximate anti-correlated linear representation of the signed distance. Moreover, for a given signed distance, r_a and r_b are in conjugate symmetric states $(0 + r_a, 0 - r_b)$, reflected about the X axis. Note also that many different A,B pairs will produce the same signed distance. For example, 10-5, 23-18, and 76-71, would all be at the same position along the X axis in Figure 4, given that they are all equal in signed distance. Only Model 5, with the conjugate symmetry prior, extracts similar representations in r, encoding the abstract relational structure as stationary over the range of inputs.

It is worth noting how this relates to the parallelogram model (Rumelhart & Abrahamson, 1973), which captures the abstract logic of linear analogies in vector space. The parallelogram model completes the analogy using fixed vector addition and subtraction operations $D = (B\text{-}A) + C$. We note that we do not see our model as standing in competition with an algorithmic parallelogram computation, a la (Rumelhart & Abrahamson, 1973). Instead, the focus of our model as deriving useful representations from experience, using only observation and standard gradient-based learning, coupled with particular inductive biases. Our model can be thought of as learning an encoding from the input (canonical) space to a latent space in which a linear parallelogram-like computation (B-A+C, (Rumelhart & Abrahamson, 1973; Mikolov, Sutskever, Chen, Corrado, & Dean, 2013)) of the analogy can be performed. Here, we use the conjugate symmetry prior on the chained weight connection to encourage r_a to encode the trajectory from b to a, and r_b to encode the reverse trajectory from a to b.

Generalization across 1D native spaces of various size. Here, we show that the extraction of relational information not only allows the network to complete analogies within the domain over which it has been trained, but also to generalize out of the domain of its support (i.e., pure extrapolation). To do so, we train the network on one range of magnitudes (1x20,1x40, 1x80, or 1x160), and test its analogical performance on magnitudes outside of that range (see Figure 5). For example, one network is trained on inputs that differ in magnitude between 1 and 20 units (1x20 space), and then tested on inputs that differ by different ranges of magnitudes (e.g., 1x40, 1x80, 1x160). We repeat this procedure by training on all four ranges, and testing on the others. Note that these different ranges have the same underlying, local transition structure (See Figure 1), but different numbers of states. In all cases, the network can generate analogies in ranges of magnitudes that are beyond the scope of training without further weight updates, including extrapolating from learning in the 1x20 range and testing in 1x160. Thus, given the assumption of suitable procedures for re-computing and normalizing the eigendecomposition in novel domains, this algorithm can naturally generalize to similarly structured environments without retraining.

Extracting and utilizing tree structured representations. Thus far, we have focused on analogy in 1D linear spaces. However, it is clear that human reasoning also exploits other forms of relational structure present in the environment (e.g., (Kemp & Tenenbaum, 2008)), such as trees, rings, and radial geometries. To explore whether the model presented above can be extended to learn, and make use of other, non-linear structure in generalization and analogical inference, we apply it to a simple hierarchical graph.

Specifically we use a tree composed of two identically structured "families" with connected root nodes (See Figure 6). Both families have 4 generations (levels), with equivalent number of individuals per generation. Edges in the graph exist only between parents and children (results are similar when edges between siblings are included). To generate the transition matrix, we assume that the probability of moving from one node to another is 1/node degree, and compute the eigendecomposition over this random-walk transition matrix. Based on the results of the 1D case, we use the top 2 eigenvectors, and compare the performance of Models 1 (standard) and Model 5 (conjugate symmetry prior), including a version of Model 5 with scrambled eigenvectors.

For this tree, the top 2 eigenvectors are highly structured and interpretable (See Figure 6): the highest eigenvalue eigenvector carries information about family identity, and the second highest-eigenvalue eigenvector about generation, invariant to family. We imposed two further constraints on the analogy test used for the 1D space. First, (a, b) training pairs were constrained to come from the same family. Second, the siblings of the target node were prevented from being foils (though, of course, other close relatives such as cousins, parents, or children could be included as foils). Notably, we again see that Model 5, with a conjugate symmetry prior, learning over the top-2 eigenrepresentations is able to successfully complete the multiple choice analogy tasks, despite no experience with the particular (a, b) pairs, and no direct training on analogy. See Figure 6. Although this particular tree structure is a simplification of more complex structures observed in the world, our results suggest that the model can be applied usefully to more complex structures than the simple linear 1D metric focused on above.

Discussion

Here, we considered the possibility that abstract relation learning can derive from the combination of (a) error-driven learning using the vast amounts of perceptually observational data available ((Rao & Ballard, 1999; O'Reilly, Wyatte, & Rohrlich, 2017), with (b) particular inductive biases in the learning algorithm and network architecture. We compared a variety of input representations and model architectures, testing their ability to extract relational information and use that to complete novel analogies in simple 1D and tree structure domains, without explicit training on analogy. We found that two properties of the models are critical for exhibiting this ability. First, the inputs to the model must be mapped into a canonical representational space that carries implicit struc-

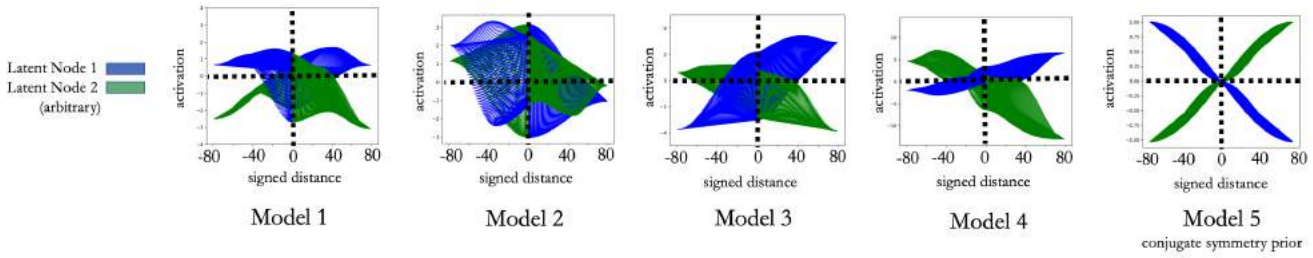

Figure 4: Latent node activations for two nodes as a function of signed distance when trained on top-2 eigenvectors. Only Model 5 (conjugate symmetry prior) learns representations that reliably track the ground truth signed distance. Note that different input pairs produce the same signed distance (e.g., 55-51, 11-7). Every possible pair was plotted here, resulting in the visible, thin individual lines. Notably, only Model 5 reliably produces similar activations in r for different tokens of the same signed distance. Note also that the two latent nodes are anti-correlated.

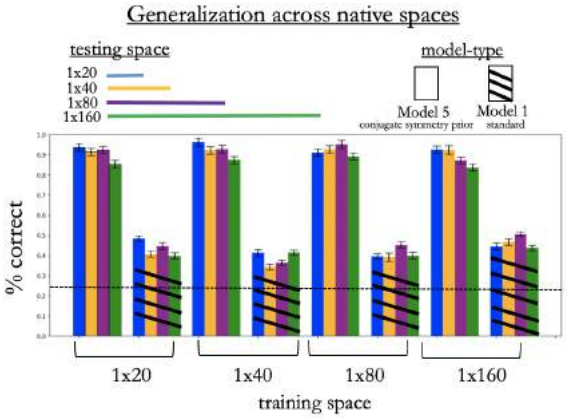

Figure 5: Analogy results when training and testing on native spaces of different size, but the same transition structure.

tural information about the domain (i.e., ordering and neighborhood relations). Learning over these low-dimensional, structured representations (Figure 1) enables the extraction of explicit relational representations, that can be used for analogy. Mapping to a canonical space also allows generalization across environments of different sizes that share structure (Figure 5).

The particular canonical representation we employ is inspired by the relationship between hippocampal place cells and grid cells in medial entorhinal cortex. These grid-cells have been suggested to reflect a decomposition of the predictive map reflecting the transition structure common to spatial environments (Stachenfeld, Botvinick, Gershman, 2017). Evidence for grid-cells has been found in the human brain beyond EC, in medial PFC, posterior cingulate, and lateral inferior parietal cortex (Doeller et al, 2010; Jacobs et al., 2013; Constantinescu et al., 2016), and in conceptual (non-spatial) tasks (Constantinescu et al., 2016). We thus take grid-cells to be one example of the abstract, structured representations that may be shared across domains and exploited for high-level relational reasoning tasks, such as analogy. More broadly, we suggest that similar mechanisms for extracting low-dimensional structure may support other common representational forms. Kemp and Tenenbaum (2008) provide a small inventory of representational forms that recur in human cognition (rings, chains, grids, hierarchies, trees, orders), presenting a hierarchical Bayesian model that identifies the best structural form for a dataset. Understanding how biologically plausible predictive learning mechanisms (coupled with inductive biases) may extract other representational structures is a topic of ongoing work.

Second, we show that if a simple neural network architecture is trained on pairwise relationships among these dimensionally-reduced encodings, and is imbued with a simple, local inductive bias that favors the extraction of conjugate bidirectional relationships among those pairs, it can learn representations that allow it to carry out analogical completions, and generalize this ability well out of the range of its training domain. Intuitively, we can think of the network as asking: having seen a and b, how would I transform a to make it b, and vice versa? We combine this objective with a prior on the relational representation that favors dedicated, but systematically anti-correlated, nodes in the latent space (r_a ,r_b). These nodes may be thought of as a conjugate pair of component relational representations that can be used to reconstruct $a(r_a, b)$ and $b(r_b, a)$. Notably, the learned relations (or trajectories) in the latent space are abstract and approximately stationary with respect to the input domain (i.e., 1-3 = 15-17) (See Figure 4), and can be composed with other object representations to generate analogies.

Though these results are encouraging, they rely on a simplified version of the problem that humans face in generating analogies. One of the most notable features of human analogical ability is the ability to *select* the relevant dimension of variation from the indefinite number of possible relations that might obtain. Indeed, some of the limits in applying the parallelogram procedure (B-A +C) on semantic embeddings as a model of human ability stem from problems handling se-

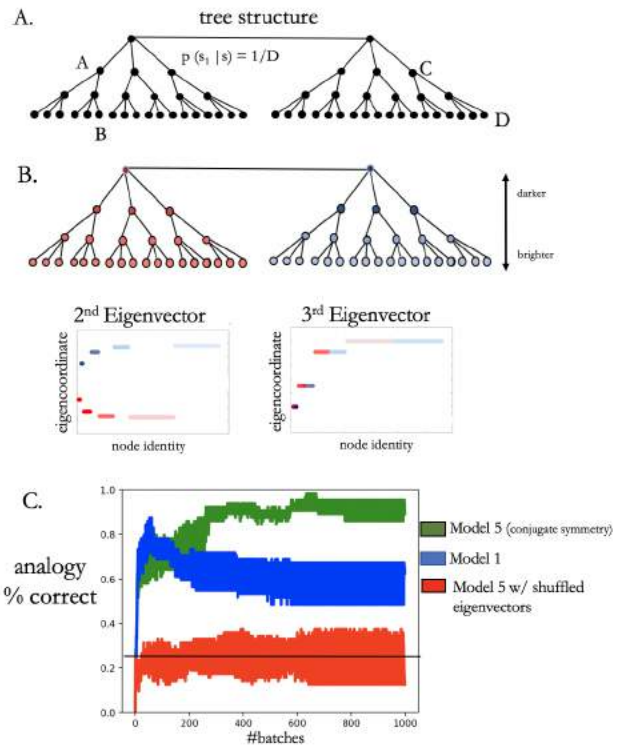

Figure 6: Extraction and utilization of structured representations for the particular tree shown in (A). (B) visualizes the 2nd and 3rd largest eigenvalue eigenvectors. Here, locations in the tree (shown in the upper portion of B) are linked to the points in the eigenplots (lower portion) that share color and brightness. The 2nd EV can be seen to encode family identity (one red, one blue), and the third encodes generation invariant to family (varying in brightness). (C) shows analogy results for this domain.

quencing and context-sensitivity (Chen, Peterson, & Griffiths, 2017). Here, we have pre-selected the relevant dimension for the analogy, focusing instead on general mechanisms for acquiring and utilizing these structured representations. However, a proper understanding of analogy, and human intelligence more broadly, requires directly addressing the relevant search and attentional selection problems, which we see as a critical target for future work.

Learning Cross-linguistic Word Classes through Developmental Distributional Analysis

Daniel Freudenthal, Fernand Gobet, Julian M. Pine
Department of Psychological Sciences, University of Liverpool

Abstract

In this paper, we examine the success of developmental distributional analysis in English, German and Dutch. We embed the mechanism for distributional analysis within an existing model of language acquisition (MOSAIC) that encodes increasingly long utterances, and compare results against a measure of 'noun richness' in child speech. We show that, cross-linguistically, the mechanism's success in building an early noun class is inversely related to the complexity of the determiner and noun gender system, and that merging of determiners gives very similar results across languages. These results suggest that children may represent grammatical categories at multiple levels of abstraction that reflect both the larger category as well as its finer structure.

Keywords: language acquisition; cross-linguistic; distributional analysis.

Introduction

A major question in the study of language acquisition is how children acquire grammatical categories such as noun and verb. One source of information that children might draw on in this process is distributional information – nouns and verbs tend to occur in different lexical contexts (i.e. are preceded and followed by different sets of words). An influential approach to the learning of word classes through distributional analysis is that of Redington, Chater and Finch (1998) who show that it is possible to accurately cluster words into syntactic categories on the basis of the distribution of a small set of high frequency words that precede and follow them. The basic ideas behind distributional analysis have been employed and adapted by several other authors and, in some cases, applied to other languages (Frank et al., 2013; Mintz, 2003; Keibel, 2005).

However, a major weakness of many studies of distributional analysis is that, while they explore mechanisms that are thought to operate in language-learning children, they make limited contact with the developmental literature and child data. Thus, the focus tends to be on building large word classes with high accuracy. As a result, distributional analysis is often carried out on large corpora of complete utterances and hence ignores the developmental fact that most of children's early utterances are just one or two words long.

Freudenthal et al. (2016a, b) aimed to develop a more plausible mechanism by 1. gradually expanding the contexts available to the mechanism in a developmentally plausible way, and 2. simulating actual child data. Freudenthal et al. do this in the context of MOSAIC (Freudenthal et al. 2007, 2015), a computational model that has been used to simulate a range of phenomena in language acquisition. The key learning constraint in MOSAIC is an utterance-final bias: MOSAIC builds up the representation of the input it is trained on in a right-to-left manner. This feature interacts with the statistics and structure of the input language and is responsible for MOSAIC's successful simulation of (amongst others) cross-linguistic differences in the rates at which children produce Optional Infinitive errors.

As MOSAIC sees more input, it represents longer (utterance-final) phrases and thus has more contexts available for distributional analysis. Freudenthal et al. show that, in English, their developmental version of distributional analysis initially tends to link together nouns (which tend to occur in utterance-final position), a finding that is consistent with the claim that children acquiring English form a productive noun category earlier than they form a productive verb category (Akhtar & Tomasello, 1997; Olguin & Tomasello, 1999; Tomasello & Olguin, 1993).

Freudenthal et al. (2016b) also show that MOSAIC builds an initial noun class that is sufficiently large to simulate the rate of noun use in early child speech. Introducing a measure of *noun richness* – the ratio of the number of nouns over the number of nouns plus main verbs – they show that this ratio is considerably higher in early child speech than in child-directed speech. Simulations with MOSAIC show that roughly half of this difference can be explained through high noun richness in the utterance-final phrases in the model's output. Productive use (i.e. substitution) of distributionally similar words was sufficient to raise noun richness in MOSAIC's output to levels near those found in English-speaking children.

Taken together, these results show that it is possible to perform a developmentally plausible distributional analysis and use it to simulate actual child data, and thus greatly enhance the psychological plausibility of the approach. However, Freudenthal et al. (2016b) only apply their mechanism to English, a language that has a relatively fixed word order and is morphologically impoverished, two features that are likely to benefit distributional analysis.

The main aim of this paper is to extend this developmental distributional analysis to German and Dutch, two languages that have more variable word order, and are morphologically more complex (in particular, through their use of gender and case). Our main focus will be on how comparable the results of distributional analysis are, and how well they fit child noun richness scores in the three languages. In particular, we will focus on the complexity of the determiner and noun gender system. Incorporating the analyses within a computational model that learns progressively longer sequences also allows us to gradually expand the contexts available for

distributional analysis and investigate how this interacts with the word orders of the three languages.

Typology of German and Dutch

German, Dutch and English differ in a number of ways that are relevant for the current analyses. Typologically, the main difference is that English is an SVO language, while German and Dutch are SOV/V2 languages where verb position is dependent on finiteness – finite forms take second position (see utterances 1a, 1b and 1c) whilst nonfinite forms take final position (see utterances 2a, 2b and 2c).

1a. I eat a cookie (E)
1b. Ich esse ein Keks (G - I eat a cookie)
1c. Ik eet een koekje (D - I eat a cookie)

2a. I want to eat a cookie.
2b. Ich moechte ein Keks essen (G - I want a cookie eat)
2c. Ik wil een koekje eten (D - I want a cookie eat)

3a. Do you want a cookie?
3b. Willst du ein Keks? (G – Want you a cookie)
3c. Wil je een koekje? (D – Want you a cookie)

English and German/Dutch also differ in terms of question formation (see utterances 3a, 3b and 3c). Where English forms (polar) interrogatives through the use of dummy modal *do*, German and Dutch use (main) verb inversion. These features mean that German and Dutch have a more variable word order, which may impact on the general success of distributional analysis. The verb-final feature may result in lower numbers of nouns occurring in utterance-final position. This in turn may affect the early construction of a noun class through distributional analysis. However, it also raises the possibility that German and Dutch children may show lower levels of noun richness than English children. A similar claim has been made for children learning languages such as Mandarin Chinese and Korean (Choi & Gopnik, 1995)

Table 1: Case marking in German

	Nom.	Gen.	Dat.	Acc.
Masc.	ein/der	eines/des	einem/dem	einen/den
Fem.	eine/die	einer/der	einer/der	eine/die
Neut.	ein/das	eines/des	einem/dem	ein/das
Plural	--/die	--/der	--/den	--/die

A second way in which the three languages differ is in their use of noun gender and case. English has neither gender nor case (except on personal pronouns). German has three genders and marks case on articles and adjectives. Dutch is like German in that it has gender, but is like English in that it does not mark case. Table 1 illustrates the Gender/Case system of German, for the definite and indefinite article. German gender extends to demonstratives, possessives and quantifiers.

Standard Dutch distinguishes two genders[1] (common and neuter), which take the same indefinite article (*een*), but differ in the definite article (*de*/*het*). Gender is marked on adjectives by the addition/omission of an *-e* suffix. This suffix is applied to all adjectives preceding common gender nouns. For neuter nouns it is applied to adjectives following the definite, but not the indefinite article. Dutch gender extends to demonstratives (but not possessives and quantifiers).

One of the consequences of the different case and gender systems of the three languages is that the degree of lexical variation in the position preceding nouns is largest for German, intermediate for Dutch and lowest for English, Construction of a noun category through distributional analysis is therefore likely to be least constrained in English and most constrained in German. However, while gender may hinder the learning of a noun class, it marks a distinction that children need to acquire, and, since it has very little (transparent) semantic or phonological basis[2], it is very likely to be one that has to be learned distributionally. We will examine how the complexity of the determiner system affects the learning of both the overall noun class as well as the finer gender classes. We will first perform a distributional analysis whilst differentiating between all determiners, and then compare the results with an analysis in which we conflate case and gender by merging the different forms of determiners. Keibel (2005) has previously shown that merging determiners in this way is beneficial for learning the German noun category.

Corpora used

A challenge in cross-linguistic research involving corpora of child-directed speech (CDS) is that of ensuring comparability. The number of corpora available is limited and they differ in terms of size, recording situations, age range of the target children and availability of morphological information. We aimed to select from CHILDES a set of corpora for each language that were as comparable as possible in terms of their overall size. For English we selected the 6 largest sub-corpora from the Manchester corpus (Theakston et al., 2001). The Manchester corpus contains corpora for 12 individual children, and contains part-of-speech information for child and adult speech on the morphology (MOR:) tier. The selected corpora typically contained 30,000-35,000 utterances of child-directed speech

[1] Though vestiges of a third gender remain.

[2] There actually are a number of phonological, morphological, and semantic cues to German gender. MacWhinney et al. (1989) show that a neural network trained on 38 of these cues can correctly classify held out nouns. However, since Macwhinney et al.'s model learns in a supervised manner, gender information is actually available to the model. Since gender is essentially defined distributionally, lexical contexts appear a more potent cue to identifying a noun's gender.

per child. For German we selected the Rigol corpus, consisting of 4 children with roughly 45,000 child-directed utterances per child. After limited cleaning up of the corpus, we were able to run the CLAN mor facility, which was able to assign part-of-speech information to ~99% of all word tokens in the corpus. For Dutch, we selected the two children from the Van Kampen corpus. These corpora contain 65,000 and 25,000 maternal utterances. Since there is currently no functioning mor-grammar for Dutch, we assigned to the words in these corpora the most common part of speech derived from the Treetagger (Schmid, 1994).

Study 1: Child Noun Richness

The first analysis concerned children's cross-linguistic use of nouns and (main) verbs[3]. All the corpora used consist of multiple recordings (tapes) at different child ages. For all corpora we counted the number of nouns and verbs in child and adult speech on a tape-by-tape basis, and plotted noun richness (i. e. #nouns / (#nouns + #verbs)) relative to the child's Mean Length of Utterance (MLU) for the relevant tape. In line with current practice in MOSAIC, analysis was performed on utterance types. Figure 1 shows the trendlines for the scatterplot of English, Dutch and German child, and child-directed speech. For clarity, individual data points are not plotted. As can be seen, noun richness scores look remarkably similar across the three languages. While German child noun richness is (initially) lower than it is for Dutch and English, it is considerably higher than it is for adults, and thus suggests that, cross-linguistically, children are equally productive around nouns in the early stages.

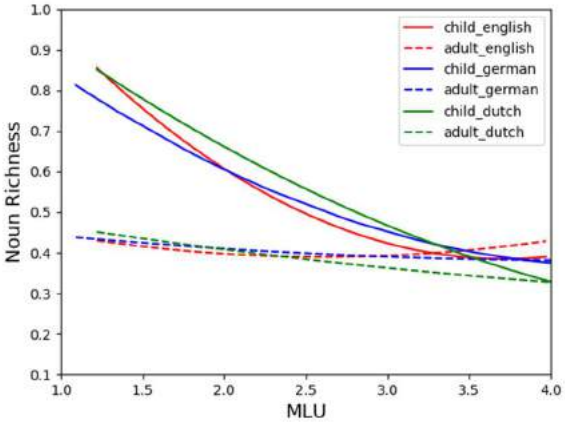

Fig. 1: Noun Richness in English, German and Dutch.

Study 2: Simulations with MOSAIC

Training MOSAIC models

MOSAIC learns from orthographically-transcribed child-directed speech and generates as output corpora of speech that can be directly compared to child speech. Learning in MOSAIC is slow, and takes place by feeding input through the model multiple times. With each exposure, MOSAIC represents more and longer (utterance-final) phrases and is thus capable of producing more and longer output, as is true of developing children. A detailed description of MOSAIC and how it is trained is provided in Freudenthal et al. (2015).

For the current analyses, we performed a distributional analysis at several points in the models' development. Here, we report results from selected runs between 36 and 50.[4] Over this range, the MLU of the utterances represented in MOSAIC (and hence of its output corpus) increases from roughly 2 to 5 words – and thus increasingly approximates corpus-wide statistics. The key consideration here is that, early in training, MOSAIC represents short utterance-final phrases that extend further to the left with increased training. This feature, which is responsible for MOSAIC's successful simulation of a number of phenomena in child speech, has the potential to interact with word order in shaping the cross-linguistic results of the distributional analysis.

The distributional analysis

The distributional analysis was carried out in the same manner for all languages. The target words were the 1,000 most frequent words for a given corpus, and the context words the 150 most frequent words. Utterance endings were also included as contextual elements. At each point in training, we searched the phrases represented in MOSAIC for the target words, and noted how often the context words occurred in the preceding and following position. Thus, for each target word, we generated two vectors that contained the counts for the context words in preceding and following position. Similarity between words was expressed as the similarity between these vectors, and two words were considered to be of the same class if their similarity exceeded a threshold value for both preceding and following position. For the current analyses we expressed similarity in both a non-parametric and a parametric way. We used a Spearman rank-order correlation, as well as cosine similarity based on the square root of the vector counts[5]. Freudenthal et al. (2013) have shown that (for English) a parametric measure is better for classifying nouns, while the rank order is better for classifying verbs. In the current analyses, the rank-order correlation gives better results when applied to English, while the parametric gives better results for German. This finding is in line with reports by Redington et al. (1998) for English and Keibel (2005) for German. Importantly, however, the two

[3] For Dutch and German, modal verbs were included as these can be used as main verbs. Copulas were excluded for all languages.

[4] Run number reflects number of exposures to the input.

[5] This is a departure from Freudenthal et al. (2016b) who used a distance measure that discarded frequency as well as counts from interrogative contexts.

measures give qualitatively similar results when used in isolation, but better quantitative results when combined.

Results

Unmerged determiners

Results for the distributional analysis are reported in Table 2, which shows the number of linked words, overall accuracy (proportion of same class links), noun richness (ratio of noun-noun to noun-noun plus verb-verb links) as well as numbers of links and accuracy for verbs and nouns. Two words were considered to be of the same word class if their rank-order correlation in preceding and following position exceeded 0.40, or their cosine similarity exceeded 0.65.

As can be seen in Table 2, the distributional analysis in English results in an early noun class, with verbs being classified later in development. This pattern is consistent with children showing early productivity around nouns and late emergence of a productive verb class (Akhtar & Tomasello, 1997; Olguin & Tomasello, 1993; Tomasello & Olguin, 1993).

It is also apparent from Table 2 that the mechanism is capable of classifying words with high accuracy, particularly for nouns, but also for verbs (in the later stages). Table 2 also shows that results for the Dutch distributional analysis are similar to those for English, though the mechanism is less successful in linking nouns, and is less accurate overall. German results mirror those from Dutch, but the distributional analysis is even less successful at building a noun class. Thus, the models never exceed 1000 noun links, even in the later stages. Across runs, the German noun class is approximately a quarter of the size of the English noun class.

The results from Table 2 thus suggest that the less constrained word order in Dutch and German leads to lower overall accuracy, but also that the size of the noun class is inversely related to the complexity of the determiner system. This pattern is not surprising, but it appears to be in conflict with the child noun-richness data from Fig. 1, which suggest that children from all three languages are equally productive around nouns. It also suggests that German and (to a lesser extent) Dutch MOSAIC models may struggle to simulate early child noun richness scores[6].

Merged determiners

We examined whether German and Dutch gender and case hamper the construction of a noun category by merging determiners into one lexical item, and adding their respective counts. For German, this meant that all 6 forms of the definite article were merged, as were all 6 forms of the indefinite article (thus maintaining the distinction between the definite and indefinite article). For Dutch, we merged both forms of the definite article. Since there is only one form of the indefinite article, this cannot be merged. Results for the distributional analysis with merged determiners are shown in Table 3.

Table 2: Results of Distributional Analysis for English, Dutch and German

Run	Links	Overall accuracy	Noun-richness	Nouns	Verbs	Noun-accuracy	Verb-accuracy
English							
36	1,641	0.80	0.94	1,218	70	0.83	0.42
38	2,215	0.80	0.91	1,553	153	0.83	0.52
40	3,037	0.83	0.89	2,230	237	0.85	0.63
44	4,144	0.90	0.86	3,164	437	0.91	0.81
50	4,576	0.91	0.83	3,375	615	0.92	0.87
Dutch							
36	1,140	0.73	0.95	774	34	0.77	0.23
38	2,030	0.78	0.96	1,467	62	0.80	0.38
40	2,995	0.81	0.96	2,260	90	0.82	0.43
44	3,496	0.85	0.91	2,582	256	0.85	0.75
50	3,310	0.84	0.80	2,122	502	0.84	0.86
German							
36	841	0.52	0.93	282	20	0.54	0.27
38	935	0.61	0.89	383	43	0.64	0.47
40	1,227	0.71	0.87	581	86	0.71	0.61
44	1,985	0.78	0.78	905	253	0.80	0.84
50	2,563	0.79	0.52	754	697	0.83	0.89

[6] Note, though, that since (unlike Freudenthal et al., 2016b) we do not currently generate output from MOSAIC, we cannot directly relate the size of the noun class to child noun richness scores.

Table 3: Results of Distributional Analysis with merged determiners for Dutch and German.

Run	Links	Overall accuracy	Noun-richness	Nouns	Verbs	Noun-accuracy	Verb-accuracy
Dutch							
36	1,515	0.70	0.96	997	37	0.73	0.17
38	2,749	0.76	0.96	1,955	70	0.78	0.30
40	4,140	0.80	0.96	3,134	104	0.81	0.36
44	5,151	0.84	0.93	3,940	292	0.86	0.65
50	4,788	0.84	0.84	3,290	573	0.85	0.80
German							
36	2,091	0.49	0.97	836	27	0.51	0.15
38	2,399	0.56	0.95	1,095	58	0.57	0.26
40	3,543	0.65	0.94	1,914	131	0.65	0.40
44	5,992	0.73	0.91	3,540	364	0.74	0.73
50	6,287	0.76	0.80	3,226	816	0.77	0.84

It is evident from Table 3 that the merging of determiners results in an increase in the number of nouns that get linked for both languages, but that this increase is considerably larger for German (by a factor of 4) than it is for Dutch (by a factor of 0.4). It is also obvious that the overall results for Dutch and German are now quite similar to the results of the English analysis (though overall accuracy scores are still lower for Dutch and German), and more in line with the cross-linguistic child noun richness scores (see Fig. 1).

Taken together, these results suggest that gender and case are detrimental to learning a noun category through distributional analysis. However, if children are able to ignore the identity of determiners, distributional analysis yields remarkably similar results across the three languages, despite their differences in word order.

Learning gender subclasses

The fact that gender (and case) hamper the learning of a noun category is not surprising since gender divides the noun category into a number of subcategories that differ in their distributional characteristics. A relevant question therefore is to what extent maintaining the distinction between the different determiners allows the mechanism to distinguish (and hence children to learn) the different noun genders. This was investigated by taking the noun-noun links from Table 2, and determining to what extent these involved nouns from the same and different genders. Results (confusion matrices) from run 50 are shown in Tables 4 (German) and 5 (Dutch).

Comparison of Tables 4 and 5 reveals that the distributional analysis is remarkably good at distinguishing the German gender subcategories, at least for the singular genders. At one level, this is not surprising since merging the determiners increases the size of the German noun class four-fold. However, inspection of the actual forms of the German determiners (see Table 1) shows that 6 different forms of each determiner are used in a paradigm containing 16 cells. Most determiners therefore occur with nouns of different genders, suggesting that the German genders are quite confusable.

Table 4: German Gender Confusion Matrix (run 50)

	Masc.	Fem.	Neut.	Pl.
Masc.	216	15	39	5
Fem.	15	198	0	18
Neut.	39	0	203	2
Pl.	5	18	2	25

Table 5: Dutch Gender Confusion Matrix (run 50)

	Common	Neuter	Plural
Common	1415	187	102
Neuter	187	249	10
Plural	102	10	17

Table 4 shows that the distributional analysis is far less successful in Dutch, with many neuter and plural nouns being linked to common gender nouns. This is caused by the fact that Dutch gender is marked on the definite, but not on the indefinite article. The Dutch noun genders are thus distributionally more similar, and far more confusable than the German noun genders. Since there are few cues to grammatical gender other than distributional information, these results suggest that acquisition of gender may be more challenging for Dutch- than for German-learning children.

Conclusions

The main conclusion to be drawn from the analyses reported here is that they provide strong support for the viability of distributional analysis. Thus, we show that it is possible to

obtain plausible (and very similar) results across three different languages that differ in their word order as well as the detail of their gender and case system. Importantly, we do so using a fixed set of parameters, and in the context of a computational model that gradually expands the contexts available to the mechanism – allowing us to investigate how the increasing length of utterances that children represent may affect their word class learning. Moreover, by comparing the results to actual child data (noun richness), we were able to evaluate the relative size of the (early) noun class across the three languages.

However, it is also clear that the successful construction of a noun category depends critically on the complexity of the determiner system, and hence on how determiners are treated. If the identity of the German determiner is maintained, distributional analysis results in a noun class that is very small compared to Dutch and English, but that distinguishes between the different genders quite successfully. Merging the determiners brings the size of the verb class more in line with English and Dutch, but necessarily conflates the different genders. This effect is less pronounced in Dutch. However, the finer-grained structure of Dutch gender is distributionally less well-defined, and thus suggests that it may be more difficult to acquire for language-learning children.

The German (and Dutch) results thus suggest that grammatical categories need to be represented at different levels of abstraction that reflect both their more general properties as well as their finer-grained structure. The suggestion that children may represent both 'merged' and 'unmerged' determiners may seem surprising since one of the key characteristics of children's early speech is the fact that it lacks closed-class items like determiners. However, there is actually considerable evidence that children represent more of the closed class items than they produce.

Lew-Williams and Fernald (2007) show that Spanish three-year-olds in a looking-while-listening task can use the identity of (gendered) determiners to orient towards a target of the relevant gender. Similar findings have been reported for 24-month-old children in French (van Heugten & Shi, 2007), a language where, like Spanish, the determiner is fully predictive of the gender of the noun. Interestingly, children learning Dutch appear delayed relative to French children in this task (van Heugten & Johnson, 2011), thus providing support for the notion that the relatively poor separation of Dutch gender found in the current analyses may make it particularly hard to acquire. Studies on German (Hőhle et al., 2004) also show that children as young as 16 months (but not 12 months), can distinguish between novel words used in a nominal vs. verbal context after being habituated with a determiner-novel word sequence, but not after a pronoun-novel word sequence. These results suggest that children can use determiners to classify nouns from a very young age, but equally that they can use gender information in the on-line processing of speech, at least in languages where determiners reliably predict gender.

Taken together, the results also highlight the strengths of our approach. By embedding distributional analysis within an existing model of language acquisition that simulates children's increasing MLU, applying it to three different languages, and comparing it to actual child data, we were able to investigate how word order and the complexity of the determiner system affect the formation of an early noun class, as well as the potential implications this has for children's representations of closed class items.

Abstract

Given identical informational content, the order in which you receive spatial information may heavily influence the correctness of your mental representation. This can reveal important insights into the specifics of human spatial cognition and the way we integrate information. Despite its importance in everyday life, its causes and the mental processes involved still remain an open question. Most cognitive models so far have focused on modeling only answer distributions or just the most frequent answer given by all participants.

In this paper we take a rather radical approach: We turn to the individual spatial reasoner and focus our analyses on the stream of spatial information and related reaction times, i.e., how the spatial information is represented and cognitively processed. By spanning a space of 243 cognitive spatial models, some of which outperform the current state-of-the art models, it is possible to test the goodness of general principles underlying such models.

Keywords: Spatial Cognition; Reasoning; Continuity Effect; Cognitive Models

Introduction

Imagine that you are new to a city. It is a common experience that it is not very likely that you will have all spatial information available at the same time. Rather, you will receive it piece by piece. However, the way of how we receive spatial information can impact our mental representation, the time to understand the information, and possible conclusions we draw. But how do we process information mentally that we receive? How do we possibly integrate the spatial information into a mental representation? How difficult is it to process the information? What can existing cognitive approaches and computational models contribute?

Spatial relational information can be formulated by two objects and a relation: the first object is the object *to be located*, the relation gives information about how the objects are spatially connected, and the second object which is termed the *reference* object. Consider the following:

(1) The post office is to the left of the train station.
The train station is to the left of the main street.
The main street is to the left of the park.

Can you easily build a mental representation integrating this information at the same time? You should have no difficulty at all! Even receiving this information step-by-step, each new information nicely integrates with the most recent information. Such a problem is called a *continuous description*. Consider now the following description:

(2) The train station is to the left of the main street.
The park is to the right of the main street.
The post office is to the left of the train station.

This time, it might have taken more time and a bit more difficult to build a mental representation from the given assertion. While the information content was identical to before, the information could not be so easily integrated as in problem (1). This was mainly due to the last assertion that related the post office to the train station. Such problems are coined *semi-continuous*. Consider now this last description:

(3) The post office is to the left of the train station.
The park is to the right of the main street.
The train station is to the left of the main street.

Again, if you have received the assertions piece by piece, building an internal representation might have been again more difficult. While again the description has the same information content as all descriptions before, the first and the second assertion were unrelated, requiring to build two unrelated scenarios. Hence, such a problem description is coined *discontinuous*. All three problems allow for constructing an identical arrangement of the objects, namely

post office – train station – main street – park.

Such an arrangement of objects from the assertions is called a *model* of the assertions. These three problems have been investigated by psychologists in the so-called continuity effect (e.g., Ehrlich & Johnson-Laird, 1982; Knauff, Rauh, Schlieder, & Strube, 1998). But, why does the second and especially the third problem appear to be more difficult to be processed by humans? The *stream* of information makes the difference between problem descriptions. In continuous and semi-continuous descriptions, a common middle-term of two successive assertions exists. Since this is not the case in discontinuous orders, these assertions are more difficult to process and may even require to keep two distinct pieces of information in working memory.

Because of the fine-grained nature of this effect, modeling the cognitive processes which underlie it can give insight into how exactly spatial information is processed in the mind. Several cognitive models have been proposed for spatial relational reasoning, among which an implementation in a cognitive architecture (Ragni, Fangmeier, & Brüssow, 2010),

a model for reasoning with intervals (Schlieder & Berendt, 1998), and a stand-alone cognitive architecture (Schultheis & Barkowsky, 2011) (for a recent overview see Friemann & Ragni, 2018). To account for the continuity effect, a cognitive model needs to describe the nature of constructing a spatial model in great detail. This includes the introduction of a measure of difficulty, the *mental cost*, of a specific mental operation to account for the increase in reading times and the drop in accuracy. The cognitive models which satisfy these requirements are the *spatial reasoning as verbal reasoning* model (Krumnack, Bucher, Nejasmic, & Knauff, 2010) and *preferred inferences in reasoning with spatial mental models* (PRISM, Ragni & Knauff, 2013), which we now introduce.

Cognitive Theories, Models, & Complexity

Verbal Reasoning Model (Krumnack et al., 2010). The core assumption underlying the Verbal Model is that deduction processes does not necessarily require deduction-specific mechanisms to operate on internal representations. Instead, a simple order of object terms and some verbal cognitive mechanisms might guide the reasoning process. Following Polk and Newell (1995), cognitive processes in deductive reasoning might be based upon the same processes as language comprehension and generation. The model satisfies the criteria of verbal reasoning as outlined by Polk and Newell (1995). Verbal in that sense refers to transforming between verbal and semantic representations, that is constructing the queue (encoding) and "reading out" information that is not explicitly provided by verbal descriptions. It is assumed that reasoning is accomplished by applying well-trained linguistic processes. The approach does not obviate specific mechanisms but provides a more parsimonious explanation on how inferences can be drawn from given information without assuming additional mechanisms.

The computational model assumes the mental spatial structure to resemble a queue. In the same vein, each mental model has an *implicit direction*. This direction depends on the relation in the first premise and is contrary to the explicit direction in this relation. This can be understood as simulating an expectation on where the next object is about to appear, which can be easily understood by considering Table 3. For example, if the first premise was "The mango is to the left of the pear", the implicit direction would be to the right:

On the other hand, if the first premise was "The pear is to the right of the mango", the implicit direction is to the left:

PRISM (Ragni & Knauff, 2013). PRISM is an implementation of the theory of preferred mental models. The model simulates and explains how preferred models are constructed, inspected to find a putative conclusion, and then varied to find possible counter-examples. A spatial working memory structure is operationalized by a spatial array. A spatial focus inserts tokens into the array, inspects the array to find new spatial relations, and relocates tokens in the array to generate alternative models of the problem description, if necessary. The focus also introduces a general measure of difficulty based on the number of necessary focus operations (rather than the number of models).

Mental Costs and Complexity. The computational model PRISM was the first model to predict reasoning difficulty of spatial problems by assigning unit costs to the focus operations in a spatial working memory, a location where spatial models are built (Ragni & Knauff, 2013). By the numbers of operations PRISM is able to explain among others the continuity effect: as a successive insertion of the terms from left to right, do cost less than switches in the focus direction (semi-continuous case), which costs less than to generate, group, and insert different submodels (discontinuous case). The Verbal Model uses a similar cost measure.

The Order of Information Effect: Data

The order effect for human inferences has been reported in a number of articles (e.g., Ehrlich & Johnson-Laird, 1982; Knauff et al., 1998; Nejasmic, Bucher, & Knauff, 2015) and is explained with the effort to construct a mental representation of the assertions.

Table 1: Order of assertions in Knauff et al. (1998) and Nejasmic et al. (2015). Please note that $\sim$ represents the relation, which is 'left of' in the case of Experiment 1 in Nejasmic et al. (2015) and Knauff et al. (1998), and 'right of' in the case of Nejasmic et al. (2015).

Order	Assertions		
continuous	A $\sim$ B	B $\sim$ C	C $\sim$ D
semi-continuous	B $\sim$ C	C $\sim$ D	A $\sim$ B
discontinuous	C $\sim$ D	A $\sim$ B	B $\sim$ C

Knauff et al. (1998) conducted an experiment, inspired by research of Ehrlich and Johnson-Laird (1982), to test effects on response times and error rates of continuous, semi-continuous, and discontinuous orders of spatial assertions (cp. Table 1) using the relation 'left of'.

The processing times and error rates are summarized in Table 2. While the continuous and semi-continuous order lead to a similar error rate of about 40%, reasoning about discontinuous orders of assertions was more difficult and lead to about 50% errors. Note that the processing time for the third assertion in discontinuous order compared to the other assertions is significantly higher.

Nejasmic et al. (2015) investigated underlying cognitive processes in two experiments using a random presentation of the 72 problems of the three premise orders *continuous*, *semi-continuous* and *discontinuous*. Each premise was presented

Table 2: The four-term-problems in the experiment of Knauff et al. (1998) with reading-times (RT in seconds) and error rates (in percentage correct). Participants were presented with interval relations.

	Assertion			
Order	RT 1	RT 2	RT 3	Error rates
continuous	13.0	11.2	10.9	39.7
semi-continuous	13.6	11.0	11.9	40.1
discontinuous	12.4	13.9	19.5	50.0

sequentially (in a self-paced manner and only one premise visible at a time). The premise described the spatial relation between four small, equal-sized, and disyllabic objects (tools, fruits, or vegetables) for example: "The mango is left of the pear, the pear is to the left of the kiwi, the kiwi is to the left of the apple."

The instruction was to imagine the arrangement described by the premises (in the example: mango – pear – kiwi – apple). Subsequently participants were asked to define the correct arrangement by typing the initial letters of the named objects using the computer keyboard. After the last letter was entered, the trial finished automatically. The next trial started not before the participant hit the "return" key. The program recorded (a) premise reading times (respective time from stimulus onset to key press calling up the next premise), (b) the number of correct responses, and (c) corresponding response times (time from request onset till enter of the last letter).

Experiment 1 and 2 differ mainly in the used relation resulting in different working direction. In Experiment 1 the relation 'left of' was used suggesting a working direction from left to right. In contrast, Experiment 2 used the relation 'right of' resulting in a working direction from right to left. The position of new named objects is leftmost (see Table 3).

Table 3: Example premises and models for a continuous order

	Experiment 1		Experiment 2	
	Premise	Model	Premise	Model
1	A left of B	AB	D right of C	CD
2	B left of C	ABC	C right of B	BCD
3	C left of D	ABCD	B right of A	ABCD

Results from the first experiment are in line with previous findings concerning the continuity effect. Participants need more time to process unrelated information and more errors occur in the discontinuous condition. In the second experiment the continuity effect was presumably counteracted by the working direction. Although processing third premises in the discontinuous condition took the most time, there was an overall and consistent increase of reading times over all conditions. It was expected that reasoners find it more difficult to work in the culturally nonpreferred right-to-left direction, but in the case that the continuity effect results from the integration of two separate models when confronted with discontinuously presented information, the working direction should not matter. So, results support the assumption that one preliminary model is constructed and modified in cases of discontinuity.

Results and Discussion on Aggregated Data

The Kendall rank correlation coefficient τ_b with the mean reaction times for Experiment 1 and 2 of Nejasmic et al. (2015) and the reported data in Knauff et al. (1998) was calculated. We removed all reading times which were outside the 1.5 interquartile range. The results can be found in Table 4.

Table 4: Correlations and significance level for PRISM and the Verbal Model on the aggregated experimental data.

	PRISM		Verbal Model	
	r_{τ_b}	p	r_{τ_b}	p
Nejasmic et al.: Exp 1	.800	.007	0.730	.018
Nejasmic et al.: Exp 2	.033	1	0.225	.501
Knauff et al.	.730	.182	.609	.044

For Experiment 1 from Nejasmic et al. (2015), PRISM had a better correlation than the Verbal Model. The same procedure was done with the data from (Knauff et al., 1998) (Experiment 3 in Table 4), which used the same setting as Experiment 1. PRISM and the Verbal Model correlated significantly with the data.

For Experiment 2 however, the correlations dropped strongly. This indicates that the process to generate a mental model are different from relational descriptions from left to right than building directions from right to left.

As outlined above, many cognitive models have focused on explaining aggregate data. But, how good are these models in predicting each individual reasoner? And, are there other models that can predict individual reasoner better? To further investigate the performance of the models, we turn to the individual reasoners.

To approach this challenge, there are two possibilities: creating cognitive models which are *adaptable to*, or creating cognitive models *designed for* individuals.

The remainder of this paper will investigate the second option. Taking features of models from the literature and insights from psychological experiments, we will span a large space of possible cognitive computational models for spatial relational reasoning.

Generating the Space of Spatial Reasoning Models

To investigate the goodness of the general assumptions, we looked at a whole family of potential models. This approach is driven by the idea that individual participants may not use

the same strategy and their flow of information processing may differ. Hence, rather than constructing a certain model, we identified features in which potential models can differ. These are inspired by proposed cognitive models for spatial relational reasoning in the literature. PRISM, for example, proposes a mental model manipulation device, called focus, which acts just like a foveal area for mental models. The Verbal Model assumes that a spatial mental model has an implicit direction, which can offer an explanation for the better performance in modeling the right-to-left task from Experiment 2 (Krumnack, Bucher, Nejasmic, Nebel, & Knauff, 2011). As for the discontinuous case, the Verbal Model does not offer a solution for the presentation of discontinuous information, as in the connection of two formerly unrelated chunks of information. *PRISM* on the other hand offers a solution in the form of constructing two unrelated mental models, and integrating them group-wise when connecting information is presented.

We chose 8 partly interdependent features to span the space of investigated models, leading to 243 possible cognitive models:

Mental Spatial Structure

The main difference between the Verbal Model and PRISM is the underlying spatial representation structure. PRISM assumes a grid-like structure in the human mind, with a mental focus which inspects one object at a time, can move through the mental representation object by object with an unary cost in each direction, and is persistent throughout the whole task (Ragni & Knauff, 2013). The Verbal Model on the other hand proposes a queue-like structure, meaning that there exists an implicit direction in the mental model, which is dependent on the relation in the first premise (Krumnack et al., 2010). The question whether a mental model has an implicit direction is the focus of the first three main features, leading to the first $2^3 + 1$ possibilities:

Implicit Model Direction Inspired the Verbal Model, models can have a queue-like mental spatial structure with an implicit direction. Moving through this queue in the implicit direction is assumed to be computationally cheap, while moving against this direction is costly. The opposite assumption would be a grid-like mental array similar as is used in PRISM.

Persistency of Direction In the Verbal Model, the implicit direction depends on the relation in the first premise. For the relation 'left of', the direction of the queue would be to the right and vice versa. We added this dependency as a possible feature, as well as the possibility of a reversed dependency, i.e. for the relation 'left of', the direction of the queue would be to the left as well.

Preliminary Integration Following the research in Nejasmic et al. (2015), it seems likely that when reading discontinuous information, such as "a is left of b, c is left of d", reasoners build a preliminary, connected model instead of a second, disjunct model. Therefore, we introduced this idea as another feature for models which assume an implicit direction: Construct a temporary model with the discontinuous information inserted into the mental model in direction of the queue.

Focus

Moving through the mental model is, in PRISM and the Verbal Model, assumed to require some mental operation. Following the terminology in PRISM, we introduce this idea as the so called *focus*, a device which is able to move through the mental model object by object.

If including the focus into the cognitive model, we can further differentiate between different types of foci. For example, while PRISM has a persistent mental focus throughout the whole task, the Verbal Model implicitly introduces a focus-like notion which resets with each premise. The idea is that when a premise contains an object which is already in the queue, the model has to move through the queue from the position of this object. In a sense, this could be described as a focus with the ability to *jump*. The focus feature adds another $2^3 + 1$ possibilities, as a model which assumes a focus can have any of the three mentioned focus features:

Jumping Focus As in the Verbal Model, when reading a premise, the focus can jump to the addressed object which is already existent in the mental model. After this jumping, the focus then has to move one by one.

Access Tail In a queue-structure, like it is assumed in the Verbal Model, the first element, the start of the queue, can be easily accessed. One could assume that the last element, the tail of a mental model, can be accessed just as easily.

Find Reference Object When a premise is read, the object which is already in the mental model has to be found to determine the positioning of the new object. However, if both items already exist in the queue, the relative positioning of the objects *in* the model have to be compared against the new premise. If the focus position is on one of the objects, it could be that for determining the relation between the objects, the focus now only has to move to the other object. However, taking into account the difference between the object *to be located* and the *reference* object, it is possible that the focus has to first move to the *reference* object and then to the object *to be located* to determine the relation between these objects.

Processing the Relation 'right of'

The experiments in Nejasmic et al. (2015) indicated that processing the sentence "a is right of b" is more difficult (at least for speakers of a language which is written from left to right (Krumnack et al., 2011)) than the 'left of'-relation. While the queue-structure in the Verbal Model can account for this fact, we introduced two features to allow a model with a direction-neutral spatial structure, like the one used in PRISM, to show this asymmetry. This feature space comprises 3 possibilities.

Revert When reading "a is right of b", insert b to the right of a first, only to break up that connection and insert it on the left.

Revert only the First Premise Revert only on the first premise, after then the insertion to the left is automatically correct. A model which has the revert-feature, does not have the feature of reverting only the first premise, as the latter is included in the former.

These features result in the following equation for the space of cognitive models:

$$\underbrace{(2^3+1)}_{\textit{implicit direction}} \cdot \underbrace{(2^3+1)}_{\textit{focus}} \cdot \underbrace{3}_{\textit{reverting}} = 243 \qquad (1)$$

Results and Discussion

Best Models for all Participants

Table 5: Correlations r_{τ_b} for individual data from Experiment 1 and all generated models.

	Median	Max	PRISM	Verbal Model
Exp. 1	.197	.22	.22	.218
Exp. 2	-.023	.059	-.05	-.05

To examine the goodness of fit of the generated models for the whole group of participants, we calculated the Kendall rank correlation coefficient τ_b for each model and normalized reading time of participants in the two experiments. The process for normalization was to first correct the reading times of each participant in each condition for outliers, and second to divide the reading times of a specific participant by her maximum reading time. This was done to account for individual processing speed differences and resulted in reading times between 0 and 1 for each trial without losing the relative speed differences of a specific reasoner across trials and conditions. Results from the correlation can be seen in Table 5.

In Experiment 1, PRISM was among the best models, correlating significantly with the normalized reading times ($p < .001$), as did the Verbal Model ($p < .001$). Again, Experiment 2 was much harder to predict for all models. However, also the close to significant correlation of the Verbal Model with the aggregated data disappeared when calculating the correlation with each individual reasoner. It even showed a significant negative correlation ($p = .001$). The correlation coefficient for PRISM was not significant ($p = .051$). Calculating the correlation for both experiments, the models which performed best ($r_{\tau_b} = .171$, $p < .001$) had the following configurations:

The models assume a mental spatial structure that is, contrary to the Verbal Model, persistent in its direction: a rightwards directed queue turned out to perform quite well. Contrary to the results from Nejasmic et al. (2015), models with *no* preliminary integration of features performed better on the two experiments combined. This indicates that this feature needs more investigation in terms of cognitive modeling and psychological investigation. A spatial focus structure with the ability to jump turned out to give the highest performance. The presence of the features considering the access of the last element (tail) and finding the reference object, in the configurations, seems to be, at least within this analysis paradigm, irrelevant.

This indicates several things, among which: (i) that PRISM and the Verbal Model are good models to reproduce the left-to-right tasks, (ii) that for the right-to-left relations, there exist models which can approximate the individual data points better than the models from the literature, and (iii) that restricting cognitive model of spatial reasoning to use only a single model for all participants might soon hit an insurmountable upper bound.

Best Models for Individual Participants

To explore further the idea that individual reasoners may use different strategies, operations or structures, we again calculated the Kendall τ_b coefficient, but this time we allowed for each participant to be assigned the cognitive model which fits best. With this, the median correlation was $r_{\tau_b} = .25$, with a maximum of $r_{\tau_b} = .489$ ($p < .001$).

The previously for the population identified best models only occurred in 42.9% of participants of Experiment 1, and in 14.3% of participants in Experiment 2. The percentage, to which features are present in the individual models, can be seen in Tables 7 and 8.

Table 7: Percentage to which main structural features are present in the best models for the individual reasoner.

	Direction			Preliminary	
	No Direction	Left	Right	Integration	Focus
Exp. 1	16.6%	21.9%	61.6%	52.4%	63.2%
Exp. 2	0%	42.9%	57.1%	28.6%	92.9%

Table 8: Percentage to which secondary features are present in the best models for individual reasoner. The percentages are conditional in the case of focus features, because they only apply if the focus is present.

	Focus				
	Jumping	Tail Access	Find Ref.	Revert	Revert First
Exp. 1	55.7%	50.0%	50.0%	30.8%	65.4%
Exp. 2	65.3%	50.0%	53.8%	17.9%	28.6%

Table 6: Best cost assignment for individual reading time prediction. Possible cost assignments were in the interval between 0 and 1, in increments of 0.1. This assignment yielded a median correlation of $r_{\tau_b} = 0.302$.

Initialization	Insert	Group	Break Links	Move with Dir.	Move against Dir.	Tail Access	New Start	Jump
0.7	0.1	0.1	0.1	0.8	0.5	0.8	0.3	0.8

Alternative Cost Measure

To examine the adequacy of the unary cost measure, we performed a search on the assignment between model actions and mental costs. This was done using Python's `scipy` library for scientific computing[1]. Using a random search algorithm, we explored the space of cost assignments in the interval between 0 and 1, in increments of 0.1. The goal is to find values for the costs, such that the correlation is maximized. For each assignment, we calculated the Kendall τ_b correlation between the predicted costs of each model and each participant's outlier corrected reading times of Experiments 1 and 2 from Nejasmic et al. (2015). We then selected the best model for the individual participants and took the mean of their correlations as the utility for the optimization. The best cost assignment can be taken from Table 6.

Using this method, the best configuration we found achieved a median correlation of $r_{\tau_b} = .302$. The most expensive actions in the assignment were the jumping movement, the access of the tail, and the movement in direction of the queue, or in any direction if there is no implicit direction. Initialization of a model is also costly. The direction *against* the implicit direction was chosen to be less costly than moving *with* the direction. Inserting a new object is not expensive in this assignment, as were breaking connections and setting a new starting node (as was assumed in Krumnack et al., 2011). Similarly, the cost of grouping objects into chunks, which was set to have a cost of n-1 with n being the number of objects in Ragni and Knauff (2013), was also assigned a low cost.

General Discussion

In this paper, we analyzed 243 cognitive models of spatial relational reasoning on their capability to predict *individual* reading times from studies on the continuity effect. These models comprised configurations of features from successful cognitive models from the literature and psychological experiments. While many configurations performed well on aggregated data and a model building direction from left ro right, none of them, including the cognitive models from the literature we based this study on, were able to correctly predict reading times for a direction from right to left. We then followed the notion that different people might use different strategies, and investigated whether assigning a specific cognitive model to individual reasoners would greatly improve performance. While we reached a better correlation using this method, it was still in question why the correlation did not increase even further. We thus challenged the unary cost measure proposed in Ragni and Knauff (2013). Using a search algorithm, we investigated whether a different cost assignment would lead to better predictions for the individual. While the fit got better, it still demonstrates that the individual variety is not yet captured. Especially Experiment 2, which explored a presentation of spatial information using the relation 'right of' revealed a low correlation, on the individual, but also on the aggregated level.

We explored the space of possible cognitive models for spatial relational reasoning using features present in cognitive models from the literature. However, this space did not yield a model which was able to predict reading times across tasks robustly. This can be due to several issues: (i) the core assumption of these models, that we build an abstract spatial representation (a mental model) is wrong, (ii) the true mental processes in our brain when processing spatial relational information differ from those assumed in the models of the literature, or (iii) the assumption of a sequential processing of spatial information has to be revised. The construction of a mental model nonetheless is a notion which is broadly accepted (Johnson-Laird, 2004; Ragni & Knauff, 2013). If the mental processes of model construction differ from those presumed by the state-of-the-art cognitive models, it stands to reason what other processes could be taking place. The sequential processing is common to most cognitive spatial models (Friemann & Ragni, 2018). Modeling of individual data is limited, as individual data, and especially reaction time, is noisy. However, if cognitive models fit averaged data well, but are not able to capture any single individual in the experiment, the meaning of cognitive modeling and goodness-of-fit needs to be reevaluated.

Conclusion

It seems we are still far from understanding the way our mind integrates spatial information. This study challenged common assumptions and practices from the area of cognitive modeling for spatial reasoning. These customs are found to be insufficient when applying them to the modeling of *whole* empirical data sets instead of the aggregated data. There is still much to be learned about the way we process streams of information, what mental operations are performed, and in how far we can generalize conclusions from the aggregated data to the individual human mind.

Abstract

Achieving linguistic proficiency requires identifying words from speech, and discovering the constraints that govern the way those words are used. In a recent study of non-adjacent dependency learning, Frost and Monaghan (2016) demonstrated that learners may perform these tasks together, using similar statistical processes — contrary to prior suggestions. However, in their study, non-adjacent dependencies were marked by phonological cues (plosive-continuant-plosive structure), which may have influenced learning. Here, we test the necessity of these cues by comparing learning across three conditions; *fixed phonology*, which contains these cues, *varied phonology*, which omits them, and *shape*s, which uses visual shape sequences to assess the generality of statistical processing for these tasks. Participants segmented the sequences and generalized the structure in both auditory conditions, but learning was best when phonological cues were present. Learning was around chance on both tasks for the visual shapes group, indicating statistical processing may critically differ across domains.

Keywords: statistical learning; speech segmentation; generalization, language learning; non-adjacent dependencies; implicit learning

Background

Learners must master a number of critical tasks in order to reach linguistic proficiency, including learning how to segment individual words from speech, and learning to identify the constraints that govern the way those words are structured and used. Learners are remarkably adept at these tasks, thanks in part to the myriad cues that speech contains that may assist learning. One such cue is the statistics that describe co-occurrences of items in speech; for instance, the co-occurrence of syllables provides a helpful cue to what constitutes possible words, while information about how those words are used in combination helps learners to discern how the language operates. The ability to detect and draw on this distributional information - *statistical learning* - is suggested to play a key role in language acquisition, for both segmenting speech and for learning about grammatical structure (e.g., Conway, Bauernschmidt, Huang, & Pisoni, 2010; Frost, Monaghan, & Christiansen, 2019; Redington & Chater, 1997).

Since word- and structure-learning appear to have distinct requirements, it is unsurprising that the nature of the (statistical) processes that underlie these tasks has been subject to substantial debate (e.g., Peña, Bonatti, Nespor, & Mehler, 2002; Perruchet, Tyler, Galland, & Peereman, 2004). Central to these discussions have been questions concerning the types of computations required to discover word-like and rule-like items in speech, and learners' capacity to do so by computing over co-occurrence statistics.

These issues have been extensively tested using a classic artificial language learning paradigm (Peña et al., 2002), which examines learners' ability to acquire linguistic structure that is defined in terms of non-adjacent dependencies (i.e., an AxC structure, where A and C are syllables that reliably co-occur, regardless of which x syllable intervenes). AxC languages are used to jointly assess learners' capacity for statistical word and structure learning, since they contain novel words that learners must discover (AxC strings), in addition to structural regularities within those words (A-C relationships).

Initial studies using this paradigm suggested that learners perform statistical computations on the non-adjacent dependencies to segment the speech into individual AxC strings (or *words*), but perform more abstract computations on those words in order to learn about their structure - and perhaps do so only when speech segmentation has been resolved (typically by inserting pauses between words in the training stream).

A recent study by Frost and Monaghan (2016) expanded on this work, aiming to shed further light on two key questions about how word- and structure-learning unfold in language acquisition: whether these tasks occur sequentially

or simultaneously, and whether they may actually utilize similar statistical computations – contrary to prior suggestions. In their study, participants were able to draw on the non-adjacent dependencies to segment continuous speech into words, *and* to learn about the non-adjacent dependency structure that those words contained, possibly simultaneously (though further work is required to conclusively establish the time-course of learning for these tasks). The key difference between this and earlier work on this phenomenon was a slight methodological change which addressed a possible confound in the previous measure of generalization. Specifically, prior generalization tasks typically required learners to indicate a preference for 'rule words' over part-words, with rule words comprising a trained dependency, intervened by an onset/coda from another dependency (e.g., $A_1A_2C_1$ or $A_1C_2C_1$). While such comparisons do permit assessment of preference for the overall structure, they require learners to use trained A and C items flexibly in a way that deviates from their knowledge of syllable position, which may affect performance. Indeed, using amended test items (trained dependencies with entirely novel intervening items), Frost and Monaghan (2016) demonstrated that adults can segment statistical nonadjacent dependencies and generalize them to novel grammatically consistent instances in the absence of additional information, such as pauses between words (see Isbilen, Frost, Monaghan, & Christiansen, 2018, for a replication of this effect).

This finding was contrary to prior suggestions that these tasks are fundamentally computationally distinct (e.g., Peña et al., 2002), and provides crucial evidence to suggest that learners may draw on the same type of statistical processing mechanisms for both of these tasks, and they may do so at the same time during language learning.

However, one possibility that cannot be overlooked is that learning in this study was not just driven by computations over transitional probabilities; learning may have been assisted by the phonological properties of the language. In line with Peña et al.'s (2002) landmark study, Frost and Monaghan (2016) employed an artificial language that contained both statistical dependencies between elements, and phonological structure, which aligned with the non-adjacency structure such that A and C syllables contained plosives, whereas intervening x syllables contained continuants.

Prior research has noted that the pattern of phonological information in artificial languages can significantly benefit learning, and phonological similarity between related elements has been found to support learning of non-adjacent dependencies in particular. For instance, in a series of experiments with a similar paradigm, Newport and Aslin, (2004) demonstrated that learning nonadjacent dependencies between syllables was remarkably difficult to accomplish in the absence of phonological cues (though the difficulty there may also have been due to additional factors, including learnability of the language - i.e., the number of dependencies, and the number of intervening items, which has been shown to impact learning - together with the relative complexity of some of the tests). Similarly, in Gomez and Gerken (1999), dependency learning was supported by phonological distinctions between A/C items and x items, where A and C were bisyllabic, and x were monosyllabic. Yet, research has also suggested that this phonological information should not be essential for learning to take place (Onnis, Monaghan, Christiansen, & Chater, 2004). Further research is therefore required to assess the extent to which this phonological information guided learning in Frost and Monaghan's (2016) study, to determine whether learners can indeed discover words and structures together, from distributional information alone.

In the present paper, we replicate Frost and Monaghan (2016), to confirm that participants can compute over non-adjacent dependencies to learn about both words and structure. We also test whether scores on these tasks correlate, to further assess whether these abilities are similar, or distinct. Crucially, we also compare performance for this replication against that for a condition in which participants are trained on the same language but with a more varied phonology (i.e., without phonological cues). Examining the extent to which segmentation and generalization are possible in the absence of these phonological cues will provide critical insights into how learners rely on statistical computations during language acquisition, by removing the possibility that successful performance is due to additional information outside of the syllable distribution.

While manipulating properties of the language allows us to determine how multiple cues interact with statistical learning, it does not inform us about whether that learning is due to domain-specific mechanisms, or whether language learning involves the specific application of general-purpose learning mechanisms (Frost, Monaghan, & Tatstumi, 2017; Siegelman & Frost, 2015). To further explore adults' capacity to compute non-adjacent dependencies, we also assessed whether their ability to do so is unique to language, by extending the paradigm to examine non-adjacent dependency learning from non-linguistic sequences (comprising shapes). This condition will help constrain theorizing on the generality of the mechanisms used for these tasks.

Thus, in this study we examine whether adults' capacity for segmenting and generalizing non-adjacent dependencies extends to more varied linguistic stimuli, or if it is contingent on a correspondence between distributional and phonological cues to structure. We will also assess whether this capacity is similar or different across modalities. We expect that participants will demonstrate knowledge of words and within-word structure (i.e., non-adjacent dependencies) in both language conditions (Frost & Monaghan, 2016; Onnis et al., 2004), and in the shapes group, in line with the suggestion that statistical learning mechanisms may serve learning broadly across modalities (e.g., Frost et al., 2017). We predict that segmentation and structure learning will benefit from phonological cues, but that these will not be essential for learning (Onnis et al., 2004). Further, we expect that structure learning will be better for linguistic than nonlinguistic input (due to increased experience with learning linguistic structure

relative to structured sequences of shapes; Siegelman & Frost, 2015).

Method

Participants

90 Cornell University undergraduates (age: M = 19.6 years, range = 18-24 years; 49 females, 41 males) participated for course credit. All participants were native English speakers.

Design

Participants were randomly allocated to one of three conditions (each N = 30): *fixed phonology*, where AxC sequences contained plosive-continuant-plosive structure (Frost & Monaghan, 2016, Peña et al., 2002), *varied phonology*, which randomized the allocation of plosives and continuants to different positions within words, and *shapes*. These conditions permit comparison of learning from the original training input (fixed phonology) with an amended version containing no reliable phonological cues to word structure (varied phonology), and also a non-linguistic analogue. This will provide critical assessment of whether the pattern of learning demonstrated by Frost and Monaghan (2016) is unique to the properties of the input used in that study, or whether it can be extended to more varied linguistic input, as well as input in a different modality.

Stimuli

Speech stimuli were created with Festival speech synthesiser, from a pool of 9 monosyllabic items (*pu, ki, be, du, ta, ga, li, ra, fo*), as used in Peña et al. (2002), and three additional monosyllabic items (*ve, zo, thi*). These additional syllables were reserved for the generalization task for the fixed phonology group in line with prior research (Frost & Monaghan, 2016), but formed part of the general syllable pool for the varied phonology group, to maximise variability. Shape stimuli were created from the Fiser and Aslin (2002) set of novel shapes (novel shapes in black on a grey background).

Familiarization Syllables/shapes were concatenated into triadic sequences that followed an AxC structure, with A, x, and C representing an individual syllable/shape. There were three A-C pairings, and three x items that could be used in all pairings ($A_1X_{1-3}C_1$, $A_2X_{1-3}C_2$, and $A_3X_{1-3}C_3$), giving 9 strings in total.

For the fixed phonology condition, syllables were mapped onto words pseudorandomly, such that A and C syllables were plosives, whereas x syllables were continuants, meaning each AxC string had a plosive-continuant plosive structure (e.g., *puraki*). For the varied phonology condition, syllables were randomly allocated to A, x, and C positions, meaning there were no reliable phonological cues that could guide learning. For the shapes condition, shapes were randomly allocated to A, x, and C positions, providing a visual non-linguistic analogue of the varied phonology condition. See Table 1 for example stimuli for each condition.

Table 1: Example stimuli for each condition

Condition	Triads
Fixed Phonology	*puliki, puraki, pufoki* *beliga, beraga, befoga* *talidu, taradu, tafodu*
Varied Phonology	*livedu, liradu, likidu* *fovezo, forazo, fokizo* *bevepu, berapu, bekipu,*
Shapes	
Syllable/shape triplets were concatenated into familiarization streams containing 900 sequences (100 repetitions of each individual AxC sequence), in line with the materials used by Frost and Monaghan (2016). For speech stimuli, this was done using the Festival speech synthesizer (Black et al., 1990), and for shape stimuli this was done using Eprime 2.0. For all conditions, training streams contained no immediate repetition of individual AxC sequences.

For the fixed phonology and varied phonology conditions, the training stream lasted for 10.5 minutes, and was edited to have a 5-second fade-in and fade-out, to avoid providing cues to word boundaries.

For the shape sequences, presentation of the training stream took 22 minutes overall. For comfort this was split into 3 blocks of 300 sequences, and participants were invited to take short breaks in between blocks if desired. To ensure stimuli were analogous to the linguistic input, sequences were programmed such that shapes were presented sequentially, one by one. Shapes were presented for 225 ms in the centre of the screen, with a 225 ms inter-item interval between all shapes for comfortable viewing (note that since this occurs between all shapes, it does not cue segmentation). Presentation criteria were in line with those used in a comparable study by Frost et al. (2017). Analogous to the 5 second fade-in/-out applied to the speech streams, visual sequences always began and ended mid-triad, to prevent participants receiving any information about sequence boundaries at the start/end of the streams (this is true for the beginning and end of the entire sequence, and also for either side of the scheduled breaks).

To control for the relative ease of learning particular dependencies, for each condition 8 versions of the language were generated and counterbalanced across participants. For the varied phonology and shapes stimuli, these were created by randomly assigning syllables/shapes to A, x and C roles. For the fixed phonology stimuli, these were created by

randomly assigning plosives to the A and C roles, while x items were always the same (see Frost & Monaghan, 2016).

Testing Learning was assessed using a two-alternative forced-choice (2AFC) test of segmentation and generalization. This contained 18 trials, nine of which assessed segmentation, and nine of which assessed generalization. Segmentation trials contained word versus part-word comparisons, with words being AxC items that occurred in the training stream, and part-words spanning word boundaries such that they comprised the end of one word and the start of another (e.g., xCA, CAx). Generalization trials contained rule-word versus part-word comparisons, where rule-words were trained dependencies but with novel intervening items (e.g., A_1NC_1), and part words were structured as before, but with one syllable replaced with a novel syllable (e.g., NCA, CNA, CAN). This was to control for the possibility that participants' responses on these trials were due to novelty alone (see Frost & Monaghan, 2016, for further discussion. Ongoing work by Isbilen, Frost, Monaghan and Christiansen further explores these generalization effects using $A_1N_1C_1$ vs. $A_1N_1C_2$ comparisons).

Procedure

Familiarization Participants were presented with a familiarization stream which comprised either sequences of speech (10.5 minutes), or sequences of shapes (~22 minutes). Participants were instructed to pay attention to the sequences, and the shapes group was instructed to take optional breaks at the designated pauses if required.

Testing At test, participants completed a 2AFC task comprising 18 trials; nine segmentation trials (words versus part-word comparisons) and nine generalization trials (rule-words versus part-word comparisons). Presentation of segmentation and generalization trials was randomized. Participants were instructed to carefully listen to/look at each test pair, and indicate which of the two best matched the training stream they had just heard/seen.

Results and Discussion

Accuracy Scores

Accuracy scores for each condition are shown in Figure 1. One-sample t-tests (two-tailed) were conducted on the data for each group to compare performance to chance.

For the fixed phonology group, performance was significantly above chance for both the segmentation (M = .709, SD = .245), $t(29)$ = 4.659, p < .001, d = .853 and generalization tasks (M = .661, SD = .173), $t(29)$ = 5.100, p < .001, d = .936, replicating Frost and Monaghan's (2016) demonstration that learners can segment and generalize non-adjacent dependencies from continuous speech. For the varied phonology group, performance was also significantly above chance for both tasks (segmentation: M = .623, SD = .199, $t(29)$ = 3.391, p = .002, d = .618; generalization: M = .594, SD = .217, $t(29)$ = 2.366, p = .025, d = .433), suggesting that acquisition of statistically defined non-adjacent dependencies in this task is not contingent on the phonological properties of the speech input (i.e., phonological similarity between dependent syllables).

For the shapes group, however, performance on the segmentation task was only marginally above chance (M = .552, SD = .156), $t(29)$ = 1.827, p = .078, d = .333), and performance on the generalization task was at chance level (M = .485, SD = .205), $t(29)$ = -.410, p = .685, d = -0.073) – indicating that adults' ability to segment and generalize sequences using non-adjacent transitional probabilities may not extend to visually presented non-linguistic input.

Segmentation and generalization performance were significantly correlated for the fixed phonology (r = .385, p = .036) and varied phonology (r = .625, p <. 001) groups, but not for the shapes group (r = .281, p = .133).

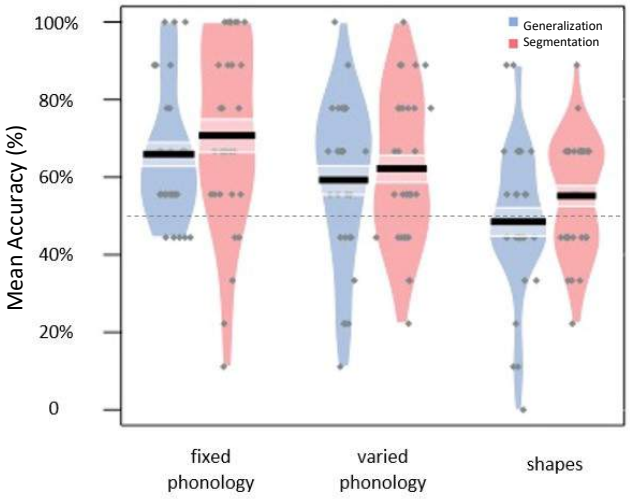

Figure 1. Pirate plot depicting performance on the segmentation and generalization tasks for each condition. Mean scores are shown in black, with standard error in white. The distribution of scores is depicted in red for the segmentation task, and blue for the generalization task, with individual participants' scores in grey. The dashed line indicates chance level.

Comparing performance across groups

To compare performance across each of these groups, Generalized Linear Mixed Effects (GLMER) analysis was conducted on the data, examining whether segmentation and generalization scores differed according to whether participants were trained on sequences comprising varied or fixed phonology, or shapes. A significant main effect of condition would imply different overall performance across the groups, while a significant main effect of test type would indicate that participants performed differently on the segmentation and generalization tasks overall. An interaction between these variables would tell us that participants' performance on the segmentation and generalization tasks differed as a function of their condition – indicating that adults' capacity for statistical learning on these tasks differs

across conditions, and possibly across domains, shedding light on the generality of the possible mechanism(s) that may underlie performance.

GLMER analysis was performed on the data (Baayen, Davidson, & Bates, 2008), modelling the probability (log odds) of response accuracy at test considering variation across participants and materials. The model was built incrementally, with random effects of subjects, particular test-pairs, and language version (to control for variation across the randomized assignments of phonemes to syllables). Random slopes were omitted if the model failed to converge with their inclusion (Barr, Levy, Scheepers, & Tily, 2013).

We then added condition (varied phonology, fixed phonology, and shapes) as a fixed effect, and considered its effect on model fit with likelihood ratio test comparisons. There was a significant effect of condition (model fit improvement over the model containing random effects: $\chi(2)^2 = 7.903$, $p = .019$), with the shapes group performing significantly worse than the fixed phonology group (difference estimate = -.767, *SE* = .257, *z* = -2.987, *p* = .003). The fixed phonology group also outperformed the varied phonology group, however this difference was marginal (difference estimate = -.389, *SE* = .217, *z* = -1.788, *p* = .074). We then added test type (segmentation and generalization), to see whether participants performed differently on each type of task. The effect of test type was marginal (model fit improvement over the model containing random effects: $\chi(2)^2 = 3.144$, $p = .076$) with participants performing better on the segmentation task than the generalization task (difference estimate = .224, *SE* = .125, *z* = 1.791, *p* = .073).

We then added the interaction between condition and test type, to see whether performance on the tasks differed according to the input participants had received. The interaction was not significant (model fit improvement over the model containing random effects: $\chi(2)^2 = .366$, $p = .833$), suggesting participants performed similarly across each of the conditions. See Table 2 for a summary of the final model.

Table 2: Summary of the GLMER (log odds) for accuracy scores.

Fixed effects	Estimated coefficient	SE	Wald confidence intervals 2.50%	97.50%	z	Pr (>|z|)
(Intercept)	.7405	.2082	.3325	1.149	3.557	.0004
Condition: Shapes	-.7658	.2583	-1.272	-.2595	-2.965	.003
Condition: Varied Phono	.-.3883	.2183	-.8161	.0395	-1.779	.0753
Test_type	.2235		-.0211	.4680	1.791	.07332
Random effects	**Variance**	**Std. Dev.**				
Subject (Intercept)	.355	.5958				
Test Pair (Intercept)	.5871	.773				
Lang_version	.0019	.0435				
	AIC	BIC	logLik	Deviance		
	2097.6	2140.8	-1040.8	2081.6		

1620 observations, 90 participants, 18 trials. R syntax for the final model is: NAD_DG3 <- glmer (testresponse.ACC ~ condition + test_type + (1|subject) + (1+lang_ver|test_pair), data =NAD_DG, family=binomial, control=glmerControl(optimizer="bobyqa",optCtrl=list(maxfun=100000))).

General Discussion

Recent evidence for the similarity (and possible simultaneity) of statistical segmentation and generalization has advanced our understanding of the way these processes unfold during language acquisition (see Frost & Monaghan, 2016, and see e.g,, Peña et al., 2002 and Perruchet et al. 2004, for more on the earlier debate about the nature of these tasks). Yet, due to the phonological properties of the training language, it is possible that learning in this recent study was not solely contingent on the statistical regularities contained within the language; learning may have been assisted by the plosive-continuant-plosive structure that AxC sequences adhered to (e.g., Newport & Aslin, 2004).

To explore this possibility, the study at hand examined adults' capacity for non-adjacent dependency learning across three conditions; the first of which used the input from Frost and Monaghan (2016) (see also Peña et al., 2002), which contained the phonological structure described above (termed the *fixed phonology* condition). The second condition omitted these phonological cues, such that AxC sequences had no fixed phonological structure (the *varied phonology* condition). The third condition tested learning from sequences of shapes, to provide a non-linguistic assessment of non-adjacent dependency learning, with a view of considering whether learning was comparable across modalities — perhaps drawing on similar statistical mechanisms. The critical test was whether participants in each group demonstrated learning (i.e., performed above chance), and whether performance in the varied phonology and shapes groups differed significantly from the fixed phonology group.

Participants in both language conditions performed significantly above chance on the segmentation and generalization tasks. This finding replicates the results of Frost and Monaghan (2016), showing that speech segmentation and structural generalization may proceed together during language learning, and can be accomplished from the same distributional statistics (though additional research is required to conclusively establish the precise time-course of learning for these tasks). Further, our results demonstrate that adults' capacity for learning non-adjacent dependencies extends to more phonologically diverse input. However, the difference in overall performance in these conditions was approaching significance, with results indicating that phonological cues were advantageous for learning (evidenced by marginally higher scores for the fixed phonology than the varied phonology group) — in line with Newport and Aslin's (2004) suggestion that such cues were important for learning. Critically though, our data indicate that these cues were not essential (Onnis et al., 2004).

In previous studies of word and structure learning, segmentation and generalization have tended to be tested separately. In the current study, these tasks were completed by all participants (within subjects). We show that the same learners can segment non-adjacencies from speech, and generalize them to new instances (see also Isbilen et al., 2018). In line with previous studies, performance on the segmentation task was higher than that seen for the generalization task (see Isbilen et al., 2018, for a comparable finding), and crucially performance on these tasks was significantly correlated for both language conditions — adding further support to the notion that they may be underpinned by similar mechanisms.

The results for the shapes group followed the same general pattern as those seen in the varied phonology and fixed phonology conditions, with a trend toward higher performance on the segmentation task than the generalization task. However, scores for this group were significantly lower than those seen for the fixed phonology group, with accuracy scores on the segmentation task being only marginally above chance, while performance on the generalization task was at chance level. It is important to note that the shape stimuli differ from the speech stimuli in two key ways: they are both visual and non-linguistic, and therefore differ both in modality and domain. Thus, this pattern of results could be attributed to a number of possible explanations.

One possibility for the difference between the language and the shape task is that there are critical differences in statistical learning across modalities, with tasks being underpinned by different mechanisms (e.g., Conway & Christiansen, 2005). A second possibility is that, for the shapes group, performance could have been negatively affected by participants' relative lack of experience with learning distributionally defined streams containing sequences of visual non-speech input (compared to experience with heard speech) (e.g., Siegelman et al., 2018). Another possibility is that the difference in performance is due to key differences in task demands: in the speech conditions, the presentation of stimuli is such that participants have no choice but to attend (be that actively, or passively). However, in the shapes condition, this is not necessarily the case. Thus, it is possible that the lower scores observed for this group are (at least in part) due to participants attending less to the input during training (and thus, learning less during familiarization). Ongoing replications of this work employing a cover task that maintains participants' attention will help to unpack these possibilities.

To summarise, these data provide further evidence that adults can compute non-adjacent dependencies to discover words and within-word structure from continuous speech. This supports the notion that these tasks may be underpinned by similar statistical processes, and may occur together during language learning. Further, results illustrate that these abilities are not dependent on phonological cues, suggesting that adults' capacity for performing statistical computations over linguistic input is even more powerful than previously suggested.

Reframing Convergent and Divergent Thought for the 21st Century

Liane Gabora (liane.gabora@ubc.ca)
Department of Psychology, University of British Columbia
Kelowna BC, V1V 1V7, CANADA

Abstract

Convergent and divergent thought are promoted as key constructs of creativity. *Convergent thought* is defined and measured in terms of the ability to perform on tasks where there is one correct solution, and *divergent thought* is defined and measured in terms of the ability to generate multiple solutions. However, these characterizations of convergent and divergent thought presents inconsistencies, and do not capture the reiterative processing, or 'honing' of an idea that characterizes creative cognition. Research on formal models of concepts and their interactions suggests that different creative outputs may be projections of the same underlying idea at different phases of a honing process. This leads us to redefine convergent thought as thought in which the relevant concepts are considered from *conventional contexts,* and divergent thought as thought in which they are considered from *unconventional contexts.* Implications for the assessment of creativity are discussed.

Keywords: Alternate Uses Task; concepts; context; convergent thinking; divergent thinking; potentiality; quantum model; Remote Associates test

Introduction

Other species perceive, make decisions, and take action, but our ability to adapt ideas to our own needs, tastes, and perspectives, and express ourselves through language, art, technology, and other means, is exceptional. Thus, understanding creative thinking is central to understanding our humanness.

In creativity research, as in other areas of cognitive science, there is a long history of dual process theories, which assert that there are two kinds of thought, or that thought varies along a continuum between two extremes (Evans & Frankish, 2009; James, 1890/1950, Sloman, 1996). In the creativity literature the distinction is usually made between convergent and divergent thinking[1]. *Convergent thought* is defined and measured in terms of the ability to perform on tasks where there is a single correct solution, while *divergent thought* is defined and measured in terms of the ability to generate multiple different solutions (Guilford, 1967). A widely used test of convergent thinking is the Remote Associates Test (RAT) (Mednick, 1968). A typical RAT question is: What is the common associate of TANK, TABLE, and HILL? The answer is: TOP. A widely used divergent thinking test is the Alternate Uses task, which asks questions like 'think of as many uses as you can for a brick' (Christensen, Guilford, Merrifield, & Wilson, 1960). Responses are most often rated in terms of *fluency,* the total number of ideas generated in a given time. Often they are additionally rated in terms of *originality,* the number of unusual or statistically infrequent ideas. Fluency and originality are considered to reflect the quantity and quality of ideation performance, respectively. Occasionally they are also rated in terms of *flexibility,* the number of different categories of ideas. On rare occasions answers are rated for *elaboration:* the amount of detail given, or evidence that the individual has followed an associative pathway for some distance.

Although these characterizations of convergent and divergent thought have stuck for half a century, as formulated, they present inconsistencies. For example, it is often said that a creatively demanding problem requires both convergent and divergent thought (e.g., Beersma & De Dreu, 2005; Gibson, Folley, & Park, 2009; Kerr & Murthy, 2004). However, given that convergent and divergent thought are defined in terms of the number of correct solutions, this makes no sense. A problem either has one correct solution or it has many; it cannot have both one and many. Moreover, the way convergent and divergent thought have been defined and measured is inconsistent with how people think about creativity; for example, although divergent thinking is thought to be the most promising candidate for the foundation of creative ability (Plucker & Renzulli, 1999; Runco, 2007), performance on the RAT would seem to be a better indicator of creativity than many tasks that would be classified as a divergent thinking task, such as 'list as many things as you can that are red'. Finally, it is often noted that earlier responses on a divergent thinking task are less creative than latter ones (Beaty & Silvia, 2012), but if divergent thinking is characterized in terms of the number of possible responses, this is the opposite of what one should expect, because with each response one gives, the number of remaining possible responses decreases by one. Thus, the conventional view would predict that, as one proceeds, one should start thinking more *convergently,* not more divergently.

More fundamentally, as noted elsewhere (Piffer, 2012), divergent thinking research, and creativity research in general, emphasizes the generation of multiple ideas over what is sometimes called *honing*—recursively reflecting on a question or idea by viewing it from different perspectives with the output of each such reflection providing the input to the next (Gabora, 2007, 2017). One thereby comes to a deeper, more nuanced understanding of it. Honing differs from elaboration in that it does not include additions or

[1] Sometimes the distinction is between associative and analytic thought (e.g., Chrusch, C. & Gabora, L., 2013), or executive versus generative (e.g., Ellamil, Dobson, Beeman, & Christoff, 2012). See (Sowden et al., 2014) for how convergent and divergent thinking relate to other dual process theories.

modifications to the idea that are tacked on willy-nilly; it refers specifically to modifications that arise in response to an overarching conceptual framework that is shepherding[2] the creative process. The structure of this overarching framework reflects the individual's *worldview:* their self-organizing web of understandings about their world and their place in that world (in other words, the creator's mind as experienced 'from the inside').

Like other self-organizing systems, a worldview continually interacts with and adapts to its environment to minimize internal *entropy,* a measure of uncertainty and internal disorder. Hirsh, Mar, and Peterson (2012) use the term *psychological entropy* to refer to anxiety-provoking uncertainty, which they claim humans attempt to keep at a manageable level. Noting that uncertainty can be experienced not just negatively as anxiety but also positively as a wellspring for creativity (or both), the term psychological entropy has been expanded to refer to *arousal*-provoking uncertainty. Redefining psychological entropy in terms of arousal rather than anxiety is consistent with findings that creative individuals exhibit greater openness to experience and higher tolerance of ambiguity (Feist, 1998), which could predispose them to states of uncertainty or worldview inconsistency (Gabora, 1999). Their higher variability in arousal (Martindale & Armstrong, 1974) reflects a predisposition to invite situations that increase psychological entropy, experience them positively, and resolve them. In this way, psychological entropy—a macro-level variable acting at the level of the worldview as a whole—generates emotions that play a role in guiding and monitoring creative tasks.

Thus, honing continues until psychological entropy decreases to an acceptable level. In Piagetian terms, during honing the individual assimilates each new understanding of the idea, and the individual's worldview changes to accommodate this new understanding. Insight is then explained in terms of *self-organized criticality* (SOC) (Gabora, 2001, 2017; Schilling, 2005), a phenomenon wherein, through simple local interactions, complex systems tend to find a critical state poised at the cusp of a transition between order and chaos, from which a single small perturbation occasionally exerts a disproportionately large effect (Bak, Tang, & Weisenfeld, 1988). Thus, while most thoughts have little effect on one's worldview, an idea we call *insightful* is one for which one thought triggers another, which triggers another, and so forth in an avalanche of conceptual change.

Surely, whether one is writing a novel, or composing a symphony, or inventing a new kind of solar panel, this kind of honing process is central to the creative act. Moreover, the ability to hone an idea may have little to do with the ability (or patience) to engage in a futile exercise like coming up with uses for a brick, or things that are red. A refinement on conventional measures of divergent thinking, in which participants indicate what they think are their two most creative answers, and these answers are rated on a 5-point scale, shows good reliability and high predictive validity without the fluency confound (Silvia et al, 2008). However, one could still score highly on this version of the test without having engaged in honing.

Our conception of convergent and divergent thinking may be distorted by our everyday experience in the physical world; because objects in the world exist in different places and have distinct, definite boundaries, it may be difficult to wean ourselves from the intuition that ideas in the mind do as well. It has been argued on the basis of evidence from research on the attributes of associative memory, that the common assumption that creativity involves searching through a space of discrete, separate possibilities, selecting the best, and tweaking it, is misleading (Gabora, 2007, 2010, 2018). This is also what is suggested by research on the formal structure of concepts and their interactions. The goal of the rest of this paper is to, without going into mathematical details, show how this research on concepts points to a new conception of convergent and divergent thinking that resolves the above inconsistencies, and potentially catalyzes a deeper understanding of how the creative process works.

The approach to concepts that I will draw upon is sometimes (somewhat unfortunately) referred to as the *quantum approach* (Aerts, Gabora, & Sozzo, 2013; Aerts & Gabora, 2005; Blutner, Pothos, & Bruza, 2013; Busemeyer & Bruza, 2012; Busemeyer & Wang, 2018;; Gabora, 2001; Gabora & Aerts, 2002; Pothos, Busemeyer, Shiffrin, & Yearsley, 2017). It is called this not because it has anything to do with quantum particles, but because it uses generalizations of mathematical structures originally developed for quantum mechanics. The motivation and rationale for this approach are provided elsewhere (Aerts, Broekaert, Gabora, & Sozzo, 2016b; Bruza, Busemeyer, & Gabora, 2009). For now it is noted that this research by no means aims to reduce cognitive psychology to physics. Rather, much as was the case with other branches of mathematics such as complexity theory and even number theory, structures originally developed by physicists were later found to have applications in other domains. In the quantum approach, concepts are viewed not as fixed representations or identifiers, but as bridges between mind and world that are sensitive to context and that actively participate in the generation of meaning (Gabora, Rosch, & Aerts, 2008).

Potentiality, Context, and Creative Thought

The gist of the new view of creative thought suggested by concepts research is conveyed by the photograph below of a woodcutting with light shining on it from three different directions, yielding three differently shaped shadows: that of a G, an E, and a B (Figure 1). Though each shadow is different, they are all projections of the same underlying object. We could say that the woodcutting has the *potentiality* to *actualize* different ways, and to actualize in one of these ways requires an *observable* or *context,* in this

[2] This word is chosen deliberately because it implies that the process is neither entirely top-down nor entirely bottom-up.

case, light shining from a particular direction. We can refer to the state of the woodcutting when no light is shining on it as its *ground state*. While it is tempting to assume that a bout of creative thought entails the generation of multiple distinct, separate ideas, there may be a single underlying mental representation that, like the woodcuttings, is ill-defined, and affords some degree of ambiguity in its interpretation. Just because the different sketches of a painting, or prototypes of an invention, take different forms when expressed in the physical world, that doesn't mean they derive from different underlying ideas in the mind. Just as the three shadows of each of the two woodcuttings in Figure 1 are projections of the same underlying object, the sketches or prototypes may be different external realizations of the same underlying idea at different stages of a creative honing process. In other words, these different outputs are different articulations of the idea as it appears looked at from different perspectives. Midway through a creative thought process one may have an inkling of an idea but not yet know whether, or exactly how, it could work. Because it is 'half-baked', it may be more vulnerable to interpretation, meaning that it could appear quite different when looked at from a different perspective.

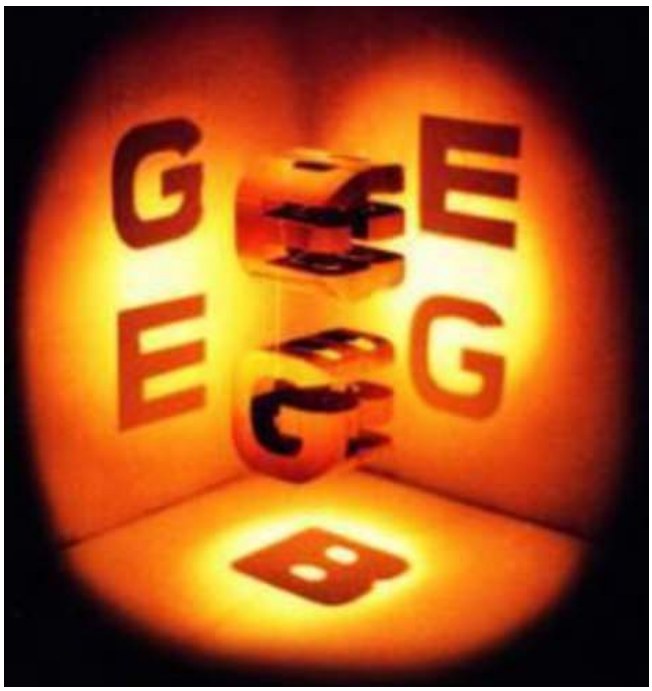

Figure 1: Photograph of ambiguous woodcuttings taken from the front cover of '*Gödel, Escher, Bach: An Eternal Golden Braid' by* Douglas Hofstadter (1979). The top 'triplet' (as he calls them) is not simply a rotated version of the one below it; it is a different shape. (Used with permission.)

Note that the two woodcuttings in Figure 1 have two different shapes, yet they yield the same three shadows. To distinguish the shape of the woodcutting above from the woodcutting below would require that light be shown on them from still more angles, casting shadows that would not look like any particular letters we know. Similarly, the more complex one's unborn creative idea, the more honing steps required to discern its underlying form and whittle it down as needed. Since it has the potential to manifest different ways, we can say that it is a *state of potentiality*.

In the quantum approach to concepts, this kind of potentiality is described as a *superposition state* represented by a vector in a complex Hilbert space. Concepts act as *contexts* for each other that alter how they are experienced; for example, the concept TREE might make you think of a deciduous tree (one with leaves), but in the context CHRISTMAS, you might think of a coniferous tree (one with needles and cones). Each possible context may actualize the potentiality of the concept differently, and these possible actualizations are represented by *basis states*. The actual, existing context is treated as an *observable* that determines how the concept changes in light of this context. It might change in such a way as to alter the weights of certain properties. (For example, 'talks' and 'lives in a cage' are not considered properties of BIRD but they are considered properties of PET BIRD (Hampton, 1987); thus, the context PET is influencing the properties we ascribe to BIRD.) A context can also alter the typicalities of certain exemplars. (As a canonical example, *guppy* is not considered a typical exemplar of PET, nor of FISH, but it is considered a typical exemplar of PET FISH (Osherson & Smith, 1981).) In the absence of any observable—i.e., when a concept is not being viewed from any particular context, or thought about at all—the concept is said to be in a *ground state*. In its ground state there are no properties associated with the concept, but also, there are no properties that are, a priori, excluded from it; thus, you could say it is a state of infinite potentiality. Conceptual change due to the impact of a context is modeled as *collapse* of the vector representing the concept to one of its basis state, as shown in Figure 2.

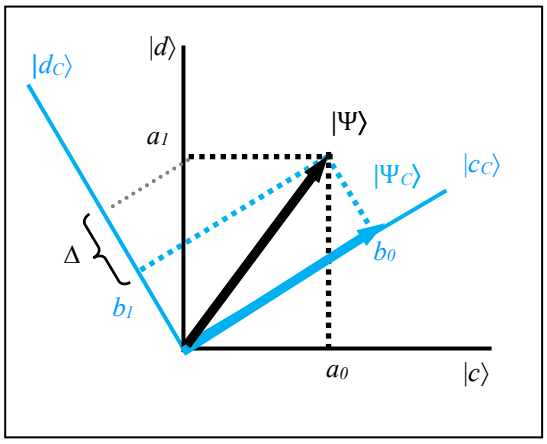

Figure 2: A graphical depiction of a vector |Ψ⟩ representing the concept TREE is shown in black. In the default context, TREE may be more likely to collapse to projection vector |*d*⟩ which represents DECIDUOUS TREE (tree with leaves) than to collapse to projection vector |*c*⟩ which represents

CONIFEROUS TREE (tree with needles and cones). This can be seen by the fact that subspace a_0 is smaller than subspace a_1; i.e., a_0 is closer to the xy origin than a_1. In the context CHRISTMAS, shown in blue, the concept TREE is likely to collapse to the orthogonal projection vector $|c_C\rangle$, representing CONIFEROUS TREE, as shown by the fact that b_0 is larger than b_1. (After collapse, the projected vector, $|\Psi_C\rangle$, is the same length as the original due to renormalization).

This approach has enabled us to cope with some of the non-compositional ways in which people use concepts—famously said to be the biggest challenge facing cognitive science (Fodor, 1998)—by describing them in terms of effects such as entanglement[3] and interference[4] (Aerts, Sozzo, & Gabora, 2016; Aerts & Sozzo, 2014; Busemeyer & Bruza, 2012). The approach can be applied to concept combinations and more complex compounds of concepts such as decisions (e.g., Busemeyer, Wang, & Townsend, 2006; Yukalov & Sornette 2009) jokes (Gabora & Kitto, 2017), worldviews (Gabora & Aerts, 2009), and creativity (e.g., Gabora & Carbert, 2015). For example, working with data from a study in which participants were asked to rate the typicality of exemplars of a concept for different contexts, and introducing a state-transition threshold, we built a model of how exemplars of a concept arise in divergent versus convergent modes of thought (Veloz, Gabora, Eyjolfson, & Aerts, 2011). By lowering a threshold of allowable deviation from the default context, seemingly atypical exemplars appeared as new possibilities. Honing an idea can be modeled as reiterated collapse, resulting in a change of state of the idea, which induces the conceptual framework to subject the idea to a new context, which in turn brings about a new collapse, and so forth, until the idea is sufficiently robust in the face of new contexts that it no longer undergoes change-of-state (Gabora, 2017). In short, it is becoming possible to move beyond crude conceptions of creative cognition to a more refined understanding that is aligned with and informed by advances in the adjacent area of concepts research.

Redefining Convergent and Divergent Thought

Let us now see how this can pave the way to a new conception of convergent and divergent thought. There is a relationship between the weights on the properties of a concept in a particular state, and its susceptibility to collapse to any particular new state. For example, if you think about TREE in terms of only its most typical properties such as 'grows in the ground', your next thought may be about something else that grows in the ground, such as a FLOWER. However, if you think about TREE in a way that encompasses not just typical properties such as 'grows in the ground' but also atypical properties, and in particular those implied by the context, your next thought may be about something semantically distant from TREE; for example, a poet might think of a word that rhymes with TREE such as BEE. Recall how, in its ground state, there are no properties associated with a concept, but also, no properties excluded from it. This means that, for any concept there exists *some* context that could come along and make any given property become relevant. The more exotic the context, the more atypical the properties that are evoked, and thus the more unconventional the subsequent thought.

This suggests that in convergent thought an idea is refined by considering compound of concepts in their *conventional contexts*. Because one is not concerned about all the remote ways in which the object of thought could be related to other things, but instead working with it in its most compact form, mental energy is left over for complex operations. This then is why convergent thought is conducive to unearthing relationships of causation, or thinking analytically, as well as simply carrying out rote tasks.

Conversely, in divergent thought one reflects on an idea by considering a particular compound of concepts from *unconventional contexts*. This is conducive to unearthing relationships of correlation, i.e., forging new connections between seemingly unrelated areas, as in analogical thinking. Note that the more unconventional the contexts one calls up, the seemingly less sensible the next thought may be, and therefore the more honing that may be required to coax it into a form that eventually makes sense. It is for this reason that the products of divergent thought (as redefined here to mean thinking of ideas from unconventional contexts) may require extensive honing.

Implications for Assessment

On the basis of this view of convergent and divergent thinking, let us now re-examine the tests used to assess these constructs. Although the RAT (Mednick, 1968) is used to assess convergent thinking because each question only has one correct answer, to determine the common associate of TANK, TABLE, and HILL you have to think of at least one of these words in a context that is not its default context. For example, unless you are a retailer in the business of selling tank tops you likely interpret the word TANK in terms of its meaning as a military vehicle. Therefore, if we go with the redefinition of convergent thinking as mental operations wherein the contents of thought are viewed from conventional contexts, convergent thought is insufficient to solve the RAT. The RAT is actually more appropriately used as a test of *divergent* thinking. This is consistent with the RAT's wide usage as a test of creativity despite that convergent thought is contrasted with divergent thought and divergent thought is frequently equated with creativity.

Since in divergent thinking tasks such as the Alternate Uses task people only reflect upon an idea from

[3] Entanglement is a phenomenon first encountered in particle physics wherein the state of one entity cannot be described independently of the state of another, and any measurement performed on one influences the other.

[4] Interference is the annihilation of the crest of one wave by the trough of another when they interact.

unconventional contexts *after* they have generated conventional responses, these tasks only test for divergent thinking during the latter part of the task. Thus it makes sense that, as noted by Beaty and Silvia (2012), this is when the most creative responses occur.

Neither the RAT nor conventional divergent thinking tests assess the capacity to hone an idea in a reiterated manner such that uncertainty decreases to an acceptable level and the idea transitions from ill-defined to well-defined. Amobile's (1982) consensual assessment technique, which involves asking multiple experts to evaluate the creativity of a work, is better in this regard, but it undoubtedly measures not just divergent thinking but what is sometimes called *contextual focus:* the capacity to spontaneously shift between convergent and divergent thought as needed, in response to the situation one is in (Gabora, 2010). What is required is a new approach to creativity testing in which each step in a creative process is broken down into a series of states and contexts, and the type and magnitude of conceptual change from one step to the next are analyzed so as to better understand the interplay of convergent and divergent thinking. Steps in this direction are underway using studies of artmaking (Choi & DiPaola, 2013) and computational models (Bell & Gabora, 2016; DiPaola, 2017; DiPaola, Gabora, & McCaig, 2018; McCaig, DiPaola, & Gabora, 2016), as well as technologies such as functional magnetic resonance imaging (Jung & Vartanian, 2018).

Conclusions

The constructs of convergent and divergent thought have been around for half a century, and the way they are defined and measured has changed little in that time. Meanwhile, we have made headway in understanding the dynamics of the compounds of concepts that constitute ideas, and in modeling how they interact as one thought gives way to the next. Given the presence of inconsistences in how convergent and divergent thought are conventionally defined and measured, it seems appropriate to revise our understanding of them in light of recent advances in understanding the internal workings of these processes. This paper has shown how formal research on concepts can pave the way to a new way of defining, measuring, and thinking about convergent and divergent thought.

Note that this is not the only potentially fruitful avenue for research yielded by a joining of forces between research on concepts and research on creativity. For example, there are hints that the above-mentioned presence of interference and entanglement effects in empirical studies of conceptual change are related to creativity, but to date this has not been systematically explored. Another direction for future research concerns the role of *incubation:* the idea that setting a creative task aside for a while, or incubating on it, can promote insight. One could model this as letting the idea return to its ground state such that it sheds its coterie of typical properties (and contexts), and taps into its reservoir of infinite potentiality (in the sense that no properties are definitively present nor absent).

Another intriguing prospect this line of inquiry leads to is the following. Creative people are more subject to adoration, as well as social disapproval and even bullying, and it is generally assumed that this is because they violate social norms (Sternberg & Lubart, 1995). However, this may not be the whole story. I have suggested that the creative mind is in the process of honing ambiguous mental forms, and indeed it has long been thought that creative people are particularly comfortable with ambiguity (e.g., Tegano, 1990; but see also, Merrotsy, 2013). This may include ambiguity with respect to how they themselves come across, which in turn may make them more vulnerable to other people's projections. In other words, they may be more subject to misinterpretation, appearing as Gods or Goddesses to some, and as devils to others.

It is hoped that this paper has provided a glimpse of how formal models of concepts can play a key role in the development of a 21st Century understanding of this most human of abilities, the ability to create.

From Deep Learning to Deep Reflection: Toward an Appreciation of the Integrated Nature of Cognition and a Viable Theoretical Framework for Cultural Evolution

Liane Gabora (liane.gabora@ubc.ca)
Department of Psychology, University of British Columbia, Kelowna BC, V1V 1V7, CANADA

Abstract

Although Darwinian models are rampant in the social sciences, social scientists do not face the problem that motivated Darwin's theory of natural selection: the problem of explaining how lineages evolve despite that any traits they acquire are regularly discarded at the end of the lifetime of the individuals that acquired them. While the rationale for framing culture as an evolutionary process is correct, it does not follow that culture is a Darwinian or selectionist process, or that population genetics provides viable starting points for modeling cultural change. This paper lays out step-by-step arguments as to why a selectionist approach to cultural evolution is inappropriate, focusing on the lack of randomness, and lack of a self-assembly code. It summarizes an alternative evolutionary approach to culture: self-other reorganization via context-driven actualization of potential.

Keywords: acquired trait; cultural evolution; inheritance; natural selection; population genetics; self-other re-organization

Introduction

Though several of the deepest evolutionary thinkers of the 20th Century cautioned against the over-zealous application of Darwinian theory (Claidière, Scott-Phillips, & Sperber, 2014; Fracchia & Lewontin, 1999; Mayr, 1996; Tëmkin & Eldredge, 2007), Darwinian models are rampant in the social sciences. The frameworks of population genetics has been applied to cultural evolution (Boyd & Richerson, 1988; Brewer et al., 2017; Cavalli-Sforza & Feldman, 1981; Creanza, Kolodny, & Feldman, 2017; Henrich et al., 2016), as well as to archaeology (O'Brien & Lyman, 2000), economics (Essletzbichler, 2011; Hodgson, 2002; Nelson & Winter, 2002), neuroscience (Edelman, 2014), the evolution of languages (Fitch, 2005; Pagel, 2017), and the unfolding of a creative idea in the mind of an individual (Campbell, 1960; Kronfeldner, 2014; Simonton, 1999; for counter-arguments see Gabora, 2007). This paper focuses exclusively on the question of whether cultural evolution is Darwinian. This is a different project from that of examining how natural selection has shaped the propensity for culture, language, artifacts, and so forth; it models cultural change itself as a second Darwinian process.

The rationale is that since cultural forms, like biological forms, evolve, i.e., exhibit cumulative, adaptive, open-ended change, culture constitutes a second evolutionary process. This is undoubtedly true. However, cultural Darwinism goes further than the claim that culture evolves; it assumes that the formal framework of population genetics, with appropriate tinkering to accommodate culture-specific phenomena, provides a viable foundation for modeling this second evolutionary process.

Many have laid out the similarities and differences between biological and cultural evolution (Godfrey-Smith, 2012; Jablonka & Lamb, 2014; Mesoudi, 2007; Wagner & Rosen, 2014). The issue addressed here is not how similar they are, but the extent to which the algorithmic structure of cultural evolution merits importation of a Darwinian framework. This paper lays out two arguments against this project, breaking them down step by step so as to facilitate the identification and settling of any points of disagreement. The first, the weaker argument, pertains to the issue of randomness. The second pertains to the existence of a self-assembly code. We will see that due to limited interaction with cognitive science, cultural evolution research has paid little attention to structure of the human minds that evolve culture, and the processes by which elements of culture take form. This has led to the misapplication of evolutionary concepts to culture, resulting in lack of appreciation of its essentially non-Darwinian character. The paper concludes with a brief discussion of an alternative, non-Darwinian evolutionary framework for culture.

Definitions

It is true that any definition of a term is fine so long as everyone agrees how it is being used. However, part of why it has been difficult to nail down the extent to which cultural forms evolve in the same sense as biological forms is that, in drawing parallels between biological and cultural evolution, existing terms have been stretched beyond their conventional meanings. When they are used in ways that do not capture the deep structure or essence of their original meaning, or when a biological referent is misleadingly retained in a cultural context, misunderstanding can result. The matter is tricky, for although cultural evolution constitutes a separate evolutionary process with its own evolving structures and processes, it is inextricably interwoven with biological evolution[1]. To maintain clarity, key terms used in this paper are defined below:

Acquired trait: a trait obtained during the lifetime of its bearer (e.g., a scar, a tattoo, or a memory of a song) and transmitted horizontally (i.e., laterally).[2]

Culture: extrasomatic adaptations—including behavior and artifacts—that are socially rather than sexually transmitted.

[1] For example, maternal diet during lactation can influence food preferences in offspring (Bilkó et al., 1994).

[2] These are acquired traits with respect to biological evolution. It will be argued that with respect to cultural evolution *all* traits are acquired.

Darwinian process: an evolutionary process that occurs through natural or artificial selection.[3]

Darwinian threshold: transition from non-Darwinian to Darwinian evolutionary process (Woese, 2002; Vetsigian, Woese, & Goldenfeld, 2006).

Evolutionary process: a process that exhibits cumulative, adaptive, open-ended change.

Gene: a component of a self-assembly code, i.e., a unit of heredity.[4]

Generation: a single transition period from the internalized to the externalized form of a trait.

Horizontal transmission: The spread of a trait within a generation.

Inherited trait: a trait (e.g., blood type, or the capacity to suntan) that is transmitted vertically (e.g., from parent to offspring) by way of a self-assembly code (e.g., DNA).

Modern Synthesis: merging of Darwin's theory of natural selection and Mendelian genetics in the 1940s.

Organism: the living expression of a particular self-assembly code, sometimes referred to as an 'individual'.

Phylogenetic network: model of the relationships amongst variants that is pictured as *reticulate,* or 'network-like'.

Phylogenetic tree: model of the relationships amongst different species that is pictured as *branching,* or 'tree-like'.

Population genetics: branch of biology central to which is a mathematical theory of how organisms evolve through natural selection due to changes in gene frequencies. It was originally developed by Fisher (1930), Wright (1931), and Haldane (1932) and subsequently expanded (Hartl & Clark, 2006).

Selection: differential replication of randomly generated heritable variation in a population over generations such that some traits become more prevalent than others. Selection may be *natural* (due to non-human elements of the environment) or *artificial* (due to human efforts such as selective breeding), and it can occur at multiple levels, e.g., genes, individuals, or groups (Lewontin, 1970).

Selectionist process: like the term 'Darwinian process' this refers to an evolutionary process that occurs through natural or artificial selection. (It will be used from this point on because it avoids potential confusion caused by the fact that Darwin considered other possibilities.)

Self-assembly code: a set of self-replication instructions.

Self-other Reorganization (SOR): a theory of how both culture, and early life, evolve through communally exchanging, self-organizing networks that generate new components through their interactions. Based on post-Modern Synthesis theory and findings in biology.

Vertical transmission: The inheritance of a trait from one generation to the next by way of a self-assembly code.

It is important to point out that we are using the term 'selection' in its technical, scientific sense. The word 'selection' also has an 'everyday' sense in which it is synonymous with 'choosing' or 'picking out'. One could say that selection—in the everyday sense of the term—occurs in a competitive marketplace through the winnowing out superior products. However, the discussion here concerns whether selection *in the scientific sense of the term* is applicable to cultural evolution.

Note that, with respect to biological evolution, a new generation (one transmission event) generally (though not in horizontal gene transfer) begins with the birth of an organism. It is not impossible for the same trait to be transmitted horizontally in one generation and vertically in another. However, with respect to cultural evolution, *a new generation begins with the expression of an idea* (again, one transmission event). Thus, over the course of a single discussion, an idea (a cultural trait) can undergo many generations. It can be said that cultural evolution proceeds more quickly than human biological evolution[5], since the lengthy period we associate with biological generations, from birth through development to puberty and reproductive maturity to parenthood, is in general significantly longer than the stretch of time between when an individual acquires a cultural trait (e.g., an idea) and then expresses (their own version of, or their own take on) that cultural trait.

Note also that vertical and horizontal transmission must be defined *with respect to the relevant evolutionary process*. A common error is to refer to the transmission of cultural information from parent to offspring as vertical transmission (e.g., Cavalli-Sforza & Feldman, 1981). The parent-child relationship is *with respect to* biological evolution; they are parent and child with respect to their status as biologically evolving organisms, but with respect to their status as participants in cultural evolution, there is no basis for this parent-child distinction. Indeed, while childbirth entails one mother and one father, there is no limit to the number of 'parental influences' on the 'birth' of an idea.

A related error is to say that in cultural evolution there is a third form of transmission, *oblique transmission*, in which traits are transmitted from non-kin members of the parental generation (e.g., Cavalli-Sforza & Feldman, 1981), for as far as *cultural* evolution is concerned it is irrelevant whether the information comes from *biological* kin or non-kin.

In a similar vein, although *dual inheritance* theorists speak of culture as a second form of inheritance (Henrich & McElreath, 2007; Richerson & Boyd, 1978; Whiten, 2017; Müller, 2017), the distinguishing feature of an inherited trait is that it is transmitted vertically—e.g., from parent to

[3] Although evolution by selection is the process Darwin's name became most synonymous with, it is interesting to note that amongst his many musings was a theory of pangenesis involving transmission of acquired traits (Darwin, 1868).

[4] In biology, the term 'gene' generally refers to a sequence of DNA or RNA nucleotides that code for a molecule with a particular function. It will be argued that, with respect to cultural evolution, there is no self-assembly code, and thus no equivalent to the gene.

[5] We are not referring here to clock time but to the *relative* mean duration of biological versus cultural generation processes.

offspring—by way of a self-assembly code (e.g., DNA), and therefore not obliterated at the end of a generation. This is not the case with respect to cultural traits (Gabora, 2011). (Nor, as we shall see, is it even the case for all biological traits.)

As a final preliminary note, it is important to keep in mind that organisms (including humans) are affected by epigenetic processes that influence the regulation and expression of genetic traits due to interactions with the environment, as well as selection effects operating on groups as well as individuals (Wilson, 1975). For simplicity, this paper does not explore these complications in detail but their relevance to the argument presented here is discussed elsewhere (Voorhees, Read, & Gabora, in press).

Randomness

It is possible for a selectionist model to be applicable even if the underlying process is not random, but in that case, although not genuinely random, the process must be approximated by a random distribution.[6] Biological variation is not genuinely random (for example, we can trace the source of some mutations to various causal agents; see Caporale 2000) but the assumption of randomness generally holds sufficiently well to serve as a useful approximation.[7]

With respect to culture, variation is not randomly generated, nor can it be described by a random distribution. Selectionist cultural theorists sometimes concede this point (Heyes, 2018), but fail to recognize its implications for the assumed validity of a selectionist framework. Natural selection *acts upon* nonrandomly generated variation, but to the extent that variation is *not* randomly generated, the distribution of variants reflects whatever is biasing the generation away from random in the first place, rather than selection (i.e., differential selection on the distribution of randomly generated heritable variation in a population over generations). Let us break this argument down step by step.

1. Natural selection is a two-step process, consisting of (i) generation of random variants that differ in fitness, followed by (ii) differential survival and reproduction of the fittest variants.
2. The first step provides variation upon which selection can operate, and the adaptiveness of the process resides not in the first step (how variants are *generated*) but the second (how fit variants are *selected*).
3. To the extent that variants do not differ in fitness, their evolution is attributed not to selection but to random genetic drift (Fisher, 1930; Hartl & Clark, 2006).[8]
4. To the extent that the generation of variants cannot be described by a random distribution, their evolution is attributed not to selection but to the nature of this nonrandom generation process.
5. Cultural change cannot be approximated by a random distribution; it is orders of magnitude more non-random than biological evolution. It is strategic and creative, with ideas emerging due to spreading activation and overlap amongst distributed mental representations encoded in associative memory (Gabora, 2013).
6. Therefore, a selectionist model is inappropriate to the description of cultural change.

In the cultural Darwinism literature there is much discussion of *social learning* (obtaining *existing* information from someone else), and some mention of *individual learning* (obtaining *existing* information through nonsocial means), but little about creativity, reasoning, planning, problem solving, i.e., the the highly non-random higher cognitive processes that *generate* cultural novelty. In a paper titled "grand challenges for the study of cultural evolution" (Brewer et al., 2017), absent from among the eight challenges is the challenge of studying the creative processes that fuel cultural evolution. The closest they come is to ask "How are innovations selectively transmitted" and "Do innovations create feedback loops leading to cumulative culture?" It seems that understanding how innovations come about in the first place is more fundamental than knowing how they are "selectively transmitted" or whether they create feedback loops. Without the creative generation of cultural novelty, there is no cultural evolution. As demonstrated in an agent-based computational model of cultural evolution (Gabora, 1995); when agents never *imitate,* cultural evolution does occur, albeit slowly, as each agent figures things out on its own, but when agents never *create,* there is no cultural evolution at all. Thus, understanding creativity would appear to be the 'grandest' challenge of all for cultural evolution research.

The 'randomness' argument puts a major dent in the theory that cultural evolution is selectionist, but it does not destroy it altogether. It is possible that after variation has been generated by way of nonrandom processes there might still be work for selection to do in winnowing out the very fittest. However, we now turn to the more serious problem, that in cultural evolution there is no self-assembly code.

Self-assembly Code

In biological evolution there are two kinds of traits: (1) inherited traits (e.g., blood type), transmitted vertically from parent to offspring by way of genes, and (2) acquired traits (e.g., a tattoo), obtained during an organism's lifetime, and transmitted horizontally amongst conspecifics.[9] A selectionist explanation works in biology to the extent that retention of acquired change is negligible compared to

[6] Few things other than radioactive decay are truly random.

[7] Actually, in some biological situations, such as assortative mating, the assumption of randomness does not hold, and in such cases natural selection is not an appropriate model.

[8] Drift has been demonstrated in human culture (Bentley, Hahn, & Shennan, 2004), and in a computational model of cultural evolution (Gabora, 1995).

[9] This is a simplification, for there exist traits that are encoded in genetic material, but this genetic material does not constitute a full-fledged self-assembly code (see Bonduriansky & Day, 2009).

retention of selected change; otherwise the first, which can operate instantaneously, overwhelms the second, which takes generations. Transmission of acquired traits is avoided through use of a *self-assembly code* (such as the genetic code), i.e., a set of instructions for how to reproduce. Because a lineage perpetuates itself using a self-assembly code, inherited traits are transmitted while acquired traits are not.[10]

Now let us turn to culture. In cultural evolution, there is no self-assembly code, and no vertically transmitted inherited traits; all change is acquired.[11] Therefore, cultural evolution is not due to the mechanism Darwin proposed: differential replication of heritable variation in response to selection. The only response to this argument I know of comes from Mesoudi (2007): "[the] point concerning the lack of self-assembly codes in cultural entities is, again, well-taken when compared to many biological organisms, but may not hold if we take viruses as our biological exemplar, which similarly cannot self-replicate in the absence of a host, or … the evolution of early RNA-based life before DNA-based replication mechanisms evolved." This response evades the problem, for the argument is not that cultural evolution differs from biological evolution, but that the assumptions underlying the formal framework developed to describe evolution by natural selection renders it inapplicable to culture. Indeed, it is also inapplicable to the description of some aspects of biological evolution, but that should be more reason for concern, not less.

Thus, to help determine whether there is a genuine flaw in the argument, and if so pinpoint what that flaw is, we again break the argument down into steps:

1. To the extent that an evolutionary process is amenable to a selectionist model, there are two kinds of traits: vertically transmitted inherited traits, and horizontally transmitted acquired traits.
2. Acquired traits are discarded from a lineage at the end of every generation.
3. This means that evolution (i.e., cumulative, open-ended, adaptive change) in biological lineages cannot be explained in terms of acquired traits.
4. Therefore, it is explained in terms of inherited traits.
5. In biological evolution, inherited traits are not discarded; they are preserved by way of a self-assembly code. The code's low-level information-bearing components must be organized in an orderly manner so they can be parsed into meaningful units; otherwise, the precisely orchestrated process by which the code is expressed to generate offspring is disrupted.
6. The population genetics framework was developed to explain change in a system such as this where the slow process of selection for inherited traits over generations is not drowned out by the fast process of acquired change (which can take place over milliseconds).
7. Biological evolution is therefore explainable in terms of differential selection on the distribution of randomly generated heritable variation in a population over generations, i.e., natural selection.
8. Since acquired change operates markedly faster than inherited change, to the extent that acquired change is *not* wiped out at the end of each generation, a population genetics framework is inappropriate as an explanatory model.
9. In cultural evolution, there is no distinction between vertically transmitted inherited traits and horizontally transmitted acquired traits. Since all traits are horizontally transmitted, we may refer to them as *cultural acquired traits*.
10. Cultural acquired traits are *not* regularly discarded from cultural lineages at the end of generations.
11. This means that evolution (i.e., cumulative, open-ended, adaptive change) in cultural lineages *can* be explained in terms of acquired traits.
12. Moreover, culture is not transmitted by way of inherited traits.
13. Therefore, cultural change, unlike biological change, cannot be explained in terms of change in the frequency of inherited traits; there exists no basis upon which to explain cultural evolution in terms of differential selection of inherited traits on the distribution of randomly generated heritable variation in a population over generations, i.e., using a selectionist framework.
14. Cultural evolution must therefore be explained entirely in terms of changes to acquired traits.

This argument has important implications for how cultural data is modeled. Since biological acquired traits are usually (though not always) discarded, and since a self-assembly code must stay intact to preserve its self-replication capacity, the joining of bifurcations in biological lineages is rare; thus, a phylogenetic tree correctly captures the branching structure. However, since cultural acquired traits are not discarded, and there is no cultural self-assembly code, the joining of bifurcations in cultural

[10] An organism may bypass the disappearance of acquired traits through niche construction, *i.e.,* by modifying its environment in such a way as to influence the behavior (and potentially gene regulation) of offspring. Thus, by 'building acquired traits into the environment', one generation may influence the traits exhibited by the next (Lewontin, 1998). However, acquired change is sufficiently negligible relative to inherited change that a selectionist explanation is still of value in explaining biological evolution.

[11] An anonymous reviewer suggested natural language is a cultural self-assembly code. However, (1) natural language is not a set of encoded instructions for the self-replication of natural languages, and (2) culture does not exhibit the signature characteristics of evolution by way of a self-assembly code: lack of transmission of acquired traits, and culture is characterized by horizontal not vertical transmission. Nevertheless, culture may be moving *toward* a cultural Darwinian threshold. In other words, it may exist in the state biological life was in before LUCA (last universal common ancestor) (Woese, 1998).

'lineages' is commonplace, and thus the structure is network-like rather than the tree-like (Gabora, 2006b). This difference has been demonstrated mathematically using split-decomposition graphs (Bandelt & Dress, 1992; Wägele, 2005). Dress and colleagues showed that while biological data generate branching graphs, reanalysis of data from a psychological experiment in which people were asked to estimate the subjective distance between colours gives a very different structure (Dress, Huson, & Moulton, 1996). This difference in the deep structure of biological data and cultural data such as languages, concepts, and artifacts arising from human cognition, is why phylogenetic tree models of culture are problematic.

Self-Other Reorganization (SOR): An Alternative Approach to Cultural Evolution

The above analysis precludes a *selectionist* but not an *evolutionary* framework for culture. Indeed, research since the Modern Synthesis has shown that even life itself is only partially explained through recourse to a selectionist framework; for example, though biological traits are generally obtained through vertical inheritance, horizontal gene transfer (HGT) involves horizontal transmission (Ochman et al., 2000). Evolution can occur in the absence of selection, and the importance of non-selectionist processes in evolution is increasingly recognized (Kauffman, 1993; Killeen, 2017; Woese, 2002). Research on the origin of life suggests that early life consisted of autocatalytic protocells that evolved through a non-selectionist means, and natural selection emerged later from this more haphazard, ancestral evolutionary process (Baum, 2018; Cornish-Bowden & Cárdenas, 2017; Gabora, 2006; Goldenfeld, Biancalani, & Jafarpour, 2017; Hordijk, Steel, & Dittrich, 2018; Steel, 2000; Vetsigian, Woese, & Goldenfeld, 2006). This non-selectionist process requires (1) a *self-organizing network* of components that generate new components through their interactions, (2) the network should be able to reconstitute another like itself through haphazard (not code-driven) duplication of components, and (3) interaction amongst networks. This process can be referred to as *Self-Other Reorganization* (SOR) because it involves an interplay between self-organized *internal* restructuring, and communal exchange *amongst* autocatalytic structures. Change occurs not through selection but through a process that has a completely different mathematical description: context-driven actualization of potential (Gabora & Aerts, 2005). The entity changes through interactions with its world, which in turn alters its potential for future configurations. Like selectionist evolution, SOR has mechanisms for preserving continuity and for introducing novelty, but unlike selectionist evolution, it is a low-fidelity Lamarckian process. The distinction between these two processes is summarized in Table One.

Vetsigian et al. (2006) showed that to cross the Darwinian threshold from non-selectionist to selectionist evolution requires the emergence of a self-assembly code. There is no evidence that culture has crossed this threshold, and it does not possess the *sine qua non* of having crossed it: vertical transmission and lack of transmission of acquired traits. It has been proposed that, as did early life, culture evolves through SOR (sometimes referred to as 'communal exchange') (Gabora, 1999, 2004, 2019). Here, the self-organizing networks are not protocells exchanging catalytic molecules, but minds exchanging ideas. Tools improve and fashions change not through selection but through context-driven actualization of potential (Gabora & Aerts, 2005). As parents share knowledge with children, an integrated network of understandings takes shape in their minds, and they become creative contributors to cultural evolution.

There are other network-based approaches (e.g., Bentley & Shennan, 2003), and non-selectionist models of cultural evolution, e.g., those based on the Price equation (e.g., El Mouden, André, Morin, & Nettle, 2014). SOR's uniqueness lies in its emphasis on the emergence of a network of understandings that is reinforced and expanded upon through its ongoing use as a scaffold to interpret and reflect upon new information; in other words, that crosses the threshold from 'deep learning' to 'deep reflection'. It has been noted that a tension exists between cultural evolution theory and the literature on human nature (Lewens, 2017). Because SOR is not incompatible with transmission of acquired traits, and because it recognizes the integrated, 'self-mending' nature of a mind, SOR provides a natural means of reconciling cultural evolution and human nature.

Table One: Comparison between evolution through selection and evolution through Self-Other Reorganization.

	Selection	**Self-other Re-organization (SOR)**
Unit of self-replication	Organism	Self-organizing autocatalytic network
Mechanism for preserving continuity	Reproduction (vertical transmission), proofreading enzymes, etc.	Communal exchange (horizontal transmission)
Generation of novelty	Mutation, recombination	Creativity, transmission error
Self-assembly code	DNA or RNA	None
High fidelity	Yes	No
Transmission of acquired traits	No	Yes
Type	Selectionist	Lamarckian (by some standards)
Evolution processes it can explain	Biological	Early life; horizontal gene transfer, culture

Conclusions

Darwin faced the problem of explaining how lineages evolve despite that acquired changes are lost from a lineage when the individuals that acquired them dies. Darwin's

solution was to come up with a population-level (macro) explanation. His theory of natural selection holds that although *acquired traits* are discarded, *inherited traits* are retained, so evolution can be explained in terms of preferential selection for those inherited traits that confer fitness benefits on their bearers. Cultural evolution research does not face the problem that motivated Darwin's solution—that of explaining how evolution takes place despite the discarding of acquired traits—because cultural acquired traits are *not* discarded. Thus, while the rationale for framing culture as an *evolutionary* process is correct, it does not follow that culture is a selectionist process, or that population genetics provides a viable starting point for modeling cultural change. Cultural evolution research has been carried out largely independent of research on the mental structures that actually evolve culture. This has led to the mis-application of biological constructs such as generations, inheritance, and vertical / horizontal transmission. This in turn has hindered appreciation of the dependence of vertical inheritance on a self-assembly code, and recognition of the implications of its absence in cultural evolution. The field needs cognitive scientists to uncover the cognitive processes by which culture actually takes shape.

Psychologists use the term mental set to refer to the persistent use of problem-solving strategies that worked in the past even when these strategies are not appropriate to the problem at hand. It appears that the persistent application of a selectionist framework to cultural evolution, despite that the conditions that make that framework applicable in biology are not present with respect to culture, may be an instance of mental set. This paper has laid out step-by-step arguments as to why a selectionist approach to culture is inappropriate, and pointed to an alternative approach.

Abstract

To understand the representations learned by neural networks (NNs), various methods of measuring unit selectivity have been developed. Here we undertake a comparison of four such measures on AlexNet: localist selectivity (Bowers et al., 2014); precision (Zhou et al., 2015); class-conditional mean activity selectivity CCMAS (Morcos et al., 2018); and top-class selectivity. In contrast with previous work on recurrent neural networks (RNNs), we fail to find any 100% selective 'localist units' in AlexNet, and demonstrate that the precision and CCMAS measures are misleading and suggest a much higher level of selectivity than is warranted. We also generated activation maximization (AM) images that maximally activated individual units and found that under (5%) of units in fc6 and conv5 produced interpretable images of objects, whereas fc8 produced over 50% interpretable images. Furthermore, the interpretable images in the hidden layers were not associated with highly selective units. We also consider why localist representations are learned in RNNs and not AlexNet.

Keywords: localist representation; grandmother cells; distributed representations.

Introduction

There have been recent attempts to understand how neural networks (NNs) work by analyzing hidden units one at a time using various measures such as localist selectivity (Bowers et al., 2014), class-conditional mean activity selectivity (CCMAS) (Morcos et al., 2018), precision (Zhou et al., 2015), and activation maximization (AM) (Erhan et al., 2009). These measures are defined below, and they all provide evidence that some units respond selectively to categories under some conditions.

Our goal here is to directly compare different measures of object selectivity on a common network trained on a single task. We chose AlexNet (Krizhevsky et al., 2012) because it is a well-studied CNN and many authors have reported high levels of selectivity in its hidden layers via both quantitative (Zhou et al., 2018, 2015) and qualitative methods using Activation Maximization (AM) images (Nguyen et al., 2017; Yosinski et al., 2015; Simonyan et al., 2013). Our main findings are:

1. The different measures provide very different estimates of selectivity.
2. The precision and CCMAS measures are misleading with near perfect selectivity scores associated with units that strongly respond to many different image categories. CCMAS scores are also ambiguous, as explained below.
3. There are no localist 'grandmother cell' representations in AlexNet, in contrast with the localist representations learned in some RNNs.
4. Units with interpretable AM images do not necessarily correspond to highly selective representations.
5. New selectivity measures are required to provide a better assessment of the learned hidden representations in NNs.

Bowers et al. (2014, 2016) assessed the selectivity of hidden units in recurrent NNs using networks similar to those developed by Botvinick & Plaut (2006) designed to explain human short-term memory performance. They reported many 'localist' units that are 100% selective for specific letters or words, where all members of the selective category were more active than and disjoint from all non-members, as can be shown in jitterplots (Berkeley et al., 1995), see Fig. 1 for a unit selective to the letter 'j').

These localist representations were compared to 'grandmother cells' as discussed in neuroscience (Bowers, 2017a). Bowers et al. (2014) argued that the network learned these representations in order to co-activate multiple letters or words at the same time in short-term memory without producing ambiguous blends of overlapping distributed patterns (the so-called 'superposition catastrophe'). Consistent with this hypothesis, localist units did not emerge when the model was trained on letters or words one-at-a-time (a condition in which the model did not need to overcome the superposition catastrophe (Bowers et al., 2014)), see Fig. 1 for an example of a non-selective unit)

In parallel, researchers have reported selective units in the hidden layers of various CNNs trained to classify images into one of multiple categories ((Zhou et al., 2015; Morcos et al., 2018; Zeiler & Fergus, 2014; Erhan et al., 2009), for a review see (Bowers, 2017a)). For example, Zhou et al. (2015) assessed the selectivity of units in the pool5 layer of two CNNs trained to classify images into 1000 objects and 205 scene categories, respectively. They reported multiple 'object detectors' (as defined below) in both networks. Similarly, Morcos et al. (2018) reported that CNNs trained on CIFAR-10 and ImageNet learned many highly selective hidden units, with CCMAS scores often approaching the maximum of 1.0.

Note that these later studies show that selective representations develop in CNNs trained to classify images one-at-

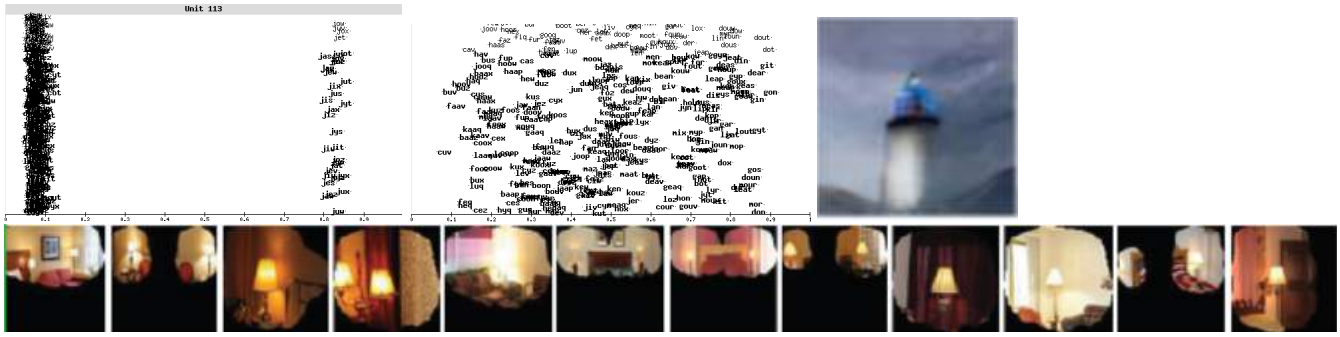

Figure 1: Examples of selectivity measures used. Top left: jitterplot of unit 113 in an RNN under the superposition constraint selective the letter 'j'. Top middle: jitterplot of non-selective unit 160 found when RNN trained on words one-at-a-time; from (Bowers et al., 2016). Top right: activation maximization (AM) image of a unit in conv5 of AlexNet that looks like a lighthouse; from (Nguyen et al., 2016). Bottom: highest activation images for a 'lamp' detector with 84% precision in layer pool5 of AlexNet; from (Zhou et al., 2015).

a-time. This appears to be inconsistent with Bowers et al. (2016) who (a) failed to obtain selective representations for letters or words under these conditions (see Fig. 1); and (b) it suggests that there are additional pressures for CNNs to learn selective representations above and beyond the challenge of overcoming the superposition catastrophe. However, the measures of selectivity that have been applied across studies are different, and accordingly, it is difficult to directly compare results.

In order to directly compare and have a better understanding of the different selectivity measures we assessed (1) localist, (2) precision, and (3) CCMAS selectivity on the prob, fc8, fc7, fc6, and conv5 layers of AlexNet. We also introduce a new measure called top-class selectivity, and show that the precision and CCMAS measures provide much higher estimates of object selectivity compared to other measures. Importantly, we do not find any localist 'grandmother cell' representations in the hidden layers of AlexNet, consistent with the hypothesis that the superposition catastrophe provides a pressure to learn more selective representations (Bowers et al., 2014, 2016).

In addition, we compared these selectivity measures to a state-of-the-art activation maximization (AM) method for visualizing single-unit representations in CNNs (Nguyen et al., 2017). AM images are generated to strongly activate individual units, and some of them are interpretable by humans (e.g., a generated image that looks like a lighthouse, see Fig. 1). For the first time, we systematically evaluated the interpretability of the AM images in an on-line experiment and compare these ratings with the selectivity measures for corresponding units. We show that hidden units with interpretable AM images are not highly selective.

It is important to emphasize that these different measures have all been used to provide insights into the same set of issues. For example, both interpretability of generated images (Le et al., 2011) and localist selectivity (Bowers et al., 2014) have been used to make claims about 'grandmother cells'. The different measures have also been directly compared to one another. For example, Zhou et al. (2015) claim that the object detectors learned in CNNs play an important role in identifying specific objects, whereas Morcos et al. (2018) challenge this conclusion based on their finding that units with high CCMAS measures were not especially important in the performance of their CNNs. Indeed, based on the finding that high CCMAS scores were not predictive of performance, Morcos et al. wrote: "...it implies than methods for understanding neural networks based on analyzing highly selective single units, or finding optimal inputs for single units, such as activation maximization (Erhan et al., 2009) may be misleading". This makes a direct comparison between measures all the more important.

Methods

Networks and Datasets All $\sim$1.2M photos from ImageNet2010 (Deng et al., 2009) were cropped to 277×277 pixels and classified by the pre-trained AlexNet CNN (Krizhevsky et al., 2012) shipped with Caffe (Jia et al., 2014), resulting in 721,536 correctly classified images. Once classified, the images are not re-cropped nor subject to any changes. In Caffe, the softmax operation (Denker & leCun, 1991) is applied at the 'prob'(ability) output layer that contains 1000 units (one for each class). We analyzed these prob units, the fully connected (fc) layers: fc8 (1000 units) that encodes the outputs prior to the softmax operation, fc6 and fc7 (4096 units), and the top convolutional layer conv5 which has 256 filters. We only recorded the activations of correctly classified images. The activation files are stored in .h5 format and can be retrieved at `https://bristol.codersoffortune.net/AlexNet_Merged/`. We selected 233 conv5, 2738 fc6, 2239 fc7, 911 fc8, and 954 prob units for analysis.

Localist selectivity Here we define a unit to be localist for class *A* if the set of activations for class *A* was disjoint with those of not A ($\neg A$).

Localist selectivity is easily depicted with jitterplots in

which a scatter plot for each unit is generated (see Figs. 3 and 4). Each point in a plot corresponds to a unit's activation in response to a single image, and only correctly classified images are plotted. The level of activations is coded along the x-axis, and an arbitrary value is assigned to each point on the y-axis (they are jittered).

Top-Class selectivity Top-class selectivity is related to localist selectivity except that it provides a continuous rather than discrete measure. We counted the number of images from the same class that were more active than all images from all other classes (what we called the top cluster size) and divided the cluster size by the total number of correctly identified images from this class. 100% top-class selectivity is equivalent to a localist representation.

Precision The precision method of finding object detectors (Zhou et al., 2015, 2018) involves identifying a small subset of images that most strongly activate a unit and then identifying the critical part of these images that are responsible for driving the unit. Zhou et al. (2015) took the 60 images that activated a unit the most strongly and asked independent raters to interpret the critical image patches. Zhou et al. (2015) developed a precision metric that calculated the percentage of the 60 images that raters judged to depict the same class of object (e.g., if 50 of the 60 images were labeled as 'lamp', the unit would have a precision index of 50/60 or 83%; see Fig. 1). Object detectors were defined as units with a precision $> 75\%$: they reported multiple such detectors. Here we approximate this approach by considering the 100 images that most strongly activate a given unit and assess the highest percentage of images from a given output class.

CCMAS Morcos et al. (2018) introduced a selectivity index based on the 'class-conditional mean activation' selectivity (CCMAS). The CCMAS for class A compares the mean activation of all images in class A, μ_A, with the mean activation of all images not in class A, $\mu_{\neg A}$, and is given by: $(\mu_A - \mu_{\neg A}) / (\mu_A + \mu_{\neg A})$. Morcos et al. (2018) states that this metric should vary within [0,1], with 0 meaning that a unit's average activity was identical for all classes, and 1 meaning that a unit was only active for inputs of a single class. Here, we assessed class selectivity for the highest mean activation class (CCMAS) as well as for the class with the second highest mean activation μ_A (what we call CCMAS_2) in order to assess the extent to which CCMAS reflects the selectivity to one class.

Activation Maximization We harnessed an activation maximization method called Plug & Play Generative Networks (Nguyen et al., 2017) in which an image generator network was used to generate images (hereafter, AM images) that highly activate a unit. We generated 100 separate images that maximally activated each unit in the conv5, fc6 and fc8 layers of AlexNet and displayed them in a grid format. We then asked 333 participants to judge whether they could identify any repeating objects, animals, or places in images after receiving some practice trials. Participants were recruited using Prolific (*Attrition*, n.d.; Palan & Schitter, 2018), with the experiment run online using gorilla (*Gorilla Experiment Builder*, n.d.). Readers can test themselves at: https://research.sc/participant/login/dynamic/63907FB2-3CB9-45A9-B4AC-EFFD4C4A95D5.

Results

Comparison of selectivity measures.

The mean top-class, precision, and CCMAS selectivities across the conv5, fc6 and fc7 layers are displayed in Fig. 2a–c. We did not plot localist selectivity as there were no localist 'grandmother units' at any internal level (and only 10% at the prob layer, due to the softmax function). The first point to note is that the top-class, precision, and CCMAS measures all increased in the higher layers, showing that they capture degrees of selectivity ignored by the localist measure. Second, the top-class selectivity was extremely low across the hidden layers, with means below 0.25% in the the conv5, fc6, and fc7 layers. Third, the different measures provided very different estimates of selectivity. In contrast with top-class selectivity, the mean precision scores are over an order of magnitude larger in the hidden layers of network, with average precision scores of 9.6%, 12.1%, and 15.4% in layers conv5, fc6, and fc7, respectively. Similarly, the CCMAS measure suggests a much higher level of selectivity than top-class selectivity, with mean scores of .49, .84, and .85 in the conv5, fc6, and fc7 layers, respectively.

This discrepancy is most striking for the units with the highest precision and CCMAS scores. For example, in Fig. 3 we illustrate why the unit fc6.1199 with the highest precision (95%) in fc6 should not be considered a Monarch butterfly detector. Fig. 3a depicts a jitterplot of activations to all accurately identified images, with Monarch butterfly images found across the range of activations. Fig. 3b shows a histogram that plots the distribution of activations for Monarch butterflies. By far the most common activation to correctly identified Monarch butterflies is 0 and the mean is 39.2 ± 0.6. Figures 3 displays example images with 0 (right top), mean (right middle) and maximal (right bottom) activations, and all are identifiable as Monarch butterflies. Thus, classifying this unit as a Monarch butterfly detector is misleading.

Another surprising result is that we did not obtain any 100% top-class selectivity units (localist units) in the prob layer of AlexNet. Rather, the mean top-class selectivity was $\sim$80% in the prob layer, and only $\sim$5% in fc8 (prior to the softmax being applied). Fig. 4 depicts the pattern of activation for units fc8.11 and prob.11 that are examples of the most top-class selective units in these layers (responding to images of 'goldfinch' birds with top-class selectivity measures of 8.4% and 95.2%, respectively). Clearly these units do respond much more selectively than the most selective units in earlier layers (*c.f.* Fig. 3), and at the same time, the jitterplots show why we did not observe any localist units (a few 'goldfinch' images were less active than a few images from other categories).

These jitterplots also show that top-class and localist se-

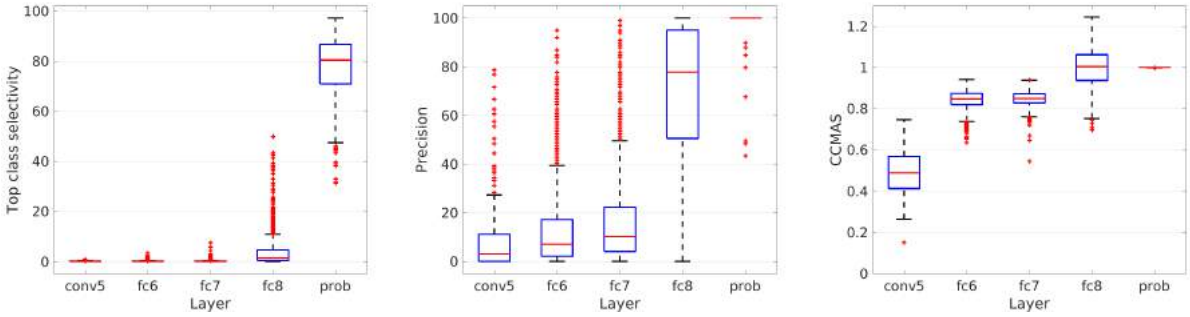

Figure 2: Selectivity measures across different layers of AlexNet. Left: top-class selectivity. Middle: precision 100 (the percentage of the top 100 images which are members of the top class). Right: Class-conditional mean activity selectivity (CCMAS), N.B. as the mean of the unselected classes ($\mu_{\neg A}$ can be less than zero) the CCMAS can go above its expected maximum of 1.

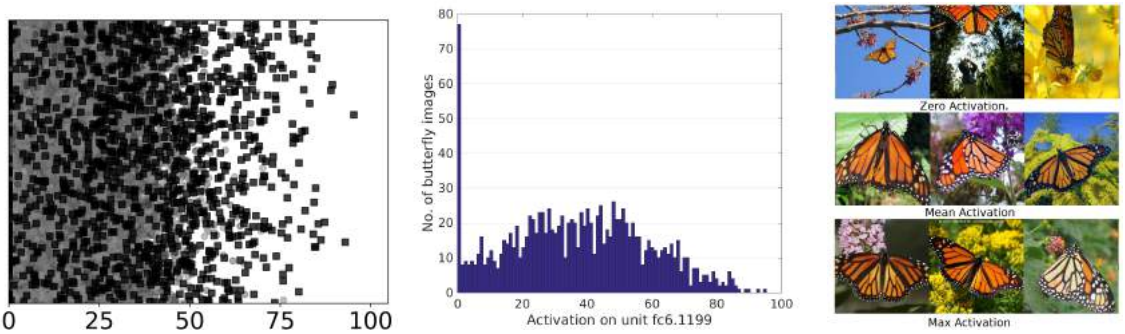

Figure 3: Data for unit fc6.1199. Left: activation jitterplot: black squares: Monarch butterfly images; grey circles: all other classes. Middle: histogram of activations of Monarch butterflies. Right: example ImageNet images with activations of 0.0 (top), the mean (middle), and the maximum (bottom) of the range. Unit fc6.1199 has a precision of 95% over the top 100 images (98.3% over the top 60) and is thus classified as a butterfly detector, yet there are Monarch butterfly images covering the whole range of values, with 72 images (5.8% of the total) having an activation of 0.0.

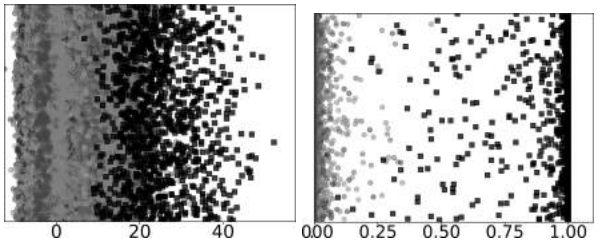

Figure 4: Example data from the fc8 and prob layers. Left: jitterplot activations for unit fc8.11 that has a top-class selectivity of 8.4%. Right: jitterplot activations for prob.11 (i.e. post-softmax) that has top-class selectivity of 95.2%. Activations for the 'ground truth' class 'goldfinch' are shown as black squares, all other classes are shown as greyscale circles.

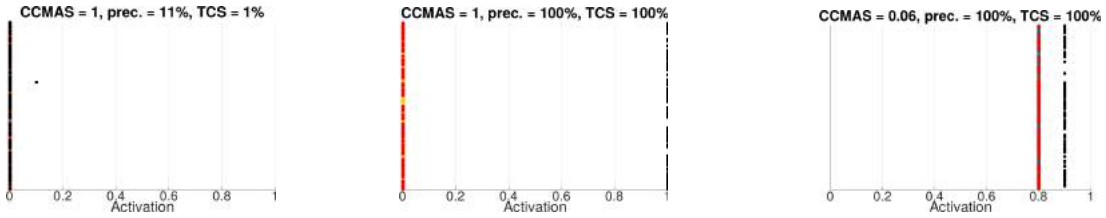
lectivity provide somewhat misleading estimates of selectivity as well. Consider Fig. 4(left) that depicts a substantial overlap between goldfinch and non-goldfinch activations on unit fc8.11. The 8.4% top-class selectivity score captures the selectivity for the most highly active goldfinch images, but it is blind to the fact that almost all goldfinch images have a reasonably high level of activation (more than most non-goldfinch images). The problem with localist selectivity is highlighted in Fig. 4(right) that shows that the measure misses all but the most extreme version of selectivity. Together, these findings suggest that new selectivity measures are required to better characterize the representations in NNs: precision and CCMAS measures strongly overestimate selectivity, and localist and top-class selectivity provide either a too strict or too narrow a measure of selectivity.

Additional problems with the CCMAS measure

The main problem with the precision and CCMAS measures is that they provide misleadingly high estimates of selectivity, but the CCMAS measure has some additional limitations. First, if the CCMAS provided a good measure of a unit's class selectivity then one should expect that a high measure of selectivity for one class would imply that the unit is not highly selective for other classes. However, the CCMAS score for the most selective category and the second most selective category CCMAS_2 were similar across the conv5, fc6 and fc7



a. One active item from one class. CCMAS = 1, precision = 11%, TCS = 1%.

b. Archetypal 'grandmother' unit. CCMAS = 1, precision = 100%,TCS = 100%.

c. One class more active than the others. CCMAS = 0.06, precision = 100%, TCS = 100%.

Figure 5: Example of where the CCMAS does not match intuitive understandings of selectivity. Generated example data: (a) If a unit is off to all but a single image from a large class of objects, the CCMAS for that class is 1 (maximum possible selectivity). (b) If a unit is strongly activated to all members of one class and off to everything else (an archetypal 'grandmother' cell) the CCMAS is the same as for (a) although the precision and top-class selectivity is vastly different. (c): If a unit has high activations for all classes, but one class (black squares) is 0.1 more than all others (coloured circles), the CCMAS is very low (0.06) despite being %100 top-class selective. The generated examples are for 10 classes of 100 items

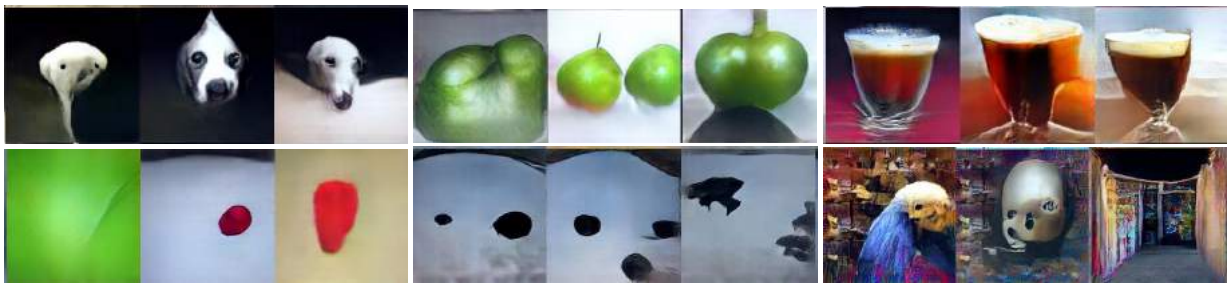


Figure 6: Example AM images that were either judged by all participants to contain objects (top row) or judged by all participants to be uninterpretable as objects (bottom row). The human judgement for conv5.183 (top left) was 'dogs' and the top-class was 'flat-coated retriever'. For fc6.319 (top middle) subjects reported 'green peppers' or 'apples' (all classified as the same broad class in our analysis), and the CCMAS and top-class was 'Granny Smith apples'. For fc8.969 (top right) humans suggested 'beverage' or 'drink': ground truth class for this unit is 'eggnog'. The ground-truth for fc8.865 (bottom right) is'toy-store'.

layers, with the mean CCMAS scores .491, .844, and .848, and the CCMAS_2 scores .464, .821, .831. For example, unit fc7.0 has a CCMAS of .813 for the class 'maypole', and a CCMAS_2 score of .808 for 'chainsaw' (with neither of these categories corresponding 'orangutan' that had the highest precision of score of 14% and a top-class selectivity score of .001%).

Second, the CCMAS measure provides an ambiguous measure of selectivity. To illustrate, consider the artificial scatter plots depicted in Figs. 5a,b. Here we obtain the same perfect CCMAS scores for one unit that selectively responds to one member of a category and another unit that selectively responds to all members of a category. This is problematic for a measure designed to assess *class* selectivity. Third, as shown in Fig. 5c, it is even possible to have a low CCMAS score for a unit with 100 percent top-class selectivity (that is, a low CCMAS selectivity for a grandmother cell). Together, these characteristics of the CCMAS measure may help explain why why Morcos et al. failed to observe the functional importance of units with high CCMAS scores.

Human interpretation AM images

For the behavioral experiment, one hundred generated images were made for every unit in layers conv5, fc6 and fc8 in AlexNet, as in Nguyen et al. (2017), and displayed as 10×10 image panels. A total of 3,299 image panels were used in the experiment (995 fc8, 256 conv5, and 2048 randomly selected fc6 image panels) and were divided into 64 counterbalanced lists for testing. To assess the interpretability for these units as object detectors, paid volunteers were asked to look at image panels and asked if the images had an object / animal or place in common. If the answer was yes, they were asked to name that object simply (i.e. fish rather than goldfish). Analyses of common responses was done for any units where over 80% of humans agreed there was an object present.

The results of the behavioral experiment in which humans rated AM images are reported in Table 1. Consistent with past research, the generated images in the output fc8 layer were often interpreted as objects, and when they were given a consistent interpretation, they almost always (95.4%) correspond to the trained category. By contrast, less than 5%

Table 1: Interpretability judgements. Number of judgments for conv5, fc6 and fc8 were 1332, 10,656 and 5,181, respectively.

LAYER	% YES RESPONSES	% OF UNITS WITH $\geq$ 80% YES RESPONSE	% OVERLAP AMONG HUMANS	% OVERLAP BETWEEN HUMANS AND: TOP CLASS	CCMAS CLASS
conv5	21.7% $\pm$1.1%	4.3% $\pm$ 1.3%	89.5%$\pm$5.7%	34.1%$\pm$14.4%	0%
fc6	21.0% $\pm$0.4%	3.1% $\pm$ 0.4%	80.4%$\pm$4.1%	23.3%$\pm$5.9%	18.9% $\pm$5.9%
fc8	71.2% $\pm$0.6%	59.3% $\pm$1.6%	96.5%$\pm$0.4%	95.4%$\pm$0.6%	94.6% $\pm$0.7%

of units in conv5 or fc6 were associated with consistently interpretable images, and as can be seen in Table 1, the interpretations only weakly matched the category with the highest top-class or CCMAS selectivity. The frequency with which objects were seen by the participants was similar in layers conv5 and fc6 layers and increased in fc8, consistent with the top-class and and precision measures of selectivity.

Apart from showing that there are few interpretable units in the hidden layers of AlexNet, our findings show that the interpretability of images does not imply a high level of selectivity given the maximum top-class selectivity for the hidden units is well under 10% (Fig. 2). In most cases, the top-class selectivity of the interpretable units was well under 1%. To briefly illustrate the types of images that participants rated as objects or non-objects see Fig. 6.

Discussions and Conclusions

Our central finding is that different measures of activation selectivity support very different conclusions when applied to the same units in AlexNet. In contrast with the precision (Zhou et al., 2015) and CCMAS (Morcos et al., 2018) measures that revealed some highly selective units for objects in layers conv5, fc6, and fc8, we found no localist representations, and the mean top-class selectivity in these layers was well under 1%. These findings are in stark contrast with the many localist 'grandmother cell' representations learned in RNNs (Bowers et al., 2014, 2016; Bowers, 2017b).

Not only did the different measures provide very different assessments of selectivity, we found that the precision and CCMAS measures provided highly misleading estimates. For example, a unit with over a 75% precision score for Monarch butterflies had a top-class selectivity of under 5%. Although Zhou et al. (2015) used 75% precision scores as the criterion for 'object detectors', it is inappropriate to call this unit a Monarch butterfly detector given that it did not respond strongly to the majority of Monarch butterfly images (and indeed, the modal response was 0.0; see Fig. 3).

At the same time, we identified problems with the localist, top-class, and activation maximization (AM) methods as well. The localist selectivity measure failed to obtain any localist representations, even at the output prob layer of AlexNet. This measure is so extreme that it misses highly selective representations that are of theoretical interest. The top-class selectivity does provide a graded measure of selectivity (with 100% top-class selectivity equivalent to a localist grandmother cell), but it can underestimate selectivity when a few member from outside the top-class are highly activated (see Fig. 4 (right) for an example). At the same time, the human interpretation of AM images provides a poor measure of hidden-unit selectivity given that interpretable AM images were associated with low top-class selectivity scores. These findings highlight the need to provide better measures of selectivity in order to better characterize the learned representations in NNs.

What should be made of the contrasting findings that localist representations are found in RNNs, but not in AlexNet? The failure to observe localist units in the hidden layers of AlexNet is consistent with the Bowers et al. (2014) claim that these units only emerge in order to support the co-activation of multiple items at the same time in short-term memory. That is, localist representations may be the solution to the superposition catastrophe, and AlexNet only has to identify one image at a time. This may help explain the reports of highly selective neurons in cortex given that the cortex needs to co-activate multiple items at the same time in order to support short-term memory (Bowers et al., 2016). It should be noted that the RNNs that learned localist units were very small in scale compared to AlexNet, and accordingly, it is possible that the contrasting results reflect the size of the networks rather than the superposition catastrophe *per se*. Relevant to this issue, Karpathy et al. (2016) reported examples of selective representations in a larger RNN with long-short term memory (LSTM) trained to predict text. Although they did not systematically assess the degree of selectivity, they reported examples that are consistent with 100% selective units, for similar findings see Lakretz et al. (2019). It will be interesting to apply our measures of selectivity to these larger RNNs. It should also be noted that there are recent reports of selective representations in Generative Adversarial Networks (Bau et al., 2019) and Variational Autoencorder Networks (Burgess et al., 2018) where the superposition catastrophe is not an issue. Again, it will be interesting to assess the selectivity of these units according to our measures in order to see whether there are additional computational pressures to learn highly selective or even grandmother cells. We will be exploring these issues in future work.

A rational model of syntactic bootstrapping

Abstract

Children exploit regular links between the meanings of words and the syntactic structures in which they appear to learn about novel words. This phenomenon, known as *syntactic bootstrapping*, is thought to play a critical role in word learning, especially for words with more opaque meanings such as verbs. We present a computational word learning model which reproduces such syntactic bootstrapping phenomena after exposure to a naturalistic word learning dataset, even when under substantial memory constraints. The model demonstrates how experimental syntactic bootstrapping effects constitute rational behavior given the nature of natural language input. The model unifies computational accounts of word learning and syntactic bootstrapping effects observed in the laboratory, and offers a path forward for demonstrating the broad power of the syntax–semantics link in language acquisition.

Keywords: syntactic bootstrapping; word learning; computational models

Children face multiple challenges of induction when acquiring their first language. They must work out the most fundamental features of language: that words exist, and that they can be used to refer to entities and relations out in the world. At a higher level, they must work out what words actually mean, and how those words can productively combine with other words to form phrases and sentences.

A successful research program has identified how children as young as 13 months can learn the meanings of a particular class of words — concrete nouns — from noisy observations of adult language use (Smith and Yu, 2008; Trueswell et al., 2013). While nouns often pick out concrete referents which are easily identifiable by a listener, other classes of words pose more substantial learning problems. Verbs, for example, often have no concrete reference in the perceptual world which the child directly observes. Certain verb meanings may also be under-determined by the perceptual facts: verb pairs such as *chase* and *flee* or *hit* and *kick* often pick out the same events, though they have vastly different meanings (Gleitman et al., 2005).

These features make learning verb meanings a challenge for both children and adults. The productive vocabularies of young children are heavily skewed toward frequent nouns with concrete referents (Fenson et al., 1994). Adult subjects in laboratory language learning experiments also routinely struggle to identify verb meanings from observations of their use (Gillette et al., 1999). But children somehow climb over these learning barriers to become adults who can *give* and *take* or *hit* and *kick*. We must account, then, for how that learning goes through. First, because verbs make reference to abstract events and relations between entities, we must account for the representations of such events and relations in the mind of the child. In other words, we must account for the **target** representations of word learning. Second, we must explain what information **sources** children exploit in order to learn which words pick out which events and relations. Because perceptual information under-determines the solution to this learning problem, there must be other sources of information in the learner's experience which help determine the meanings of these words.

This paper addresses the theory of *syntactic bootstrapping*, which claims that children exploit systematic relations between the syntactic structures in which verbs are used and their semantics in order to learn about the meanings of novel words (Landau and Gleitman, 1985; Fisher et al., 2010). After reviewing corpus and experimental evidence regarding the syntax–semantics link, we formalize syntactic bootstrapping in a probabilistic computational model, proceeding from minimal assumptions about the structure of the lexicon to a model which replicates the qualitative behavior of children in syntactic bootstrapping experiments. We show how the knowledge assumed by this model can be learned *from scratch* on naturalistic data, as it constructs both a concrete lexicon and abstract beliefs about the correspondence between verb form and meaning.

Syntactic bootstrapping

On the syntactic bootstrapping account, children analyze the syntactic structures in which verbs appear in order to predict aspects of their meaning not well determined by the perceptual context. At a high level, this theory is a claim about the relation between two representational spaces in the mind of the learner: the space of meanings M and the space of syntactic representations S. As such, these theories must make assumptions about the structure of these spaces. As we will see, many theories regarding the syntax–semantics link presuppose the existence of core meaning predicates such as CAUSE and BECOME (Levin and Rappaport Hovav, 2011; Pinker, 1989). While such predicates have been motivated by theoretical work elsewhere in cognitive development (see e.g. Hespos and Spelke, 2004; Muentener and Carey, 2010), the continued success of the syntactic bootstrapping paradigm

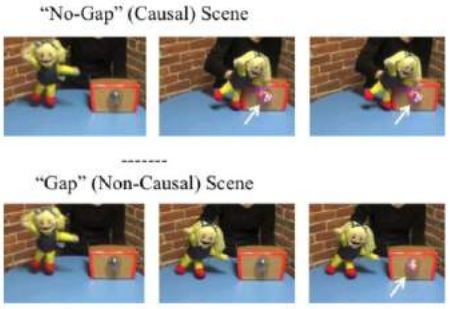

Figure 1: From Kline et al. (2017), fig. 2. Scene pairs contrast minimally in the presence or absence of a *causation* event. In the "causal" scene, the puppet moves to contact the toy, which immediately activates; in the "noncausal" scene, the puppet moves but does not contact the toy, and the toy only activates after a delay.

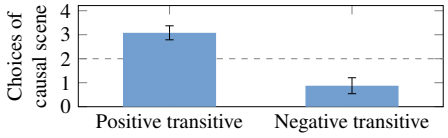

Figure 2: From Kline et al. (2017). Children point to the "causal" scene when given a positive sentence with a novel transitive verb (*can you find where she wugged the round thing?*), and to the "noncausal" scene for a negative sentence with a novel transitive verb (... *didn't wug the round thing?*).

provides orthogonal positive evidence for the reality of these structures in the mind of the child.

Corpus studies have shown how aspects of verb meaning both coarse-grained (causation and movement) and fine-grained (movement of liquids vs. movement of solids) can be predicted from the constructions in which verbs appear (Naigles and Hoff-Ginsberg, 1995; Levin, 1993). Decades of experimental evidence also support the idea that children exploit such structural relationships between a verb's syntactic behavior and its meaning. One of the most productive lines of research has focused on the correspondence between a verb's appearance in transitive syntactic constructions (*the X Ys the Z*) and a semantic predicate CAUSE (Naigles, 1990). Some of the most recent experimental evidence argues for such a fine-grained link between transitive syntax and physical causation (Kline et al., 2017). Kline et al. presented children with pairs of scenes, each involving a moving puppet and a toy which activated or lit up. An example scene pair is shown in Figure 1. While each scene pair involved similar motion events, a "causal" scene in each pair also exhibited an event of external causation, using cues known to be salient to young children (spatial and temporal continuity between an agent's action and an object's response) (Michotte, 1963; Muentener and Carey, 2010). In two-alternative forced choice test trials, children were given a sentence containing a novel verb and asked to pick the scene it referred to: either in a positive frame (*Can you find where she wugged the round thing?*) or a negative frame (... *didn't wug the round thing?*). Figure 2 shows the main effect in the experiment of Kline et al. (2017). Across several tested minimal-contrast scene pairs, children preferred to point at the causal scene when queried with the positive frame and at the non-causal scene when queried with the negative frame.

The findings of Kline et al. show that 3- and 4-year-olds latch onto a reliable relationship in English between transitive syntax and the semantic predicate CAUSE documented elsewhere in the cognitive development literature. This is a case of syntactic bootstrapping: children exploit a word's syntactic behavior in order to make guesses about its meaning.

As a broad theory regarding the construction of the lexicon, though, syntactic bootstrapping needs to eventually do quite a bit more work. Taken to its extreme, it needs to explain how each of the semantic contrasts present in a meaning space M can be explained by corresponding contrasts in a syntactic representation S. In the absence of other good accounts of verb meaning, the contrast between *chase* and *flee* and the contrast between *hit* and *kick*, for example, must be predictable from contrasts in syntactic behavior. To test the full power of syntactic bootstrapping as a theory of the construction of the lexicon, then, we must further formalize our assumptions about the structure of the syntactic space S and the meaning space M, and provide clear proof of the learnability of relations between the two spaces.

The remainder of this paper takes some first steps in that direction. We first formalize syntactic bootstrapping in a probabilistic model, showing how we can proceed from minimal assumptions about the structure of the lexicon to a model which replicates the qualitative behavior of children in syntactic bootstrapping experiments. We next show how this probabilistic model can be learned from scratch on naturalistic data, constructing both a concrete lexicon and abstract beliefs about the syntax–semantics link through only *unsupervised* experience of ambiguous language use in grounded contexts.

Related work

Most past computational models of word learning have focused on the acquisition of words with concrete referents, explaining the learning dynamics and characteristic patterns of success and failure observed in adults and children (Frank et al., 2009; Trueswell et al., 2013; Stevens et al., 2017). Our model will replicate the important structural features of these models — explicit representations of uncertainty over possible lexica, stored under strong resource limitations — and further extend to the more challenging task of acquiring verb meanings, which have either ambiguous reference or no concrete reference at all in the world of the learner.

While other computational models have been used to replicate verb learning and syntactic bootstrapping phenomena (Abend et al., 2017; Barak et al., 2014; Alishahi and Stevenson, 2008), they have been deployed only in simplified learn-

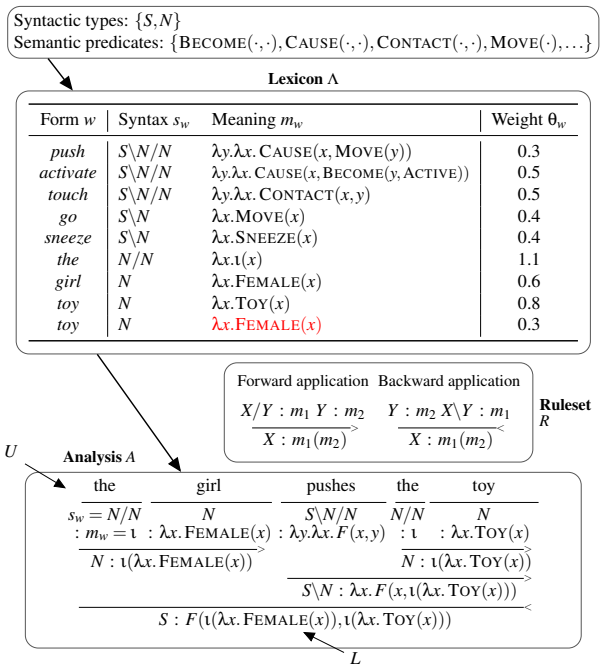

Figure 3: A CCG combines a learned lexicon Λ with a fixed ruleset R in order to yield analyses of input utterances. The bottom of the figure shows an analysis of the utterance *the girl pushes the toy* (read from top to bottom), which jointly yields syntactic and semantic representations of the sentence.

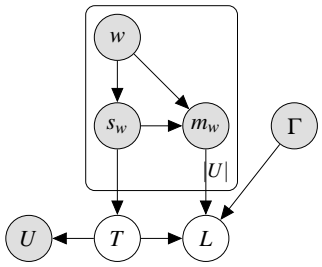
ing situations, where a learner is shown utterances explicitly paired with their ground-truth meaning representations (or a set of possible meaning representations). In contrast, our model learns in a *distantly supervised* setting: it is only explicitly told that the utterances have meanings which are *true* in the current scene, and must work out word-level meanings and utterance-level meanings on its own. Because no word-level meanings are ever explicitly presented to the learner, it must induce word meanings by searching through the infinite space of possible lambda-calculus meaning representations. This learning setting is thus qualitatively different than the direct-supervision setting studied in past bootstrapping work.

We see our model as complementary to those of Sadeghi and Scheutz (2018) and Gauthier et al. (2018), who show how more minimal syntactic representations can support specific types of early syntactic bootstrapping. Our model integrates both a full syntactic formalism and a general ability to track probabilistic links between syntactic and semantic representations. As such, the model is able to scale to the more complex syntactic bootstrapping phenomena studied in this paper, using syntactic features to resolve finer-grained features of verb meaning.

A formal model

We visualize the major details of our model in Figure 3. A learner constructs a *lexicon* Λ, associating particular word-



w	Wordform
s_w	Syntactic type of wordform w
m_w	Meaning of wordform w
Γ	Scene/context
U	Utterance (word sequence)
T	Derivation (syntactic analysis)
L	Logical form (semantic analysis)

Figure 4: A generative model of an utterance U situated in a scene Γ, drawing on lexical items $(w, s_w, m_w) \in \Lambda$.

forms w with syntactic types s_w and meanings m_w.[1] The syntactic types of words are represented using the formalism of combinatory categorial grammar (CCG; Steedman and Baldridge, 2006). Word meanings are represented as expressions in a typed lambda calculus, built from core semantic predicates ranging from concrete properties (e.g. FEMALE) to abstract relations (e.g. CAUSE). These representations draw on the lexical conceptual structures often discussed in literature on the syntax–semantics link (see e.g. Levin and Rappaport Hovav, 2011).

The contents of this lexicon are combined with parsing *rules* in order to produce joint syntactic and semantic representations of full utterances. Figure 3 shows how entries from the lexicon Λ combine with a ruleset R to analyze a sentence.

The grammar's *syntactic types* describe how words combine with their arguments. These syntactic types may be of either a *primitive* type (e.g. N) or of *functional* type (e.g. S/N). Functional types combine with syntactic arguments to their left or right, eventually yielding a phrase of a particular primitive type.

The CCG rule set R, shown in the middle of Figure 3, specifies these combination rules.[2] Figure 3 (lower section) shows how the two rules in our ruleset are used to analyze the example sentence *the girl pushes the toy*. After first retrieving lexical entries for each of the tokens in the sentence (top row), we iteratively run the application rules, composing functional types with primitive types to their left or right. Whenever such syntactic composition occurs, we likewise unify the corresponding semantic expressions by function application.

Each CCG analysis yields a tree structure (bottom of Figure 3) whose root contains the syntactic type and semantic analysis of the entire input string. We call this final semantic representation the *logical form* of a sentence, and the particular tree structure of rule applications the *derivation* (analogous to a syntactic parse). We let $A = \langle L, T \rangle$ denote the full analysis of an utterance, where L is the logical form and T is the derivation.

[1] This walkthrough involves a minimal amount of equations, focusing instead on applications to concrete word learning problems. Model details are provided in the appendix of this paper.

[2] See Steedman and Baldridge (2006) for a full description.

Scene	Events
Γ_1	CAUSE($girl$, BECOME(toy, $active$))
	CONTACT($girl$, toy); MOVE($girl$)
Γ_2	BECOME(toy, $active$); MOVE($girl$)

Table 1: Two sample scene representations from our model of the two-alternative forced choice test trial of Kline et al. (2017).

We next design a minimal probabilistic model on top of this CCG formalism which can realize, among other things, the behavior of the children in the experiment of Kline et al. (2017). Our model adapts past work on probabilistic CCGs (see e.g. Zettlemoyer and Collins, 2007; Artzi and Zettlemoyer, 2013), adding a critical inductive bias linking syntactic and semantic representations within the lexicon. We illustrate the model as a plate diagram in Figure 4, and walk through its behavior in the following paragraphs.

We will walk through this model in the context of the Kline et al. (2017) paradigm, showing how it can realize the subjects' observed behavior. For the rest of this section, we assume the provisional lexicon shown in the top of Figure 3, associating particular words with candidate syntactic types and meanings. Later, we will remove this assumption and show how such a lexicon can be learned from experience alone.

Consider an utterance $U =$ *the girl pushes the toy* given in a grounded context Γ.[3] We can combine the CCG framework with our weighted lexicon to compute the probability of an arbitrary analysis:

$$P(A = \langle L, T \rangle \mid \Lambda, \Gamma) \propto P(\Gamma) P(L \mid \Gamma) \exp\Big(\sum_{(w, s_w, m_w) \in T} \theta_w\Big) \quad (1)$$

where $P(\Gamma)$ is a uniform prior over potential contexts, and $P(L \mid \Gamma)$ is one only when a logical form L is true of the context Γ. The final term in the above equation does the majority of the work, combining the weights θ_w of lexical entries involved in the derivation T. The lexicon in Figure 3 licenses multiple analyses of the sentence *the girl pushes the toy*, since it contains two candidate entries for the word *toy*. Equation (1) can be used to rank the resulting analyses — one of which is shown in the bottom section of Figure 3 — according to the constituent lexical weights θ_w.

In the experiment of Kline et al. (2017), a child hears the utterance $U =$ *the girl gorps the toy* and is asked to pick which of two scenes Γ_1, Γ_2 the utterance refers to. We represent the scenes as lists of propositions like those in Table 1.

Unlike our previous example, this utterance contains a novel word which has no corresponding entries in the lexicon. We must induce candidate syntactic types s_w and meanings m_w using the remainder of the probabilistic model.

We begin by enumerating the possible syntactic types s_w of the novel word. Given the contents of the provisional lexicon Λ (shown in the top left of Figure 3) and our parsing ruleset, there is just one syntactic analysis of *gorps* which yields a valid parse. This parse has the same structure as that shown in bottom section of Figure 3. The parse assigns the word the syntactic type $S\backslash N/N$: the syntactic type of a transitive verb.[4]

We next make predictions about the candidate meanings of *gorps*. This prediction process is visualized in Figure 5. We begin by sampling meanings m_w conditioned on the possible syntactic representations s_w. This is the point at which syntactic bootstrapping plays a critical role: the model calculates a distribution $P(m_w \mid s_w = S\backslash N/N)$, which we expect should favor meanings involving the predicate CAUSE:

$$P(\text{predicate}_i \mid s_w) \propto C + \sum_{\substack{(s_i, m_i, \theta_i) \in \Lambda \\ : s_w = s_i \wedge \text{predicate} \in m_i}} \theta_i \quad (2)$$

$$P(m_w \mid s_w) \propto \prod_{\text{predicate}_i \in m_w} P(\text{predicate}_i \mid s_w) \quad (3)$$

where C is a smoothing constant, fit as a hyperparameter. Equation (2) aggregates the total weight mass in the lexicon allocated to any particular predicate for lexical entries with syntactic type s_w. The product term of Equation (3) combines these individual predicate probabilities in order to score possible complete meanings m_w of the word *gorps*. The left panel of Figure 5 shows a ranked list of meanings computed by this equation under our provisional lexicon.

Each candidate meaning and syntactic representation of the word *gorps*, when combined with the rest of the words in the sentence, yields a full syntactic derivation T and logical form L. These utterance-level meaning representations are scored based on the scene Γ. Here we incorporate the critical constraint that logical forms L must consist of messages which are *true* of the scene Γ. This effectively filters the candidate complete meanings L, yielding a renormalized distribution over full sentence meanings as shown in the middle panel of Figure 5.

We can combine the above distributions in order to perform the critical inverse inference $P(\Gamma \mid U, \Lambda)$: which scene does the utterance *the girl gorps the toy* refer to? This distribution is computed via Bayes' rule, yielding the posterior distribution shown in the right panel of Figure 5. The positive sentence containing the novel word *gorps* is predicted to refer to the scene with a salient causation event. By a similar logic as shown in this walkthrough, the negative sentence *the girl doesn't gorp the toy* is taken to refer to the scene missing the salient causation event.

This section has demonstrated how the probabilistic model sketched in Figures 3 and 4 reproduces syntactic bootstrapping behavior, using the transitive syntax of novel words to predict meanings containing the semantic predicate of CAUSE. The model integrates the CCG parsing formalism with a statistical mechanism for tracking the relations be-

[3] Contexts will become relevant later in the paper. See Table 1 for an example context representation.

[4] In cases where there are multiple syntactic types for a novel word, they are scored according to a distribution $P(s_w \mid \Lambda)$, given in Equation (9).

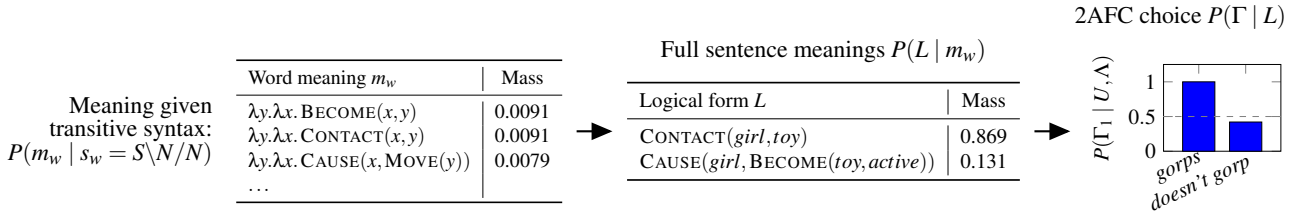


Figure 5: Computation of the meaning of a novel word *gorps* in the sentence *the girl gorps the toy* proceeds in three steps: word meanings are enumerated according to a distribution $P(m_w \mid s_w)$ (Equation (3)), full sentence meanings L are produced via CCG parsing, and the candidate scenes Γ_1, Γ_2 are scored according to which sentence meanings are true of which scene.

tween syntactic structures and their semantic correlates, helping the learner to make predictions about the meanings of novel words.

Learning

The previous section assumed that the learner already possessed a knowledge state as given in Figure 3, where wordforms like *girl* and *push* already have correct meaning representations. In this section, we show how such a lexicon can be acquired across multiple instances of ambiguous language use in context, in a manner that requires minimal long-term memory capacity and remains robust to noise in the input.

We expose our model to a sequence of observations $O = (\langle U_i, \Gamma_i \rangle)$ of utterances U_i grounded in particular scenes Γ_i. We proceed by observing each data point O_i in sequence and updating a lexicon Λ, inducing novel lexical entries as necessary and updating weights θ_w in the lexicon. The learner never directly observes the mapping between words and their referents, or between sentences and their meanings. The task of the learner is to derive word meanings, and methods for composing words, such that each utterance U_i is true in its context Γ_i.

We also constrain our word learner to encode only a limited number of lexical entries per word at all times. We label this limit ℓ, and evaluate its influence as a free parameter in the following experiments. Concretely, after each observation O_i, we retain only the ℓ highest-weight lexical entries per wordform.

Let Λ_i be a learner's lexicon representation before observing the example O_i. Suppose that the utterance U_i is observed in a context Γ_i which contains a novel word $w = gorps$: *the girl* ***gorps*** *the toy*. The machinery already presented in the previous section can be used to induce candidate novel meanings for the word *gorps*. In order to support incremental learning, we include an additional *weight update* step after each utterance is observed. Given the utterance U_i, we update the weights of each lexicon entry in order to increase the probability of observing the utterance under the model given in Figure 4. Further details on the learning algorithm are given in the appendix.

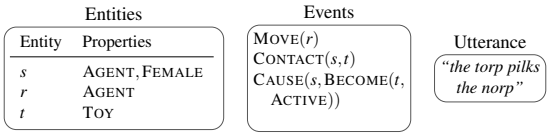

Figure 6: An example observation. Utterances refer to objects (*the norp*) or events (*the torp pilks the norp*).

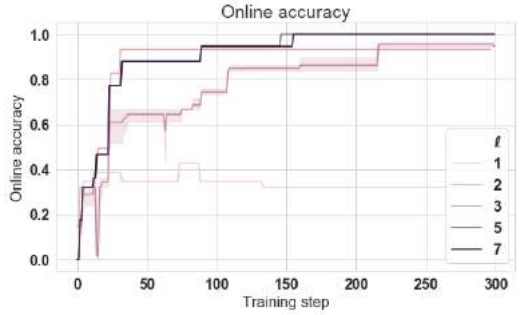

Figure 7: Online accuracy in predicting sentence meanings for word learning models with different numbers of allowed stored meanings ℓ. Shaded regions represent 95% CI.

Experiments

We deploy the above learning model on a synthetic dataset in which short utterances pick out objects, events, and relations in a simulated environment. This environment is similar to those used in artificial intelligence research on visual question answering (see e.g. Johnson et al., 2017), but contains more complex utterances which make reference to abstract events and relations (such as causation, state change, and movement). Figure 6 shows an example scene–utterance pair drawn from this dataset.

We generate observations O_i by first sampling a context Γ_i. Each context contains a random number of entities (agents and objects), and a random number of events relating those entities, structured as propositions like those shown in Table 1. Contexts always contain multiple simultaneous events, such that the learner is only ever exposed to ambiguous and indirect observations of sentence meaning.

Each entity and event is assigned a fixed random wordform throughout the experiment, and utterances are gen-

erated by combining the wordforms for the involved entities and events according to pre-designed templates. For example, if we sample a scene which contains an event $\textsc{Cause}(girl, \textsc{Move}(toy))$, we might generate an utterance *the torp pilks the norp*, where *torp* refers to female agents, *norp* refers to toys, and the whole sentence must pick out the complete event structure. We also randomly generate *negative* utterances, where verbs are modified by words to their immediate left who function to negate the overall sentence meaning. For example, *the torp doesn't pilks the norp* has the meaning $\neg\textsc{Cause}(girl, \textsc{Move}(toy))$.[5]

The task of the learner is to infer the meanings of each of these words by observation of random scenes $O_i = \langle U_i, \Gamma_i \rangle$. While we have access to the ground-truth correspondence between sentences and their full logical forms during scene generation, this mapping is not provided to the learner.

We evaluate the learner's lexicon acquisition by two metrics: 1) its accuracy in predicting the ground-truth semantic representations of test sentences, and 2) its accuracy in the syntactic bootstrapping two-alternative forced choice task of Kline et al. (2017). Figure 7 shows the model's performance on the first across learning time, as the model is incrementally exposed to more examples O_i. Both graphs contrast models with different settings of the hyperparameter ℓ, which controls the maximum number of entries that can be stored across observations for any wordform in the lexicon. For all settings of $\ell > 1$, the model reaches high performance within 100 examples. All models reach perfect performance on the second syntactic bootstrapping 2AFC task after just a few examples: the correct acquisition of just one or two transitive verbs is enough to support the induction of a productive belief about the link between verb syntax and semantics.

The results in Figure 7 demonstrate that even highly resource-constrained Bayesian learners can acquire an accurate lexicon in a data-efficient manner. These same learners quickly derive a syntactic bootstrapping capacity from their own lexicons, supporting more efficient learning in the future.

Conclusion

This paper has presented a computational word learning model which actively tracks the correspondences between the syntactic and semantic behavior of words. We demonstrated how this framework can capture experimentally observed syntactic bootstrapping phenomena, and that such phenomena can be explained as the rational behavior of a cross-situational learner exposed to a corpus of naturalistic data. Critically, both word learning (of nouns and verbs) and also the acquisition of the high-level syntactic bootstrapping behavior still go through given substantial long-term memory constraints, in which models store just a few candidate interpretations per wordform in their language.

As a computational model of acquisition, this framework makes predictions about how people should interpret and generalize novel words. Our framework allows us to make rigorous and explicit statements about the structure of the mental representational spaces underlying these generalizations. In ongoing work, we are using the same model class presented in this paper to detect candidate links between word syntax and word semantics which a rational learner can (and should) exploit.

[5]The training corpus is generated from a collection of 3 unique referents and 5 unique event types, each of which has one fixed referring expression. This yields a total of 51 unique utterances.

Model details

This final section provides mathematical details on the model for completeness.

Reading from Figure 4, the probability of a full utterance is:

$$P(U \mid \Gamma, \Lambda) \propto P(\Gamma) \sum_{L,T} P(T \mid \Lambda) P(U \mid T) P(L \mid T, \Gamma, \Lambda) \tag{4}$$

We assume a uniform prior over scenes $P(\Gamma)$, and let $P(U \mid T)$ be 1 exactly when the span of T is equivalent to U, and zero otherwise. Lastly, we define the probability of a logical form L in terms of the derivation T and context Γ as follows:

$$P(L \mid T, \Gamma, \Lambda) = P(L \mid T, \Lambda) P(L \mid \Gamma) \tag{5}$$

$$P(L \mid T, \Lambda) \propto \mathbf{1}\{L \text{ is determined by } T, \Lambda\} \tag{6}$$

$$P(L \mid \Gamma) \propto \mathbf{1}\{L \text{ is true in } \Gamma\} \tag{7}$$

Novel word induction Given a novel word w, we resort to the full Bayesian model to make predictions about its syntactic type s_w and meaning m_w.

$$P(w \to (s_w, m_w) \mid U, \Gamma) \propto P(s_w \mid w) P(m_w \mid s_w) P(U \mid \Gamma, \Lambda \cup (w, s_w, m_w)) \tag{8}$$

The only term not yet defined is the distribution over syntactic types $P(s_w \mid w)$. This distribution is computed by simple inspection of the lexicon. The probability mass assigned to a particular syntactic category s is proportional to the total weight assigned to entries in Λ with category s:

$$P(s_w \mid \Lambda) \propto C + \sum_{(w, s_w, m_w, \theta_w) \in \Lambda} \theta_w \tag{9}$$

where C is a smoothing constant.

As shown in the earlier model walkthrough, Equation (8) is used to initialize the weights for the lexical entries of novel words.

Weight updates Let g be the highest probability correct analysis of a sentence $\langle L, T \rangle$, and let B be the set of the k most probable incorrect analyses.[6] For each lexical entry $x_i = (w_i, s_i, m_i, \theta_i)$ with weight θ_i, we perform the following perceptron update:

$$\theta_i \mathrel{+}= \eta \left(\mathbf{1}\{x_i \in g\} - \frac{1}{|B|} \sum_{b \in B} \mathbf{1}\{x_i \in b\} \right) \tag{10}$$

where η denotes a learning rate, and $x_i \in A$ is true iff the lexical item x_i participates in the analysis A. Note that this update will only affect lexical entries with wordforms used in the utterance U_i.

[6]Here a "correct" analysis is one which has nonzero probability under Equation (1). Note that, consistent with the cross-situational paradigm, only analyses with meanings that are true of Γ_i have nonzero probability.

Abstract

In natural languages, closed-class items predict open-class items but not the other way around. For example, in English, if there is a determiner there will be a noun, but nouns can occur with or without determiners. Here, we asked whether language learners' computations are also asymmetrical. In three experiments we exposed adults to a miniature language with the one-way dependency "if X then Y": if X was present, Y was also present, but X could occur without Y. We created different versions of the language in order to ask whether learning depended on which of these categories was an open or closed class. In one condition, X was a closed class and Y was an open class; in a contrasting condition, X was an open class and Y was a closed class. Learning was significantly better with closed-class X, even though learners' exposure was otherwise identical. Additional experiments demonstrated that the perceptual distinctiveness of closed-class items drives learners to analyze them differently; and, crucially, that the primary determinant of learning is the mathematical relationship between closed- and open-class items and not their linear order. These results suggest that learners privilege computations in which closed-class items are predictive of, rather than predicted by, open-class items. We suggest that the distributional asymmetries of closed-class items in natural languages may arise in part from this learning bias.

Keywords: language acquisition; statistical learning; computational mechanisms; morphosyntax; function words; closed-class items

Introduction

In natural languages an important contrast is between open class lexical items—for example, nouns or verbs—and closed class or function items—for example, *is* or *the*.[1] Open class categories like noun or verb contain many members and typically carry the important lexical content of the sentence. In contrast, closed class items, which are used to mark grammatical functions of other words, are typically very short, few in number, are each used with high frequency, and occur in predictable positions in their phrases. For example, English marks definiteness with the article *the*, which is one of the most frequent words in the language and always occurs before its noun. There is wide variation in the distribution of functional items across languages: in contrast to English, definiteness in Amharic is marked on lexical items in a particular structural position and can attach to nouns, adjectives, numerals, or even verbs depending on sentence structure (Kramer, 2010). The distribution of closed-class items is always predictable in certain ways, but learners must do a substantial amount of distributional analysis in order to learn the particular patterning of closed-class items in their language. The goal of the present paper is to explore the computational mechanisms that enable language learners to do this.

From previous research we know that closed-class items draw special attention from language learners. Infants can identify them on the basis of correlated distinctive phonological, prosodic and distributional properties such as short duration, light syllable structure, and high frequency (Shi, Morgan, & Allopenna, 1998; Shi, Werker, & Morgan, 1999), and children begin to represent these items long before producing them (Shafer, Shucard, Shucard, & Gerken, 1998; Shi, Werker, & Cutler, 2006). Early attention to closed-class items could facilitate other aspects of language acquisition. For example, since these items often occur at grammatically important parts of the sentence (e.g., phrase boundaries), focusing on them could help learners acquire grammatical structure. There is substantial empirical support for this idea, known as the Anchoring Hypothesis (Mintz, 2006; Morgan, Meier, & Newport, 1987; Valian & Coulson, 1988; Zhang, Shi, & Li, 2015).

However, it is not yet clear what computational mechanisms underlie learners' distributional analyses, once they have noticed closed-class items. The literature on statistical learning has not focused particularly on closed-class items; and only a few studies identify specific statistical computations that learners might draw on. These studies have revealed, for example, that learners can compute transitional probabilities to find word boundaries (Aslin, Saffran, & Newport, 1998; Saffran, Aslin, & Newport, 1996; Saffran, Newport, & Aslin, 1996) and to acquire grammatical phrases (Thompson & Newport 2007). Despite this progress, we are only beginning to identify the computational mechanisms underlying many aspects of language acquisition. It thus remains a mystery how learners manage to sort out patterns as complicated as (for example) Amharic definiteness. What kind of computations would a learner need to perform in order to acquire this type of pattern?

Consider the statistical information about closed-class items that is present in learners' input. As already noted, these items generally do not independently contribute semantic

[1] The terms 'functional item' and 'closed class' are often used interchangeably. We adopt the terminology of closed and open classes because these terms more readily apply to our miniature languages.

meaning; rather, they specify the grammatical properties of the meaning-bearing elements (the lexical categories). This role gives closed-class items a highly predictable syntactic context. For example, *the* indicates that its noun refers to a specific referent identifiable in context and therefore must appear with a corresponding noun, never alone. In statistical terms, the probability of seeing a noun, given that there is a determiner, is 100%. The reverse is not true, however, since nouns can occur in a variety of grammatical contexts, with or without determiners.[2]

The statistical asymmetry in the distribution of closed- and open-class items is especially interesting in light of the recent emphasis in syntactic theory on the role of functional categories in sentence structure (see Rizzi & Cinque, 2016 for discussion and historical context). Increasingly, linguists have argued that properties of closed-class items determine the behavior of other words in the sentence. This extends beyond the presence of certain open-class categories to their positions in the sentence as well. To illustrate, consider the pattern of verb placement in French. Lexical verbs such as "eat" (*mang-*) can either precede or follow the negative marker (*pas*) depending on whether the verb is morphologically finite, as in *tu manges pas?* ("You're not eating?), or non-finite as in *tu vas pas manger?* ("You aren't going to eat?"). Linguists capture this contingency between finiteness and verb position by positing that the abstract features of finite and non-finite morphemes are represented in different positions in the sentence. If there is finite morphology, there will be a verb and that verb will occur in the "finite" position (pre-negation). In this way the presence and location of verbs is determined by the kind of morphology that occurs in the sentence.

Of course, linguists' analyses are intended to be formal mathematical descriptions of sentence structure, and not necessarily claims about the psychological representation of sentences. However, this kind of analysis demonstrates an important empirical point: *regularities of word order and word form can be stated as restrictions on the distribution of closed-class items*. Consider now the problem of distributional learning. One way to begin learning, given this view from syntactic theory, would be to identify closed-class items (for example, based on their salient perceptual properties) and then proceed to learn their distribution. Because this distribution is asymmetrical—closed-class categories always predict but are not predicted by open-class categories—the computations that learners perform could also be asymmetrical. Learners need to learn what a closed-class item *predicts*—the presence of other categories, the placement of words, and so on—but they need not expend any effort finding distributional patterns that a closed-class item is *predicted by*, because there are none.[3]

Here we explored the possibility that learners privilege computations in which closed-class items are *predictive of* open-class items over computations in which they are *predicted by* open-class items. In Experiment 1 we exposed adult learners to a miniature language containing a one-way grammatical dependency between two form-class categories, X and Y. When an X word was present, a Y word always had to be present as well, but Y words could occur with or without X words ("if X then Y"). This is mathematically like the relationship between determiners and nouns in English. In two contrasting conditions, we assigned different types of words to the X and Y categories. In one condition the predictive category (X) was a closed class (short, monosyllabic, and containing only one item, *ka*), while in the other condition the predictive category was an open class (mono or disyllabic and containing three possible lexical items). Learning was better when X was closed-class, suggesting that learners' computations are biased: they identify patterns where closed-class items are predictive of open-class items more readily than the reverse. Additional experiments demonstrated that learners analyze closed-class items differently because they are perceptually distinctive (Experiment 2) and that learning outcomes are driven by the mathematical relationship between closed- and open-class items and not their linear order (Experiment 3). Together, the results suggest that learners analyze closed-class items in certain biased ways, searching preferentially for the kinds of patterns that exist in natural languages. In the Discussion we return to the question of why learners should be biased in this way. We do not mean to suggest that they know in advance about languages in particular, but rather that their computational biases may shape languages to be structured in this way.

Before proceeding, it is important to clarify a component of our experimental design. The artificial language that we created for these experiments is not very language-like. The experiments are focused on a specific computational question about how learners analyze closed and open-class items. To test our hypothesis, it was necessary to design a language that could only be learned by computing the precise mathematical relationship between two specific terms (X and Y). Therefore X was the only category whose distribution with respect to other words was constrained; all other words in the language appeared and disappeared freely, which is unlike the more constrained sentence structure of natural languages. This

[2] In some cases, predictiveness goes both ways (e.g., in French, all non-proper nouns require determiners). Nonetheless, computing how often determiners are accompanied by nouns will *always* reveal a pattern, whereas the reverse computation only sometimes will. Thus analyzing closed-class items as predictive of open-class items is the most effective way to discover linguistic patterns.

[3] Of course closed-class items do not appear randomly in sentences. Their presence is determined by the semantic meaning that the speaker wishes to express. The learner does eventually need to learn which meanings go with which forms, but this is a separate and somewhat uncorrelated problem. As the comparison between Amharic and English definiteness marking illustrates, learning that a given form means "definite" does not tell the learner where, distributionally, that form occurs, nor does learning the distribution of a form reveal its meaning (e.g., both definite and indefinite articles precede nouns in English). Both learning problems are important, but we are concerned here only with the distributional one.

experimental design allowed us to test empirically whether learners' computational analyses are biased in a certain way. If the results of these experiments do reveal such a bias, this would be motivation to explore how this bias affects the acquisition of more naturally structured languages—a line of work that is in progress.

Method

Participants

Three groups of sixteen adults from the Georgetown University community (age 18-28, mean=20.4) participated in this study. Two additional participants' data did not save due to an error.

Description of the miniature language

The design of the language used in all three experiments is summarized in Figure 1. The word order was AXYBC, where each letter represents a form-class category. All categories were optional, with the constraint that only up to three categories could be omitted per sentence (i.e. sentences must each have at least two words). The fixed and consistent rule of the language was that if X was present, Y had to be present ("if X then Y"). Thus every sentence with X also contained Y, but sentences with Y did not have to contain X. Note that this dependency is defined in terms of the conditional relationship, not the linear order, of X and Y. In Experiment 1, X preceded Y while in Experiment 3 X followed Y; this did not change the conditional relationship between the two terms.

In each experiment we created different versions of the language in order to ask whether learning this conditional relationship between X and Y depended on which of these terms was a closed-class or an open-class category. None of the words had any meaning, so this contrast was defined by the number of words in each category and the phonological properties of those words. Each experiment had a condition where X was closed class and Y was open class (Closed X) and a contrasting condition where X was open class and Y was closed (Open X). Across experiments we varied the phonological properties of the closed-class item and the linear order of X and Y.

Experiment 1 In this experiment the closed-class category contained a single item *ka*, which had several properties common to closed-class items in English: it was short, lacked a coda or consonant clusters, and was high frequency by virtue of being the only member of its form class. Each open-class category contained three words that were a mixture of mono- and disyllabic forms. All words in the language, including the closed-class item, carried stress (i.e., *ka* was not prosodically dependent on any other item). In the Closed X condition, the X category contained *ka* and Y contained *lapal, tombur,* and *zup*. Thus the closed-class item *ka* predicted any of these three open-class items. In the contrasting Open X condition, X contained *lapal, tombur,* and *zup* and Y contained *ka*. Here the closed-class item *ka* is predicted by each of three open-class items.

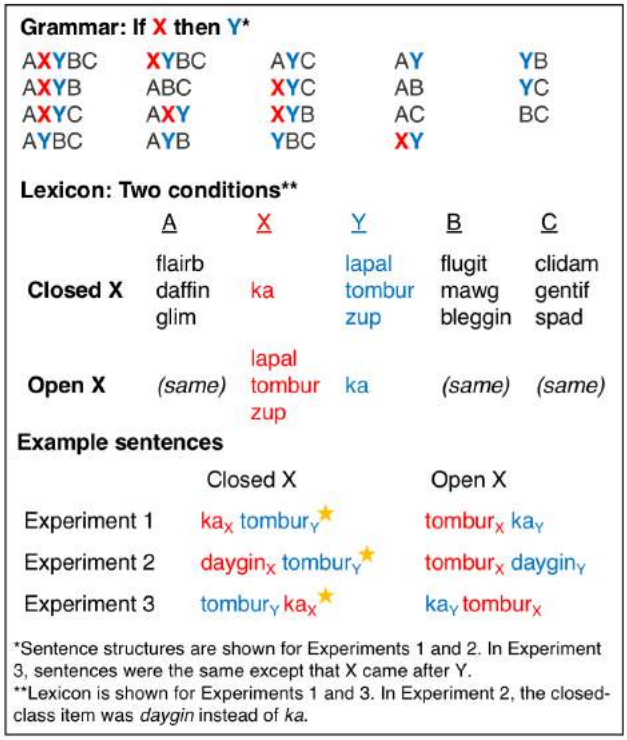

Figure 1: Design of the miniature languages used in Experiments 1-3. The critical feature of all languages is a one-way dependency between X and Y: every sentence with X also contained Y, but Y occurred without X. In Experiments 1 and 2, X came before Y (XY); in Experiment 3, X came after Y (YX). Each experiment had a condition where X was closed class and Y was open (Closed X) and a contrasting condition where X was open class and Y was closed (Open X). If learners are biased to analyze closed-class items as predictive, learning should always be better in the Closed X condition (marked with yellow stars).

Other than the specific lexical items in the X and Y categories, the two languages were identical. In both languages, sentences with X must also contain Y, while sentences with Y may or may not contain X. Because either X or Y is *ka*, learners in both conditions had an "anchor" for their distributional analyses. In both conditions, the predictive category (X) comes before the category it predicts (Y); this linear order was like subjects' native language, English, where (for example) determiners precede nouns. (In Experiment 3 we reversed the linear order such that the predictive category came last, as in languages like Japanese.) At a lexical level, in both conditions the dependency involved exactly one closed-class item and three open-class items; acquiring the dependency required computing exactly three word-level forward transitional probabilities (either X1-Y1, X1-Y2, X1-Y3 in the Closed X condition or X1-Y1, X2-Y1, X3-Y1 in the Open X condition). Our manipulation did of

course create different statistical patterns at the item level. In the Closed X condition, each of the three possible X-Y sequences had a transition probability of 0.33, whereas in the Open X condition each X-Y sequence had a transition probability of 1.0. Thus the item-level transition probabilities cued the XY unit more strongly in the Open X condition.

Because these languages are structurally identical except for the closed-open class contrast for X and Y, learning outcomes will differ only if learners' computational analyses treat closed-class and open-class items differently. If learners preferentially analyze closed-class items as predictive, they should easily learn "if X then Y" in the Closed X condition, where *ka* predicts an open-class category; but they should struggle in the Open X condition, where *ka* is predicted *by* an open-class category. Alternatively, if learners analyze closed-class and open-class items similarly, learning outcomes will be equivalent across conditions.

Experiment 2 Part of the hypothesis is that the distinctiveness of closed-class items drives learners to analyze them differently. In Experiment 2 we tested this by making the closed-class item less distinctive. Here the closed-class item (*daygin*) was disyllabic, carried initial stress, and had a closed final syllable, making it phonologically like the open-class words in the language; its only distinguishing property is its high frequency. If distinctiveness of *ka* drove learning outcomes in Experiment 1, learning should be weakened in Experiment 2.

Experiment 3 In Experiments 1 and 2 the Closed X condition was superficially like English: the closed-class item came before the open-class item (Figure 1). English does also have closed/open dependencies where the closed-class item comes last (e.g., walk + s), but only in morphology. Therefore better learning for Closed X in Experiments 1 and 2 could be due to a preference in native speakers of English for syntactic phrases where frequent words come first (cf. Gervain et al., 2013). In Experiment 3 we changed the word order of the language so that Y preceded X. Now the Open X condition is superficially more like English (frequent word first), whereas the Closed X condition is superficially like Japanese (frequent word last). If learning outcomes in Experiments 1 and 2 reflect superficial word order biases, then the results of Experiment 3 should be opposite to those of Experiment 1, with better learning for Open X. However, if learning outcomes depend on the structural relationship between closed-class and open-class items rather than superficial linear order, results should be similar to those of Experiment 1: Closed X should learn "if X then Y" and Open X should fail.

Materials

We generated a 38-sentence exposure set by selecting two sentence types for each of the 19 structures. The sentence structures were always the same across conditions and experiments, but the actual sentence strings differed across conditions and experiments according to the lexical items in the X and Y categories and the linear order of X and Y. Sentence sound files were created by concatenating individually recorded words (spoken by a female native speaker of English) with 50 msec of intervening silence. The 38-sentence exposure set was presented 16 times as part of a 1-back task (see Procedure).

Procedure

Participants learned the language through a computer game. A robot "Bot" instructed participants to listen as an alien named Zooma practiced saying sentences in an alien language. After each sentence, participants pressed a button to indicate whether Zooma had just repeated herself. After exposure, participants began the test. Bot explained that Zooma would try to say each sentence two different ways, and the participants' job was to decide which one was better. The entire experiment lasted approximately 45 minutes.

Test

Learning was measured with a two-alternative forced-choice (2AFC) test. The structure of the test was identical across experiments. Specific test strings varied according to the vocabulary of the language. The target choice on each trial was always a grammatical complete sentence. The alternative was identical to the target except that either one word was changed, or the words were the same but in a different order. The test was designed to ask whether participants had acquired a very specific piece of knowledge: the precise conditional relationship between X and Y. In order to answer this question it was important to create test items on which all other distributional properties (e.g., bigram frequency) were controlled. Only two types of test items could be carefully controlled in this way, described below. Items with confounds (not scored) included four additional items testing XY constituency and 20 items testing the XY relationship within longer sentences. In addition, we included four items testing basic word order and six filler items in order to balance the frequency with which targets and foils for the critical XY trials appeared on the test. Results for these items are not described for space reasons, but they are generally consistent with the results here.

There were two trials for each of the critical test item types. One item type served as a constituency test: XY was compared to YB (Experiments 1,2) or XB (Experiment 3). Both choices are legal two-word sequences (in Experiments 1 and 2, both choices are also complete sentences). They have the same relative frequency in learners' input, and are medial bigrams in the basic sentence structure (AXYBC (Experiments 1,2) or AYXBC (Experiment 3)). However, X and Y are related grammatically whereas the elements in the foil sequence are not. A preference for XY would indicate that participants represent this grammatical relationship. A second item type (AY vs. AX) tested whether participants learned that X predicts Y, but not the reverse. In Experiments 1 and 2, both choices are legal two-word sequences and occurred in learners' input with the same relative frequency; the two sequences had exactly the same forward transitional

probability (.36). However, only AY is a complete sentence. AX is a grammatical sequence but not a complete sentence, since it contains X but not Y. If participants have learned that X predicts Y (but not the reverse), they should prefer AY over AX. In Experiment 3, the foil was no longer a grammatical sequence in the language. Thus, it should be relatively easier in Experiment 3 than in Experiments 1 and 2 for both conditions to do well on these test items. Accuracy on the test was measured as choice of the target sequence.

Results

In Experiment 1 we asked whether learning of "if X then Y" would be different when X was a closed versus open class. Figure 2 illustrates that the answer is clearly yes. In the Closed X condition, learners chose the target item much more often than learners in the Open X condition (Closed X: 84%, Open X: 53%, $t(14) = 3.16$, $p = .007$). The grammatical coherence of XY as a unit was identical in these two conditions, since X always perfectly predicts Y. Yet learning outcomes differed across conditions, indicating that learners analyze closed-class items as predictive of open-class items more readily than the reverse.

Part of our hypothesis was that learners analyze closed-class items differently because these items are distinctive. In Experiment 2 we tested this by making the closed-class item less distinctive: here it was high frequency but phonologically like the open-class words in the language. Learning in the Closed X condition in this experiment was weaker than in Experiment 1 (Figure 2) and was no longer significantly better than the Open X condition ($t(14) = 1.94$, $p = .07$). This supports our hypothesis: closed-class items are analyzed differently because they are distinctive.

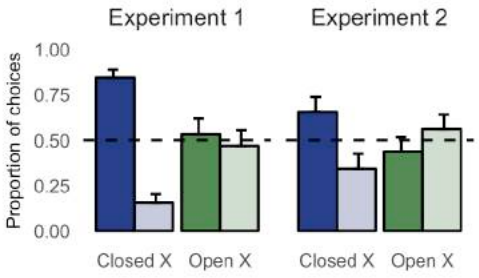

Figure 2: Choice of the target item (darker colors) or foil (lighter colors) on the 2AFC test in Experiments 1 and 2.

In Experiment 3 we asked: did the Closed X condition perform better because their language was superficially like English (the frequent item came first)? In this experiment Y came before X, but X still predicted Y. Thus the Open X condition was superficially like English. However, the Open X learners still struggled to learn "if X then Y" (59% correct, not significantly different from chance: $t(7)=2.05$, $p = .08$). In contrast, the Closed X condition continued to perform well above chance (72% correct, $t(7)=2.97$, $p = .02$), even though their language was superficially *unlike* English and more like an unfamiliar language, Japanese. These results demonstrate that the primary determinant of learning is the mathematical relationship between closed-class and open-class items and not their linear order.

The results just reported are collapsed across two types of items: the constituency test (YX vs. XB) and the predictive direction test (AY vs. AX). Based on these collapsed results, learning in the Open X condition appears to be slightly better than expected. Although learners were not significantly above chance, the difference was marginal, and accuracy was numerically higher than in Experiment 1 (59% vs. 53%). An analysis of results for the two different test item types provides some insight. In Experiments 1 and 2, results were equivalent across item types. However, the Open X condition in Experiment 3 showed a different pattern (Figure 3): learners passed the constituency test (88% correct), but were numerically *below* chance on the predictive direction test (33% correct). A 2-way mixed ANOVA over condition and trial type confirmed this impression statistically: there was no main effect of condition ($F(1) = 2.07$, $p = .17$), but there was a significant main effect of test item type ($F(1) = 4.77$, $p = .047$), and—importantly—a significant interaction between condition and test item type ($F(1) = 7.45$, $p = .02$), driven by a preference in the Open X condition for the ungrammatical sequence *AX over AY.

Why would the Open X condition perform so poorly on the AY/*AX items? Based on the raw statistical properties of learners' input, these items should be easy: *AX is not a complete sentence or even a legal sequence, whereas AY is both. In fact, an explanation for these results is provided by our hypothesis: that learners attend to (or search for) some statistical patterns over others, prioritizing patterns in which closed-class items are predictive. Such a bias would lead learners in the Open X condition to initially analyze their closed-class item Y as predictive of another item. Statistically, the item that Y best predicts is X (the probability that a sentence contains X, given that it contains Y, is .53). Thus, a preference for *AX could reflect an incorrect hypothesis that the conditional relationship between X and Y is reversed ("if Y then X"). This generalization is not consistent with learners' input, but it is consistent with the patterning of closed-class items in natural languages.

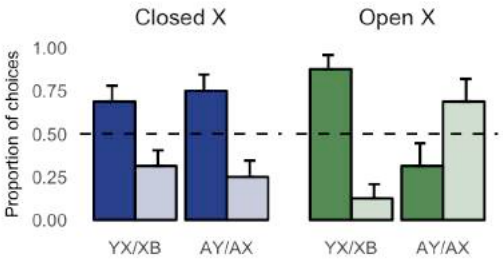

Figure 3: Choice of the target item (darker colors) or foil (lighter colors) on the two item types of the 2AFC test in Experiment 3. Participants in Closed X still learned, even though the linear order was opposite English. In contrast, participants in Open X succeeded on the constituency test (YX/XB) but not the predictive direction test (AY/AX), apparently having incorrectly analyzed Y as predictive of X.

Discussion

In three experiments, we showed that adults easily acquire a grammatical dependency "if X then Y" when X is a closed-class, but fail to acquire the same dependency when X is an open class (Experiment 1). Successful learning of "if X then Y" is facilitated by the distinctive perceptual properties and high frequency of the closed-class item (Experiment 2). Importantly, the primary determinant of learning is the mathematical relationship between closed-class and open-class items and not their linear order (Experiment 3). These results suggest that learners privilege computations in which closed-class items are predictive of open classes—the same computations that are most relevant for natural language dependencies.

We emphasize that, within each experiment, the Closed X and Open X conditions had exactly the same statistical evidence for the rule "if X then Y": class X always perfectly predicted class Y. Furthermore, learners in contrasting conditions were always exposed to the same number of lexical items, sentence structures, and sentence types. To acquire the XY rule, learners needed to compute exactly three transitional probabilities, and contrasting conditions within each experiment always contained the same linear direction of the X-Y relationship (forward for Experiments 1 and 2, backward for Experiment 3). Despite this mathematical equivalence, learning was always better when X was a closed class. If participants were computing statistics over items rather than classes, the results are even more striking: in that case, participants learned three low-probability dependencies with a predictive closed-class item (*ka*→*lapal*, *ka*→*tombur*, *ka*→*zup*) more easily than three high-probability dependencies with a predictive open-class item (*lapal*→*ka*, *tombur*→*ka*, *zup*→*ka*).

These results indicate that—whether learners computed statistics over classes or items—their distributional analyses are biased. Rather than tracking all possible pairwise transitional probabilities involving a closed-class item, learners apparently analyze closed-class items asymmetrically, more easily learning patterns in which a closed-class item is predictive *of* another element than patterns in which it is predicted *by* another element.

Conclusion

The original idea of the Anchoring Hypothesis (Valian & Coulson, 1988) was that, because closed-class items tend to occur at grammatically important points in the sentence, focusing on them could help learners acquire grammatical structure. Our results add a computational component to this approach. Our hypothesis is that, because closed-class items are noticed first, due to their distinctive phonological properties and their high frequency, these will be the constant terms in learners' computations; other patterns are learned and represented relative to them.

A learning mechanism that operates in this way would ultimately represent a broad range of language patterns in terms of the distribution of a small set of closed-class items. As we pointed out in the Introduction, this is increasingly the way that language patterns are described by modern syntactic theory as well. The results of our experiments suggest that human languages may acquire this type of structure at least in part as a consequence of computational biases in the human language learner. This account is appealing because, if correct, it would explain the privileged role of closed-class items in human linguistic representations without positing that these representations are innate. However, it is important to note that in all three experiments, learners' preferred conditional relationship had the same abstract structure (though not always the same linear order) as the closed/open dependencies in all natural languages, including English. It is difficult to rule out the possibility that learning was affected by participants' experience with this abstract property of natural languages; even infants have experience with closed-class items (cf. Shi et al., 1998). Studies of learning in a non-linguistic domain could be informative (cf. Saffran, Johnson, Aslin, & Newport, 1999).

Our results raise several other important questions. First, what about closed-class items that behave differently? Our claim is that learners analyze closed-class items as predictive of open-class items, and that this approach is useful because it matches the abstract structure of grammatical dependencies in natural languages. However, there are exceptions to this pattern. For example, pronouns like *him* do not depend on open-class items the same way that articles do. Interestingly, pronouns are also special in other ways (Chomsky, 1980). The proposed computation could be useful not only for discovering predictive dependencies, but also—when this analysis fails to uncover a dependency—for flagging elements with a more complex grammatical distribution. Second, we must also ask whether this computational bias is present in children, who are the real natural language learners. Our results in ongoing work with child participants suggest that they do share this bias. This in turn raises a puzzle: if children organize their languages around closed-class items, why do they not produce these words in their own speech for several years? The available evidence suggests that children do indeed process closed-class items early, despite omitting them in production (Gerken et al., 1990; Shi et al., 2006; Zhang et al., 2015). Future work is required to understand the discrepancy between what children represent and what they initially produce. Finally, we need to test our predictions on materials that are more like natural languages than what we have studied here. In order to test our computational predictions most cleanly, the languages in these experiments were unlike natural languages in several ways: all of the categories other than X and Y were optional, there was only a single grammatical phrase (XY), and none of the words had any meaning. We are in the process of testing whether learners privilege the same types of computations in the acquisition of miniature languages that are more natural. If so, we can ask what kinds of natural language patterns can be acquired and represented using these privileged computational mechanisms, and to what extent these learning mechanisms explain why these patterns come to exist in languages of the world.

Abstract

In this paper, we study cross-cultural differences in strategic reasoning in turn-taking games, as related to game-theoretic norms as well as affective aspects such as trust, degrees of risk-taking and cooperation. We performed a game experiment to investigate how these aspects play a role in reasoning in simple turn-based games, known as centipede-like games, across three cultures, that of The Netherlands, Israel and India. While there is no significant main effect of nationalities on the behaviour of players across games, certain unexpected interactive effects are found in their behaviour in particular games.

Keywords: intercultural differences; game theory; reasoning in games; trust and trustworthiness; risk considerations; cooperation

Introduction

Cognitive science is not only concerned with universal patterns of cognition, but also variations in those patterns, induced by relevant factors. As D'Andrade (1981) and Levinson (2012) argue, studying variation, and in particular cross-cultural differences, provides important insights. In this article, we study cross-cultural differences in strategic reasoning in turn-taking games, as related to affective aspects such as trust, degrees of risk-taking and cooperation. To this end, we performed a game experiment in three countries: The Netherlands, India and Israel.

Cross-cultural differences and games

It has been known for a long time that in turn-taking games of perfect information, people in general do not act exactly according to the prescriptions of game theory, which are based on the common knowledge of the rationality of participants (Aumann, 1995; Nagel & Tang, 1998). There has been a lot of interest in the possible differences between people from different countries with respect to adherence to game-theoretic predictions (Camerer, 2011). Note that national cultures should not be interpreted in an essentialist way: Cultural tendencies can be induced by incentives (Peysakhovich & Rand, 2016). For our experiments, we are mainly interested in four aspects:

- adherence to strategies defined in game theory, namely, forward versus backward induction;
- degree of trust and degree of trustworthiness;
- degrees of risk-taking;
- cooperative versus competitive tendencies.

As far as we know, our experiment is the first one to compare adherence to forward induction versus backward induction reasoning between different nationalities. The notions of forward and backward induction are explained in the next subsection on games.

With respect to trust and cooperation, however, there have been a number of previous cross-cultural studies, using both games in which participants meet an opponent only once and games in which they repeatedly interact with the same opponent (Roth et al., 1991; Ho & Weigelt, 2005; Henrich et al., 2005). Differences in trust, cooperativeness, and risk-taking between British and Japanese participants in turn-taking centipede games have been studied in Krockow et al. (2017).

Trust and trustworthiness Yamagishi & Yamagishi (1994) have distinguished two types of trust:

- *assurance-based trust* needed in relationships with high social certainty with an expectation of future interaction;
- *general trust* needed in encounters with strangers with low social certainty and low expectation of long-time future interaction.

Yamagishi & Yamagishi (1994) have also shown that different cultures score very differently on these two types: Assurance-based trust is high in cultures like Japan, as incentivized by long-time employment by the same company. In the United States and Great Britain, in contrast, high general trust corresponds with the prevalence of short-time employment and commerce with strangers. Based on the literature, we expect that trust for strangers is relatively low in India (where assurance-based trust is high, like in Japan) and high in The Netherlands (like in Great Britain), with Israel probably in between.

Cooperation, competition, and self-interest According to Hofstede (1991) (see the left part of Figure 1), Israel is an interesting mix between collectivist cultures such as India, which are expected to be more cooperative in nature,

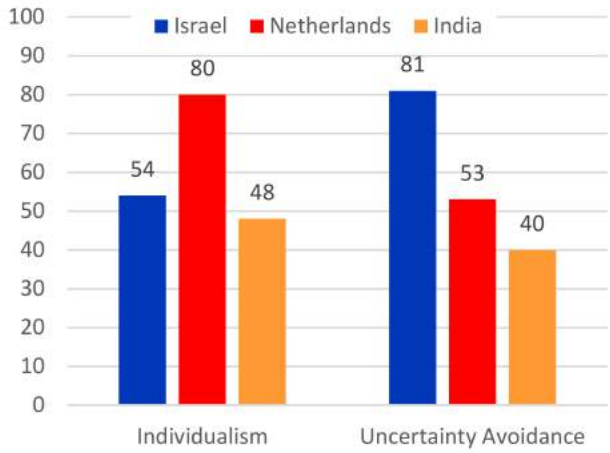

Figure 1: Individualism and uncertainty avoidance ratings of Israel, the Netherlands and India. The numbers for the countries were provided by the country comparison tool on Hofstede's website `https://www.hofstede-insights.com/`, based on the six dimensions distinguished by Hofstede (1991).

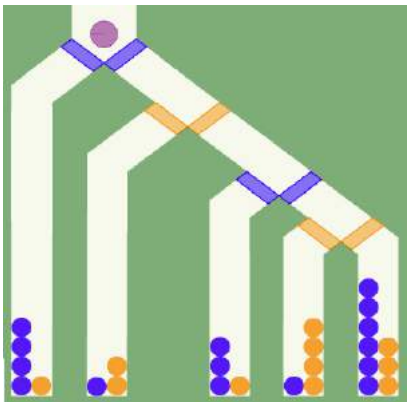

Figure 2: Marble Drop game. Players, assigned blue and orange, control the marble's course by opening the left or right trapdoor of their color once the purple marble arrives there. When the purple marble ends up in a certain bin, each player earns the marbles of their color in that bin. This example payoff structure corresponds to Game 1 of Figure 3 below.

and individualist ones such as the Netherlands, in which self-interested behaviour is more common.

Attitudes toward risk According to Hofstede (1991), people in Israel predominantly try to avoid uncertainty, while people in The Netherlands are rather neutral and people in India can handle uncertainty and risk most easily, see the right part of Figure 1.

The main focus of this paper is an experiment to investigate how the above-mentioned aspects play a role in reasoning in simple turn-based games, known as centipede-like games, across the three cultures. The games are introduced in the next subsection.

Games for the experiment

The participants in our experiments played a turn-based game called Marble Drop (Figure 2) against a computer opponent, and accordingly, we denote the two players by '*C*' and '*P*'. An important advantage of using computer opponents in experiments with turn-taking games is that the experimenter can control the strategies used by the computer opponent, which allows better interpretation of the participants' decisions. The choice of the Marble Drop games was inspired by (Halder et al., 2015; Ghosh et al., 2017; Verbrugge et al., 2018). These games can be visually represented as binary tree structures (Figures 3 and 4). The difference between Game 1 and Game 2 lies in the payoff of player *C* when choosing *a* at C_1. That payoff of player *C* after choosing *a* is also the only difference between Game 3 and Game 4. In addition, the only difference between Game 1 and Game 2 on the one hand and Game 3 and Game 4 on the other hand is the payoff of player *P* after choosing *h* at P_2. Since the structure of these games is reminiscent of a centipede, with its body extending from top left to bottom right, the games are termed as 'centipede-like' games.[1]

In the textbook approach of solving such turn-based games in game theory, players who are commonly known to be rational use the *backward induction* (BI) strategy (Perea, 2010): one should ignore previous information, and work backwards from the end of the game tree to reach a decision. For example, in the 'orange' player's last turn in the marble drop game (Figure 2), he has to decide between going to the left or to the right, for payoffs of 4 or 3 orange marbles, respectively. Using BI, because 4 is more than 3, he chooses to go left, delivering the outcome pair (1,4): 1 for the blue player, 4 for the orange player. One can then continue backwards to compare the left and right choices in the blue player's second turn: going right gives (1,4) while going left gives (3,1); because 3 is more than 1, the blue player would choose to open the left blue trapdoor. One then continues to reason backwards to compare the actions in the orange player's first turn, where the outcome is (1,2) when playing left and (3,1) by playing right. One assumes that, 2 being more than 1, the orange player chooses to open the left orange trapdoor. Finally, one compares the actions in the blue player's first turn, where going left leads to (4,1) and going right leads to (1, 2). Because 4 is more than 1, the blue player will choose to open the left trapdoor to obtain 4 points. Note that playing rationally by BI does not necessarily lead to the outcome with the highest sum of players' payoffs – that would have been achieved by both players choosing to open their right trapdoors at all four decision points and ending up with a combined payoff of 6+3.

The 'surprising opponent' component of these experimental games comes from the fact that player *C* (blue) when starting the game does not always play according to the strategy

[1]The games we consider do not always comply with the conditions on payoffs of the original centipede game (Rosenthal, 1981).

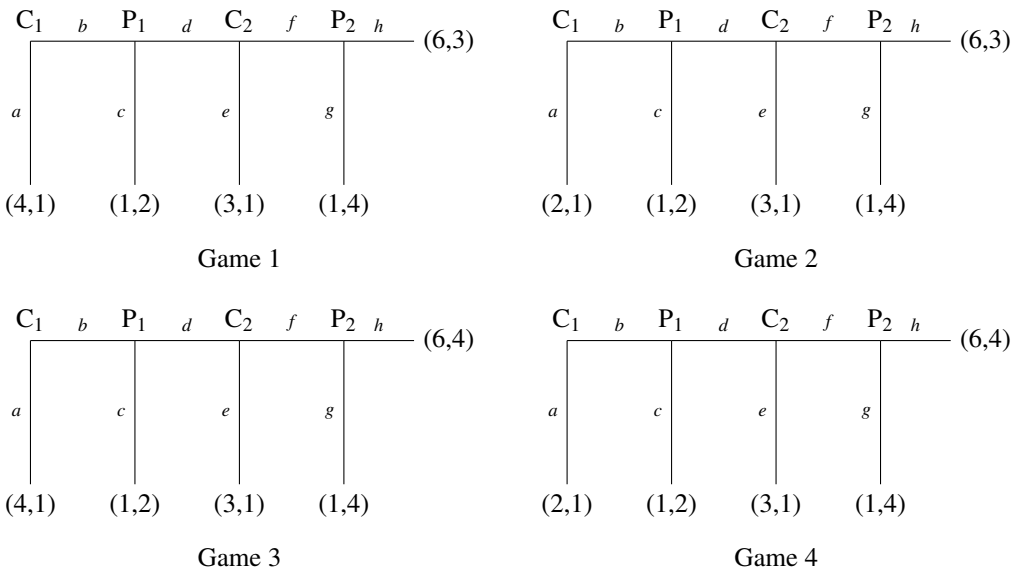

Figure 3: Collection of the main games used in the experiment. The ordered pairs at the leaves represent payoffs for the computer (C) and the participant (P), respectively.

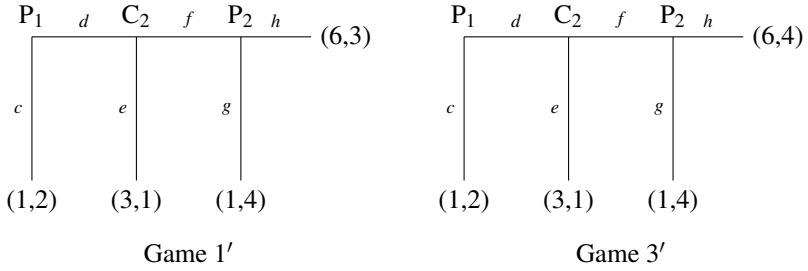

Figure 4: Game $1'$ corresponds with the parts of Games 1 and 2 from P_1 onwards. Game $3'$ corresponds with the parts of Games 3 and 4 from P_1 onwards.

described above. Note that in Games 1-4 in Figure 3, the BI strategy suggests for player C to choose a at the first decision node. In our experiment, the computer player often goes to the right to give player P (orange) a turn to move in the game. The orange player may or may not take into account this 'surprising' move of the blue player while considering his future moves. He can disregard his opponent's past move and play as if he is playing a 'new' game from the current turn and continue according to the BI strategy. Such players would play as if they were playing Game $1'$ or Game $3'$ (see Figure 4). Alternatively, the orange player can play according to a completely different strategy as described below.

In *forward induction* (FI) reasoning, a player takes into account his opponent's past moves and tries to rationalize the past behaviour in order to assess that opponent's future moves (Perea, 2010). We consider a particular kind of forward induction reasoning here, namely, *extensive-form rationalizability* (Pearce, 1984). The underlying idea is that when a player is about to play at a decision point that has been reached due to some strategy of the opponent that is not consistent with common knowledge of rationality for each of the players, the player may still rationalize the opponent's past behaviour. For example, suppose that the participant P has the opportunity to play at her first pair of orange trapdoors in the marble drop game (Figure 2, corresponding to Game 1 of Fig. 3), which has been reached because the computer C has chosen to open the right blue trapdoor. This first move is inconsistent with the choice determined by the assumption of rationality of both players (see BI example above), that is to open the left blue trapdoor. The participant might reason as follows: "The computer will definitely refrain from choosing the left trapdoor at his next choice getting 3 marbles, because he could have got more (4) marbles had he chosen the left trapdoor in his first decision node. He must be thinking that I would choose the right trapdoor in my second decision node if it is reached, in which case he would get 6 marbles, which is more than 4. So, if I choose the right orange trapdoor now, he will choose the right blue trapdoor at his next choice, and then I could choose the left trapdoor which would give me 4 marbles, more than the 2 marbles I would get if I chose the left trapdoor now." According to extensive form rationalizability, it would therefore be irrational for a computer opponent C to choose b at C_1 only to choose e later at C_2 in Game 1 and in Game 3. However, it would be possible for the computer opponent to behave in this way in Game 2 and in Game 4. Similarly, extensive form rationalizability would

also consider it rational for a computer opponent C to play e at C_2 in Game $1'$ and in Game $3'$.

Ghosh et al. (2017) investigated whether people are inclined to use forward induction in centipede-like games, rather than backward induction, in an experiment performed in The Netherlands. They found that in the aggregate, participants showed forward induction behaviour in response to their opponent surprisingly deviating from backward induction behaviour right at the beginning of the game. However, participants' verbalized strategies most often mentioned their own attitudes towards risk and those they assigned to the computer opponent, sometimes in addition to considerations about cooperativeness and competitiveness, rather than game-theoretic considerations. In our current study, we investigate variations in reasoning strategies across nationalities.

Hypotheses

We first note that in all these games, we are trying to study participants' reasoning methods in terms of their moves (i.e., participants' behaviour). There are certain challenges regarding linking behaviour in games to the underlying reasoning processes of players. For example, one can explain a given action in a turn-based game with different reasoning patterns. In this paper, we interpret the moves with respect to particular reasoning patterns they represent, namely, game-theoretic reasoning strategies such as backward and forward induction reasoning as well as strategies influenced by affective aspects like trust, degrees of risk-taking and cooperation.

In Game 1 and Game 3, the action c at P_1 would suggest backward induction reasoning performed by the participant. In addition, the same action might also suggest uncertainty avoidance or risk-averseness in the participant. On the other hand, the action d might suggest a risk-taking attitude in addition to extensive-form rationalizable (forward induction) reasoning. Taking note of such variations in reasoning patterns, we now formulate hypotheses about the cultural differences that we expect, based on the relevant features discussed in the Introduction.

Backward versus forward induction, uncertainty avoidance and trust Taking a cue from the fact that at P's first decision point, the uncertainty avoidance action is the same as the backward induction reasoning action in all our experimental games, we argue that there is a link between these two reasoning patterns in the present context. Accordingly, because of highest uncertainty-avoidance we expect that backward induction reasoning is strongest in Israel, then the Netherlands, then India. So we expect the 'safe' choice of c (backward induction) at the first decision point P_1 in all the games of Figure 3 to be most prevalent in Israel, followed by The Netherlands, and least in India.

Looking more specifically at game items, the higher level of generalized trust in The Netherlands than the two other countries leads us to expect higher choices of d especially in Game 1 and Game 3, based on forward induction and/or trust that the other player will reciprocate and choose f at C_2.

Cooperation and trustworthiness With respect to self-interested goals, in Games 3, 4 and $3'$, choices g and h provide the same number of points to the participant, namely 4. Among these, g is the competitive choice (allowing only 1 point to C) and h the cooperative one (allowing 6 points to C). Based on the collectivist culture in India, we expect h to be chosen most in India (we expect more than 50 % h), followed by Israel (mix of collectivist and individualist), followed by The Netherlands (individualist).

Methods

The experiment was conducted at the Indian Statistical Institute in Kolkata, The Open University of Israel, and the Institute of Artificial Intelligence at the University of Groningen, The Netherlands. In each of the three countries, a (different) group of 50 Bachelor's and Master's students from several disciplines took part. That is, the experiment included 50 Indian students (44 male, mean age 24.0), 50 Dutch students (26 male, mean age 23.8), and 50 Israeli students (23 male, mean age 27.1).[2] The participants had little or no knowledge of game theory.

The tasks that the participants had to perform in these experiments are mentioned in Table 1. Participants were instructed by an experimenter at the university, who was also available for questions. The participants played the turn-based games through a graphical interface on the computer screen (Figure 2). Participant were informed that each round, they would play against a different computer opponent (C, blue). Each of these opponents would play according to some plan that was a best response to some plan of the participant. The participant's goal was that the marble should drop into the bin with as many orange marbles as possible. The computer's goal was that the marble should drop into the bin with as many blue marbles as possible. Before the experiment itself, participants played 14 games to familiarize them with the game and its controls, the colored marbles, and the turn-taking aspect of the game.

In some rounds of each game, the participants' were asked certain multiple-choice questions regarding the choices of their opponent: (i) "The computer just chose to go [direction computer just chose]. If you choose to go [direction corresponding to playing d], what do you think the computer would do next?" or, (ii) "The computer first chose to go [direction computer chose at its first decision point]. When you made your first choice, what did you think the computer would do next if you chose to go [direction corresponding to playing d]?" Three options were given regarding the likely choice of the computer: "I think the computer would most likely open the left side" or "I think the computer would most likely open the right side" or "Both answers seem equally likely". The first two answers translated to the moves e or f of the computer, respectively. In case of the third answer, we assumed that the participant was undecided regarding the

[2]We'd like to thank the experimenters Eric Jansen, Saikat Palit, Aviel Swissa and Stav Edry.

computer's next choice.

Participants were paid according to the number of marbles they gained in one of the experimental games, selected at random for each participant. Participants were paid proportionally to the number of marbles they gained (1-4), irrespective of the number of marbles gained by the computer opponent. The amounts were balanced across countries so that the minimum payout would be enough to go out for coffee, while the maximum amount would pay for going out for pizza.

For the current study, we compare data between the participants of India, Israel and The Netherlands, all of whom performed the same tasks.

Step 1	- Introduction to the experiment. - Instructions to the participants.
Step 2	Practice Phase: 14 marble drop games.
Step 3	- Experimental Phase: 48 marble drop games, divided into 8 rounds of 6 different games each, distinguishing factor being the pay-off structures. - Each of the 6 games of Figures 3, 4 occurs once in each round; the 6 games occur in a random order in each round. - Questions were asked about computer's behaviour in several rounds.
Step 4	Questions were asked at the end of the experiment regarding decisions at all nodes of a sample game.

Table 1: Steps of the experiment

Results

As mentioned in the description of the marble drop game, participants face up to two decision points, P_1 and P_2, when playing the games represented in Figures 3 and 4. The first is whether to stop the game by choosing c or continue playing by choosing d at their first decision point P_1. To determine to which extent nationality influences this decision, we performed logistic regression of their first decision on Game (1, 2, 3, 4, $1'$, $3'$), nationality (India, Israel, The Netherlands), and their interaction.

Trust versus uncertainty avoidance, forward versus backward induction

Figure 5 depicts the proportion of d choices in Games 1, 2, and $1'$. In addition, Table 2 shows the estimation results of logistic regression of the participants' tendency to choose d in these games. In this regression, Dutch nationality and Game 1 are taken as the base case scenario and each coefficient is read as a change in the likelihood of playing d when compared to a Dutch participant playing Game 1.

Table 2 shows that there is no significant main effect of nationality on the behaviour of players. On average, we therefore find no differences in the levels of trust and uncertainty avoidance across nationalities for their first decision. However, we do observe a significant main effect of Game 2. Recall that participants who engage in forward induction reasoning would be more likely to pick d in Game 1 than in Games 2 and $1'$. The results in Table 2 are consistent with forward induction reasoning, since the coefficients of Game $1'$ and Game 2 are both negative. Interestingly, only the difference between Game 1 and Game 2 is significant. That is, even though Game $1'$ and Game 1 provide participants with different information on their opponent's strategy, participant choices do not differ significantly.

Variable	Coefficient	z value
India	-0.035	-0.250
Israel	-0.334	-1.240
Game $1'$	-0.100	-0.489
Game 2	-0.609	-2.787**
Israel × Game $1'$	0.557	2.038*
Israel × Game 2	0.724	2.593**
India × Game $1'$	0.337	1.316
India × Game 2	0.510	1.875

Table 2: Estimated logistic regression coefficients for the proportion of d choices in Games 1, 2, and $1'$. Coefficients represent the difference in d choices compared to Dutch participants in Game 1. Significance at the 5% level and 1% level are indicated by * and **, respectively.

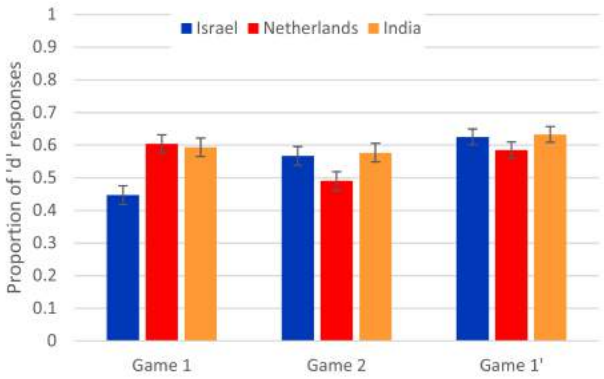

Figure 5: Proportion of d choices in games 1, 2, and $1'$ across nationalities. Whiskers indicate one standard error.

In addition, there is a significant interaction between Game 2 and Israeli nationality. Together, these results indicate that while Dutch participants are more likely to choose d in Game 1 than they are in Game 2, Israeli participants tend to choose d less in Game 1 than in Game 2. Thus, while some Dutch participants may have used forward induction, Israeli participants' behaviour does not show a lot of strategic reasoning per se.

Figure 6 shows the proportion of d choices in Games 3, 4, and $3'$. Table 3 shows the estimation results of the logistic regression for these games, where Game 3 and Dutch nationality are the base case scenarios. The table shows that only Game 4 has a coefficient that deviates significantly from zero, indicating that participants were less likely to choose d

Variable	Coefficient	z value
India	-0.373	-0.519
Israel	-0.601	-0.993
Game 3′	-0.184	-0.879
Game 4	-0.428	-1.989*
Israel × Game 3′	0.195	0.666
Israel × Game 4	0.117	0.249
India × Game 3′	0.162	0.559
India × Game 4	0.357	0.637

Table 3: Estimated logistic regression coefficients for the proportion of *d* choices in Games 3, 4, and 3′. Coefficients represent the difference in *d* choices compared to Dutch participants in Game 3. Significance at 5% level is indicated by *.

Variable	Coefficient	z-value
India	-0.942	-1.043
Israel	-1.714	-2.467*
Game 3	-0.344	-0.403
Game 3′	-0.279	-0.219
Israel × Game 3	0.276	0.138
Israel × Game 3′	0.097	0.442
India × Game 3	-0.516	-1.185
India × Game 3′	-0.744	-1.537

Table 4: Estimated logistic regression coefficients for the proportion of *h* choices in Games 3, 4, and 3′. Coefficients represent the difference in *h* choices compared to Dutch participants in Game 4. Significance at 5% level is indicated by *.

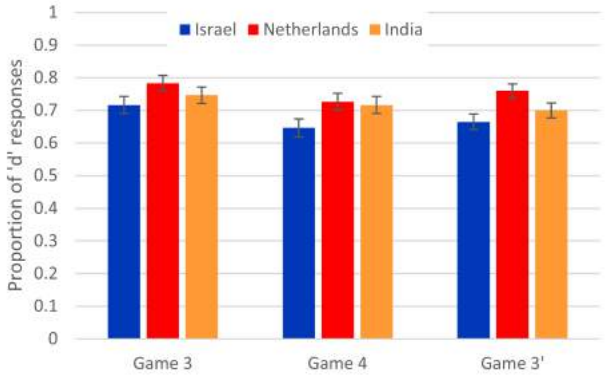

Figure 6: Proportion of *d* choices in Games 3, 4, and 3′ across nationalities. Whiskers indicate one standard error.

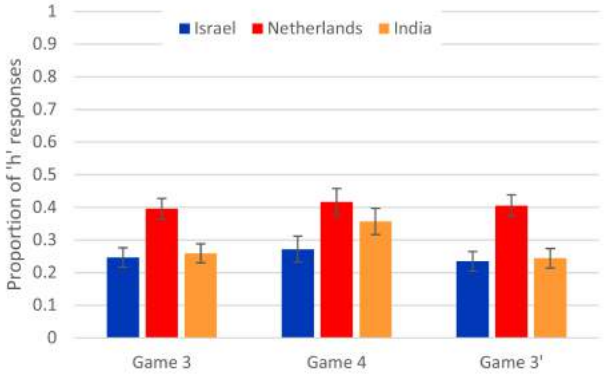

Figure 7: Proportion of *h* choices in Games 3, 4, and 3′ across nationalities. Whiskers indicate one standard error.

in Game 4 than they were in Game 3. Note that this is consistent with forward induction reasoning, which would lead a participant to be more likely to choose *d* in Game 3 than in Games 4 and 3′.

Similar to the findings presented in Table 2 for Games 1, 2 and 1′, Table 3 shows that none of the nationality-dependent coefficients differ significantly from zero. In particular, for the participants' first decisions in Games 3, 4 and 3′ , there appear to be no significant differences in trust and uncertainty avoidance across nationalities.

Competition, cooperation and trustworthiness

In addition to the decisions at the first decision point P_1, we performed a logistic regression on participants' choices at their second decision point P_2 to investigate differences in cooperation and trustworthiness. Since the choices of the participants affect their own payoffs in Game 1, 2, and 1′, our analysis of participant behaviour at decision point P_2 is limited to Games 3, 4, and 3′, in which their choice only affects the payoff of the computer opponent, their own payoff being 4 in all cases. Participants could choose the cooperative option *h*, which would yield the opponent a payoff higher than their own, or the competitive option *g*, which would leave the opponent with the lowest possible payoff.

Figure 7 depicts the proportion of *h* choices in Games 3, 4, and 3′. In addition, Table 4 shows the logistic regression results on the proportion of *h* choices, where Dutch nationality and Game 4 are taken as the base case scenarios. The results show no significant differences in the decision to choose *g* or *h* across games. That is, the interpretation participants have of the opponent's previous actions do not appear to affect participant choices at the second decision point significantly.

While Table 4 shows that the differences between Dutch and Indian participants are not significant, Israeli participants were significantly less likely to choose *h* than Dutch participants. Moreover, Figure 7 shows that across Games and nationalities, participants were more likely to choose the option that would yield the opponent a lower payoff. Overall, participant behaviour can therefore be described as competitive.

Discussion and conclusion

We hypothesized that at their first decision point, participants from Israel would show uncertainty avoidance behaviour most often in our experiment, followed by those from The Netherlands and finally India. However, our results suggest that on average, levels of uncertainty avoidance in centipede-like games are similar across nationalities. Based on our results, we were not able to distinguish any differences between Israeli, Dutch, and Indian participants in choosing a certain outcome over an uncertain outcome.

Interestingly, our results do confirm our hypothesis that actions of Dutch participants can be interpreted as indicative of forward induction. In contrast, the actions of Israeli participants showed no strategic behaviour at all. This may indicate that Israeli participants were more likely to distrust or to get confused by a surprising opponent.

We hypothesized that, based on the collectivist nature of Indian society, at least half of the Indian participants would show cooperative behaviour. In contrast, our results show high levels of competitiveness across nationalities. When faced with the choice of giving their opponent a high payoff or a low payoff at their last decision point, participants on average preferred to give their opponent a low payoff. In fact, while we expected Dutch participants to be more self-interested than Indian and Israeli participants, Figure 7 suggests Dutch participants to be the least competitive.

In general, the previous actions of the opponent did not influence participants' decisions to behave competitively or cooperatively. However, Figure 7 shows an interesting trend suggesting that Indian participants are cooperative towards opponents that have previously behaved cooperatively to them: the more often an opponent has surprised the an Indian participant by choosing the uncertain, possibly cooperative, option, the more likely they are to respond cooperatively.

In summary, the take-home message of our experiment is that the levels of uncertainty avoidance are similar across nationalities, and that Israeli participants are more likely to distrust an opponent. Levels of competitiveness are high for all three cultures, but surprisingly, the Dutch are the least stingy.

Future work This inter-cultural study is based only on the decisions made by the participants. In order to be able to draw conclusions about the reasoning strategies behind the decisions, we are currently looking at the reaction times of the participants, similar to Bergwerff et al. (2014). We intend to continue our study on the differential roles of affective and game-theoretic aspects, by designing new experiments based on both perfect and imperfect information turn-taking games. We will apply techniques such as eye-tracking and computational cognitive modeling to be better able to distinguish reasoning strategies (Meijering et al., 2012; Top et al., 2018).

Abstract

When people understand language about their own actions they activate premotor regions they use to perform these actions. Do people understand language about other peoples actions by imagining how they perform these actions themselves, or how they perceive others performing them? Here, we recorded BOLD fMRI while left- and right-handers read about and then imagined their own unimanual actions (e.g. you write) or others actions (e.g. she writes). When imagining their own manual actions, participants preferentially activated PMC circuits controlling their dominant hand. By contrast, when imagining others actions, participants PMC activity reflected both how they perform actions themselves and how they typically see actions performed by right-handers (about 90% of people they see). Language-induced motor imagery for our own actions reflects how we use our own bodies, whereas imagery for others actions also reflects how others use their bodies, even if their bodies differ from our own.

Seeking evidence and explanation signals religious and scientific commitments

Maureen Gill (mcg3@princeton.edu), Tania Lombrozo (lombrozo@princeton.edu)
Department of Psychology, Princeton University, Princeton, NJ 08544

Abstract

Scientific norms value skepticism; many religious traditions value faith. We test the hypothesis that these different attitudes towards inquiry and belief result in different inferences from epistemic behavior: Whereas the pursuit of evidence or explanations is taken as a signal of commitment to science, forgoing further evidence and explanation is taken as a signal of commitment to religion. Two studies (N = 401) support these predictions. We also find that deciding to pursue inquiry is judged more moral and trustworthy, with moderating effects of participant religiosity and scientism. These findings suggest that epistemic behavior can be a social signal and shed light on the epistemic and social functions of scientific vs. religious belief.

Keywords: explanation; evidence; information search; science; religion; moral cognition

Introduction

In his influential work on the sociology of science, Robert Merton introduced the idea of "organized skepticism" as a norm that governs the scientific enterprise. "Most institutions demand unqualified faith," he wrote, "but the institution of science makes skepticism a virtue" (Merton, 1973). Whether or not this norm accurately characterizes all scientific behavior and aspirations, it nicely encapsulates a value that many uphold: the value of critical and unlimited inquiry.

Yet in some walks of life, skepticism and unfettered inquiry can compete with other values. For instance, demanding an explanation for a friend's loyalty, or hiring a private investigator to gather evidence that a spouse is indeed faithful, could damage those relationships by sending a signal about one's (uncharitable) beliefs or (weak) commitment to the relationship. In fact, in economic games, examining the available evidence can be a maladaptive strategy for promoting cooperation (Hoffman, Yoeli, Nowak, 2015). As Merton suggested, organized skepticism can interfere with "values which demand an unquestioning acquiescence."

Within some religious traditions, willingness to believe (e.g., in Jesus or in God) in the absence of evidence is itself regarded as a virtue. In the well-known story of "doubting Thomas," to take an example from the Christian tradition, Jesus tells his apostle who demanded evidence: "because thou hast seen me, thou hast believed: blessed *[are]* they that have not seen, and *[yet]* have believed" (John 20:29). Indeed, faith – whether it is faith in God or in one's partner – may be an epistemic attitude that involves a certain *abdication* from the need for further evidence (Buchak, 2012).

The diverging norms of skepticism and faith introduce an interesting possibility: that the choice to pursue (vs. forgo) inquiry could send a signal about the strength and nature of one's commitments to scientific versus religious norms, and correspondingly, to science versus religion. That is, demanding further evidence or explanation could be seen as a mark of *commitment* regarding science, but a sign of doubt or insincerity in religion, at least within those traditions that value faith. Insofar as commitment to skeptical versus faith-based norms are taken to have other social or epistemic implications, we might also expect individuals who decide to pursue or forgo further inquiry regarding scientific or religious matters to be judged differentially moral, trustworthy, or committed to truth.

Based on these ideas, the current paper asks the following two questions: (1) What kinds of social and moral inferences do people (specifically, American and predominantly Christian adults) make on the basis of another person's decision to pursue or forgo inquiry? (2) Do inferences vary across scientific and religious domains?

Prior work

Research has shown that people interpret others' decisions as signals of moral and socially relevant traits. For example, those who make harm-averse moral judgments or engage in third-party punishment are more trusted and preferred as social partners (Everett, Crockett, Pizarro, 2016; Jordan, Hoffman, Bloom, Rand, 2016). Moral values and group affiliation are also thought to influence belief formation and revision: increased analytic thinking is associated with more polarized views, potentially because analytic individuals use different evidence to support pre-determined conclusions (Kahan & Stanovich, 2016). It remains unknown, however, whether people infer moral and social traits on the basis of epistemic behaviors, namely, the decision to pursue or forgo information search. In the current work we consider two epistemic behaviors: pursuing versus forgoing an *explanation*, and pursuing versus forgoing further *evidence*.

Prior work has found that judgments about the "need for explanation" differ across the domains of science and religion (Liquin, Metz, & Lombrozo, 2018). In particular, participants judged scientific statements – such as "the center of the earth is very hot" – to demand an explanation

to a greater extent than religious statements – such as "there is a hell" – even when confidence in the truth of the two statements was matched. When participants were presented with the "explanation" that it's a mystery (e.g., "Why is the center of the earth very hot [is there a hell]? It's a mystery"), they judged the answer more acceptable for religious questions than for scientific ones. These findings suggest that explanation-seeking – or abdication from explaining – could play different roles within science vs. religion, consistent with the diverging norms of skepticism vs. faith.

There is also reason to believe that science and religion could differ when it comes to attitudes towards evidence. Van Leeuewen (2017) develops a proposal according to which science and religion tend to involve distinct epistemic attitudes – what he calls factual *belief* versus religious *credence*. A characteristic of the latter is that it is "evidentially invulnerable": religious credences are not typically extinguished by contrary evidence. If this view is right, evidence should be more relevant to the evaluation of factual versus religious propositions.

In sum, prior work suggests that various decisions can serve as social signals, and that the domains of science and religion could differ in the epistemic attitudes they typically involve. Across two studies, we investigate novel questions that build upon this work: whether epistemic behaviors (the decision to pursue vs. forgo explanation or evidence) send different social signals across domains.

Study 1

In study 1, we examine the inferences that people make from an agent's epistemic behavior. To do so, we presented a story about a character, Jen, who learns about a new issue: either near-death experiences or the shroud of Turin (scenario: NDE vs. shroud). These issues were chosen because they can be framed as scientific or religious (domain: scientific vs. religious). Jen contemplates whether the issue *demands an explanation* or whether the issue *requires more evidence* (inquiry: explanation vs. evidence). Critically, Jen ultimately decides that it does or does not (decision: pursue vs. forgo). Participants rated the morality of Jen's behavior, her trustworthiness, and her commitment to truth, science, and religion. We predicted that the decision to pursue inquiry would be taken as a signal of scientific commitment, and the decision to forgo as a signal of religious commitment. We also predicted (but failed to find) that these effects would be strongest within their corresponding types of framing.

Method

Participants Participants in Study 1 were 97 adults recruited from Mechanical Turk (63 male, 34 female, mean age 36, range 22-73). Participation was restricted to MTurk workers in the U.S. who had completed 5000 past HITs with a minimum approval rating of 99%. Nine additional participants were excluded for leaving responses blank.

Materials & Procedures Participants were randomly assigned to read one of 16 vignettes about Jen, who learns about an issue and decides whether to inquire further about it. The issue was either near-death experiences or the shroud of Turin (scenario: NDE vs. shroud), framed in a scientific or religious manner (domain: scientific vs. religious). For example, the text for the shroud of Turin with a scientific framing included the following:

> Jen learns about the shroud of Turin, a piece of cotton cloth that may have been the burial shroud that Jesus (1st century preacher and religious leader) was wrapped in after being crucified by the Roman government.
>
> Scientific findings in disciplines ranging from chemistry to biology shine light on whether the shroud of Turin is indeed the burial shroud of Jesus. Multiple radiocarbon dating and vibrational spectroscopy tests date the shroud between 300 BC and 400 AD, corresponding with the timing of Jesus's crucifixion.
>
> Though most scientific leaders believe the shroud to be the burial cloth of Jesus, the matter is still not settled. Some people believe that it is not authentic and/or was created at a later date.

The version with religious framing was similar, but instead of offering scientific evidence and appealing to scientific consensus, it included biblical references and appealed to consensus among religious leaders.

After reading this information, participants learned about Jen's subsequent epistemic behavior: she either decided to pursue further inquiry or not (inquiry decision: pursue vs. forgo), and her inquiry took the form of either seeking (or not seeking) further evidence or seeking (or not seeking) an explanation (inquiry: evidence vs. explanation). Following prior work (Liquin et al., 2018), explanation seeking was framed broadly: that is, the specific type of explanation available (such as mechanistic or teleological) was not specified. For the Shroud of Turin, for example, participants read one of the following sentences, depending on inquiry condition (evidence vs. explanation) and decision (indicated by text in brackets):

> Evidence: Jen decides that she does [not] need more evidence that the cloth was the burial shroud that Jesus was wrapped in.
> Explanation: Jen decides that she does [not] need an explanation for how the shroud came to have its characteristic markings.

Crossing scenario (NDE vs. shroud), domain (scientific vs. religious), decision (yes vs. no), and inquiry (evidence vs. explanation) resulted in the 16 distinct vignettes.

After reading the vignette, participants were asked to rate 14 statements designed to probe their inferences about Jen, including her morality, trustworthiness, commitment to truth, commitment to science, and commitment to religion. All items and rating anchors are indicated in Table 1. Items

about truth, science, and religion were presented in random order before items about morality and trustworthiness. Nine participants failed to answer at least one item and are therefore excluded from reported analyses. Participants then answered an open-ended question about what they thought of the fact that Jen did [not] pursue further evidence or explanation. We do not analyze these open-ended responses here.

Next, participants completed a set of individual difference measures, which are not reported here. Finally, participants reported their political orientation, age, and gender.

Table 1: Study 1 and 2 rating questions. Items with an asterisk were reverse-scored. For the composite measures, we additionally report Cronbach's α (Study1 / Study 2).

Moral and character inferences
Morality
Jen's decision that […] was…
(1 = "very immoral/bad" – 7 = "very moral/good")
Trustworthiness
Jen is probably…
(1 = "very untrustworthy" – 7 = "very trustworthy")
Commitment to truth (α = .88 / .79)
Jen values truth above all.
When it comes to what she believes, Jen cares about getting things right.
Jen is not concerned about whether she is right or wrong.*
Jen values some things more than getting things right.*
(1 = "strongly disagree" – 7 = "strongly agree")
Commitment to science (α = .94 / .94)
Jen has a strong commitment to the methods of science.
Jen is a deeply scientific person.
Jen values her identity as a scientifically-minded person.
Jen trusts scientific authorities.
(1 = "strongly disagree" – 7 = "strongly agree")
Commitment to religion (α = .93 / .94)
Jen has strong religious faith.
Jen is a deeply religious person.
Jen values her religious identity.
Jen trusts religious authorities.
(1 = "strongly disagree" – 7 = "strongly agree")

Results

Our key dependent variables were the single ratings for morality and trustworthiness, as well as our composite ratings for commitment to truth, science, and religion, which were calculated by averaging the four ratings for each scale. The reliability of these scales, as assessed by Cronbach's α, ranged from good to excellent (see Table 1). For each dependent variable, we performed an ANOVA with domain (scientific vs. religious), decision (yes vs. no), scenario (Shroud of Turin vs. NDE) and inquiry (evidence vs. explanation) as between-subjects factors (see Figure 1a). Given the large number of tests, we adopted the more conservative *p*-value of .01 as our threshold for significance; we report all significant effects.

The ANOVA with ratings of morality as a dependent variable revealed a main effect of decision: deciding to inquire was rated morally better than deciding not to, $F(1, 81) = 37.58$, $p < .001$. Analysis of trustworthiness as a dependent variable also revealed a main effect of decision, $f(1,81) = 22.22$, $p < .001$, such that the character was rated as more trustworthy when she decided to inquire than when she decided not to.

Analyzing composite ratings of commitment to truth also showed a main effect of decision, $f(1,81) = 70.40$, $p < .001$, with decisions to inquire associated with higher perceived commitment to truth. However, this effect was qualified by a significant interaction with domain, such that decision had a greater impact on perceived commitment when the issue was framed as religious, $f(1,81) = 8.41$, $p = .005$.

Composite ratings of commitment to science exhibited a similar pattern, revealing a significant main effect of decision in the same direction, $f(1,81) = 45.208$, $p < .001$, as well as a marginal interaction with domain, trending in the same direction, $f(n) = 5.95$, $p = .02$.

Finally, composite religious commitment ratings revealed a significant main effect of decision, $f(1,81) = 45.618$, $p < .001$, but in a direction opposite to that observed for our other dependent variables: the decision to inquire was associated with a *decrease* in perceived commitment to religion. Once again, there was a suggestive trend for decisions to be more informative in the religious domain (decision x domain interaction), $f(1,81) = 2.72$, $p = .10$. There was also a significant main effect of scenario, qualified by an interaction with decision, such that perceived commitment to religion was rated higher when Jen learned about the shroud of Turin, $f(1,81) = 10.68$, $p = .001$, especially when Jen decided not to pursue more information, $f(1,81) = 9.56$, $p = .002$.

Discussion

Participants in our study viewed evidence- and explanation-seeking behaviors favorably: participants viewed the decision to pursue both evidence and explanation as morally good and a cue to trustworthy character. Critically, evidence- and explanation- seeking was also treated as a signal of commitment to truth and science, where *forgoing* further inquiry was treated as a signal of commitment to religion. These effects were remarkably consistent across modes of inquiry (evidence versus explanation), and across our manipulation of domain (science versus religion), though we found modest evidence that pursuit decisions might be regarded as more informative in the domain of religion than science.

We initially hypothesized that the effect of inquiry decisions on inferences about the inquirer would be moderated by participants' own religious and scientific commitments. Because our sample was overwhelmingly non-religious, however, we were unable to test this hypothesis. We revisit this question in Experiment 2, for which we recruited a more religious sample.

Study 2

In Study 2, we again tested the effect of epistemic behaviors (pursuing vs. forgoing evidence vs. explanation) and domain (religious vs. scientific) on inferences about morality, trustworthiness, commitment to truth, commitment to science, and commitment to religion. However, we restricted participation to MTurk workers from the nine states in the U.S. with the highest proportion of religious residents – this involved drawing from the generally protestant population of the South (Lipka & Wormald, 2016). We also aimed to strengthen the manipulation of domain (religious vs. scientific), editing scenarios to be more identifiably religious or scientific. Finally, by including a larger and more religious sample, we aimed to test two hypotheses about individual differences that could moderate the effect of inquiry decision on perceived morality and trustworthiness: religiosity and scientism. Specifically, we predicted that more religious participants might see greater value in the epistemic attitude of faith, resulting in higher ratings of morality and trustworthiness (relative to non-religious participants) after Jen decides to forgo further inquiry. On the other hand, participants who endorse a narrow commitment to science might be especially likely to value associated norms (such as organized skepticism) and therefore judge Jen more favorably (relative to less-scientistic participants) when she decides to pursue inquiry.

Method

Participants Participants in Study 2 were 304 adults recruited from Amazon Mechanical Turk (117 males, 186 females, mean age 40, range 19 to 77). Participation was restricted to MTurk workers from Alabama, Mississippi, Tennessee, Louisiana, Arkansas, South Carolina, West Virginia, Oklahoma, and Georgia. Thirty-six additional participants were excluded for failing one or more attention checks (explained below).

Materials & Procedures The materials and procedures were the same as those in Study 1, with the following modifications. First, we made slight modifications to the 16 original vignettes to further differentiate the religious and scientific framing. For example, for the religious version of the Shroud of Turin vignette, we replaced the original sentence "could it be the burial shroud of Christ," with "could it be the burial shroud of Jesus Christ, son of God?" Second, we collected fewer individual difference measures than in Study 1. Those retained included the religiosity inventory from Pennycook et al. (2012; sample items: "There is a life after death," "Religious miracles occur"), the moralized rationality and importance of rationality scales from Stahl et al. (2016), and the scientism scale from Farias et al. (2013; sample items: "Science provides us with a better understanding of the universe than does religion," "Science is the most valuable part of human culture"), presented in this order. An attention check ("select 'strongly agree'") was included in the religiosity inventory, and 31 participants were excluded for failing to answer correctly. Participants then reported their political orientation, age, and gender.

Finally, participants answered two additional attention check questions about the content of their vignette and Jen's decision; these were simple multiple-choice questions based on what they had read (e.g., "What did Jen decide?"). Four participants were excluded for failing to answer at least one question correctly.

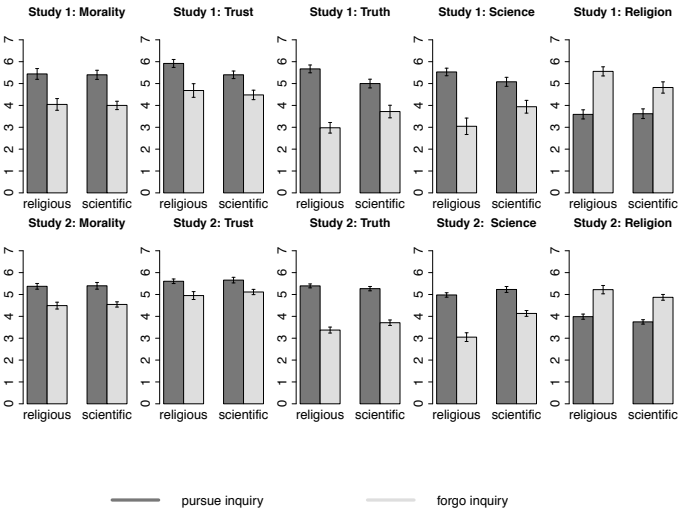

Figure 1: Mean ratings in Study 1 and 2 for the inferred characteristics of the vignette's character as a function of domain and her decision to pursue or forgo further inquiry. Error bars correspond to SEM.

Results

As with Study 1, our key dependent variables were the single ratings for morality and trustworthiness, as well as our composite ratings for commitment to science, religion, and truth, calculated by averaging the four ratings for each scale. The reliability of these scales, as assessed by Cronbach's α, ranged from good to excellent (see Table 1). For each dependent variable, we performed an ANOVA with domain (scientific vs. religious), inquiry decision (pursue vs. forgo), inquiry type (evidence vs. explanation), and scenario (shroud vs. NDE) as between-subjects factors (see Figure 1b). Given the large number of tests, we adopted the more conservative *p*-value of .01 as our threshold for significance, and we report all significant effects.

The ANOVA with ratings of morality as a dependent variable again revealed a main effect of decision, $f(1, 288) = 39.50$, $p < .001$, as well as a marginal interaction between domain, decision, and inquiry type, $f(1, 288) = 6.51$, $p = .01$. Both kinds of inquiry were associated with higher moral goodness judgments, but explanation-seeking behaviors were more informative for morality in a scientific context than a religious one, and conversely, evidence-seeking behaviors were more informative in a religious context than a scientific one. There was also an interaction between

decision and scenario, such that the main effect of decision was more pronounced in the NDE scenario, $f(1,288) = 6.95$, $p = .008$.

Analysis of trustworthiness judgments also revealed a main effect of decision, $f(1,288) = 20.25$, $p < .001$, with the decision to pursue inquiry associated with greater trustworthiness.

Analyzing composite ratings of commitment to truth revealed a main effect of decision, $f(1,288) = 266.52$, $p < .001$, with greater perceived commitment when inquiry was pursued, and a main effect of inquiry type, $f(1,288) = 16.78$, $p < .001$, with greater perceived commitment in the evidence condition than in the explanation condition. There was also a marginal interaction between decision and domain, $f(1,288) = 4.52$, $p = .03$, with decision having a greater impact in the religious condition.

Analysis of commitment to science revealed a main effect of decision, $f(1,288) = 111.10$, $p < .001$, as well as an interaction between decision and domain, $f(1,288) = 9.3$, $p = .003$. As in Study 1, Jen was regarded as having a higher commitment to science when she sought out evidence or explanation, with a greater effect of decision with religious framing. There were also main effects of domain and scenario, such that Jen was perceived as having a higher commitment to science both when the issue was framed as scientific, $f(1,288) = 21.23$, $p < .001$, and when the issue was near-death experiences rather than the shroud of Turin, $f(1,288) = 9.48$, $p = .002$.

The ANOVA with composite commitment to religion revealed a main effect of decision in the opposite direction of truth, morality, truth commitment, and science commitment, as in Study 1. Forgoing inquiry was associated with *greater* commitment to religion, $f(1,288) = 86.626$, $p < .001$. There was also a main effect of scenario, $f(1,288) = 38.349$, $p < .001$, as well as an interaction between decision and scenario, $f(1,288) = 15.75$, $p < .001$: for the Shroud of Turin scenario, perceived commitment to religion was higher overall, and decision was more influential.

We additionally explored whether two of our individual difference measures, religiosity and scientism, moderated the effect of inquiry decision on perceived morality and trustworthiness (see Figure 2). To test for a moderating effect of religiosity, we constructed two pairs of linear mixed effects models (predicting morality or trustworthinesss), treating participant religiosity (centered) and decision as fixed factors, and treating scenario as a random factor with respect to intercept. We fit a full model with the main effects of both fixed factors as well as their interaction and a partial model that included the same factors without an interaction. An ANOVA comparison of the two models revealed that the full model better predicted moral judgments, $X^2(1) = 7.28$, $p = .006$, and trustworthiness judgments, $X^2(1) = 14.56$, $p < .001$. As participant religiosity increased, epistemic decision mattered less for judgments of morality and trustworthiness. Equivalent analyses for participant scientism also revealed that a model with the scientism-decision interaction term better predicted morality, $X^2(1) = 15.19$, $p < .001$, and trustworthiness, $X^2(1) = 27.776$, $p < .001$. However, the pattern was opposite to that observed for religiosity: participants rejecting scientism were likely to see forgoing inquiry as more moral and trustworthy, whereas participants endorsing scientism saw the pursuit of inquiry as more moral and trustworthy.

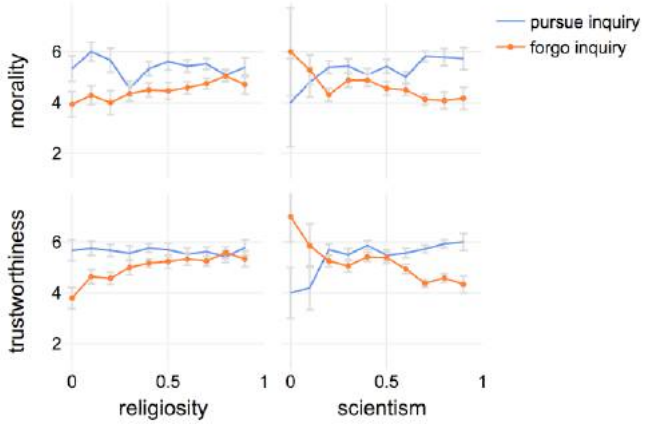

Figure 2: Moral and trustworthiness judgments by participant scientism and religiosity.

Discussion

In Study 2, we replicated our main findings from Study 1 with a larger and more religious sample drawn predominantly from the American South. Jen was regarded as more moral and trustworthy for seeking evidence and explanations. Inquiry behaviors were associated with an increase in commitment to truth and science, but a decrease in commitment to religion. We also found additional evidence of a trend observed in Study 1: inquiry decisions in the domain of religion (vs. science) were generally more informative in the sense that they had a larger impact on inferences about Jen's commitments, especially to science.

Going beyond Study 1, we identified two individual difference factors that moderated the effect of inquiry decision on inferences about morality and trustworthiness: religiosity and scientism. Scientistic participants were inclined to draw inferences about Jen's morality and trustworthiness that were *more* dependent on her decision about whether to pursue or forgo inquiry, showing a more pronounced effect favoring inquiry. On the other hand, religious participants tended to draw inferences about Jen's morality and trustworthiness that were less dependent on her decision about whether to pursue or forgo inquiry.

General discussion

People infer a number of moral and social traits from another person's epistemic behavior. We found evidence that pursuing inquiry is viewed as a signal of commitment to truth and to science, but that forgoing inquiry is perceived as signaling commitment to religion. A person who pursues evidence or explanation is regarded as more moral and trustworthy, but only among certain groups: for more

religious participants, the effect of inquiry on inferences of trust and morality diminishes; for participants who very strongly reject scientism, the relationship reverses.

Keeping track of epistemic behavior is key to learning from others. The finding that adults infer moral character traits from an agent's epistemic behavior contributes to a literature showing a connection between how people track others' epistemic and moral status. Research has shown that young children use epistemic markers, such as past accuracy, to guide evaluations of source trustworthiness (Birch, Vauthier, & Bloom, 2008). However, children also use a source's moral qualities, such as niceness/meanness, in evaluating the truth-value of a claim (Landrum, Mills, & Johnston, 2013). Adults are less likely to trust a source with different political values, even when the information is non-political, e.g., about geometric shapes (Marks, Copland, Loh, Sunstein, & Sharot, 2018). Future research should investigate why we use moral information in epistemic judgments and epistemic information in moral judgments. When does trusting a source mean trusting a person?

The social consequences of information search might carry implications for real epistemic decisions. People often face the choice between accepting a proposition at face value and searching for more information. Our research suggests the possibility that epistemic considerations (e.g., strength of prior evidence, uncertainty) may not fully account for behavior. Social context may play a role in the decision-making process. For instance, a person who wants to signal commitment to religion may be more likely to forgo inquiry, risking false beliefs for potential social rewards (a "display of faith"). A person could also choose to pursue costly inquiry (high search cost, low information value) to be perceived as moral and trustworthy (a "display of skepticism").

The current studies are limited in a number of respects, including the range of materials and underspecified forms of inquiry. Explanation in particular was broadly defined in our experimental materials. There are different kinds of explanations, and participants may have differed in what they took an explanation to be. Indeed, given differences in the need for explanation across domains (Liquin, Metz, & Lombrozo, 2018), and differences in the *kinds* of explanations offered across domains (e.g., Kelemen, 2004; Lupfer, Brock, & DePaola, 1992), it could be that different kinds of explanations are more or less closely tied to religious and scientific norms.

It's also important to note that our sample – while diverse in some respects – drew from an overwhelmingly Christian (and mostly Protestant) population, considerably limiting the extent to which we can make general claims about religion or religiosity. Indeed, we expect a great deal of heterogeneity in religious attitudes towards inquiry, and additionally expect that scientific propositions can be "taken on faith." Future work should explore this heterogeneity, for instance testing more diverse samples, and additionally consider how a more nuanced understanding of science (as opposed to the "scientism" measured here) might affect attitudes towards and inference from the choice to seek further explanation or evidence.

Despite these limitations, the present work contributes to a growing body of work suggesting that beliefs and processes of belief revision are sensitive to both epistemic and social goals. Researchers have proposed that religious belief serves a social coherence function (Norenzayan, 2013), and politicized "scientific" beliefs (such as the endorsement or rejection of anthropogenic climate change or human evolution) are strongly related to cultural / group identity (e.g., Kahan & Stanovich, 2016). As Van Leeuwen (2017) suggests: "If my credence that our god exists can be banished by something so trifling as mere evidence, how can you be sure that I am really committed to our group, which defines itself by allegiance to our god?" Our research shows that forgoing inquiry can send a signal of religious commitment. On the other hand, for most observers, the decision to inquire is considered the more moral action, and a stronger marker of trustworthiness, commitment to science, and commitment to truth.

Abstract

Event cognition is a rapidly developing and promising research area. Meanwhile, some domains are not considered in detail in this scope. In particular, event cognition is not precisely explored from the perspective of cognitive development. In this paper, we compare the capacity to cut a visual narrative into events for kindergarten students, primary school students, high school students and adults. “The pear film” by W. Chafe (1975) is used as the material for our experiment. We also examine a correlation between event comprehension and other cognitive skills for primary school students. Our work provides clear evidence that, in contrast with high school students and adults, kindergarten students and primary school students perceive visual narrative on the surface level.

Keywords: event cognition, event model, cognitive development, primary school students, narrative comprehension.

Introduction

Event cognition is an intensively developing domain of cognitive science and a promising avenue of research. A number of insightful conjectures and seminal ideas supported by dozens of experiments have been suggested in this domain over recent decades (Suh & Trabasso 1993; Zwaan et al. 1995; Zacks et al. 2001; Rinck & Weber 2003; Ditman et al. 2008; Shipley & Zacks 2008; Yarkoni et al. 2008; Zacks et al. 2009; Tamplin et al. 2013; Radvansky & Zacks 2014; Zacks 2015; Richmond & Zacks 2017, etc.).

The main results of this research line can be presented as follows:

- Humans do not perceive reality in a continuous way; they cut it into a number of chunks called events. This feature is a fundamental characteristic of humans that underpins their way of reasoning and making decisions.
- There is a high level of coherence among humans in cutting the stream of life into events; they detect event boundaries in a highly similar way.
- A shift through event boundaries impairs an ability to predict a future state of affairs and also event memory; this is caused by a change of space, time, characters, objects, causes, and goals, concerned with a particular situation.
- Event cognition is based on the creation and further elaboration of event models that "capture the entities and functional relations involved in understanding a specific state of affairs" (Radvansky & Zacks 2014, 17); event models allow to predict a development of such state of affairs within an event.
- "...event cognition, and event memory in particular, appears to have distinct neurological underpinnings apart from more general knowledge... it seems possible to disrupt the long-term storage of event models, leaving more general knowledge intact, as well as the reverse, disrupting general knowledge, but leaving the ability to process and remember individual events" (Radvansky & Zacks 2014, 131).

At the same time, some methodological flaws seem to hinder further development in this direction. Strangely enough, we could not find any working definition of both event and event model in works of event cognition researchers. We admit that the demand to define correctly the concept ‘event’ may sound a bit scholastic in this scope (see, e.g., Shipley 2008; Schwartz 2008 as an example of the discussion), but the concept ‘event model’ is the key concept which underpins the body of experimental research addressing event cognition. Nevertheless, the researchers usually focus on event boundaries and changes what take place when these

boundaries being passed, whereas a structure of an event model within boundaries is only sketched. The definition by Radvansky and Zacks quoted above is not clear-cut enough to apply it to a particular experiment (What does ‘a specific state of affairs’ mean? How can we measure it?), and it is not clarified in other works. Scholars usually pick out five aspects characterizing event model: temporality, spatiality, protagonist(s), causality, and intentionality (e.g., Rinck & Weber 2003, 1284–1285; Radvansky & Zacks 2014, 61); however, it is not clear how these aspects are represented in a particular event model.

In other words, there is a bunch of important questions which remain unanswered in this scope. Let us stress only few of them. How many basic types of event model can be singled out? What is the structure of each of them; what are the cornerstones of this structure and links between them? Are there any discrepancies between event boundaries which separate events of the same type and boundaries which separate events of different types? Is the ability to produce event models innate, or it is a result of cognitive development? If the latter, how it develops through the life span? Is there any difference between event model typology for kids and adults?

Indeed, there is no opportunity to tackle all these and similar questions here. We address only some of them concerned with the problem of cognitive development. To be more precise, we have explored how an ability to cut reality into events and to produce event models is acquired in childhood, what is the difference between kids and adults in event cognition, how an acquisition of this capacity correlates with language acquisition and the development of other cognitive skills (there are a few papers addressing age differences in event cognition (e.g., Copeland & Radvansky 2007; Kurby & Zacks 2011), but they do not explore the problem from the perspective of cognitive development). This paper can be considered as the first step in this direction.

Our work examines age differences in cutting a visual narrative into events as a part of a process of cognitive development. We have used "the Pear Film" made by Wallace Chafe and his colleagues in 1975 as a material for the experiments. Importantly, "the Pear Film" includes actions, pictures and sounds, but no words, deploying the same chain of events for all viewers. This film contains a wide range of interactions between protagonists, spatial and temporal changes; its understanding presupposes the capacity to ‘read’ complex intentions and distinguish between physical and social causality. In other words, it provides good material for producing different event models, and, therefore, for exploring event cognition from the perspective of cognitive development. It is worth also noting that "the Pear Film" has opened an avenue of research tackling different aspects of a language and culture interconnection in the process of conceptualizing particular stream of events (Bernardo 1980; Chafe 1980; Clancy 1980; Downing 1980; Du Bois 1980; Tannen 1980; Orero 2008; Fon et al. 2011; Matzur & Mickievicz 2012; Vilaró et al. 2012; Blackwell 2015; Cummings 2015, 59–63; Kibrik et al. 2015; Glebkin et al. 2017).

A plot of "the Pear Film" is important for understanding the results of our experiment, therefore, it looks reasonable to begin with a brief description of the story taken from Chafe 1980, XIII–XIV.

The film begins with a man picking pears on a ladder in a tree. He descends the ladder, kneels, and dumps the pears from the pocket of an apron he is wearing into one of three baskets below the tree. He removes a bandana from around his reek and wipes off one of the pears. Then he returns to the ladder and climbs back into the tree.

Toward the end of this sequence we hear the sound of a goat, and when the picker is back in the tree a man approaches with a goat on a leash. As they pass by the baskets of pears, the goat strains toward them, but is pulled past by the ruin and the two of them disappear in the distance.

We see another closeup of the picker at his work, and then we see a boy approaching on a bicycle. He coasts in toward the baskets, stops, gets off his bike, looks up at the picker, puts down his bike, walks toward the baskets, again looking at the picker, picks up a pear, puts it back down, looks once more at the picker, and lifts up a basket full of pears. He puts the basket down near his bike, lifts up the bike and straddles it, picks up the basket and places it on the rack in front of his handlebars, and rides off. We again see the man continuing to pick pears.

The boy is now riding down the road, and we see a pear fall from the basket on his bike. Then we see a girl on a bicycle approaching from the other direction. As they pass, the boy turns to look at the girl, his hat flies off, and the front wheel of his bike hits a rock. The bike falls over, the basket falls off, and the pears spill out onto the ground. The boy extricates himself from under the bike, and brushes off his leg.

In the meantime we hear what turns out to be the sound of a paddleball, and we see three boys standing there, looking at the bike boy on the ground. The three pick up the scattered pears and put them back in the basket. The bike boy jets his bike upright, and two of the other boys lift the basket of pears back onto it. The bike boy begins walking his bike in the direction he was going, while the three other boys begin walking off in the other direction.

As they walk by the bike boy’s hat on the road, the boy with the paddleball sees it, picks it up, turns around, and we hear a loud whistle as he signals to the bike boy. The bike boy stops, takes three pears out of the basket, and holds them out as the other boy approaches with the hat. They exchange the pears and the hat, and the bike boy keeps going while the boy with the paddleball runs back to his two companions, to each of whom he hands a pear. They continue on, eating their pears.

The scene now changes back to the tree, where we see the picker again descending the ladder. He looks at the two baskets, where earlier there were three, points at them, backs up against the ladder, shakes his head, and

tips up his hat. The three boys are now seen approaching, eating their pears. The picker watches them pass by, and they walk off into the distance.

We chose four age groups for the experiment: 5-7-year-old kindergarten students (KS), 7-9-year-old primary school students (PS), 14-16-year-old high school students (HS), and adults (A).

Based on the previous experiments (Glebkin et al. 2017), we expected that kindergarten students and primary school students would be less skillful in producing event models than high school students and adults which would entail serious problems in detecting event boundaries for KS and PS subjects. In particular, in the case of "the Pear Film" they would be inclined to 'paste' event boundaries and to minimize a number of parts in this visual narrative. To be more precise, we supposed that a mean number of events for kindergarten students and primary school students would be less than for high school students and adults, and kindergarten students and primary school students would determine event boundaries in a less systematic way. We also expected to discover some correlation between the ability to cut a narrative into events and other cognitive and communicative skills concerned with story retelling for primary school students. Our hypothesis in this scope was that the more correct and more detailed was a film retelling the more accurate was a choice of event boundaries by a subject.

Experiment

Method

Subjects. 34 (14 m, 20 f) 5-7-year-old kindergarten students; 73 (35 m, 38 f) 7-9-year-old Moscow primary school students; 36 (12 m, 24 f) 14-16-year-old Moscow high school students; 35 (13 m, 22 f, mean age 37) adults.

Material. "The Pear Film" by Wallace Chafe (6 min 32 sec).

Procedure. The procedure of the experiment followed the model well-established in modern cognitive psychology (e.g., Newtson 1973; Speer et al. 2003). Each subject was processed individually. Where were two versions of the experiment. In the first version subjects watched the film on MacBook Air, 13,3″, 2560x1600 two times. Before the first viewing, the subjects were instructed to watch the film closely as passive viewers. Before the second viewing, they were asked to cut the film into events, i.e., the largest meaningful parts, in any way they find appropriate (this task is similar to the coarse segmentation task in Speer et al. 2003). In addition, a special explanation was given to the groups of kindergarten students and primary school students. The idea of the event segmentation was illustrated on the example of book chapters and some other similar examples. Then the subjects watched the film for the second time and pressed a button at the beginning and at the end of any meaningful part of the film.

In the second version, the procedure was similar, but after the first viewing the participants were asked to retell the story as precisely as they can. This version of the experiment was carried out only for primary school students. In order to make sure that the retelling has no significant influence on the event segmentation task, a control group of 20 primary school students was tested in the first version before the main experiment. No significant difference between two groups was discovered both in a total of episodes each subject cut the film ($F(1, 89) = 0.017$; $p=0.89$) and in the percentage of subjects identifying main event boundaries (χ^2 (12)=16.56, p=0,17).

Two groups of parameters were measured. The first group represented the event segmentation task. It included two variables: a total of episodes that the film was cut into by each subject (TE), and, accordingly, a number of subjects pointed to a particular point as an event boundary (NS) (more precisely, because of some difference in subjects' reaction time it was a set of points located near each other which can be considered as characterizing the same change of a situation). Also for PS group a total of "right" boundaries for each subject (TB_r) (i.e., the boundaries picked out by a significant number (40% and more) of adults and high school students) was calculated. We considered TB_r as a characteristic of cognitive skills involved in event cognition important for the comparison with cognitive skills involved in narrative comprehension and retelling.

The second group of variables, actual only for the primary school students, was concerned with the film retellings. It checked memory for events and also basic cognitive and communicative skills important for narrative understanding and retelling, namely, an ability to categorize objects, an ability to understand the causal chain of events and represent it in the retelling, the richness of language used by subjects. The set of variables was an extended version of the set of variables presented in Glebkin et al. 2017. The following variables were measured: the total number of words exploited in retelling, discounting selfrepetitions and false starts (TW); a total of events presented in retelling (TE_r); a total of events correctly presented in retelling (TEc); a total of errors in action description (FA) (e.g., 'guys picked up pears' instead of 'the boy hands pears to one of the guys'); a total of errors in object description (FO) (e.g., 'apples' instead of 'pears'); a total of incorrect description of causal chain of events and sub-events (FC) (e.g., ambiguous reference, missing connections within an event and between events); a total of interpretations (TI) (e.g., 'stole a basket of pears' instead of 'picked up a basket of pears'); a total of dependent words (TDp) (such as 'who', 'which', 'because', etc.); a total of details mentioned in the retelling (TDt) (e.g., the color of the bike, the peddleball, etc.).

TE_r, TEc and TDt may need a clarification. A total of events was calculated according to the most frequent event boundaries picked out by high school students and adults. These boundaries divide the film into meaningful episodes some of which are connected with others and

some are autonomous (e.g., appearance and disappearance of a man with a goat). The primary school students mentioned some episodes in their retellings and missed others. Some of mentioned episodes were retold correctly (all protagonists and main interactions between them were included in the description), others were presented with serious gaps (e.g., in the episode with the fall of the boy on the bike some subjects missed the girl on the bike). In other words, the complex TE-TEc characterizes the correctness of the film framework representation in a retelling.

TDt points to another feature of the retellings. As a rule, PS subjects focused on actions and missed an appearance of protagonists, their clothes, scenery, etc. Only few of them mentioned such details. For us, such interest to particular details is a special cognitive characteristic important to event cognition. Some arguments for that are presented in the next sections.

Results

As predicted, a mean number of episodes that the pear film was cut into by each subject (TE) for KS was less than for PS, and TE_{PS} was less than TE_{HS}. At the same time, there were no significant difference between TE_{HS} and TE_{A} (TE_{KS}=2.61; TE_{PS}=4.58; TE_{HS}=8.61; TE_{A}=8.23; F_{KSPS} (1, 102) = 61.38; p_{KSPS}<0.001; F_{PSHS} (1, 105) = 18.36; p_{PSHS}<0.001; F_{HSA} (1, 68) = 0.26; p_{HS}=0.6).

As we expected, KS were less consistent in the determination of event boundaries than PS, and PS were less consistent in that than HS and A. The distribution of subjects' choices through the event boundaries, which are most frequent and most important for the narrative, is presented in Table 1.

Table 1. The percentage of subjects identifying most frequent event boundaries

№	Event boundaries	A	HS	PS	KS
1	A man with a goat appears	49	47	17	11
2	A man with a goat disappears	57	56	23	2
3	A boy on a bike appears	49	52	26	22
4	The bike boy stops near the baskets	17	13	20	11
5	The bike boy steals a basket	71	69	30	13
6	A girl on a bike appears	17	17	13	2
7	The bike falls over	71	69	41	25
8	Three boys appear	46	43	20	11
9	The free boys finish to put the pears back in the basket	49	47	27	11
10	The exchange of the pears and the hat	14	8	19	11
11	The boy with the paddleball hands a pear to each his two companions	40	39	24	8
12	The scene changes back to the tree	60	56	24	5
13	The three boys pass by the picker	40	39	19	5

The difference between the results of KS and PS and, accordingly, between the results of PS and HS is significant ($\chi^2_{KSPS}(12)=26.27$; $p<0.05$; $\chi^2_{PSHS}(12)=70.18$; $p<0.001$). Meanwhile, data for HS and A are located extremely close to each other. Fig. 1 presents these results in a graphic form.

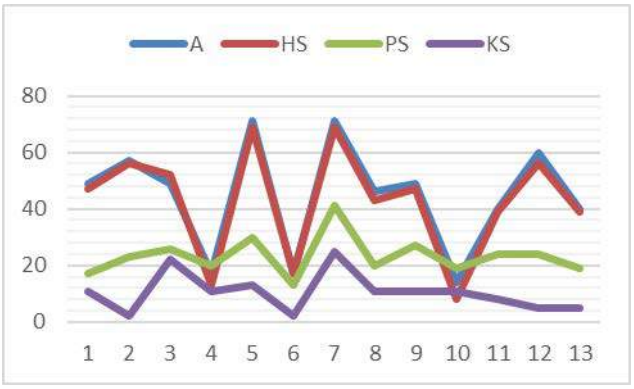

Fig. 1. The diagram of a percentage of subjects identifying main event boundaries for A, HS, PS and KS.

Interestingly, a comparison of data within PS does not reveal any significant differences. In particular, the comparison of TE of 34 first year PS and TE of 26 second year PS (TE_{1PS}=4.62; TE_{2PS}=5.42) gives p=0.34; the comparison of TE of 26 second year PS and TE of 13 third year PS (TE_{3PS}=4.77) provides p=0.54.

We also checked, as mentioned, a possible correlation between event cognition skills and skills in narrative comprehension and retelling for the group of primary school students. It seems reasonable to distribute all correspondences among three groups. The first group ($p<0.001$) includes the correlation between a total of episodes that the film was cut and a total of details mentioned in the retelling ($r(TE,TDt)=0.422$); the correlation between a total of "right" boundaries and a total of details ($r(TB_r,TDt)=0.410$); and the correlation between a total of "right" boundaries and a total of events correctly presented in retelling ($r(TB_r,TE_c)=0.420$). The second group ($p<0.01$) includes the correlation between a total of episodes and the total number of words exploited in retelling ($r(TE,TW)=0.383$); between a total of "right" boundaries and the total number of words ($r(TB_r, TW)=0.344$); between a total of episodes and a total of events correctly presented in retelling ($r(TE,TE_c)=0.382$); between a total of "right" boundaries and a total of events presented in retelling ($r(TB_r, TE_r)=0.339$). The third group ($p<0.05$) includes the correlation between a total of episodes and a total of events presented in retelling ($r(TE, TE_r)=0.250$); between a total of episodes and a total of

incorrect description of causal chain of events and sub-events (r(TE,FC)=-0.245); between a total of episodes and a total of interpretations (r(TE,TI)=0.287); between a total of "right" boundaries and a total of dependent words (r(TB_r, TDp)=0.263); between a total of "right" boundaries and a total of incorrect description of causal chain of events and sub-events (r(TB_r,FC)=-0.266); and between a total of "right" boundaries and a total of interpretations (r(TB_r,TI)= 0.261).

Discussion

The results support the conjecture of serious problems that kindergarten students and primary school students encounter when cutting a visual narrative into events. They lose some key event boundaries, and they are less consistent in detecting event boundaries than high school students and adults. In other words, they are inclined to interpret the narrative as the whole story not picking out any significant parts within it. Indeed, this does not mean that kindergarten students and primary school students do not cut the film into events when they watch it. They may encounter serious difficulties in making sense of the task. This is especially important for kindergarten students (primary school students perform similar tasks from time to time in their school lessons). Therefore, it is hard to distinguish between difficulties in defining events and event borders in process of real viewing (which is, mainly, unconscious) and difficulties in conscious efforts to cut the film into events.

In order to cast additional light on this issue, some other data need to be addressed. In Glebkin et al. 2017 clear evidence was provided for serious problems which kindergarten students encounter in "The Pear Film" retellings in comparison with high school students (TW, TE_r, FA, FO, FC, TI, TDp values differed significantly for KS and HS groups). Further investigations have shown that similar problems characterize retellings of primary school students. Therefore, difficulties in event cognition correlate in age aspect with difficulties in narrative comprehension and retelling, and we can expect substantial correlation in the acquisition of these groups of cognitive skills.

A precise look to the data presented above might clarify this issue. In particular, the figures in Table 1 (and the diagrams in Fig. 1) are interesting. There are only three points in which high school students and adults are less consistent (or almost equally consistent) than primary school students: the moment of bike boy stopping near the baskets (Point 4); the moment when a girl on a bike appears (Point 6); and the moment when the bike boy and the boy with the paddleball exchange the pears and the hat (Point 10). Why high school students and adults do not generally detect these points as event boundaries?

In order to clarify this issue, let us focus on "The Pear Film" narrative at hand. Point 4 and Point 10 characterize some local changes in the narrative, but there are strong arguments for interpreting these points as situated within events; they are unlikely to be basic event boundaries. In particular, Point 4 is situated within the event "The bike boy steals a basket of pears", and this was the reason for high school students and adults not to detect it as an event boundary. Similarly, Point 10 – the exchange of the pears and the hat – is not an event boundary, because the boy with the paddleball when taking three pears from the bike boy is expected to hand the pear to each of his two companions to end the event.

The case of Point 6 – a girl on a bike appears – is a bit more complicated. The girl is a new character, and she is introduced in the story with a close-up, therefore, her appearance may look as the beginning of a new event. Meanwhile, she is not a main character; she is engaged in the event "The bike boy rides down the road". Her part in this event is implemented later on when she brings to bear the boy's fall. If so, this moment is unlikely to be an event boundary.

Why, in this case, primary school students did often detect these points as event boundaries? There are, at least, two aspects of PS subjects' strategy in event boundaries detecting which may underpin these particular decisions. Firstly, two levels in the structure of event model can be singled out. The first level characterizes changes in location, actions and interactions given in visual perception, situated, so to say, on a superficial level. For instance, "the boy's bike falls over". Some of such changes are autonomous, but some others are signs of elements, which are located on a deeper level and need a special interpretation (e.g., the fact, that the boy places the basket on the rack in front of his handlebars, and rides off, means that he steals the basket). On average, primary school students do not include some important links on the deeper level into their event models. As a result, their models are 'poorer' than and models of high school students and adults addressing the same event; they are 'flat', but not 'volumetric' ones. If it is so, some changes in the visual field, such as ones, happened in Point 4, Point 6, and Point 10, are sufficient for them to detect these points as event boundaries.

Secondly, an analogy with language comprehension helps to explore this issue from another perspective. Researchers single out three levels of text representation: the surface form, the propositional textbase, and the situation model (e.g., Schmalhofer & Galvanov 1986; Radvansky & Zacks 2014, 57–58). A difference between sentences on the first level concerns words and grammatical structures, but not the facts and their interpretation (e.g., *Anna cleaned the room and then went to the cinema* and *After cleaning the room Anna went to the cinema*). On the second level, a situation is the same, but a focus and an interpretation may be different (e.g., *The ball flew into the goal from the foot of Peter* and *Peter scored a goal*; in the first case it may be also ricochet). On the third level, the situations are different.

If expanding this model on a visual narrative, a difference on the first level would mean different wide shots of the same event; difference on the second level – e.g., a close-up of different objects within the same event; and difference on the third level – different events. From

this perspective, in contrast with high school students and adults, primary school students are inclined to 'paste' together different levels. In particular, the close-up of the girl on a bike may be a reason for them to detect Point 6 as an event boundary.

Finally, let us zoom in on the comparison between event cognition skills and skills in the narrative comprehension and retelling. These data support the conjecture that the 'flat' event model dominates for primary school students. The variable, which shows the most significant correlation with both a total of episodes and a total of right boundaries, is a total of details mentioned in the retelling (TDt). At the same time, TDt is hardly to be a characteristic of logical aspects of the narrative comprehension; rather, it characterizes visual attention and visual memory. In other words, high TDt values are not valid signs of high quality of event models.

Also, the strong correlation between a total of right boundaries and a total of events correctly presented in retelling, and a significant correlation between both a total of right boundaries and a total of events and the total number of words exploited in the retelling, between a total of episodes and both a total of events presented in retelling and a total of events correctly presented in retelling show that the more detailed a retelling is the more event boundaries are detected by the subject.

The correlation between a total of events (or a total of right boundaries) and characteristics of understanding and representation of logical structure of the narrative (a total of incorrect description of causal chain of events and sub-events; a total of interpretations; a total of dependent words) is less significant. It is worth paying special attention to the lack of any correlation between a total of events and a total of errors in object description (a variable characterizing categorization skills).

Overall, our data support the conjecture that event models evolve through the life span, and event models of kindergarten students and primary school students subjects are 'poorer' than whose of high school students and adults. Therefore, the age of 10-14 years old is likely to be crucial for the development of event cognition ability. The problem of correlation between this ability and other cognitive skills in diachronic perspective needs further investigation.

Abstract

Becoming a proficient reader is a critical skill that supports future learning. Toward the end of the primary grades, reading becomes increasingly automatized, and children begin to transition from *learning-to-read* to *reading-to-learn*. Yet, the design of beginning reader books may be suboptimal for novice readers. Colorful illustrations that contain irrelevant information (i.e., seductive details) presented in close proximity to the text may increase attentional competition between these sources of information; thus, hampering decoding and reading comprehension. Study 1 examines this hypothesis by experimentally manipulating components of the book design (e.g., presence/absence of seductive details) and investigating its effect on attention and reading performance in first grade students. In Study 2, we conduct an analysis in which we identify common design features in books for beginning readers and examine the prevalence of design features that were found to tax attention in Study 1 and in prior research. Collectively this work identifies an important opportunity in which instructional materials can be optimized to better support children as they learn-to-read.

Keywords: attention; selective sustained attention; reading comprehension, decoding, reading, book design

Introduction

Learning to read is an important skill that enables future learning (National Association for the Education of Young Children, 1998). As reading becomes increasingly automatized, children begin to transition from *learning-to-read* to *reading-to-learn,* and thus can more readily apply this skill to learn novel information. But acquiring this skill set is challenging due to a number of factors including (but not limited to) deficits in prior knowledge (e.g., pre-reading skills such as phonological awareness; Kirby, Parrila, & Pfeiffer, 2003), learning disabilities (e.g., dyslexia), as well as cognitive limitations (e.g., working memory, processing speed; Jacobson et al., 2011). The difficulty many children experience in becoming competent readers is reflected in a 2005 report in which *only* 31% of 4th grade students in the United States were identified as "Proficient" or above on the NAEP reading assessment and rates were lower still for some groups of minority students: Black 13%, Hispanic 16%, American Indian/Alaska Native 18% (Perie, Grigg, & Donahue, 2005, pp. 3-4). These sobering statistics highlight the need to identify malleable factors that can be leveraged to better support children's reading achievement. One potential factor is book design.

The design of beginning reader books may not be optimized to support early reading, which may further increase the difficulties children experience acquiring this skill. Prior research has found that the close proximity between text and illustrations in books for beginning readers increases attentional competition between these sources of information hampering reading performance (Godwin, Eng, Todaro, Murray, & Fisher, 2018; Torcasio, & Sweller, 2010). By increasing the spatial separation between text and illustrations (Godwin et al., 2018) or reducing extraneous details from illustrations (Eng, Godwin, & Fisher, 2018), attentional competition is reduced (indexed by gaze shifts away from the text), and reading comprehension improves. These results are promising, as they point to a malleable factor (i.e., book design) that could in principle be optimized to better scaffold young readers' attention to the text and in turn enhance their developing literacy skills. However, it is currently unknown whether these design choices (e.g., close proximity between text and illustrations, inclusion of irrelevant details in illustrations) are typical in beginning reader books. If these design choices represent a standard design practice, then this emerging body of research points to an unrecognized opportunity for intervention.

The present paper reports two studies. Study 1 provides a conceptual replication of Eng et al. (2018), but also extends prior work with second grade students to a younger age group, first-graders. In Study 1, we investigate experimentally whether an element of the book design (i.e., presence/absence of attention-grabbing, but irrelevant to the text, details in illustrations) negatively affects children's

attention to the text, diminishing their reading performance. Study 1 makes an important contribution given growing concerns regarding the replicability crisis (e.g., Camerer et al., 2018; Nosek et al. 2015). Study 2 makes a novel contribution by examining issues of generalizability, namely examining whether the design features of the book utilized in prior research are commonplace and thus represent a potential avenue for intervention. In Study 2, we conduct an analysis of 100 beginning reader books in which we identify common design features and assess how prevalent the design choices that were found to tax children's attention in Study 1 (and in prior research) are in children's books.

Study 1

Method

Thirty first-grade children participated in the present study (M = 7.09 years, SD = .32 years, 16 females, 12 males, 2 did not report). The sample represents local diversity with children being 63.3% White, 13.3% African American, 16.7% Multi-Racial, and 6.7% reported as other. Participants were recruited from schools in and around a mid-sized city in the Northeastern United States. Participants were tested individually by trained hypothesis-blind research assistants.

Design and Procedure

In order to ensure ecological validity, Study 1 utilized a commercially available beginning reader book selected from the *Hooked On Phonics Learn to Read* series. Children were asked to read aloud the book "Good Job Dennis," by Amy Kraft. Following Eng et al. (2018), the book design was manipulated within-participants such that half of the book was presented in the Standard layout of unaltered pages from the commercially available book, and half of the book was presented in the Streamlined layout in which the illustrations were simplified by removing the irrelevant details. The presentation order of conditions (Standard condition or Streamlined condition first) was counterbalanced across participants. Each half of the book contained 6 pages. Minor modifications were made to the text to ensure that each half of the book had approximately equivalent number of words (average number of words per page: 43.0 first half, 42.3 second half). Identification of irrelevant details was based on a separate calibration study (Eng et al., 2018). Fifteen college students were given photocopies of the book and were asked to outline details in the illustrations that they believed were *relevant* to the story text for each page. The illustration details in which participants reached over 90% agreement were included in the Streamlined condition and all other remaining details were removed (See Figure 1A and 1B).

The book was presented on a laptop computer and children's gaze shifts away from the text were recorded using eye tracking technology. Decoding was assessed prior to reading the story (Word Recognition in Isolation Test) and while children read aloud (Running Record). Following the story, a post-test was administered to assess reading comprehension.

Figure 1A: Sample page of the Standard layout condition

Figure 1B: Sample page of the Streamlined layout condition

Measures

Gaze Shifts Children's attention allocation to the text was measured using a RED250 mobile eye tracker (SensoMotoric Instruments, Inc.) in which gaze shifts away from the text were recorded. For each page of the book, Areas of Interest (AOIs) were created for the text, white space, and illustrations. The number of gaze shifts away from text AOIs (to illustration AOIs or white space AOIs) was calculated using the SMI BeGaze software and the average number of gaze shifts per page is reported.

Decoding Measures Decoding is thought to be an important component of reading Fluency (Rasinski, 2004). The decoding measures assess children's ability to accurately

identify words (either in isolation or embedded in text). Two decoding measures were employed: the Word Recognition in Isolation task and a Running Record.

Word Recognition in Isolation Task Children completed a modified Word Recognition in Isolation (WRI) task which served as an independent measure of children's ability to decode words fluently (Morris, 2013). The WRI was administered prior to children reading the story. Children are shown leveled lists of words and asked to read the words aloud as quickly and accurately as possible. The number of words read correctly (out of 100 possible words) within the time limit was recorded.

Running Record (RR) The research assistant manually recorded the child's decoding accuracy for each word in the story and the proportion of correct responses was calculated (Clay, 1972).

Reading Comprehension Measure Children were asked six open-ended comprehension questions. Responses were recorded by hypothesis-blind research assistants. We slightly modified the questions provided by the book manufacturer to maintain the ecological validity of the comprehension assessment. Questions were designed such that they probed memory for content presented on specific pages. The post-test included six questions, three questions from each half of the book. Rather than scoring children's responses in a binary fashion (correct vs. incorrect), partial credit was possible. In each half of the book, children completed two 2-point questions and one 3-point question and thus could earn up to 7 points per condition. For example, children were asked to recall Dennis' job. Children earned full credit (2 points) if they stated that Dennis directs traffic and helps children cross the street. Partial credit (1 point) was awarded if children provided an incomplete answer (e.g., "he helps children"), and 0 points if children provided an incorrect answer or failed to recall Dennis' job. The percentage of correct responses (out of 7) is reported. Scoring was completed by condition blind research assistants. To ensure inter-rater reliability, the data was scored twice by two research assistants and Cohen's Kappa (Cohen, 1960) was calculated (.88).

Results

There were no significant differences in average reading time per page in the Standard condition (M = 55000.21 ms; SD = 35065.49 ms) compared to the Streamlined condition (M = 54066.81 ms; SD = 37571.03 ms), paired-sample $t(29) = .27$, $p = .79$. There were also no significant differences in participants' Running Record scores while reading in the Standard condition (M = 94.78%; SD = 5.13%) compared to the Streamlined condition (M = 94.87%; SD = 5.03%), paired-sample $t(29) = .34$, $p = .74$.

Reading Comprehension Children's comprehension scores were significantly higher in the Streamlined condition (M = 80.48%, SD = 20.37%) than in the Standard condition (M = 51.90%, SD = 24.74), paired-sample $t(29) = 4.72$, $p < .0001$ (see Figure 2); Cohen's d = 1.26. In order to test for order effects, we conducted a mixed factorial analysis of variance (ANOVA), factoring condition order as the between-subject variable and comprehension as the within-subject variable. There was no main effect of condition order, $F(1, 28) = .02$, $p = .90$, and no significant interaction between order and comprehension, $F(1, 28) = 2.09$, $p = .16$. These results indicate that reading in the Streamlined condition resulted in higher comprehension compared to reading in the Standard condition, regardless of the amount of time spent reading, the quantity of words a child accurately read aloud, and the order in which the layout was presented.

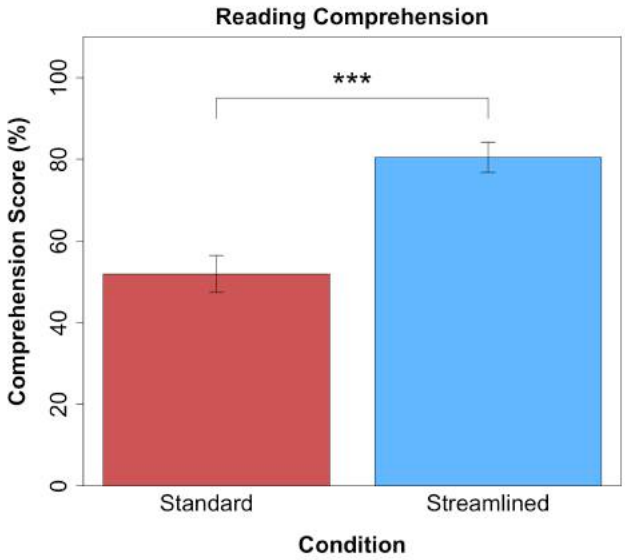

Figure 2: Percentage of correct answers on the story questions as a function of book layout. ***$p < .0001$).

Gaze Shifts On average, children switched their point of fixation away from the text 27.78 times per page (SD = 26.48) in the Standard layout compared to 13.71 times in the Streamlined layout (SD = 11.07), paired-sample $t(29) = 4.67$, $p = <.0001$; Cohen's d = .69. Three outliers were identified. With the removal of these outliers, there was still evidence of a significant main effect of book layout on children's gaze shifts (paired-sample $t(26) = 5.65$, $p<.0001$. Cohen's d = .89). Children looked away from the text almost twice as much in the Standard condition than they did in the Streamlined condition (See Figure 3).

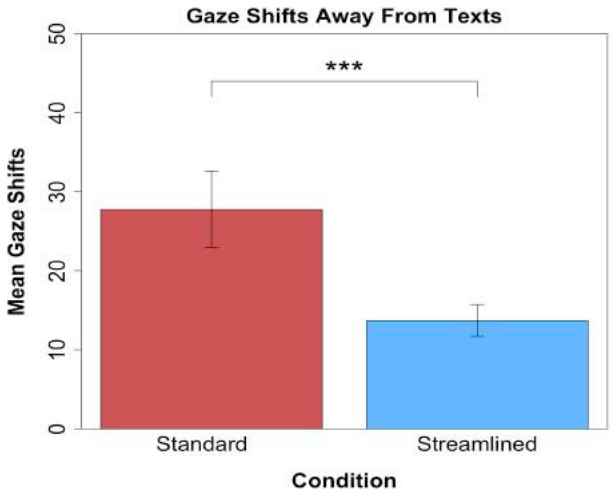

Figure 3: Average gaze shifts away from the text per page as a function of book layout. ***$p < .001$).

The Role of Individual Differences Next we examined whether the Streamlined layout might be especially beneficial for children who often shift their attention away from the text. For this analysis, a difference score for each child was calculated by subtracting the Standard layout comprehension score from the Streamlined layout comprehension score. Difference scores estimated changes in reading comprehension performance from the Streamlined layout, such that higher and positive scores indexed greater gains in comprehension. Difference scores ranged from -57.14% to 85.71%, with a mean of 28.10% (*SD* = 33.24%). Children's gaze shifts in the Standard layout condition were positively associated with Comprehension Gain scores ($r = .49$, $p = .003$), as shown in Figure 4. Thus, the Streamlined layout was especially helpful for children who frequently shifted their gaze while reading: the more children looked away from the text, the more their comprehension benefited from reading the book in the condition in which extraneous details were removed.

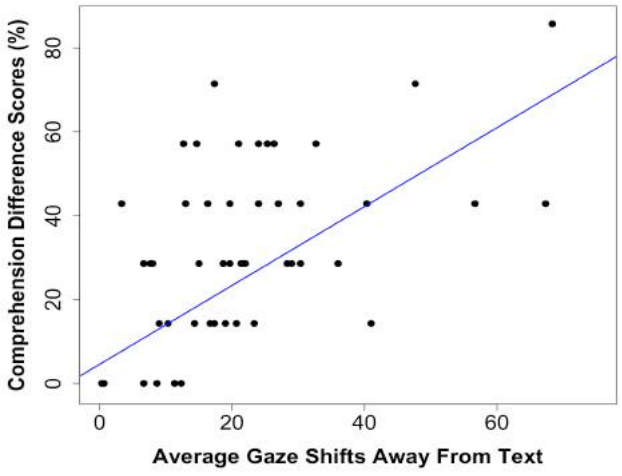

Figure 4: Association between gaze shifts and comprehension gains with outlier removed.

Unique Contribution of Gaze Shifts to Comprehension Gains To ensure that the findings were not entirely due to variance shared with reading ability, children completed the WRI test prior to the reading session to assess participants' decoding fluency ($M = 55.90$, $SD = 20.04$). To examine the extent to which children's gaze shifts away from the text while reading uniquely predicted how much children's comprehension improved from the Streamlined layout condition, we conducted a multiple regression analysis that included gaze shifts and WRI scores as predictors of children's comprehension difference scores. Results show that gaze shifts ($\beta = 5.57$, $t = 2.28$, $p = .003$) accounted for unique variance in comprehension gains when reading from the Streamlined layout, but reading fluency (indexed by the WRI) did not ($p > .10$; see Table 1). The results suggest gaze shifts away from the text while reading account for unique variance in comprehension gains independent of the overall reading ability.

Table 1: Relation of Gaze Shifts to Comprehension Gains

	β	*SE*	*t*
Eye Gaze Shifts	3.37**	0.24	2.28
WRI Score	-.55	0.32	-1.72

** $p < 0.01$. $R^2 = .45$. $F = 11.05$. $df = 2, 27$.

Study 1 successfully replicates the results from prior research (Eng et al., 2018) with a younger age group (first-graders) and demonstrates that extraneous illustration details are a source of distraction for beginning readers. Extraneous, nonessential illustration details were found to disrupt attention as evidenced by the increase in gaze shifts away from the text. This design choice not only affected children's patterns of attention allocation, but it also reduced children's reading comprehension.

While the successful replication points to a robust finding, it remained unclear whether the design features characteristic of the book used in Study 1 are prevalent in other books for beginning readers. If the inclusion of irrelevant details in illustrations is a common practice, then it points to an opportunity in which we could better support children's reading by modifying the design of beginning reader books. We begin to address this question in Study 2.

Study 2

Method

Design and Procedure

Guided by a children's librarian, 100 children's beginning reader books were selected from local libraries near a Midwestern town in the United States. The books were subsequently analyzed to investigate common design

elements. Books were pseudo-randomly chosen to ensure representation of multiple publishers (17 total) and topics. The sample of books represent work from 101 authors and 92 illustrators. Trained coders rated each story page, excluding publisher pages, on 10 categories relating to aspects of the book design including: features of the illustrations (e.g., color, alignment, irrelevant details), text (location, enhancements), and general design (layout, use of white space, borders). Of particular interest for the present study was the category irrelevant details as well as page layout given that Study 1 and prior research (Eng et al., 2018) have found that the inclusion of irrelevant details in illustrations as well as including illustrations in close proximity to the text (Godwin et al., 2018) increase attentional competition and reduce reading performance. The remaining 8 categories were included to provide a more comprehensive analysis of the common design features employed in beginning reader books.

For each book, the percentage of pages in each category level was calculated and means for the data set are reported. Coders received extensive training on the coding protocol using worked examples. Coders also completed a training set, consisting of 7 beginning reader books in order to establish interrater reliability (Cohen's kappa = .80, range: .76 to .85).

Results

All of the books were leveled for beginning readers. The average number of pages per book was 27 (*SD* = 8.77).

Features of the illustrations

Beginning reader books tend to contain illustrations that are very colorful and detailed: on average 93.42% of a book's pages contained illustrations that included five or more colors and 97.79% of a book's pages contain some or intermediate levels of detail. Most book pages contained a single illustration (93.19% of a book's pages), and the illustrations were generally aligned to the text (86.98% of a book's pages). However, the inclusion of irrelevant details in illustrations was found to be a common practice with 86.56% of a book's pages containing some or several irrelevant details.

Features of the text and general layout

Text location varied, but common text locations included centered at the top (35%) or bottom of the page (21.8%), or in multiple locations (13%). Design features intended to enhance the saliency of the text including text boxes, fading, or bubbles were rare (4.65% of a book's pages) as were the use of borders (6%). Surprisingly, white space was not utilized on 28.73% of a book's pages. Although publishers

Note. For every book, the percentage of pages in each category-level was calculated, and means are reported.

tended to include some spatial separation between text and illustrations (62% of a book's pages), embedding the text *inside* illustrations was also a frequent design choice (27.46% of a book's pages).

Discussion

During the primary grades, young children are just beginning the challenging work of learning how to decode text. The difficulty many children experience aquiring literacy skills may be compounded by the design of beginning reader books. These instructional materials may fail to take an important cognitive constraint into consideration; namely, children's immature attention regulation system (e.g., Ruff & Rothbart, 2001). Placing text and illustrations in close proximity may unintentionally create attentional competition between these sources of information, hampering reading comprehension. Such attentional competition may be particularly disadvantageous when illustrations contain irrelevant information. The present work explored this possibility with a group of first grade students (Study 1) and provides an extensive analysis of book design features that may influence children's attention allocation across 100 beginning reader books (Study 2).

Several notable findings emerged from this work: Study 1 informs our understanding of how beginning readers allocate their attention while reading independently, and identifies a design feature that influences children's ability to maintain attention to the text. The inclusion of irrelevant details in illustrations for beginning readers was found to disrupt attention allocation and hampered reading comprehension. This finding corroborates prior work (Eng et al., 2018) and provides an important conceptual replication with a novel age group; thus, demonstrating the robustness of the effect. Study 2 examined the prevalence of this design choice, as well as other design features, in books for beginning readers by conducting a detailed analysis of 100 books. The results point to several common design features that may increase attentional competition for young readers including: embedding the text within the illustrations and often not including white space. Critically for the present work, illustrations containing irrelevant details was found to be a common design practice. The prevalence of these design choices point to an opportunity in which we could better support children's emergent literacy skills by modifying the design of beginning reader books.

Abstract

We investigated whether induced affective states can affect the process and outcomes of decisions under risk. A mood induction task was used to elicit a positive or negative mood in a sample of adult participants (N=48). The participants then responded to 28 decision problems, each offering a choice between two mixed-domain risky alternatives. The dependent variables of interest were decision-making choices, as well as an eye-tracking based attentional measure: the total fixation durations for certain critical aspects of the two presented risky decision options. Mood condition did not have a significant main effect on participants' choices, or on mean total fixation time for problems. However, fixation times showed a three-way interaction between mood condition, domain (gain versus loss), and time (block). The fixation time data also provided some general insights into participants' patterns of attention allocation during decision-making. They generally spent more time looking at values compared to probabilities, and more time looking at potential gains compared to losses (although this difference declined over time, especially for positive-mood participants).

Keywords: emotion; decision making; mood induction; affect; allocation of attention; eye tracking; risk; cognitive processing; strategy; choice

Incidental affect has been used to predict and explain a wide variety of judgments and decisions (Peters, Västfjäll, Gärling & Slovic, 2006). Incidental affect refers to feelings or mood states induced by a situation that is normatively irrelevant to a given decision. Most early studies on incidental mood induction took a simple valence-based approach, dividing emotions into positive and negative categories. Researchers found that individuals in a happy rather than a sad mood tend to make optimistic judgments and choices by overestimating the likelihood of positive outcomes and underestimating the likelihood of negative outcomes (Loewenstein & Lerner 2003; Johnson & Tversky, 1983; Raghunathan & Pham, 1999).

More recent research has focused on how particular affective states can affect the general information processing strategy adopted by an individual, towards more analytic or more heuristic strategies (Lerner 2015). Findings suggest that individuals who are in a happy mood are more likely to adopt a heuristic processing strategy, a tendency to use intuition and "gut feelings" with relatively little attention being paid to details. By contrast, individuals who are in a sad mood are more likely to adopt a systematic processing strategy, with careful analysis of information (Bolte, Goschke & Kuhl, 2003; George & Dane, 2016; Schwarz & Clore, 1996; Schwarz, 2000).

Affective states may influence decision-making because the decision maker selectively attends to, encodes, and retrieves emotion-relevant information (Niedenthal & Setterlund, 1994). This phenomenon can be seen as consistent with the affect infusion model (AIM), which posits that affectively loaded information influences an individual's cognitive and behavioral processes, pushing their decision outcomes in a mood-congruent direction (Forgas, 1995). If such mood priming occurs, then individuals in a positive mood should be more likely to access thoughts about the positive aspects of a risky situation compared to those in a neutral mood (Forgas & George, 2001; Nygren, Isen, Taylor & Dulin, 1996). Thus, positive moods may increase an individual's risk-taking tendency with mixed-domain options, because positive potential outcomes will be emphasized over potential losses, so that risky choices will be perceived as more favorable. Individuals in a negative mood, by contrast, are more likely to access thoughts about the negative aspects of risky situations, which consequently would lead to more conservative decision-making choices so as to avoid potential loss (Yuen & Lee, 2003).

Nevertheless, prior research provides mixed results regarding the direction of influence of incidental affect on decision-making processes (Lerner, Li, Valdesolo & Kassam, 2015). An alternative model, the mood-maintenance hypothesis (MMH), posits that incidental mood states motivate behavior such that individuals act to maintain or attain positive mood states (Kliger & Kudryavtsev, 2014). Accordingly, individuals in a positive mood avoid risk in order to maximize the likelihood of maintaining their positive mood, whereas individuals in a negative mood seek risk in an attempt to obtain gains that

might relieve their negative mood (Mishra, et al, 2010; Mishra, 2014; De Vries, Holland, & Witteman, 2008; Hills, et al, 2002).

The contrasting predictions of these models, we argue, can be directly examined using eye-tracking based attentional measures, in studies of mixed domain decisions under risk. This type of design allows us to track individuals' focus of attention on both positive and negative aspects underlying their decision-making processes. Thus, by examining participant's attention to gain vs. loss information, we can assess whether participants' attention allocation is in line with the predictions of a mood-congruence (affect infusion) or mood-maintenance hypothesis.

Empirical Study

The purpose of the present study was to investigate the influence of induced affective states on the process and outcomes of decision-making with a set of risky choice problems. A mood induction task (watching short videos) was used to elicit a positive (happy) or a negative (sad) mood. Previous research has shown that the use of movie or story procedures is an effective means of manipulating participants' moods (Drouveli & Grosskopf, 2016; Ellard, Farchione & Barlow, 2012; Gerrards-Hesse, Spies, & Hesse, 1994; Westermann, Spies, Stahl, & Hesse, 1996). The decision-making task using mixed domain problems gave participants a chance to systematically compare and weigh different aspects of the two risky decision options. According to an affect infusion or mood congruence (AIM) account, positive mood should enhance attention to information about gains, while negative mood should make information about losses more salient and more viewed. In contrast, the mood-maintenance hypothesis (MMH) predicts that individuals in a negative mood should be especially motivated to attend to information about potential gains. Finally, from the standpoint of the heuristic/analytic dichotomy, we investigate the hypothesis that individuals in a negative mood may be more likely to adopt a systematic processing strategy, perhaps by calculating expected value or by using an equivalent procedure, whereas participants in a positive mood may be more likely to use a heuristic processing strategy (George & Dane, 2016; Schwarz & Clore, 1996; Schwarz, 2000).

It seems important in assessing the effects of incidental emotion on decisions to look at decision *process* (as well as outcomes). We accomplish this by using eye-tracking-based attentional measures. By studying attention in the context of mixed-domain decision problems under risk, we can track the decision-maker's focus of attention on positive (gain) and negative (loss) information. These aspects of the present study constitute a novel approach to investigating the possible influence of induced affective states on risky decision-making.

Method

Participants

Forty-eight participants were recruited from a large private University community in North America, either by responding to flyers posted on campus bulletin boards or for course credit. Participants included both undergraduate and graduate students (36 females and 12 males. Most (90%) participants ranged in age from 20 to 30 years, 94% had obtained at least a bachelor's degree, and 88% had completed a basic statistics course. They participated in the study for either a payment of $10 or course credit.

Overview of Procedure

Participants were tested individually. They were informed that the purpose of the study was to examine the factors influencing decision-making for problems involving potential financial gains and losses, and the process of how such decisions were made. Each participant was randomly assigned to one of two mood induction groups: positive or negative. The participant first was taken through a calibration procedure with the eye-tracker, to enable accurate gaze point calculations. Following the viewing of the mood-induction movie clip, the participant was asked to make choices for each of 28 risky decision problems displayed on a computer screen equipped with an eye tracking equipment. During this task, participants were encouraged to work at their own pace.

Mood Induction

Movie clips were used to induce emotions "incidental" to the decision task. Two movie clips of similar length (6 to 7 minutes), one categorized as "happy" (from *The Muppet Show*), and the other as "sad" (from *Schindler's List*), were utilized. These clips have previously been shown to successfully induce positive and negative mood states, respectively (De Vries et al., 2008). The success of the mood induction procedure of the experiment was checked via a self-reported mood questionnaire administered after the video watching and before the decision-making task. All participants were asked to rate on a 7-point Likert scale (ranging from 1 to 7) how well each of the following terms (*happy, joyful, cheerful, enthusiastic, sad, blue, upset, distressed*) described how they felt at that moment. All of the terms are taken from the PANAS-X positive and negative affect schedule (Watson & Clark, 1999), and have been previously classified as representing either a positive valence or a negative valence.

Mixed Decision-making Task

Twenty-eight risky decision problems were presented, each consisting of two decision options (labeled 'a' and 'b'). Each option was a risky mixed prospect, consisting of a loss and a gain with associated (complementary) probabilities. The display format for an example decision problem is shown in Figure 1. Note that an analytic strategy

such as calculating expected value (EV) requires attention to both values and probabilities for both gains and losses of each decision option (all eight discrete pieces of information).

A Tobii model T60 eyetracker (version:3.2.3) with associated software was used to monitor the participants' attention paid to the eight consequential regions of each decision problem. Specifically, the eye tracking-based attentional measures included duration of fixations on eight critical regions, defined by: gain value, gain probability, loss value, and loss probability for each of the two decision options. The total fixation duration (TFD), in seconds, within each critical region or 'area of interest' (AOI) was computed as the total viewing time for each area across all episodes in which a participant had looked within the AOI, starting with a fixation within the AOI and ending with a fixation outside the AOI. Due to eyetracker calibration issues, we eliminated data from five participants whose fixations were not accurately identified, resulting in an effective N of 43 (positive mood condition n=21, negative mood condition n=22).

Participants' choices on the twenty-eight decision problems were also analyzed, including whether they chose the EV-maximizing option.

Figure 1. Display format for a sample decision problem offering a choice between option a and option b.

Results

As a manipulation check for the mood induction procedure, summary positive and negative mood rating scores were obtained by averaging the participants' self-ratings on the four relevant adjective scales: positive = (*happy, joyful, cheerful, enthusiastic*), negative = *(sad, blue, upset, distressed*). Figure 2 presents the mean rating scores on the positive words (Pos_Score) and negative words (Neg_Score), by condition (induced positive or negative mood). It can be seen that the mood induction was effective, as measured by the self-ratings of positive and negative mood. A multivariate ANOVA was conducted (overall) on the two self-rating summary dimension, and the overall omnibus F-test for the mood induction Condition was significant, $F(2, 45) = 89.112$, $p<.001$, suggesting strong mood-induction effects. Both positive (Pos_Score), $F(1, 46) = 97.04$, $p<.001$, and negative (Neg_Score), $F(1, 46) = 124.47$, $p<.001$, scores were significantly affected by the manipulation.

Decision outcomes:

To assess whether induced positive or negative mood affects the degree to which a participant engages in analytic processing, we first tested whether participants in the negative mood condition tended to show more EV-maximizing choices (based on EV calculations or equivalent procedures) than did participants in the positive mood condition. The relevant data consisted of information on participant's choice (a or b) for each pair of mixed domain problem. To analyze the data, we created a summary variable, EV score, defined as each participant's total number of EV-maximizing choices on those 28 pairs of problems. Therefore, these maximization scores could range from 0 to 28. Descriptive statistics showed that for the negative mood condition, $M = 19.3$, $s = 3.28$; for the positive condition, $M = 19.5$, $s = 3.88$. A one-way ANOVA indicated that this difference in the mean maximization score was not significant ($F(1, 46) = .026$, $p > .05$).

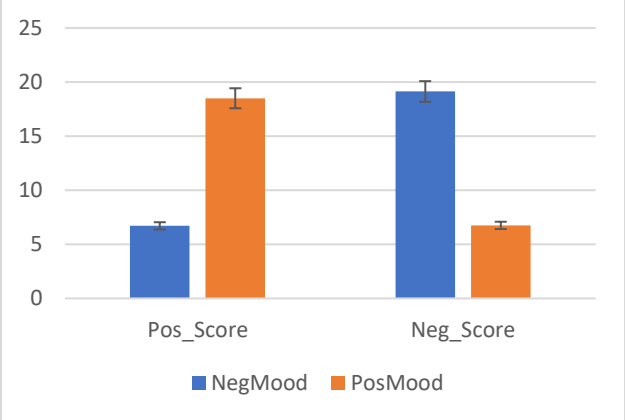

Figure 2. Results of the manipulation check for the effects of viewing two alternative videos (Condition = NegMood, PosMood) on self-rated positive and negative emotional valence.

Patterns of attention:

By analyzing the eye tracking-based attentional measure of total fixation durations (TFDs), we sought to find out how induced moods affect decision *process*, as reflected in the amount of attention that participants pay to certain critical aspects of the considered decision options. Specifically, we sought to answer the following questions: 1) Do participants in a positive mood state tend to pay more attention to positive aspects of the problems (as consistent with an affect infusion or mood congruence account, AIM)? 2) Are participants in a negative mood state more likely to pay attention to the negative aspects of the problem (as consistent with AIM), or more motivated to seek out positive information (as predicted by the mood-maintenance hypothesis, MMH)?

Because our decision-making task included 28 relatively difficult problems, time effects (due to fatigue and/or practice) were thought likely to occur. Also, it is possible that any effect of the emotion manipulation might be short-lived (Andrade & Ariely, 2009). Thus, we analyzed mean TFDs across four equal time blocks: problems 1-7, 8-14, 15-21, and 22-28. Due to practice/fatigue effects, we expected to see a decreasing trend in TFDs.

The marginal-mean TFDs and standard deviations are presented in Table 2, for the main effects of Type of information and Domain.

Participants in both mood conditions spent more time looking at values compared to probabilities, and more time looking at gains compared to losses. As expected, a time effect occurred whereby participants' fixation time spent on 'type' and 'domain' generally decreased from block 1 to block 4 (with exceptions for 'values' and 'losses' - an increase in TFDs from block 2 to block 3). One possible explanation is that block 3 contains relatively more high conflict problems (defined as having a small EV difference between the two options for each problem).

Table 2. Marginal (main effect) descriptive statistics for total fixation duration (TFD) by Type of information (values vs.probabilities) and by Domain (gains vs. losses) for each block of problems.

			Negative Mood		Positive Mood	
		Block	M	SD	M	SD
Type of Information:	Values	1	67.26	6.07	70.69	7.08
		2	45.54	4.54	49.70	5.50
		3	49.73	5.33	54.06	6.64
		4	44.16	5.41	47.33	5.60
	Probabilities	1	34.08	2.79	35.68	4.72
		2	25.17	2.40	28.64	3.85
		3	25.85	2.17	27.90	3.92
		4	25.59	2.41	26.05	3.99
Domain:	Losses	1	38.87	4.41	39.92	4.60
		2	26.85	2.72	29.76	3.74
		3	29.93	3.50	35.20	4.61
		4	26.86	3.26	31.71	4.81
	Gains	1	62.46	4.36	66.45	7.26
		2	43.86	4.15	48.58	5.75
		3	45.65	3.90	46.76	5.98
		4	42.89	4.53	41.66	5.02

Inferential Analyses

A repeated-measures ANOVA predicting mean TFD for each critical area was conducted using one between-subject factor of 'condition' (induced positive mood vs. negative mood), and three within-subject factors: 'domain' (potential gains vs. potential losses), 'type' of information (payoff values vs. payoff probabilities), and 'block' (1-4). Note that this analysis averages looking times (TFDs) for a given critical region (e.g., gain values) across the two decision alternatives.

In this ANOVA, statistically significant effects were found for the within-subject factors of Type ($F(1, 41) = 124$, $p < .001$), Domain ($F(1, 46) = 103.1$, $p < .001$) and Block ($F(2.685, 110.09) = 30.28$, $p < .001$), with a two-way interaction between Type and Domain ($F(1, 41) = 6.22$, $p = .017$), as well as a three-way interaction among Condition, Domain, and Block ($F(2.337, 95.814) = 2.99$, $p = .038$).

The descriptive and inferential results reveal that participants in both mood conditions spent significantly more time looking at values than probabilities, and more on gains than losses. However, it must be recognized that these main effects are to some degree confounded with the left-right position of these quantities on the screen, so some of the differences might be due to a reading order effect.

To interpret the interaction patterns, we first examined the significant three-way interaction among Condition, Domain, and Block. This interaction is shown in Figure 3. In this interaction, the payoff value and probability for a decision option are not separated, presumably because participants' looking times for these two components tended to be correlated. In Figure 4, it can be seen that looking times (TFDs) generally declined across the four blocks of problems (some small discontinuities between Blocks 2 and 3 are interpreted as being due to relatively difficult or high-conflict problems in Block 3). The main effect of Domain, with more time allocated to gain information, is also apparent. The interaction itself seems to be due to the fact that the difference in looking time for gains versus losses is very high in Blocks 1 and 2, and

much lower in Blocks 3 and 4. This pattern is more apparent in Figure 3, which plots those gain versus loss differences directly by comparing the difference between gain values and loss values, and in Figure 4.

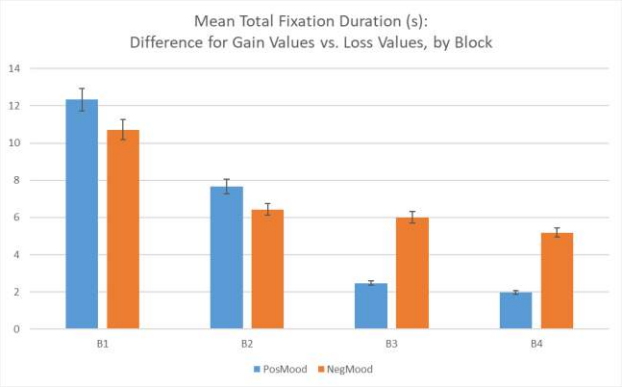

Figure 3. Mean Total Fixation Duration (s): Difference for Gain Values versus Loss Values, by Block and Condition.

Theoretically, the overall pattern of attention results can be explained in at least two ways. First, the positive induction may have had only a transitory effect, as follows. In the first two time-blocks, when the effects of the mood induction were presumably strongest, the pattern of means seems to be consistent with the Affect Infusion Model, such that participants in the positive mood condition paid slightly more attention to information about gains than did negative-mood participants. However, this difference declines in Blocks 3 and 4, perhaps due to a fading effect of the mood induction.

The second interpretation invokes the mood-maintenance hypothesis (MMH). According to the MMH, negative-mood participants focused more on information about potential gains rather than losses, in order to try to attain a positive mood state, and this difference in attention persisted across all four blocks. In contrast, positive-mood participants initially also paid more attention to gains, perhaps to maintain their positive mood. But this effect faded relatively quickly for the positive-mood participants. It is possible that the positive mood induction (watching a silly video) had a more transitory effect than the negative mood induction (watching a clip depicting Nazi murders). But this interpretation should be substantiated via future research.

Conclusion

The results did not provide evidence that induced positive or negative moods can affect the prevalence of analytic processing, at least as measured by EV-maximization success. Nor do they confirm the main predictions of the mood-congruence and mood-maintenance hypotheses regarding attention allocation, as measured by total fixation durations (TFDs). Neither a main effect of condition nor an interaction of condition with domain on attention was found.

However, a significant three-way interaction among Domain, Condition, and Block was found (Figure 4). The nature of the interaction suggests that the mood induction, particularly the positive induction, may have had only a3transitory effect. In the first two blocks, when the effects of the mood induction were presumably strongest, participants in both conditions paid more attention to information about gains, and participants in the positive mood condition paid slightly more attention to information about gains than did negative-mood participants. But this pattern is not confirmed by inferential tests. We should be aware that the samples size was relatively small. In order to detect effects of incidental emotion on such subtle patterns of attention allocation, many more participants would be needed.

Nonetheless, the significant main effects of Type of information and Domain (gain versus less) do suggest some insights into participants' allocation of attention in their decision-making processes. These significant effects suggest that participants, regardless of their assigned mood conditions, allocate more attention to value information than to probabilities, and more attention to gains than to losses. We plan future investigations to confirm and further explore these findings.

Further research in this area might also explore other types of emotion induction manipulations, of varying strengths and durations, to more fully investigate the effects of incidental emotion on decision process and outcomes.

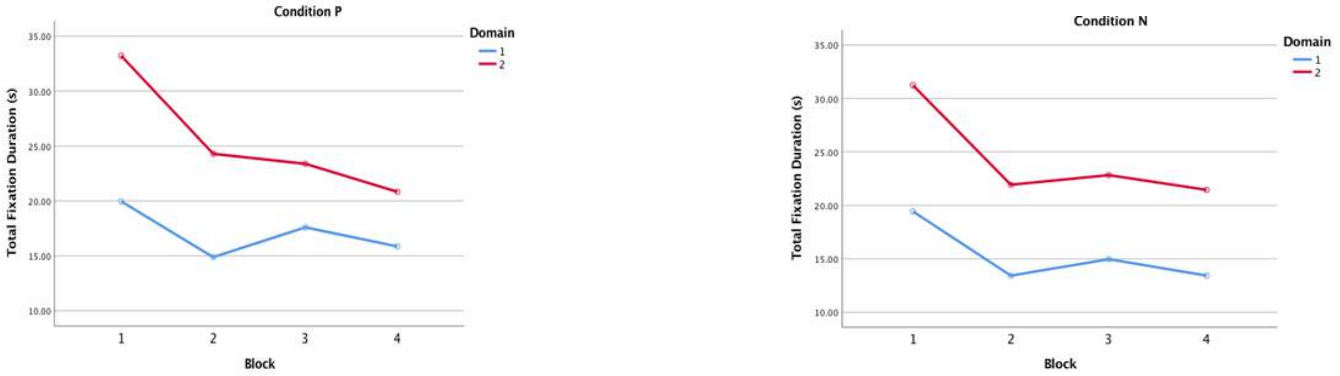

Figure 4. The three-way interaction among mood induction Condition (P=positive mood condition; N=negative mood condition), Domain (1=loss, 2=gain), and Block.

Abstract

Human concept learning is surprisingly robust, allowing for precise generalizations given only a few positive examples. Bayesian formulations that account for this behavior require elaborate, pre-specified priors, leaving much of the learning process unexplained. More recent models of concept learning bootstrap from deep representations, but the deep neural networks are themselves trained using millions of positive and negative examples. In machine learning, recent progress in meta-learning has provided large-scale learning algorithms that can learn new concepts from a few examples, but these approaches still assume access to implicit negative evidence. In this paper, we formulate a training paradigm that allows a meta-learning algorithm to solve the problem of concept learning from few positive examples. The algorithm discovers a taxonomic prior useful for learning novel concepts even from held-out supercategories and mimics human generalization behavior—the first to do so without hand-specified domain knowledge or negative examples of a novel concept.

Keywords: concept learning; deep neural networks; object taxonomies

Introduction

One of the hallmarks of human intelligence is the ability to rapidly learn new concepts given only limited information (Lake et al., 2016). This task is difficult because we are often presented with only a handful of (positive) examples of a new concept, and no examples outside of the concept (negative examples). Quine (1960) was the first to recognize that this poses a seemingly crippling problem for induction: hearing only the word "gavagai" as a rabbit passes by, we have no way of knowing with certainty whether the new word applies to all animals, all rabbits, one pet rabbit, potential food, or any other of a nearly infinite number of likewise compatible hypotheses.

Nevertheless, humans appear to possess prior knowledge, whether learned, innate, or both, that makes for effective generalizations even under such conditions. In some situations, these constraints are simple and easy to model (Tenenbaum, 1999; Tenenbaum & Griffiths, 2001; Kemp et al., 2007). However, in general, modeling the rich prior knowledge that humans bring to bear on problems in complex domains such as natural images is difficult and reliant on explicit domain knowledge (Xu & Tenenbaum, 2007; Jia et al., 2013). A recent line of follow-up work has made strides by using deep neural networks as a proxy for psychological representations (Campero et al., 2017; Peterson, Soulos, et al., 2018). Although these representations are largely perceptual, they are nevertheless an improvement over hand-specified features given that they are less prone to experimenter bias and have been shown to explain some aspects of human visual representations (Peterson, Abbott, & Griffiths, 2018). However, unlike most cognitive models of concept learning and unlike humans, these networks are trained on millions of both positive and negative examples of mutually exclusive categories. Moreover, they fail to capture the taxonomic biases that humans bring to bear in concept learning (Peterson, Abbott, & Griffiths, 2018).

Challenged by the cognitive science community (Lake et al., 2015), machine learning researchers have developed a number of their own improvements to deep learning algorithms to tackle the problem of learning from few examples (e.g., Vinyals et al., 2016; Ravi & Larochelle, 2017). These approaches constitute impressive new candidate accounts of human concept learning from naturalistic stimuli, but differ from human learning scenarios in that they (1) rely on negative evidence to infer the extent of a novel concept, and (2) ignore the overlapping and hierarchical structure of real-world concepts that humans use to inform their generalization judgments (Rosch et al., 1976; Xu & Tenenbaum, 2007).

In the following paper, we aim to address many of the shortcomings of previous work by demonstrating how a deep meta-learning algorithm combined with a novel stimulus sampling procedure can provide an end-to-end framework for modeling human concept learning, for the first time with no hand-specified prior knowledge or negative examples of a novel concept. We introduce a new, taxonomically structured dataset of concepts compiled by sampling from both internal nodes and leaf nodes within the ImageNet hierarchy (Deng et al., 2009). Our method learns concepts at different levels of this hierarchy, but the hierarchical structure itself is never provided to the model explicitly at any point. To evaluate our model against human behavior, we present a new human benchmark inspired by Rosch's classic object taxonomies (Rosch et al., 1976). Our model not only mimics human generalization behavior, reproducing classic generalization gradients (Shepard, 1987; Xu & Tenenbaum, 2007), but also encompasses a general taxonomic prior that allows for human-like generalization even when presented with novel concepts from different image taxonomies (*i.e.,* held-out supercategories).

Background

Computational models of concept learning in cognitive science have historically focused on the problem of density estima-

tion (Ashby & Alfonso-Reese, 1995). Under this paradigm, learning about a category C amounts to the estimation of the density $p(x \mid C)$, where x represents the space of stimuli. This modeling framework assumes that a density can be learned for each of a set of mutually exclusive categories, where positive examples from one category implicitly serve as negative examples for all other categories. However, the conditions under which humans learn concepts are rarely this straightforward.

Learning concepts from few positive examples. More recent work has begun to examine how humans learn concepts in more natural settings where often only a few positive examples of a single concept are provided. Despite this impoverished learning environment, even young children are able to generalize surprisingly well (Carey, 1978; Markman, 1991). Extending Shepard (1987), Tenenbaum (1999) and Tenenbaum and Griffiths (2001) formalize the concept learning problem as follows: Given n positive examples $\mathbf{x} = \{x_1, ..., x_n\}$ of a concept C, the learner estimates the probability $p(x^* \in C \mid \mathbf{x})$ that a new stimulus x^* is also an example of that concept. The challenge the learner faces in making such a generalization is that the extension of C is underspecified (*i.e.,* it could include only the present examples, all possible stimuli, or anything in between). To address this challenge, the authors propose a Bayesian generalization model that averages the predictions made by a number of hypotheses about the extent of C. By making the plausible assumption that learners expect examples to be randomly sampled from concepts, the authors show that smaller hypotheses will be preferred, thus deriving constraints on the expected extent of C.

Armed with this framework, Xu and Tenenbaum (2007) conducted an extensive analysis of human generalization behavior through *word learning* experiments. Participants were given either one or three examples of a new concept such as "dax" and asked to pick out other instances of that concept from a set of test stimuli. The examples of each concept were unique images that could be drawn from either a subordinate-level (e.g., Dalmatian), basic-level (e.g., dog), or superordinate-level (e.g., animal) category, and the test stimuli were sampled from all three levels. An example of this task is shown in Figure 1. Replicating Shepard (1987), the authors found that generalization from a single example of a concept to a test stimulus decreases with psychological similarity. However, their experiments also yielded two new insights into human concept learning:

1. Given multiple examples of a concept, generalization goes only as far at the most specific level that contains those examples. For example, shown three examples from different dog breeds, other dog breeds are included in the concept at test time, but not other animals.
2. There is a bias towards generalizing to test items at the basic level, in particular when only a single subordinate example is shown. For example, given a single example of a Dalmatian, participants predictably generalize the concept to other Dalmatians, but also generalize to other breeds.

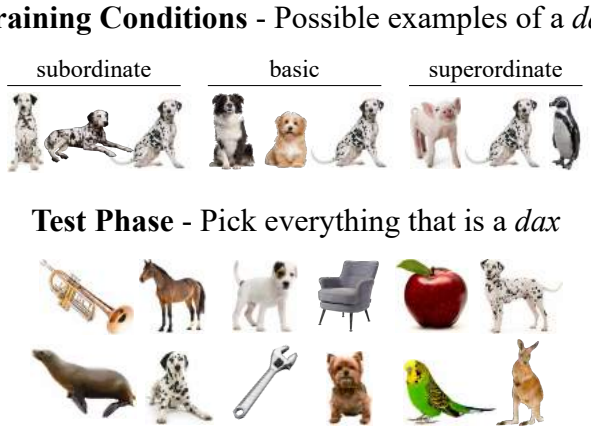

Figure 1: The *word learning* paradigm from Xu and Tenenbaum (2007). In each trial, participants see a few instances exemplifying a novel word such as "dax" and are asked to select other instances that fall under the same word from a test array. The training conditions vary by the levels of the underlying image taxonomy from which the instances are drawn, *e.g.,* Dalmatians (subordinate) vs. dogs (basic) vs. animals (superordinate).

The only modification to the Bayesian concept learning model required to capture these data was a structured, taxonomic prior computed from human similarity judgments over the set of objects used in the experiments. While this work constitutes one of the first successful attempts to explain concept learning in realistic contexts, it arguably leaves much of the structured, taxonomic representation assumed and raises questions about how this knowledge is acquired.

The role of prior knowledge. Given the aforementioned dependence on highly structured priors in explaining people's robust generalization behavior, subsequent work has focused on incorporating this information into the modeling of human concept learning. Jia et al. (2013) provided an automated framework for modeling human generalization behavior by leveraging perceptual stimulus features provided by a computer vision algorithm along with information contained in the WordNet taxonomy (Fellbaum, 1998), but gave no account for how this information is learned by humans. Kemp et al. (2007) provided the first account of how such knowledge could be acquired: The authors start with an unstructured representation and apply a structured hierarchical Bayesian model that learns taxonomic abstractions from data. Despite its elegance, the method does not immediately scale to high-dimensional stimuli such as the images used in Jia et al. (2013).

Deep neural networks (LeCun et al., 2015) have served as both candidate models of object perception and rich image representations that can be used for cognitive modeling. However, these model do not capture even coarse taxonomic information out-of-the-box (Peterson, Abbott, & Griffiths, 2018). Despite this, Peterson and Griffiths (2017) found that the sampling assumptions of Bayesian concept learning could be verified in human generalization judgments when modeling stimuli using deep feature representations. Campero et al. (2017) deployed a hierarchical model similar to Kemp et al. (2007) over a deep

Superordinate	Basic	Subordinates	
Musical Instrument	Guitar	Acoustic guitar	Electric guitar
	Piano	Grand piano	Upright piano
	Drum	Tambourine	Bass drum
Fruit	Apple	Delicious apple	Mackintosh apple
	Currant	Black currant	Red currant
	Grapes	Concord grapes	Thompson seedless grapes
Tool	Hammer	Ball-peen hammer	Carpenter's hammer
	Saw	Hack saw	Cross-cutting saw
	Screwdriver	Phillips screwdriver	Flat tip screwdriver
Clothing	Trousers	Jeans	Sweat pants
	Socks	Athletic socks	Knee-high socks
	Shirt	Dress shirt	Polo shirt
Furniture	Table	Kitchen table	Dining-room table
	Lamp	Floor lamp	Table lamp
	Chair	Armchair	Straight chair
Vehicle	Car	Sports car	Sedan car
	Airplane	Airliner plane	Fighter jet plane
	Truck	Pickup truck	Trailer truck
Fish	Snapper	Grey snapper	Red snapper
	Trout	Rainbow trout	Lake trout
	Salmon	Atlantic salmon	Chinook salmon
Bird	Owl	Barn owl	Great gray owl
	Eagle	Bald eagle	Golden eagle
	Sparrow	Song sparrow	Field sparrow

Table 1: The eight taxonomies adapted from Rosch et al. (1976).

feature space and found both good one-shot learning performance as well as the ability to recover some stimulus clusters representative of human categorization judgments. Noting that most deep networks are trained using subordinate-level labels, Peterson, Soulos, et al. (2018) trained a deep neural network with coarser, basic-level labels to more closely mimic the supervision children receive. A relatively simple generalization model over the resulting representation reproduced both the basic-level bias and the gradient of generalization from Xu and Tenenbaum (2007).

Few-shot learning in machine learning. The problem facing cognitive models of concept learning is closely related to *one-* or *few-shot* classification in machine learning, in which the aim is to learn to discriminate between classes given only a few labeled examples from each class (Fei-Fei et al., 2003; Vinyals et al., 2016). A powerful solution to few-shot learning is *meta-learning*, where learning episodes—themselves consisting of training and testing intervals—are used to train a model to adapt quickly to solve a new task given only a small amount of labeled task data (Schmidhuber, 1987). The learning episodes are leveraged in the form of a data-driven prior that is combined with a small amount of test-time evidence (*i.e.,* a few "shots" of labeled data from a novel task) in order to make a test-time inference.

Modeling Approach

We propose to bridge cognitive science and machine learning by formulating concept learning as a few-shot learning problem. As we will see, the meta-learning problem formulation allows a machine learning model to estimate a decision boundary from only positive samples of a class, similarly to how people learn concepts from only a few positive examples. Moreover, the use of a meta-learning algorithm provides a principled way to present entirely novel concepts at test time as held-out test *tasks*. As such, we can investigate the taxonomic priors encoded in a neural network embedding function, as compared to prior work that examines the representations of images from categories observed during training time (Peterson, Soulos, et al., 2018).

Concept learning as meta-learning. Meta-learning algorithms aim to learn how to learn by extracting task-general knowledge through the experience of solving a number of specific tasks (Thrun & Pratt, 1998; Hochreiter et al., 2001). In the case of concept learning, the jth task corresponds to learning a decision boundary for the jth concept using only positive examples, and meta-learning corresponds to learning how to estimate decision boundaries for arbitrary unseen concepts. We can thus formalize the concept learning problem as the task of predicting a target label y (which indicates whether or not the input belongs to a given category) from an input observation x (i.e., an image). Note that this formulation differs from the standard discriminative classification problem, where the task corresponds to a K-way discriminative classification task in which each of the K class labels are mutually exclusive.

Formally, let $\mathcal{T}_j = (\boldsymbol{X}_j^{\text{trn}}, \boldsymbol{Y}_j^{\text{trn}}, \boldsymbol{X}_j^{\text{val}}, \boldsymbol{Y}_j^{\text{val}})$ denote a task drawn from a given task distribution $p(\mathcal{T})$, where $\boldsymbol{X}_j^{\text{trn}}$ and $\boldsymbol{Y}_j^{\text{trn}}$ are a small collection of training inputs and labels, disjoint from validation samples $\boldsymbol{X}_j^{\text{val}}$ and $\boldsymbol{Y}_j^{\text{val}}$ but belonging to the same task $\mathcal{T}_j$. A meta-learning algorithm (*e.g.,* Vinyals et al., 2016; Ravi & Larochelle, 2017) aims to estimate parameters $\boldsymbol{\theta}$ that can be adapted to solve an unseen task $\mathcal{T}_j \sim p(\mathcal{T})$, using only the training samples $(\boldsymbol{X}_j^{\text{trn}}, \boldsymbol{Y}_j^{\text{trn}})$, to ensure the updated model achieves good performance on the validation samples $(\boldsymbol{X}_j^{\text{val}}, \boldsymbol{Y}_j^{\text{val}})$ according to some loss function $\mathcal{L}$.

In this work, we use the *model-agnostic meta-learning* (MAML; Finn, Abbeel, & Levine, 2017) algorithm, which formulates meta-learning as estimating the parameters $\boldsymbol{\theta}$ of a model so that when one or a few gradient descent steps are taken from the initialization at $\boldsymbol{\theta}$ on the training data $(\boldsymbol{X}_j^{\text{trn}}, \boldsymbol{Y}_j^{\text{trn}})$, the updated model has good generalization performance on that task's validation set, $(\boldsymbol{X}_j^{\text{val}}, \boldsymbol{Y}_j^{\text{val}})$. At test time, a new task from the test set is presented to the model for few-shot adaptation, *i.e.,* gradient descent with $(\boldsymbol{X}_j^{\text{trn}}, \boldsymbol{Y}_j^{\text{trn}})$, and computation of test-time performance metrics, *e.g.,* accuracy on $(\boldsymbol{X}_j^{\text{val}}, \boldsymbol{Y}_j^{\text{val}})$. The training examples in the inner gradient computation are strictly positive examples (*i.e.,* $\boldsymbol{Y}_j^{\text{trn}} = 1$) of a particular concept j, whereas validation examples in the outer gradient computation include both positives and negatives (*i.e.,* $\boldsymbol{Y}_j^{\text{val}} \in \{0, 1\}$); thus, at test time, the meta-learning algorithm is able to estimate a decision boundary for a novel concept from only positive examples of that concept.

Behavioral Experiment

In order to compare our method directly to human behavior, we conducted a large-scale human generalization experiment using a test set of naturalistic stimuli used for the simulations in the next section. We assess generalization behavior using a concept learning experiment that follows previous work on Bayesian concept and word learning (Xu & Tenenbaum, 2007; Abbott et al., 2012; Jia et al., 2013).

Stimuli. We mapped a subset of the graph structure embedded in the ImageNet dataset used for the ImageNet Large Scale Visual Recognition Competition (ILSVRC; Russakovsky et al., 2015) to the classic taxonomy used by cognitive scientists and developed by Rosch et al. (1976). ILSVRC is a commonly used object-classification dataset that contains more than 1 million images distributed across 1000 categories. Instead of using the leaf classes as categories, we create concepts by picking a node in the ImageNet hierarchy and sampling images from leaves dominated by the given node. Note that, in this case, concepts are not necessarily mutually exclusive in the sense that a single image may belong to one or more classes (*e.g.,* a Dalmatian may be labeled as both a *dog* and an *animal*). If the exact subordinate node from Rosch et al. (1976) was not available in ImageNet, we found a close semantic match via the WordNet (Fellbaum, 1998) taxonomy. We provide the full taxonomy for this dataset in Table 1.

Task. In each of 8 trials, participants observed 5 images of a single concept, sampled from one of the three levels of taxonomic abstraction. For instance, in a subordinate training condition, the examples could be all Dalmatians; in a basic-level training condition, all dogs; in a superordinate training condition, all animals. To test generalization behavior, participants were then given a test array of 24 images and were asked to pick which images also belonged to the learned concept. The test array comprised 2 subordinate matches (*e.g.,* other Dalmatians), 2 basic-level matches (*e.g.,* other breeds of dog), 4 superordinate matches (*e.g.,* other animals), and 16 out-of-domain items (*e.g.,* inanimate objects), following Xu and Tenenbaum (2007). See Figure 2 for an example set of training and test stimuli. In total, we collected data for 180 unique trials and 1 180 unique images.

Participants. We recruited 900 unique participants from Amazon Mechanical Turk to each complete 8 trials as described above, one randomly sampled for each of the superordinate categories. The test sets were fixed within a superordinate category. Participants were paid $0.40 each.

Results. Figure 3 (a) presents the results of the behavioral experiment for each of the three taxonomic levels. As expected on the basis of previous work, there is an exponentially decreasing generalization gradient as the level of taxonomic abstraction of the test matches (bar color) increases. However, this effect diminishes as the intra-class variation of the few-shot examples (x-axis) increases: Moving from the *subordinate* condition to the *basic*-level condition, we find an increase in the number of basic-level matches selected from the test set. The condition in which there is greatest intra-class variation–the superordinate condition–exhibits only a small generalization gradient.

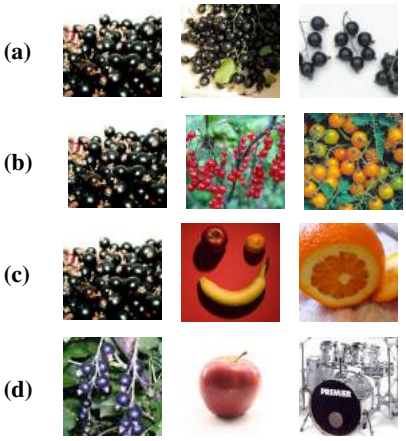

Figure 2: Examples of training stimuli for the **(a)** subordinate, **(b)** basic-level, and **(c)** superordinate level training conditions, as well as **(d)** a subset of the stimuli from the test array for a specific concept learning task (here, learning the concept *black currant* **(a)**, *currant* **(b)** or *fruit* **(c)**). The test array **(d)** displays, from left to right, a subordinate match, a basic-level match and a superordinate match.

Meta-Learning Simulations

Our modeling goal is to investigate whether we can use meta-learning to learn new concepts from only few positive examples, even though these concepts are potentially overlapping and therefore not mutually exclusive. Furthermore, we aim to investigate whether a meta-learning algorithm is able to use information about the underlying concept taxonomy that generates observations of the extension of a concept in order to generalize to novel concepts in a human-like manner.

Meta-learning formalism. Our model observes K positive examples $\boldsymbol{x} = \{x_1, \ldots, x_K\}$ of a concept C, and must learn the generalization function $p(x^* \in C)$ to correctly identify whether a novel example x^* is also a member of the concept. Training proceeds as follows: A concept index j is sampled from the meta-training set. Then, for K-shot learning, $2K$ positive examples of the concept and K negatives are sampled. The parameters $\boldsymbol{\theta}$ are adapted using K of the positives, and then the model is optimized with a loss computed using the remaining positive and negative examples of the concept. At test time, the model with trained parameters θ is presented with K positive examples from a new concept in the test set; the model adapts $\boldsymbol{\theta}$ and is evaluated on its ability to distinguish new positive examples of that concept from negatives.

Taxonomic dataset construction. For training and validation, we created a large-scale taxonomy of classes by using the graph structure embedded in the subset of the ImageNet dataset used for the ImageNet Large Scale Visual Recognition Competition (ILSVRC; Russakovsky et al., 2015), similar to the behavioral experiment described earlier, but using the entirety of the ImageNet hierarchy. We then created few-shot concept learning tasks for training by sampling positive and negative examples for each concept, where negative examples of a concept are generated by sampling from the complement set of leaf nodes. Superordinate-level nodes are not shared between training, validation, and test to ensure that test-time generalization is measured on novel concepts. We use 494, 193, and 223 leaf nodes in the training, validation, and test sets, respectively (*c.f.,* 80, 20, and 20 in the few-shot classifi-

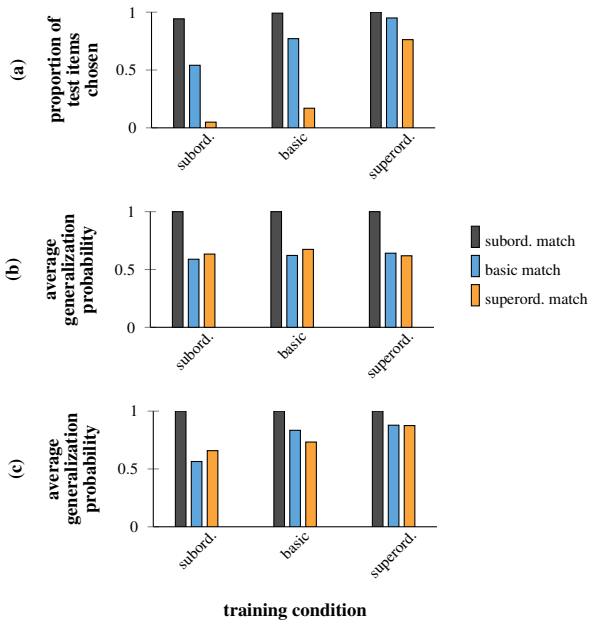

Figure 3: Human behavioral data **(a)** and `flat` **(b)** and `hier` **(c)** modeling results on the concept generalization task. The horizontal axis identifies the training condition (*i.e.,* the level of taxonomic abstraction from which the few-shot examples are drawn). The vertical axis identifies, for each type of match in {subordinate, basic-level, superordinate}, the proportion of selections from the test array **(a)**, or the average probability of generalization **(b, c)**.

cation dataset *mini*ImageNet (Vinyals et al., 2016)). The training, validation, and test node sets do not comprise all of the nodes in the ImageNet hierarchy, as some nodes are redundant (*i.e.,* have a single parent) or are too abstract to appropriately define a visual concept (*e.g., physical entity*, *substance*, *equipment*). We make use of the training and validation dataset for training and hyperparameter selection, respectively; the test set is not used in this work but reserved for future works that may wish to perform large-scale evaluation of concept learning. Instead, the evaluations reported in this work are performed on the Rosch-inspired human benchmark described above. We also wish to emphasize that while we make use of the ImageNet hierarchy, we do so only to generate a natural distribution of concepts to learn from, and never present the explicit hierarchical relations to the model at any time.

We consider two dataset conditions in our simulations: In the `hier` dataset condition, the meta-learning algorithm observes concepts sampled from the internal and leaf nodes of the ImageNet hierarchy, and thus can learn a taxonomic prior; in the `flat` dataset condition, the algorithm observes only leaf-node concepts, and thus has no access to such information.

Hyperparameters. The base model that is optimized by model-agnostic meta-learning (MAML) is a binary classifier consisting of a convolutional neural network with a sigmoid output.[1] In our experiments, we downsample the images to each have a width and height of 84 pixels, as is common in the use of *mini*ImageNet (Vinyals et al., 2016) as a few-shot learning dataset. We select hyperparameters on the same hierarchically structured validation set for both the `hier` and `flat` dataset conditions and evaluate algorithms after a fixed number of training iterations (40K with a batch size of 4). We take the value of the scalar output of the network evaluated on a test example as the *generalization probability* and average this quantity across all test examples from a specific level of taxonomic match to produce the *average generalization probability*. When reporting the average generalization probability metric, we standardize each set of probabilities for each training condition by treating the distractor (out-of-domain) generalization probability as a baseline of zero and further dividing by the largest probability in the set. In line with prior work (Peterson, Abbott, & Griffiths, 2018), this highlights the quantity of interest: the relative differences in average generalization probabilities across the subordinate, basic-level, and superordinate levels of the taxonomy.

Results. The generalization gradient observed in humans is also exhibited by the `hier` dataset condition in Figure 3 (c): When the few-shot examples are taken from a basic-level category (the *basic* condition; *e.g.,* different breeds of dog) as opposed to a subordinate category (the *subord.* condition; *e.g.,* Dalmatians), the model generalizes to more basic-level matches (*e.g.,* different dog breeds) from the test array. In the plot, this can be seen by comparing the ratio of subordinate generalization (black column) to basic-level generalization (blue column) within each training condition (*i.e.,* the gap between the black and blue bars is diminished in the *basic* condition *vs.* the *subord.* condition). Furthermore, when the few-shot examples are taken from a superordinate category (*superord.* condition), both the model in the `hier` dataset condition and humans are equally likely to pick subordinate, basic-level, or superordinate matches from the test array. In Figure 3 (a, c), this can be seen as the generalization to all levels of the taxonomy (black, blue, and yellow bars) being close to equal.

One notable departure of Figure 3 (c), from the human generalization behavior in Figure 3 (a), is overgeneralization to the superordinate category in the subordinate training condition, and to a lesser extent, in the basic-level training condition, suggesting that it is difficult for the algorithm to discriminate between basic-level and superordinate matches given only subordinate examples of a concept. Nevertheless, in comparison to the `flat` dataset condition in Figure 3 (b), which does not change generalization behavior on the basis of the training condition, the behavior of the algorithm exposed to the hierarchically structured `hier` dataset suggests a learned sensitivity to the underlying taxonomic organization of new concepts.

[1] The architecture of the model is similar to prior work in meta-learning (e.g., Ravi & Larochelle, 2017) with 4 convolutional layers each with 32 3×3 filters, leaky ReLU activation functions with a slope of 0.2, and 2×2 max-pooling, all followed by a linear layer with sigmoid activation. We do not employ batch normalization because of strong batch interdependence, as all of the training examples for a concept are of the same (positive) class.

Discussion

When humans are presented with an example from a new concept, they can quickly infer which other instances belong to that same concept even without the strong constraints provided by negative examples. In order to achieve this feat, humans bring to bear information about the taxonomic structure of natural categories. Targeting the robustness of human generalization even in highly novel domains (Schmidt, 2009), we investigated the extent to which taxonomically structured biases for complex, naturalistic stimuli taken from the ImageNet Large Scale Visual Recognition Challenge (ILSVRC) could be acquired and leveraged to learn the extent of novel concepts from only a few positive examples. In contrast to previous work (Peterson, Abbott, & Griffiths, 2018), we validate the generalization behavior of our model using *unseen* supercategories drawn from the superordinate levels of Rosch's classic taxonomy (Rosch et al., 1976).

While our method is successful in both learning a general taxonomic prior and exhibiting human-like generalization behavior, there is room for improvement as the quantitative gradients are not a perfect match to humans. However, it should be noted that our model faces the atypically challenging task of both learning a highly structured representation for complex stimuli and making use of it to generalize to entirely novel concepts. As such, this framework draws on many of the strengths of both cognitive models and deep neural networks in machine learning, and constitutes the most comprehensive account of human visual concept learning to date. Lastly, we note that we do not build in any explicit preference for simple concepts or attention to the number of examples (Tenenbaum, 1999; Peterson, Soulos, et al., 2018), although this may be an interesting avenue for improvement in future work.

A Surprising Density of Illusionable Natural Speech

Melody Y. Guan
Stanford University, Stanford, California, United States

Gregory Valiant
Stanford University, Stanford, California, United States

Abstract

Recent work on adversarial examples demonstrates a brittleness of many state-of-the-art machine learning systems. We investigate one human analog, asking: What fraction of natural speech can be turned into illusions which alter humans perception or result in different people having significantly different perceptions? Using generated videos, we first empirically estimate that 17% of words occurring in natural speech have some susceptibility to the McGurk effect–the phenomenon by which adding a carefully chosen video clip to the audio channel affects the viewers perception of the message. We develop a bag-of-phonemes prediction model for word-level illusionability that we extend with natural language modeling to build a sentence-level framework. We train an instantiation using Amazon Mechanical Turk evaluations on sentence-level illusions. Finally we generate several new instances of the Yanny/Laurel illusion, demonstrating that it is not an isolated occurrence. The surprising density of illusionable instances warrants further investigation from cognitive and security perspectives.

Stopping Rules In Information Acquisition At Varying Probabilities And Consequences: An Integrated Psychophysiological Measures Approach

Roberto Guedes de Nonohay

Richard Gonzalez
University of Michigan, Ann Arbor, Michigan, United States

Guilherme Lannig
UFRGS, Porto Alegre, Brazil

Abstract

An experiment aiming to assess the use of stopping rules in information acquisition was performed. An exploratory experimental paradigm was used. Participants (47 healthy individuals) were requested to make a decision in 24 financial scenarios with the possibility of buying information pieces. Participants were able to accept, reject or choose not to decide. Behavioral, EEG, ECG and Eyetracker data were recorded and integrated offline for analysis. Results showed that participants followed primarily Bayesian calculations in order to determine when to cease information acquisition and decide. Participants would tend to rely more on the valences (BAL) of the information acquired (positive or negative) than on sheer quantity. Acceptance tended to be made with mean positive BAL, rejection with mean negative BAL and procrastination with mean zero BAL. Uncertainty was seen to affect the information acquisition and decision process; EEG data suggest Slow Cortical Potentials at fronto-central electrodes for risk with low consequences and uncertainty with high consequences. Eyetracker data shows greater mean fixation time for decisions and information areas of interest (AOI). Heart rate data shows no difference in scenarios and/or information acquisition behavior, meaning that the decision scenarios did not elicit significant emotional engagement. Integrated psychophysiological measures were of important assistance to the conclusions given that they provided information as to what happened or not both behaviorally and physiologically.

Resource-Rich versus Resource-Poor Assessment in Introductory Computer Science and its Implications on Models of Cognition: An in-Class Experimental Study

Tobias Halbherr[1, 2] (tobias.halbherr@gess.ethz.ch), Hermann Lehner[3] (hermann.lehner@inf.ethz.ch), Manu Kapur[1] (manukapur@ethz.ch)

Abstract

Outside university, students encounter disciplinary practices mediated by technological resources. In this sense, the real world is decidedly resource-rich. In contrast, most educational assessments remain decidedly resource-poor. Situated versus mindbased perspectives of cognition fundamentally differ in the role they ascribe to such resources in cognition and learning. To mindbased perspectives, they are a source of input, to situated perspectives they are constitutive to cognition itself. We assessed the validity of resource-rich versus resource-poor assessments of learning outcomes from resource-rich versus resource-poor learning activities. The study implemented an in-class 2x2 between-subjects experimental design in an introductory programming course with 192 first semester BSc engineering students. Both types of assessment were sensitive to differences in learning outcomes, indicating validity for both. Results indicate resource-rich assessments may be more ecologically valid, while – intriguingly – the resource-poor assessments were more sensitive to transfer of learning. Furthermore, the resource-rich learning activities better facilitated learning for transfer.

Keywords: assessment; examinations; resource-rich assessment; resource-affordances; higher education; learning science; computer science education; e-assessment; educational technology; situated cognition

Introduction

Examinations in (higher) education usually remain restricted to pen and an empty piece of paper – or in their computer-based counterpart, keyboard, mouse, and a standardized e-assessment environment. What examinations typically lack – indeed prohibit – is access to any additional resources. In this sense, conventional examinations are *resource-poor*. In contrast, upon leaving university students will usually have access to a wide array of resources, such as specialist tools, easy access to information, and support from networks of experts and peers. In this sense, most professional practices outside the classroom are decidedly *resource-rich*. However, if the practices in the real world – for which we ultimately learn – are resource-rich, how can we justify a resource-poor examination practice? Conversely, how could we demonstrate the need for examinations to become resource-rich? In this study, we render first empirical evidence unto this question for the case of *tools* as resource. Specifically, we are interested in the question whether the availability or absence of disciplinary technological tools in an assessment environment has implications on the *validity* of the corresponding assessments of learning.

Our research question lies at the intersection of three larger topics which to date have rarely been linked. First, the above-mentioned discrepancy between (increasingly) resource-rich disciplinary practices versus resource-poor conventional examination practice and its implication on validity. Second, the resurgent epistemic debates on appropriate perspectives of cognition and learning. Third, advancements in educational technology, which enable novel learning and assessment environments. We will briefly elaborate on each.

Resource-Rich Assessment

When asked to formulate intended learning outcomes, lecturers typically emphasize outcomes associated with deep learning, transferrable skills, and rich conceptual understanding. Conventional examinations in contrast, are frequently associated with surface learning, cramming, factual recall, poor retention, and an inability to transfer (Biggs, 2014; Keehner, Gorin, Feng, & Katz, 2017). In other words, there seems to be a problem with the validity of conventional examinations: Lecturers intend to assess outcomes associated with deep learning, but in effect, students may achieve success through surface learning. To make matters worse, examinations strongly motivate student learning and when examinations reward surface learning, they also encourage surface learning. Assessment drives learning (Baird, Andrich, Hopfenbeck, & Stobart, 2017) and poor assessment drives poor learning.

Alternative Assessment (Sambell, McDowell, & Brown, 1997), Authentic Assessment (Gulikers, Bastiaens, & Kirschner, 2004), Assessment for Learning (Baird et al., 2017), or Performance Assessment (Moss, 1992) all share with our proposition for resource-rich assessment a concern for the above-mentioned issues with assessment validity and/or assessment driven learning. However, none of these approaches foreground the access to relevant disciplinary resources (tools, information, and/or social interactions). We propose that the absence of relevant disciplinary resources in assessment contexts may be a crucial mediator of longstanding issues with both assessment validity and assessment driven learning. We propose three principal reasons for this. First, technological resources mediate and pervade an ever-increasing number of disciplinary practices: Computer scientists develop code in integrated development environments (IDEs), psychologists do statistics in R,

engineers design machine parts in CAD software, medical practitioners treat and diagnose patients with the aid of clinical decision support software, and virtually everyone writes texts with word processors. Second, learning sciences research indicates that successful, transferrable learning is associated with learners' active engagement with appropriate tools and learning resources (e.g. Danish & Gresalfi, 2018; Schwartz & Martin, 2004; (Hmelo-Silver, Kapur, & Hamstra, 2018). If successful learning is resource-mediated, then the resource-poorness of conventional examinations may explain issues with assessment driven learning: Resource-poor assessment may drive resource-poor learning. Third, cognition itself may be substantially resource-mediated.

Cognition

Established examination practice and its frameworks have been criticized for paying too little attention to the cognitive models in which they are grounded (Baird et al., 2017), and/or for being based on impoverished, outdated, or unsuitable models of cognition (Pellegrino, 2002; Sawyer, 2014). For the purpose of this study, we compare a rigid interpretation of two contrasting perspectives of cognition: Cognition as *mindbased* processing versus cognition as *situated* action. The mindbased perspective corresponds to cognitivist (sic), computational, representational, information-processing, connectionist, or constructivist models of cognition and learning (Abrahamsen & Bechtel, 2012; Shapiro, 2011). The mind is the manifest locus of cognition and learning, and mediator of the relationship between stimuli and response. Fundamental to this perspective is the 'opening of the black box' by modelling processes and states within the mind. Two simultaneous and intertwined streams of processing in the mind/brain together constitute cognition: Directed feedforward sensory-to-motor, stimulus-response, input-output streams of processing in combination with recursive feedback loops within the mind/brain itself. The contrasting situated model on the other hand, does not separate cognitive processing ('mind') from action ('response') or social and physical task contexts ('stimuli'). Instead, it regards the dynamical interaction between the cognitive agent and those elements of the environment with which he/she situationally interacts as conjointly constitutive of cognition and learning: Cognition as *situated action* or as *emergent* upon loosely coupled processes in the agent-environment complex system (Clark, 2012; Danish & Gresalfi, 2018; Hutchins, 1995). Actions of the cognitive agent effect changes in the environment, which in turn feed back to the cognitive agent in the form of new/altered stimuli. The directed stimulus-response flow of processing of the mindbound perspective is closed into a single complex system of dynamical feedback loops, from the cognitive agent through the environment back unto the cognitive agent him/herself. Examples of situated perspectives include embodied, extended, and distributed cognition, sociocultural theory, or social constructivism. While these situated perspectives have led to a rich body of research on learning and effective learning interventions, there is a lack of corresponding research in assessment and educational measurement (Mislevy, 2018 is one exception).

Gibson (1977) introduced the term 'affordance' for "whatever it is about the environment that contributes to the kind of interaction that occurs [with the cognitive agent]". Accordingly, we define the term *resource-affordance* for 'whatever it is about the disciplinary (technological) resources with which the cognitive agent interacts, that contributes to the kind of disciplinary practice that occurs'. Resource-affordances constitute the loose coupling of processes between the cognitive agent and the task environment. They are fundamental to the situated perspective. Much like a skier's body is inseparably connected with his boots and skis in the practice of skiing – effectively forming a single functional unit – so too do a programmer's mind and a computer-based programming environment interact in an inseparable manner in the practice of programming. Just as attempting to assess someone's skills in skiing while denying them skis would be rather absurd, so it is absurd that we routinely assess students' competency in computer science while denying them access to computers. It follows that the valid assessment of competency in disciplinary practices directly depends on adequate access to practice-relevant resource-affordances in the assessment task environment. Hence, the situated perspective demands an examination practice that is equally resource-rich (RR) as are the disciplinary practices in which we intend to assess competency. In the mindbased perspective on the other hand, there is no need to model resource affordances because cognition is fully contained in the mind/brain. Writing a recursive algorithm on paper or in a programming environment are not fundamentally different cognitive tasks, but fundamentally similar. Resources do not contribute anything substantial to cognition or its assessment. On the contrary, they are a potential source of construct irrelevant variance. Hence, the mindbased perspective of cognition favors a resource-poor (Rp) assessment practice. Indeed, we argue that a main reason for conventional examination practices being resource-poor likely lies in the fact that most students, teachers, educators, and assessment specialists share a deeply mindbased conception of cognition.

Educational Technology

Over the past years, educational technology and corresponding e-learning practices, including computer-based assessments and examinations, have become increasingly widespread in higher education (Bennett, 2015; Crisp, Guàrdia, & Hillier, 2016; Halbherr, Reuter, Schneider, Schlienger, & Piendl, 2014). Computer-based assessment services frequently prioritize efficiency by focusing on auto-correction, computer-adaptive testing, or remote proctoring – all largely within a conventional Rp paradigm. However, there also exists a competing trend, emphasizing the potential for improvements in examination quality by enabling examination task environments that are more authentic, competence-oriented, aligned with corresponding practice – and/or RR (Crisp et al., 2016; Halbherr, Dittmann-

Domenichini, Piendl, & Schlienger, 2016). One example of such a learning and assessment environment is Code Expert.

Code Expert

Code Expert (Lehner, Avanthay, & Sichau, 2018) is a browser-based integrated development environment (IDE) and online learning environment developed at ETH Zurich. Code Expert facilitates open programming assignments for in-class or take-home exercises, as well as supervised examinations. Code Expert includes an auto-grader, which provides automatic and immediate feedback to students by compiling, running, and testing submitted code against predefined test cases. Furthermore, tutors can annotate or apply direct changes to students' attempts in order to provide additional, more personalized feedback. The Code Expert interface is illustrated in Figure 1. It consists of a file system pane, a code editor window, a terminal and output window for compiling and running the code, and a tutorial pane for instructions, task descriptions, and learning materials.

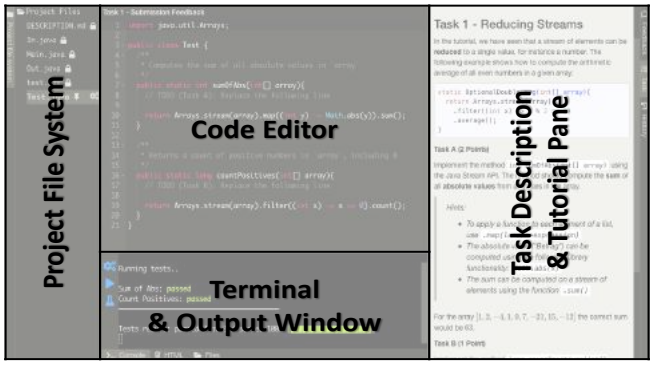

Figure 1: Schematic overview of Code Expert GUI.

Method

The study was conducted as part of an introductory course in programming for non-CS students at first year BSc level. The course focuses on imperative and object oriented programming paradigms, as well as problem solving, and uses Java as programming language and Code Expert as learning environment.

In the study, we investigated how the presence or absence of resource-affordances of the Code Expert environment affected student learning on the one hand, and the assessment of corresponding learning outcomes on the other. Slightly different than usual, the main focus of this study is not on the learning activity, but on the assessments, more precisely: The *validity* of the assessments. Specifically, we are interested whether and to what extent RR versus Rp assessments are sensitive to differences in learning outcomes as induced by RR versus Rp learning activities.

Validity

Validity is "the degree to which a test or examination measures what it purports to measure" (Ruch, 1924). It is a unitary construct (Messick, 1989). It is an ontological and/or epistemic construct, rather than a statistical or psychometric one (Kane, 2006). This holds particularly true in the context of this study, since we do not have any impartial source of base truth against which we could validate the RR versus Rp assessments. Instead, validity has to be determined through an appropriate validity argument. Borsboom, Mellenbergh, & van Heerden (2004) propose the following operational definition of validity: "A test is valid for measuring an attribute if and only if (a) the attribute exists and (b) variations in the attribute causally produce variations in the outcomes of the measurement procedure".

Operationalizing Validity

We apply the earlier propositions – resource mediation facilitates learning and cognition as a resource-mediated construct – to the above operational definition of validity. We operationalize variations in the measurement attribute – student learning – by letting one group of students learn with access to relevant resource-affordances, the RR learning condition (LC), while the other group is denied access, the Rp LC. Everything else is kept strictly identical across the two LCs. Subsequently, we assess half of students of each LC in a RR assessment with access to resource-affordances, the RR assessment condition (AC), or in a Rp assessment without access, the Rp AC. Again, everything else is kept strictly identical across the two ACs. We then evaluate whether the RR and/or the Rp assessment are able to differentiate between students from the RR LC versus the Rp LC. If they do, then this is evidence in favor of the assessment's validity, and evidence against, if not. This results in a 2x2 between-subjects experimental design. The RR LC versus Rp LC and the RR AC versus Rp AC constitute the independent variables, and assessment performances – to be more precise, the performance differences between the students in the RR LC and the Rp LC as measured either in the RR AC or the Rp AC – constitute the independent variables.

Operationalizing the Resource-Affordances

We identify the compiler as the key resource in the Code Expert environment. The compiler is both essential for generating the product of the practice – running code – as well as for sustaining the practices and processes required for achieving that goal. We thus operationalize the RR experimental conditions with a Code Expert environment with a fully functional compiler. The Rp conditions we operationalize with the *identical* Code Expert environment save for a deactivated compiler. This leads to the disappearance of the following resource-affordances: Students cannot compile or run code, correspondingly cannot receive any messages in the console from either the compiler or their compiled code, cannot run their code against test cases in the auto-grader, and there is no syntax highlighting of their code in the code editor. In the Rp condition, the students are essentially working with a 'naked text editor version' of Code Expert, while in the RR condition they have access to the fully functional Code Expert IDE. Across all

experimental conditions, students were instructed not to access any other resources (e.g. lecture notes, Google, StackOverflow, other Code Expert exercises) than those available through the study tasks in Code Expert.

Learning and Assessment Tasks

In the study's learning activity, we introduced a new paradigm: Functional programming. Java implements functional programming with the Stream API. The learning activity consisted of an interactive self-study tutorial. Key concepts of functional programming were introduced and consolidated in five consecutive tasks using hands-on exercises with the example of manipulating data-streams of numbers. Students received the canonical solution to each tutorial task at the start of the subsequent tutorial step. This ensures that also the students in the Rp LC received adequate feedback on the correctness of their solutions.

The subsequent assessment consisted of three tasks. In Task1 students had to perform identical manipulations of data-streams of numbers as in task 4 of the tutorial. Task1 operationalizes the direct replication of learning. Task2 introduced a novel and more complex problem that can be solved elegantly using the new paradigm. Task2 operationalizes transfer of learning. In Task3, students had to manipulate streams of Java objects instead of streams of numbers after reading a brief introduction to a number of new concepts and operations for manipulating objects in a functional manner. Task3 operationalizes transfer of learning with the aid of a learning resource, i.e. students' preparation for future learning (Schwartz & Martin, 2004). All three assessment tasks were scored manually by the course assistants. For each task 0, 1, 2, or 3 points were awarded according to task-specific rubrics. Small syntax errors, such as missing or unmatched brackets or slightly incorrect syntax in lambda expressions, were ignored. The manual scoring procedure was identical for both the RR AC and the Rp AC. To ensure a high correspondence with actual educational practice 'in the wild', both the learning activity and the assessment, all tasks contained therein, the scoring rubric, and the scoring procedure were all designed and performed entirely by the course lecturer and the course assistants, with no or only minimal intervention from the lead investigator.

Hypotheses from the Cognitive Perspectives

Let us now revisit the situated versus mindbased perspectives of cognition. What kind of results would each perspective predict for this experiment? To the situated perspective, the loose coupling of processes through resource affordances remains intact in the RR LC and the RR AC, while in the Rp conditions this coupling is severed. Hence, the RR and the Rp experimental conditions correspond to qualitatively fundamentally different kinds of cognitive processes – both regarding what is learned in the LCs, as well as regarding what is assessed in the ACs. Since programming is a resource-mediated practice, the situated perspective would predict larger learning gains in the RR LC, to which the RR AC is sensitive, but not the Rp AC (or only to a lesser extent). Furthermore, since cognition is emergent from the loosely-coupled agent-resource complex system, the larger learning gains of the RR LC and the higher sensitivity of the RR AC would not merely relate to 'superficial' resource-specific knowledge, but also deep conceptual understanding and transfer of learning. To the mindbased perspective on the other hand, resources are not central to cognition. Decoupling should not affect learning as long as students still receive adequate feedback. If anything, the Rp LC should facilitate learning, particularly learning for transfer, because it reduces cognitive load associated with managing the resource, freeing up cognitive capacity for focusing on developing a deep understanding of underlying concepts. Furthermore, the mindbased perspective would expect the Rp AC to be more sensitive to differences in learning gains, especially transfer of learning, because it eliminates construct-irrelevant variance related to managing the resource and resource-specific knowledge irrelevant to a deep understanding of underlying concepts.

Procedure

The study was conducted as part of regular in-class exercise activities of the first year BSc introductory programming course. The course took place across fourteen weeks, during fall semester 2018, from late September until late December. It entailed two weekly hours (i.e. 2x45 minutes) of lectures, two weekly hours of on-site exercises in small groups supervised by student teaching assistants (11 groups with between ca. 15-45 students each), weekly homework in Code Expert, and a final sixty minute summative examination in January 2019. The course is mandatory for first semester Bachelor students in Civil Engineering, in Geospatial Engineering, and in Environmental Engineering. The study activities took place in November 2018 during the second hour (45 minutes) of the on-site small group exercises of course weeks nine and ten, with one week between the learning activities and the assessments. We planned the study activities near the end of the course to ensure that all students were deeply familiar with the Code Expert environment, such that differences in assessment performance between the RR and Rp LCs could not reasonably be attributed to increased familiarity of students in the RR LC with surface features of the Code Expert environment. On the first study day, the students engaged in the learning activity consisting of the five-step tutorial on functional programming, either under RR (compiler active) or Rp (compiler deactivated) conditions. On the second study day, the students sat the assessment, again either under RR or Rp conditions. Time available for both the learning activity and the assessment was thirty minutes. While the students could progress through the five tutorial tasks at their own pace, in the assessment they had precisely ten minutes time available for each of the three tasks. In the week between day one and day two, there were no exercises or other activities related to the topics covered on day one. Figure 2 illustrates the experimental procedure: Group1 participated in the RR LC

and Rp AC; Group2 in the RR LC and RR AC; Group3 in the Rp LC and RR AC; and Group4 in the Rp LC and Rp AC.

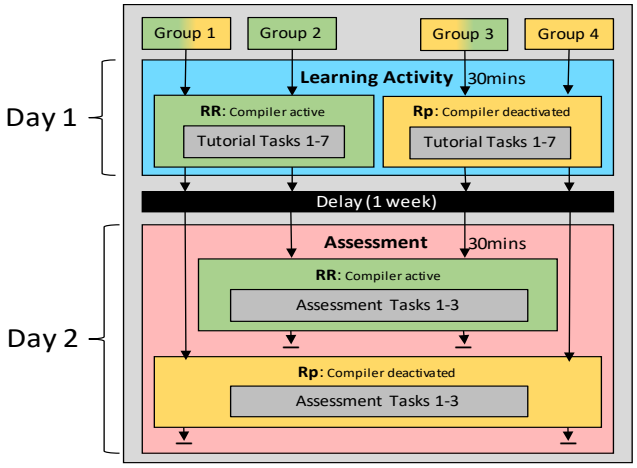

Figure 2: Illustration of the experimental procedure.

Sample

234 out of 272 enrolled students participated in the study. Of these, 21 students participated only on one of the two study days and had to be excluded from the analyses. For another 21 students we could not rule out for certain, that they had not accessed tasks or resources not intended for their experimental conditions, and were also excluded. The resulting sample of n=192 students is distributed across the experimental conditions as follows: n(RR→RR)=49, n(Rp→RR)=48, n(RR→Rp)=53, n(Rp→Rp)=42.

Results

Table 1 reports the mean percentage of points achieved in the complete test consisting of Task1, Task2, and Task3; in the replication task Task1; and in the transfer tasks, Task2 and Task3 taken together. Three things are worth note. First, students in the RR LC outperform students in the Rp one both in the RR and in the Rp assessment and in all tasks. Second, the RR assessment is more difficult (i.e. students performed worse) than the Rp assessment for students of both the Rp *and* the RR LC. Third, the performance difference in the transfer tasks between the two LCs is larger for the Rp assessment, with a 27% difference (63% - 37%) compared to a 14% difference (36% - 22%) in the RR assessment.

Table 1: Mean percentage of points achieved

LC →AC	RR →RR	Rp →RR	RR →Rp	Rp →Rp
Complete Test	46%	31%	70%	47%
Task1	67%	50%	83%	67%
Transfer Tasks	36%	22%	63%	37%

Figure 3 illustrates the assessment results in the complete test, the direct replication task, Task1, and the transfer tasks, Task2 and Task3 together. The vertical histograms illustrate the frequencies (x-axis) of total points achieved (y-axis) for each of the four experimental groups. The background and bar colors represent the LCs and ACs, respectively, green for RR and yellow for Rp. To illustrate appropriate interpretation of the histograms: 67% of students in the RR→Rp experimental condition achieved the maximum of three points in Task1. Furthermore, non-parametric Mann-Whitney *U* inferential statistics, corresponding p-values, effect sizes *r*, and mean ranks (lower values correspond to better performances) are reported for the comparisons between the RR LC and the Rp LC as measured in the RR AC and the Rp AC, respectively. Example: The comparison between the RR and Rp LC as measured by the complete test in the RR AC is highly significant with p=.008, *U*= 1'539, effect size *r*=.27 and better performance of the students from the RR LC (mean rank 41.43 < mean rank 56.42).

All test and subtest comparisons between the RR and Rp LC are statistically significant. The reported effect sizes *r* constitute small to medium effects (Field, 2009). Effect sizes are consistently larger for the Rp test than for the RR test, are consistently larger for the transfer tasks than the direct replication task, and the difference in effect size between RR and Rp assessment is larger for the transfer tasks.

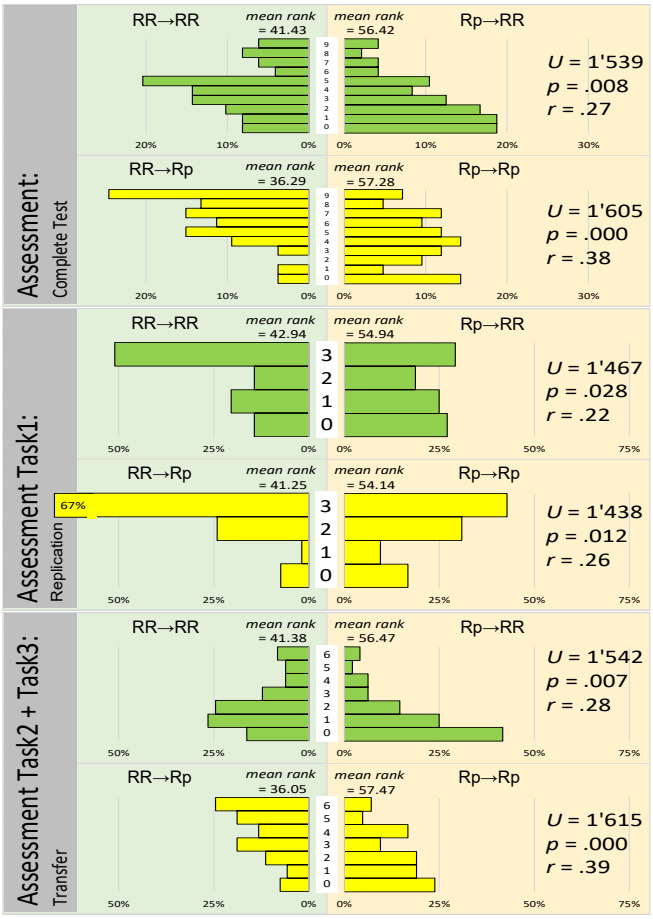

Figure 3: Assessment performances and inferential statistics.

Discussion

Learning

The findings convincingly confirm the proposition that resource mediation facilitates learning. RR learning consistently outperformed Rp learning. Effect sizes were small to medium for the direct replication task and medium for the transfer tasks. Of particular note, the effect is consistent and robust even across RR and Rp ACs, and even after only thirty minutes of tutorial-guided learning. The fact that this effect was stronger in the transfer tasks, and not only in the RR AC but even more so in the Rp AC, is strong evidence that resource-mediation facilitates not just learning of superficial resource-specific details, but in fact deep conceptual understanding and successful learning for transfer. Furthermore, our results support the assumption that it is indeed the presence or absence of practice-relevant resource-affordances that mediated these differences in learning. First, because the only difference between the otherwise identical LCs was whether the compiler was active or not, second, because not only the students in the RR LC, but also the students in the Rp LC received feedback on the correctness of their solution.

Assessment Validity

Both the RR and the Rp assessments successfully differentiate between the two LCs and are thus sensitive to the experimental manipulation of resource-mediated learning. Hence, we cannot reject the validity of neither the RR nor the Rp assessment. However, the Rp assessment was more sensitive to the experimental manipulation than the RR one, and especially in the transfer tasks. We identify two possible reasons for this. First, the higher sensitivity of the Rp assessment could be an indicator of better validity of the Rp assessment in general. Alternatively, the higher sensitivity could be an indicator of superior *differential* validity of the Rp assessment for assessing the transfer of (resource-mediated) learning in specific, but not necessarily for learning outcomes as they relate to the disciplinary practice at large. Two observations support this second interpretation. First, the RR assessment was consistently more difficult than the Rp assessment. It clearly required students to demonstrate competencies that go beyond what would have been sufficient to succeed in the Rp assessment. Second, the RR assessment is more directly representative of the target disciplinary practice of programming (which also includes a functional compiler), i.e. it is more 'ecologically valid'. If we assume that disciplinary competencies in all their complexity usually constitute the intended measurement constructs of examinations, then – somewhat paradoxically – the higher sensitivity observed in this study would imply that the Rp assessment suffers from construct underrepresentation in relation to the ecologically valid intended measurement construct. To further illustrate this argument: If the RR and Rp assessments captured the exact same amounts of variance in *transfer of resource-mediated learning*, but the RR assessment in addition also captured *other* variance relevant to competency in the disciplinary practice, then we would indeed expect precisely the observed pattern of higher sensitivity of the Rp assessment to the experimental manipulation. Taken together, this indicates that RR tasks may render more valid estimates of students' effective competency in a target practice, while Rp tasks may be more valid for the differential assessment of associated (developing) conceptual understanding.

Cognition

Neither the proposed situated nor mindbased perspective facilitated the prediction of the study's results. The mindbased perspective proved rather unsuitable for explaining the substantial and robust learning facilitation in the RR LC, while the situated perspective does not offer a meaningful account for the higher sensitivity of the Rp assessment. Regarding the ontological question of the nature of cognition, it is indeed quite intriguing that the uncoupled 'mindbound' Rp assessment was *more* sensitive to transfer of resource-mediated 'situated' learning, than the RR assessment. This pattern in many ways appears reminiscent of learning as (resource) internalization in a Vygotskian or Piagetian sense. Alternatively, from a complex systems perspective we might conclude that the mindbased perspective does not adequately account for cognitive phenomena emergent from agent-resource interaction, while the situated perspective does not adequately account for near decomposability. Such considerations notwithstanding, our data show that there is something more complex going on than can be explained with either a rigidly mindbound or rigidly situated perspective alone. This approach did not lead to parsimony, but instead to poor predictions.

Implications for Practice

We identify three main implications for practice. First, the RR tasks were more difficult than the Rp ones. When moving from Rp assessments to RR ones, this increase in difficulty needs to be accounted for. We can confirm this experimental finding from our own experience in supporting lecturers when transitioning from conventional Rp paper-based examinations to RR computer-based ones – e.g. with Code Expert. The new RR examinations usually require substantially more time for students to be able to solve them meaningfully. Second, we found robust evidence confirming RR learning activities facilitate deep conceptual learning and successful learning for transfer. If assessment drives learning, then we are well advised to include at least some RR tasks in any examination, providing students an effective incentive to engage in according and productive RR learning activities. Third, mixed examinations consisting of both RR and more conventional Rp tasks may be best, because Rp tasks may be more suitable for the differential assessment of developing conceptual understanding, while RR tasks may be more suitable for 'ecologically valid' and exhaustive assessments of accomplished disciplinary competency.

Abstract

Listeners must integrate multiple sources of information to construct an interpretation of a sentence. We concentrate here on the alignment of prosodic and syntactic grouping during online sentence comprehension. We present the results from a pupillometry study on the use of prosodic boundaries in resolving well-known attachment ambiguities. Using growth curve analyses to capture the non-linear dynamics of pupil dilation, we found increased pupil excursions for sentences that were disambiguated towards the dispreferred, non-local relation, especially when accompanied by supporting prosodic information. However, when prosodic and structural information did not align, pupillary response was muted, potentially indicating a failure to commit to a specific interpretation. More generally, the study shows how the currently under-utilized pupillometry method offers insights into spoken language comprehension.

Keywords: Relative clause attachment; prosody; pupillometry

Introduction

Sentences like (1) are structurally ambiguous. The relative clause (RC) after a complex noun phrase (NP) may be interpreted as modifying the first noun (NP1; in *High attachment*: the maid was on the balcony) or the second noun (NP2; in *Low attachment*: the actress was on the balcony).

(1) Someone shot the maid $_{\text{NP1}}$ of the actress $_{\text{NP2}}$ [$_{\text{RC}}$ who was on the balcony]

Many classical theories of sentence processing assume a strong role for relations privileging locality (Kimball, 1973; Frazier & Fodor, 1978) or recency (Gibson, 1998). For example, the principle of *Late closure* prompts the language parser to resolve ambiguous strings like (1) towards a structure in which the RC attaches to the most recently accessed constituent that is grammatically possible, resulting in a Low attachment interpretation. Under their strongest interpretation, locality or recency based principles represent universal properties of the human language processing system and are not subject to variation within languages or individuals.

However, subsequent research has argued that the preferred interpretations of strings like (1) are moderated by a great many other factors, such as plausibility, experience, or prosodic grouping, and may even reflect parsing preferences from specific languages (see Fernández, 2003 for review). Several explanations for this variation have been proposed. Perhaps the first study to find a High attachment preference for non-local RC modification was Cuetos & Mitchell (1988), who proposed that the statistics of a language strongly influence how the processor resolves ambiguity – i.e., a language shows a High attachment preference because this resolution is the most frequent in the language. Others have explained the variation in terms of additional contraints competing with a universal recency bias (Gibson et al., 1996), or with respect to the availability of alternative parses in different languages (Hemforth et al., 2000; Grillo & Costa, 2014; Grillo et al., 2015). Others still have exempted relative clauses from the domain of Late closure, instead arguing that they are construed using a collection of grammatical and non-grammatical interpretive principles (Gilboy et al., 1995; Frazier & Clifton, 1996). While many factors may well contribute to relative clause attachment preferences, we focus here on the relation between prosodic and syntactic grouping during online sentence comprehension.

In general, prosody refers to the organizational structure of speech, expressed through changes in pitch, duration, and amplitude, among other factors (Ladd, 2008). Although the prosodic grouping of words can reflect metrical preferences (such as the location of prominence or the alternation of feet), it can also signal higher levels of linguistic structure, especially syntactic or information structural relations. We adopt a simplified description of prosodic information, and concentrate on how prosodic groups are formed via the presence of a prosodic boundary (**%**), which can be indicated by word final lengthening, pitch movements that conventionally mark the end of a group, and pauses in the speech signal.

Previous work indicates that the location of a prosodic boundary between the complex NP and the relative clause disambiguates RC attachment. A prosodic boundary placed between NP2 and the RC (2b) results in a bias towards High attachment, a generalization that appears to be robust across languages (Jun, 2003). In contrast, a boundary separating NP1 from NP2 (2a) appears to reinforce the low attachment construal, even in languages with a general high attachment preference (Fromont et al., 2017). We assume that in such cases comprehenders interpret the prosodic boundary loca-

tion as a cue to syntactic constituency (depicted as parentheses below) in an attempt to align prosodic and syntactic junctures.

(2) Someone shot ...

a. (the maid) **%** (of the actress who was on the balcony)

b. (the maid of the actress) **%** (who was on the balcony)

As most studies on attachment ambiguity in complex NPs are conducted using offline measures (though see, for instance, Kim & Christianson, 2013 and Fernández & Sekerina, 2015), it is unclear whether prosodic boundaries guide online sentence processing, and if so whether each boundary location is used immediately. We report the results of a pupillometry study addressing the role of prosodic boundaries on attachment ambiguity resolution in real time comprehension. The experiment was designed to explore two distinct possibilities. First, it is possible that non-local dependencies are computationally taxing to process, regardless of prosodic boundary information. In this case, we would predict that (i) sentences grammatically disambiguated to a high attachment construal would elicit processing costs, which (ii) would not be mitigated by corroborating prosodic information. As an alternative, it is possible that non-local dependencies are avoided for independent prosodic reasons, e.g., if a boundary after NP1 is preferred to keep the prosodic units of equal weight (Fodor, 1998). Such a view would predict that high attachment resolutions are only costly when not supported by prosodic boundary information.

Pupillometry

Pupil dilation is likely to reflect a multitude of components, some related to demands on cognition and attention, and others to the autonomic nervous system. The pupil naturally fluctuates, dilating in response not only to neural inhibition from the parasympathetic oculoumotor system and the the noradrenergic system, but also to the presentation of an external stimulus (Wilhelm et al., 1999), including emotionally arousing stimuli, challenging math problems, and unconscious or barely discernable stimuli (Beatty & Kahneman, 1966; Kahneman & Beatty, 1966; Hess & Polt, 1960; Laeng et al., 2012).

Although the tools and techniques for pupillometry are still developing, existing literature has already provided convincing evidence that pupil dilation indirectly indexes increased demands on mental effort and attention associated with difficult to interpret material along various linguistic dimensions (Schmidtke, 2018 for review). While some early studies found a relation between increased pupil dilation and syntactic complexity (Just & Carpenter, 1993), more recent studies have begun to explore a wider range of ways in which pupil size might reflect other factors in language comprehension. Major findings include an association between increased pupil size and structurally complex sentences (Demberg & Sayeed, 2016), prosodic disambiguation in garden path sentences (Engelhardt et al., 2010), semantic anomalies (Demberg & Sayeed, 2016), lexical frequency or increased emotional valence (Kuchinke et al., 2007), violations of expected meter (Scheepers et al., 2013), and inadequate or misleading pitch accent (Zellin et al., 2011). In keeping with the current pupillometry literature, we will assume, as a basic linking hypothesis between cognition and behavior, that increased pupil size indirectly reflects increased cognitive load, including mental effort directed at managing language comprehension processes.

Further, pupillometry offers an appealing supplement to other online methods. It is easy to administer and comparatively inexpensive, while offering an online and passive measurement. As pupil size is not under conscious control, pupil dilation measurements are likely to be resilient to task-specific strategies that subjects may learn or employ during the experiment. Thus, pupillometry studies offer a promising avenue for exploring the role of prosodic information in resolving structural ambiguity.

Pupillometry study

Participants

Forty-eight native college-aged speakers of American English were recruited from a Psychology Subject Pool at the University of California, Los Angeles, and were compensated with course credit. No participant reported any history of hearing loss or language disorder. Experimental sessions typically lasted no more than 30 minutes.

Materials and method

Twenty quartets were constructed in a 2×2 design. Quartets crossed Boundary location (post-NP1, post-NP2) and Attachment (High, Low). All sentences involved a complex noun phrase (*the brother of the musicians*) containing two noun phrases (NP1, NP2) of opposite grammatical number, followed by a relative clause disambiguated to high (modifying NP1: *the brother*) or low (modifying NP2: *the musicians*) attachment. The attachment height was grammatically specified by the plurality of the verb (*was, were*) within the relative clause (*who was really quiet*), which was kept constant within each quartet. Half of the items were disambiguated by the singular form of the auxiliary (*was*), half by the plural form (*were*). A sample item is shown in Table 1. In addition, comprehension questions were presented after half of the items to encourage participants to pay attention. Questions did not ask about relative clause attachment height.

We obtained measures for the lexical level characteristics of length, frequency and number of syllables using the English Lexicon Project (Balota et al., 2007) for NP1 and NP2. Nouns did not differ on length, number of syllables, or frequency, as determined by several measures, including (log) HAL (Lund & Burgess, 1996) and (log) $\text{SUBTLEX}_{\text{US}}$ (Brysbaert & New, 2009).

Sentences were recorded with a high-quality microphone in a sound attenuated chamber by a trained phonologist. Audio files were truncated after the relative clause (marked by

Boundary	High attachment	Low attachment
NP1	Everybody met the brother **%** of the musicians who was really quiet // although the club was really noisy.	Everybody met the brothers **%** of the musician who was really quiet // although the club was really noisy.
NP2	Everybody met the brother of the musicians **%** who was really quiet // although the club was really noisy.	Everybody met the brothers of the musician **%** who was really quiet // although the club was really noisy.

Table 1: Sample quartet item crossing Boundary location (NP1, NP2) and Attachment (High, Low). The underlining identifies the noun modified by the relative clause (*who was really quiet*). The prosodic boundary is indicated by the **%** symbol.

the // symbol in Table 2). 100ms of computer generated silence was inserted after the relative clause, and the post-relative clause segment was spliced into the recording, so that pupillary response was recorded on acoustically identical material within items. Items were then acoustically normalized to make the transition into the spliced segment as seamless as possible.

The 20 experimental item quartets were presented in counterbalanced and individually randomized order, and were interspersed with 40 items from two separate experiments (one also manipulating boundary placement, and another manipulating contrastive accent), along with 26 filler items unrelated to any experiment. Participants were instructed to fixate on a cross at the center of the screen without blinking for the duration of the sentence. They were encouraged to blink before and after the sentence presentation, and to rest their eyes as needed, in order to minimize the possibility of eye blinks due to fatigue.

Items were presented with Experiment Builder (SR Research) to subjects over sound-isolating headphones in a moderately lit room dedicated to experimentation. Eye position and pupil area were recorded using an SR Research EyeLink 1000 Plus eye tracker sampling at 500Hz. The tracker was mounted to the table at 55cm from a 27 inch LCD monitor with a light gray background. A 5-point calibration procedure was used before recording and as necessary, and drift correction was conducted between every trial.

Results and discussion

Subjects performed very well on post-sentence comprehension questions ($M = 96\%$), which did not probe the interpretation of the relative clause. There was a marginal effect of mismatches between Boundary location and Attachment, so that comprehension questions following High attachment sentences were less accurate when paired with an NP2 boundary location (*diff* = 3%), and questions after Low attachment sentences were less accurate when paired with an NP1 boundary (*diff* = 3%), $t = 1.96, p = 0.05$. No other effects were observed. The pattern suggests that incompatible boundaries interfered with comprehension, but that there was no general effect of boundary or attachment on general comprehension. However, performance on all conditions was uniformly high, averaging at 94% or above.

Pre-processing of gaze location and pupil size was conducted in Data Viewer. Fixations outside of the fixation cross were removed. Trials with eye blinks (less than 5% of the total data) were also removed to avoid reconstructing pupil size during noisy trials. Mean pupil size was downsampled into 100 20ms bins starting from the end of the relative clause, for a total recording time of 2000ms past the relative clause. The remaining analyses were conducted in R (R Core Team, 2016). Data were fit with a growth curve model (Mirman, 2016) to avoid assuming a linear form or an arbitrary time window for analysis. Growth curve models have been used previously to quantify continuous changes in pupillary response, and we adopt those authors' interpretations of the curve with respect to pupil response (Kuchinsky et al., 2013; McGarrigle et al., 2017).

We report a third-order (cubic) orthogonal polynomial model with fixed effects of Boundary, Attachment, and their interaction on polynomial terms, and by-subject and by-item random slopes (Baayen et al., 2008), as shown in Table 2. Experimental predictor variables received deviation (sum) coding with NP1 and Low Attachment conditions specified as reference levels for their respective factors. Orthogonal polynomials were used to avoid extreme multicollinearity between adjacent samples in the time series.

	Estimate	**Std. Error**	***t*-value**
(Intercept)	0.106	0.315	0.337*
Linear poly	-0.857	0.237	-3.616*
Quadratic poly	-1.799	0.246	-7.311*

Table 2: Growth curve analysis in a linear mixed effects regression model. The * indicates a significant effect at the $\alpha = .05$ threshold.

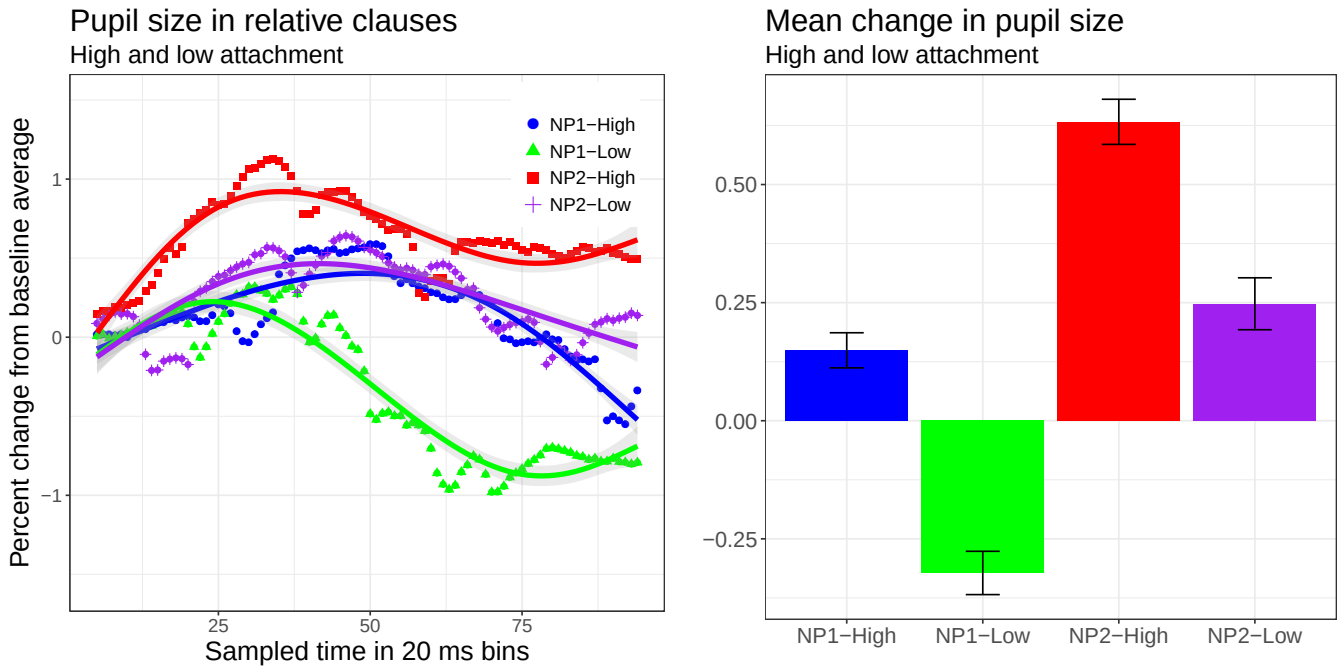

Figure 1: Percent change of pupil dilation over time with standard errors (left panel) and mean percent change of pupil size collapsing across time bins (right panel).

In growth curve analyses, polynomial terms capture distinct components of the functional form of a curve as it develops over time, and will be interpreted with respect to pupil dilation as follows (Kuchinsky et al., 2013; McGarrigle et al., 2017). The INTERCEPT corresponds to the overall mean pupillary response, so that positive coefficients indicate greater amplitudes. The LINEAR polynomial term coefficient corresponds to the slope of pupillary response, so that a positive increase in the coefficient indicates more steeply rising pupil dilation. The QUADRATIC polynomial term describes the shape of the primary inflection point, revealing the degree to which the curve is non-linear. Negative quadratic coefficients indicate an inverted U-shaped curve, characteristic of pupil peaks. The CUBIC term captures the properties of any secondary inflection point in the curve, so that positive coefficients indicate that pupil dilation peaks are more compressed or transient, rising and falling more sharply.

Positive coefficients of High attachment and NP2 boundary indicate increased average pupil dilation (the area under the curve) for High attachment over Low attachment, and NP2 boundary location over NP1 boundary location, respectively. Interactions between the planned predictor variables and the polynomial terms indicate how the experimental conditions differentially affect the shape of the pupillary response over time.

The mean change in pupil size for each condition is shown in Figure 1. In the left panel, the shape of the best-fitting non-linear regression line is plotted against change in pupil size within a 2000ms period immediately after the relative clause. The values on the vertical axis represent the percent change from the baseline average, defined here as the entire 100ms segment of silence inserted between the end of the relative clause and the remainder of the sentence (*although the club was really noisy*). The right panel reports the overall mean pupil change (with standard errors in grey) in pupil size during the same period for visual comparison.

In the growth curve model, effects of all three orthogonal polynomial terms were observed. Modulo the manipulation, pupil growth was less steep (a negative Linear coefficient), showed greater inverted U-shaped curve (a negative Quadratic coefficient), and a sharper secondary point of inflection (a positive Cubic coefficient), corresponding to a change or bend in the direction of the response.

More importantly, the two experimental factors in the manipulation showed that a prosodic boundary after NP2, and relative clauses that were grammatically disambiguated to a High attachment relation elicited greater pupil excursions from the grand mean compared to their respective NP1 and Low attachment reference levels. Both NP2 boundary and High attachment conditions also elicited more steeply rising slopes, as indicated by their interaction with the linear orthogonal polynomial.

In addition, the interaction between NP2 boundary and High attachment conditions further interacted with linear and cubic polynomials, indicating that the NP2-High condition elicited a smaller slope and increased transience of the pupil peak. The overall interaction is perhaps best visualized in the right panel of Figure 1, where the effect of NP2 is greater for High attachment conditions.

Perhaps more intuitively, the plot in the left panel of Fig-

ure 1 suggests the following conclusions. First, the conditions where the syntax and the prosody aligned largely conform to expectations. The theoretical baseline condition (NP1-Low) elicited the least extreme growth in pupil size, whereas the NP2-High elicited the most extreme changes. Low attachment is thought to be compatible with a boundary after NP1. Low attachment instantiates the empirically preferred relation between a RC and a complex nominal head in English, and, by hypothesis, is the least taxing relation to compute. The fact that the response was relatively muted in this condition is therefore entirely compatible with current linguistic theory. Similarly for the NP2-High condition: a boundary after NP2 aligns with the proposed syntax of High attachment structures. Assuming that non-local relations, including High attachment, are costly to compute, the fact that the NP2-High condition elicited the most extreme response is also consistent with current theory. However, our findings do not support the possibility that the bias against High attachment could be solely attributed to lack of supporting prosodic information; even when structures were disambiguated by prosodic boundary location, High attachment structures elicited increased cognitive load.

Second, the conditions where the prosodic grouping did not align with the syntactic constituency reveal a more complicated pattern. We predicted that the NP1-High attachment condition would be more anomalous than the NP2-Low attachment condition. Our reasoning was that the prosody of NP1-High would encourage grouping the relative clause and NP2 together, e.g. *the musicians who was really quiet*, creating a local number mismatch violation between NP2 (*the musicians*) and the verbal agreement marker (*was*). In contrast, the NP2-Low condition (*the musician % who was really quiet*) is locally grammatically coherent despite an infelicitous prosodic boundary. However, the two mismatching conditions elicited similar response patterns.

We entertained three main possible explanations. The first was that, in cases of mismatching cues, the processor makes weaker online processing commitments, and may defer the attachment decision until later, if it commits at all, as in models employing syntactic underspecification for attachment ambiguities (e.g., Frazier & Clifton, 1996). This interpretation is broadly compatible with results from Johnson et al.'s (2014) digit span task, which found decreased pupil size in response to digit sequences exceeding normal capacity. Decreased pupillary response may also indicate that the subject has abandoned an excessively difficult task, highlighting the role of attention in relating pupil size growth to cognitive effort (see also Beatty, 1982 and Winn et al., 2018)

A second possibility was that systematic differences between items may have prompted different processing strategies. For example, half of the items were disambiguated with the singular auxiliary marker (*was*), half were disambiguated with the plural marker (*were*). Our intuition was that relative clause attachment relations that were disambiguated with a singular form (*Everybody met the brother % of the musicians who was really quiet*) would be less anomalous than cases with plural disagreement (*I got a call from the friends % of the lawyer who were in politics*). We further addressed this possibility by including which number (singular vs. plural) was used to disambiguate the attachment location. Impressionistically, NP1-High conditions elicited greater pupil excursions in the Plural condition. However, grammatical number failed to differentiate effects within the statistical model.

A third explanation was that the processor resolves to High or Low attachment on the basis of another unidentified factor, such as by-item differences in boundary strength, prominence, or plausibility. To address these possibilities, we conducted a *post-hoc* boundary identification and rating norming study. The post RC material was removed, and the items were placed into four counterbalanced lists along with 46 filler items from the pupillometry experiment. Twenty additional participants from the same population as before were instructed to listen to each sentence over headphones in a noise-attenuated sound booth as many times as necessary, in order to manually mark prosodic boundaries on written versions of the sentence, and to rate how well the produced sentence matched its likely intended meaning (1 = completely unnatural, 7 = completely natural).

While participants were at ceiling (99.8%) at identifying the prosodic boundaries at the intended location after NP1 and NP2, additional boundaries after NP2 were perceived in post-NP1 boundary conditions 22% of the time. Subjects may have reverted to their default prosodic preference for an additional, potentially weaker, boundary before the RC (as discussed in Jun, 2003). Consistent with that interpretation, there was a main effect of prosody in ratings ($p<.01$), in which NP2 conditions (M=4.80, SE=0.12) were rated a more natural match with the intended meaning than NP1 conditions (M=3.66, SE=0.11). The penalty for non-local relations was evident in the ratings, as well. Sentences with Low attachment RCs (M=4.41, SE=0.12) were rated as more naturally matching with the prosody than sentences with High attachment RCs (M=4.05, SE=0.12), $p<.01$. The two factors did not significantly interact, suggesting that subjects were not sensitive to mismatches between syntactic and prosodic cues in this relatively conscious offline task.

General discussion

We used pupillometry to explore how prosodic and structural information interact during online language comprehension. Though relatively under-utilized in language processing research, pupillometry offers a promising methodological avenue for exploring how prosodic and structural information are integrated in real time processing. This method is especially useful for investigating how listeners use acoustic information to construct an interpretation, and offers a naturalistic and cost-effective complement to better known methods, such as neuroimaging or eye tracking in the visual world paradigm.

The results of the study replicate the well-studied bias for Low attachment of relative clauses in complex noun phrases

in English, a preference known to be modulated by prosodic boundary placement. However, our results cast doubt on an account which would attribute the preference to a lack of prosodic information alone. Even in the presence of overt prosodic boundaries, sentences with non-local dependencies were found to elicit online processing penalties. In addition, when the prosodic and grammatical information did not agree, pupillary response was reduced, indicating that prosody and structure are incorporated into an unfolding representation in concert. While more work is needed to investigate how language users integrate multiple sources of information together, the current study is compatible with the claim that comprehenders may avoid or delay making certain processing decisions in the face of inconsistent information.

Acknowledgments

Our thanks to Bethany Sturman for recording and preprocessing the materials, and to Joonhwa Kim, Nathan Mallipeddi, Alison Suh, Chenchen Wang, and Rebecca Wu for administering the study. Thanks also to Sun-Ah Jun for discussion of prosodic boundaries and to the UCLA Psycholinguistics Seminar for insightful comments.

Sample stimuli from experiment

Six additional experimental items (from a total of 20 sentences). Low attachment disambiguation is presented prior to High attachment disambiguation. Disambiguation was evenly balanced across singular (*was*) and plural (*were*) auxiliary markers.

1. I got a call from the friends (%) of the lawyer (%) who was / were volunteering for the campaign // but my phone died halfway through the call.

2. We were all listening to the neighbor (%) of the pilots (%) who were / was raising exotic pets // even though we were in a hurry.

3. I spoke to the apprentices (%) to the librarian (%) who was / were wearing blue jeans // but I do not remember what we discussed.

4. Somebody saw the manager (%) of the architects (%) who were / was planning to buy a Mercedes // although it was very dark outside.

5. Someone kissed the sisters (%) of the medic (%) who was / were expecting to work late // yet nobody saw it happen.

6. Everybody admired the parent (%) of the artists (%) who were / was dancing the waltz // even though there was no music playing.

What are you talking about?: A Cognitive Task Analysis of how specificity in communication facilitates shared perspective in a confusing collaboration task

Abstract

This study investigated how participant's specificity in sharing of information in collaborative problem solving was critical to them reaching a successful shared perspective. We analyzed participants' communication strategies in a collaborative task designed to make finding common ground challenging. We set out to better understand the difference between successful and unsuccessful collaborations by conducting a cognitive task analysis. From participants' utterances, we inferred cognitive processes associated with repeating communication moves and coded those processes as if-then production rules. We thereby specified the communication strategies used during interactions and developed a production-rule model to explain whether and how shared perspective developed or not. Our cognitive task analysis indicated that although all collaborating pairs described the objects they were seeing with a variety of features, the successful pairs were more specific in using combinations of features. Quantitatively, we found significant correlations between frequency of combined feature statements and success in sharing perspectives.

Keywords: Collaborative Problem Solving; Scientific Reasoning; Creativity; Coordination; Cognitive Task Analysis; Production Rules

Introduction

As discussed by cognitive scientists Herbert Simon and Allan Newell (Dasgupta, 2003), collaborative problem solving based on different perspectives helps generate new knowledge and scientific discoveries. Researchers in cognitive science have investigated the nature of collaborative problem solving (CPS), aiming to understand what kind of cognitive process underlie interactions (Okada & Simon, 1997; Salomon, 2001). Throughout these studies, it has been noted that CPS enables generation of meta-cognition, such as explanation activities (Chi, Leeuw, Chiu, & Lavancher, 1994), externalizing one's thoughts (Shirouzu, Miyake, & Masukawa, 2002), and receiving reflective responses from recipients of explanations (Miyake, 1986). Studies show that collaborating with partners with different types of knowledge and perspectives provides an opportunity to produce effective interactions (Greeno & de Sande, 2007). However, when conducting CPS research with individuals who hold different perspectives, it is important to consider constraints, such as interpersonal conflicts, which may occur due to the discrepancies among perspectives (Hayashi, 2018). Previous studies of dyads show that individuals work by role-sharing each other's different perspective (Hayashi, Miwa, & Morita, 2006). However, it is not fully understood what kind of communication processes underlie such activities, particularly regarding how dyads establish common ground by which to share their perspectives. To investigate this issue, this study reanalyzed data from Hayashi et al. (2006), by conducting cognitive-task analysis (Koedinger & Terao, 2002; Rittle-Johnson & Koedinger, 2001). We first review the CPS literatures, discuss the constraints on communication, and explain how common ground is achieved in our research paradigm (CPS based on different perspectives). We then state our specific goals and hypotheses.

CPS by taking different perspectives

Previous studies of scientific discovery in CPS showed scientists reason by taking different perspectives during interactions; this is termed distributed reasoning (Dunbar, 1995). Discussing different types of knowledge among individuals provides opportunities to generate conceptual changes (Roschelle, 1992), and is important for facilitating conceptual understanding (Greeno & de Sande, 2007). With this theoretical background, studies have shown that arguments and explanations within groups facilitate conceptual changes (Asterhan & Schwarz, 2009). Arguments made by group members by taking different perspectives are considered types of constructive and interactive joint collaborative activity (Chi, 2009); this is accomplished by coordinating individuals who hold different knowledge and perspectives. There exist group-based learning practices called jigsaw learning (Aronson & Patnoe, 1997), which focus on generating arguments by bringing together group members with different knowledge and asking them to discuss and integrate their knowledge. Throughout such studies, results show that cognitive bias and disagreements represent constraints on interaction; these factors should be considered when investigating CPS performance. Taking in these issues into consideration, Hayashi et al. (2006) conducted a laboratory based experiment using a simple reasoning task in which participants experienced difficulties on establishing common ground about each other's perspective. The results showed that when participants made substantive contributions to others by providing information by role sharing, they were able to generate broader perspectives by which to solve the problem. Moreover, successfully establishing coordination, such as correctly understanding others' perspectives, led to success in collaborations. Regarding the coordination process, recent stud-

ies of CPS have noted that collaborative problem-solving is composed of the following phases: (1) task work (problem solving), which builds internal knowledge, and (2) team work (coordination), during which internalized knowledge is exchanged and shared to build collective knowledge (Fiore, Rosen, Smith-Jentsch, Salas, & Letsky, 2010). However, it is not fully understood what kinds of knowledge and interaction strategies are used for coordination in team work, especially for CPS based on different perspectives, as considered in Hayashi et al. (2006).

Grounding in CPS based on different perspectives

Communication studies in cognitive science have shown how speakers establish common ground during conversation (Richardson & Dale, 2005; Galantucci, 2005). Grounding is the interactive process by which communicators exchange evidence in order to reach mutual understanding (Clark, 1996; Clark & Brennan, 1991). Studies of group decision-making have indicated that information shared among group members is an important factor in successful decision-making (Tindale, Kameda, & Hinsz, 2003). Thalemann and Strube (2004) showed that sharing information in initial and goal stages leads to better performance during collaborative problem solving. In contrast, cognitive science studies of collaboration have shown that common ground is unnecessary in cooperative tasks, in some cases (Barr, 2004). Computer simulations using multi-agents showed that a population of egocentric agents can establish and maintain systematic conventions without sharing common knowledge. This observation is partially supported by empirical experimental results Hayashi et al. (2006), which indicated that some participants were able to complete a task (discovering a rule) by simply using the shared information without developing common ground. However, when generating correct mental models of others' perspective during CPS, developing common ground is necessary.

Then, what kinds of interaction processes can develop successful grounding in CPS? Communication studies in cognitive science show that individuals coordinate with each other by generating explicit sign signals, which are implicitly aware of each other (Galantucci, 2005). Garrod and Anderson (1987) investigated how dyads developed different languages associated with different mental models in a maze configuration task. Individuals with different perspectives established common ground by generating spatial descriptions to successfully coordinate with each other. Additionally, in the initial phase, speakers used detailed, concrete descriptions to specify situations. Individuals used abstract signs as they proceeded during the task. Analysis of communication in the study of Hayashi et al. (2006) also showed that individuals use spatial characteristics (called regions) regarding the presented stimuli. However, the aim of the dialog analysis in this previous study was to capture the degree of perspective bias; spatial expressions were analyzed based on which perspectives were mentioned. Therefore, further analysis of the types of detailed knowledge that were used to attain shared perspective and further establish common ground would be valuable.

Goals and Hypotheses

The present study focused on how individuals share perspectives while establishing common ground in CPS in which members interact based on different perspectives. Based on Hayashi et al. (2006), our first goal was to conduct a cognitive task analysis to determine what kind of communication strategies participants used to reach shared perspectives. The cognitive task analysis was based on the method of Rittle-Johnson and Koedinger (2001) and Koedinger and Terao (2002). According to Rittle-Johnson and Koedinger (2001), developing cognitive models during cognitive-task analysis enables one to specify unambiguous problem representations and thus detail comparisons of the problem-solving strategies. This is useful here in terms of specifying the types of featured knowledge that were used during conversations on sharing perspectives. We hypothesized that coding individuals' utterances based on production rules would provide knowledge regarding what types of featured knowledge are used to share perspectives. Then, based on this cognitive task analysis, our second goal was to investigate which type of knowledge helps dyads to successfully reach shared perspectives. We hypothesized that dyads who used more specific features, and combinations of knowledge of those features, would be more likely to reach a shared perspective.

Method

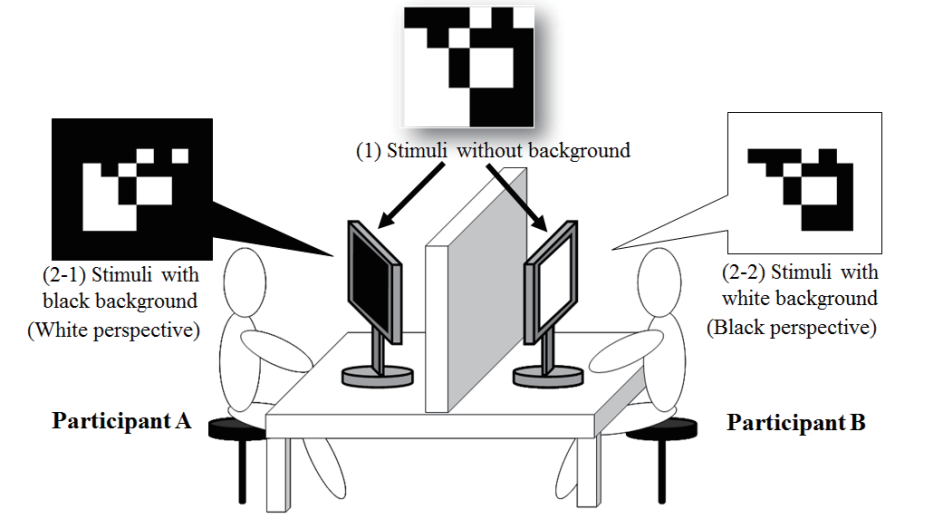
Participants

The present study reanalyzed the dataset of Hayashi et al. (2006) by analyzing dyads working with different perspectives (distributed view condition). The data of 22 Japanese university students (5 female, 17 male; *M*age: 20.73 years, SD: 2.27) who participated in dyads were reanalyzed.

Task

Controlling the participants' perspective

We reanalyzed data obtained from a simple rule-discovery task called the figure-ground reversal task, which was developed by (Hayashi et al., 2006) (for details, also see Hayashi (2018)). This task is similar to the story of "blind men and the elephant", where all individuals were touching an elephant but because they touched different parts they came to different conclusions about what they are touching. Pairs of participants collaborated through computer terminals that were separated by a partition so that neither could see the partner's display (see Fig 1). First, a square frame was presented for one second, and then the stimulus was presented in the frame. The presentation of a frame and a stimulus was considered as one trial. The participants were instructed to find the sequence rule of the number of objects that are presented through the trials. The participants were told to discuss the target rule and press the termination button presented on their screen when



Introductory phase(~ 16th trial) | Conflict Phase(17th~ trial)

Black objects	3	4	5	6	…	3	4	5	6	4	6	6	7	4	3	…
White objects	3	4	5	6	…	3	4	5	6	2	2	4	5	2	5	…
Total (Target)	**6**	**8**	**10**	**12**	…	**6**	**8**	**10**	**12**	**6**	**8**	**10**	**12**	**6**	**8**	…

(3) Sequence of presented stimuli (Sum of black and white objects rotate 6-8-10-12)

Figure 1: Experimental situation and task.

they reached the solution. The target rule was set to as the sequence of the sum of the black and white objects, i.e. the sum of the numbers of white and black objects rotating between 6, 8, 10, and 12. To manipulate a situation where the dyads were interacting based on different perspectives, principles from Gestalt psychology (Koffka, 1935), were used where the number of objects were fixed to change from figure to ground based on the background color. By putting the objects in different background, participants are led to have one of the distributed perspectives: i.e., either a perspective focusing on black objects or one focusing on white. In an example stimulus in Fig 1, there is a total of eight objects comprising three black objects and five white objects. This stimulus is displayed on either a black or white background and the participants have distributed perspective focusing on either one color as figure. The instructions stressed that the stimuli presented to each participant within the square frame were identical to each other, but the information about the background color was not mentioned.

Controlling disagreement about each other's perspectives

To control how the dyads incorporated different perspectives, the number of objects was adjusted to generate discrepancies when participants reported the numbers. In the initial stage (Introductory Phase), participants observed different colored objects (figure color) but reported the same number of objects (see Fig 1). Previous results using this task showed that participants reported the same number of objects in the Introductory Phase and therefore believed that they were looking at objects of the same color. As shown in (3) in Fig 1, participants simply reported varying numbers of objects (such as 3, 4, 5, or 6) in the Introductory Phase and thus generated misconceptions regarding the target rule. On the seventeenth trial (Conflict Phase), the number of the objects rotated by 3, 4, 5, or 6 and was scrambled. The number of objects was arranged so that only the sum of the number of objects would represent a valid response. After the Conflict Phase, participants needed to modify their misconceived initial hypothesis and instead count both black and white objects to discover the rule. It should be noted that, the participants have to discover the rule across observing the trials within the single task conducted in this experiment.

Data collection

Task Analysis

This task could proceed by two different types of interaction: (1) each participant reported only the number of figure objects (non-shared perspective method), or (2) each participant counted figure and ground objects (shared perspective method). To proceed with method (2), participants need to set a sub-goal, which was to develop mutual understanding of why they were reporting different numbers after the 17th trial. To develop a concrete shared perspective, they needed to discuss details of the display and understand how to count both figure- and ground-colored objects. Taking these issues

into consideration, we provide an overview flowchart for representative dyads working on the task by establishing common ground in Fig 2.

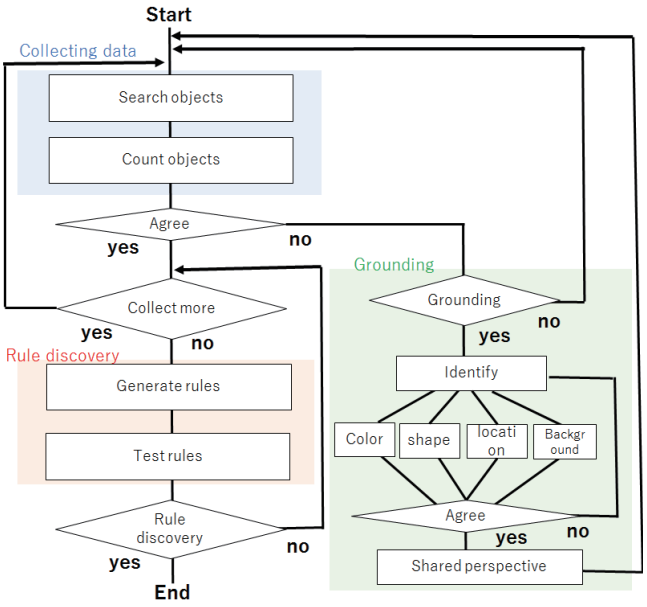


Figure 2: Flow of problem solving based on task analysis.

To establish common ground, featural knowledge, such as (a) color, (b) shape, (c) location, and (d) background, was essential. We conducted cognitive task analysis based on the type of these features, as explained in the next section.

Production-rule model for shared perspective

Production rules in this study consisted of declarative and procedural knowledge, as in ACT-R (Anderson, Corbett, Koedinger, & Pelletier, 1995). The production rules were stated in IF-THEN format, which consisted of declarative chunks. In our task, we focused on the four types of information shown, namely (1) location of the object: ?E[“location”’], (2) shape of the object: ?F[“shape”’], (3) color of the object: ?G[“color”’], and (4) background of the object: ?H[“background”’]. Using these variables, a declarative knowledge “chunk” can be defined. For example, a chunk associated with mentioning a particular object can be defined in the following way.

#Location-shape
-color(3-way)

isa	object
trial	1
number	1
location	?E[upper left]
shape	?F[tetra-zoid]
color	?G[white]
background	null

In this analysis, we only focused on combinations with color(?G[]) and other knowledge for the 2-way and 3-way, because color information was considered key for perspective-taking in this task. Next, we examined associations between the number of dyads who used specific featural knowledge (using more feature combinations) and success in sharing perspectives. Utilizing shared perspectives was defined based on the following evidence: (1) explicitly mentioning that they can see the partner’s perspective (opposite color to the background) during their grounding process, or (2) counting both black and white colored shapes after their grounding process. For example, evidence for (1) could be ”I understand what you mean and I can see the tetra-zoid in the black”, whereas (2) could be ”Now I know your perspective I will count both and I see four in black and six in white.”

Results: Association between # of featural knowledge types and shared perspective

For all 11 dyads, we conducted Fisher’s exact test to compare 2 (Featural knowledge: Mentioned vs. Not mentioned) $\times$ 2 (Shared perspective: Successful vs. Unsuccessful).

one-way strategy The results revealed no significant differences between establishing shared perspective and feature type, i.e., location (p = 0.49, FET), shape (p = 0.15, FET), color (p = 0.27, FET), or background (p = 0.06, FET). This indicates that sharing only one feature did not facilitate success in sharing perspectives.

two-way strategy Results revealed significant differences in establishing shared perspective by combinations of feature types, namely according to color & location (p = 0.02, FET) and the combination of color & shape (p = 0.02, FET). However, there was no relationship between establishing shared perspective and the combination of color & background (p = 0.18, FET). Comparing these results with the one-way strategy, we can see that the more features were mentioned during the conversations, the more likely it was that participants successfully shared perspectives.

three-way strategy There were also significant differences between establishing shared perspective and three-way combination of features, namely color & location & shape(p = 0.02, FET). This also supports the hypothesis that the more features are used, the more participants are able to share perspectives. Table 2, 3, 4 shows a summary of the results. F/S stands for feature mentioned/shared perspective, F/N stands for feature mentioned/not shared perspective, N/S stands for not feature mentioned/shared perspective, N/N strands for not feature mentioned/not shared perspective.

Discussion and Conclusions

Our first goal was to conduct cognitive task analysis to understand the types of featural knowledge that were used during interactions during the grounding process. Based on Rittle-Johnson and Koedinger (2001), we developed production rule models for knowledge regarding features of the images pre-

Table 1: Example dialog coded by production rules and types of chunks.

Speaker	Example Dialog	Productions rules	Chunk Type
B	"I see a tetra-zoid on the upper left corner"	If goal is to grounding and there is an object ?E[upper left] with feature ?F[tetra-zoid] Then express "the object is ?F[tetra-zoid]"	#Location-shape (2-way)
A	"(tetra-zoid)On the upper left? I don't see such thing"	If goal is to grounding and If partner says object has feature ?F[tetra-zoid] and object does not have feature ?F[tetra-zoid] in ?E[upper left] Then express "NO " and search new feature	#Location-shape (2-way)
B	"What about a shape "T" on the upper right?"	If goal is to grounding and there is an object ?L[upper right] with feature ?F[T] Then express "the object is ?F[T] at ?E[upper right]"	#Location-shape (2-way)
A	"You mean (upper right T) in black? Not in white?"	If goal is to grounding and partner mentions a new feature perspective ?F[T] and the object ?E[upper right] being is discussed is ?G [Black] Then confirm ?F[T] is ?G[Black] not ?G[White]	#Location-shape -color(3-way)
A	"Oh! I see it(upper right T) in black!"	If goal is to grounding and there is an object ?L[upper right] that matches the feature ?F[T] from partner in color ?G[Black] Then say ?G[Black] and "yes"	#Location-shape -color(3-way)

Table 2: Summary of association between knowledge types and shared perspective: 1-way feature.

1-way feature	F/S	F/N	N/S	N/N
color	8	2	0	1
shape	7	1	1	2
location	6	1	2	2
background	6	0	2	3

Table 3: Summary of association between knowledge types and shared perspective: 2-way feature. * indicates statistical significance.

2-way feature	F/S	F/N	N/S	N/N
color & shape*	7	0	1	3
color & location*	7	0	1	3
color & background	5	0	3	3

Table 4: Summary of association between knowledge types and shared perspective: 3-way feature. * indicates statistical significance.

3-way feature	F/S	F/N	N/S	N/N
color & shape & location*	7	0	1	3

sented in the experiment. The conversations within the dyads were transcribed into production rules, defined by declarative features of knowledge, which consisted of shape, location, color, and background. Through this cognitive task analysis, we discovered that dyads used combinations of featural knowledge when developing mutual understanding of each other's different perspectives. Simply put, collaborators who were more specific about what they were talking about were more likely to reach shared perspective. More precisely, our cognitive task analysis indicated that although all collaborating pairs described the objects they were seeing with a variety of features (e.g., color, shape, location), the successful pairs were more specific in using combinations of features (e.g., "the white T in the upper right" rather than "the white one" or the "the T"). Returning to the blind men and the elephant example introduced earlier, our results suggest that might, eventually, individuals reach agreement if they are more specific – describing as much as they can, the shape, texture, smell, relative location of their observations, etc. Past studies of communication showed that speakers use combinations of detailed spatial information to establish common ground (Garrod & Anderson, 1987); the current results are consistent with those studies. Moreover, once the participants established common ground, they tended to use simple phrases

when counting shared perspectives such as "two-four"' and "four-four". These can be considered as types of conceptual packs (Brennan & Clark, 1996), which are used when common ground is established during conversations.

In our study, we used quantitative analysis to investigate whether use of specific combinations of knowledge yielded higher performance in sharing perspectives. As hypothesized, dyads who were more specific in their grounding, i.e., mentioned more combinations of features, were more likely to reach a shared perspective. More specifically, participants who mentioned color and shape (2-way strategy), or color, shape, and location (3-way strategy) performed relatively well in sharing perspectives. Thus, specifying spatial information facilitates success in shared perspectives. There may be general critiques such as, "can common ground achieved by simply describing what is relevant?" To answer this question, we must first consider the point how did the participants determine what's relevant. In trying to achieve common ground with another, it seems possible, even likely, that one cannot fully anticipate the ambiguities that the other person may be experiencing or anticipate the alternative view of the world that they are seeing and perceiving. As mentioned previously, from the example of the story of the "blind men and the elephant", what features to focus on may be unclear and therefore, one cannot figure out what's relevant. One can simply try to be as specific as possible about in describing what they are seeing and perceiving.

Another important point that should be stressed from this study is the type of expressions that the speakers were using after they recognized about their conflicts. In natural conversations it is more efficient in most settings to not be specific(Grice, 1975). However, in a situation such as in this task, where participants have become aware of confusions and discrepancies, one must work hard to avoid our natural tendencies to be more efficient (less redundant) in our speech. Speakers need to strive for more redundancy and explicitness. Apparently, this switch is not easy to make as many of our participants do not seem to make the switch and continue to speak in natural, efficient but less specific and redundant ways. As future work, we will further investigate these points to uncover the conversational dynamics and discover the mechanisms of shared understanding in collaborative tasks.

This paper provides new implications regarding the methods one may use to capture the collaborative process in a systematic way. Although, there are limitations to the current study, primary among which is the small number of dyads used. As mentioned above, one of the next steps is to conduct a more focused experiment on how participants establish common ground. Specific analysis using eye movements and conversational data will likely be useful to elucidate the nature of coordination, too. Another possible future directions of this study is to further conduct simulations using the production-rules to further confirm our results on how the individual establish common ground.

An Ontology of Decision Models

Abstract

Decision models are formal algorithms that are used to represent decision processes and predict choice across a wide range of disciplines. These models are often highly complex, which makes it difficult to understand the relationships between different models, the unique features of individual models and, in turn, the fundamental properties of choice behavior captured by these models. We address this issue in a large-scale computational analysis that uses parameter bootstrapping cross-fitting techniques to derive pairwise measures of decision model distances. Our analysis includes over 80 prominent models of risky and intertemporal choice, and results in an ontology of decision models, with data-driven model clusters and hierarchies that synthesize over seven decades of quantitative research on human choice behavior.

Rapid Unsupervised Encoding of Object Files for Visual Reasoning

Abstract

Visual thinking plays a central role in human cognition, yet we know little about the algorithmic operations that make it possible. Starting with outputs of a JIM-like model of shape perception, we present a model that generates object file-like representations that can be stored in memory for future recognition, and can be used by a LISA-like inference engine to reason about those objects. The model encodes structural representations of objects on the fly, stores them in long term memory, and simultaneously compares them to previously stored representations in order to identify candidate source analogs for inference. Preliminary simulation results suggest that the representations afford the flexibility necessary for visual thinking. The model provides a starting point for simulating not only object recognition, but also reasoning about the form and function of objects.

Keywords: visual reasoning; shape perception; object files; structural description; type-token problem

Introduction

Visual thinking plays a central role in human cognition. From deciding whether a quantity of soup will fit into a storage container, to interpreting graphical representations of data, or reading a circuit schematic, people routinely engage visual reasoning in the service of understanding the world and solving problems. Visual thinking figures prominently in our most creative and uniquely human acts, including mathematics, engineering, art and design. But in spite of its centrality, comparatively little is known about the algorithmic basis for visual and visually-assisted reasoning (but see Hummel & Holyoak, 2001, Johnson-Laird, 1983, Lovett and Forbus, 2017, for progress in this direction). Instead, most computational work in high-level vision has been and continues to be addressed to the problem of object recognition, the tacit assumption often being that object recognition is the final stage of ventral visual processing, as though once an object has been visually recognized, there is nothing left to be done. Most models in this tradition, including modern deep nets for object recognition, represent objects as holistic templates of various kinds, which is a representational format that does not lend itself to any kind of explicit visual reasoning (Hummel, 2000; see Hummel, 2013, for a review).

The problem of visual thinking places strong constraints on the kinds of representations—for example of object shape or scene layout—the visual system must deliver to the rest of the cognitive architecture. It places equally important constraints on the kind of cognitive architecture that operates on those representations (Hummel, 2000; Lovett & Forbus, 2017). In particular, that architecture must be prepared to reason and generalize extremely flexibly—specifically, with the flexibility of an explicitly relational (i.e., symbolic) system (Hummel & Holyoak, 1997, 2001, 2003a; Lovett & Forbus, 2017). And for that purpose, the visual system must be equipped to represent the visual world in terms of arrangements of objects and object parts in terms of their spatial relations (as opposed to, e.g., their literal locations in the retinal image; Hummel, 2000).

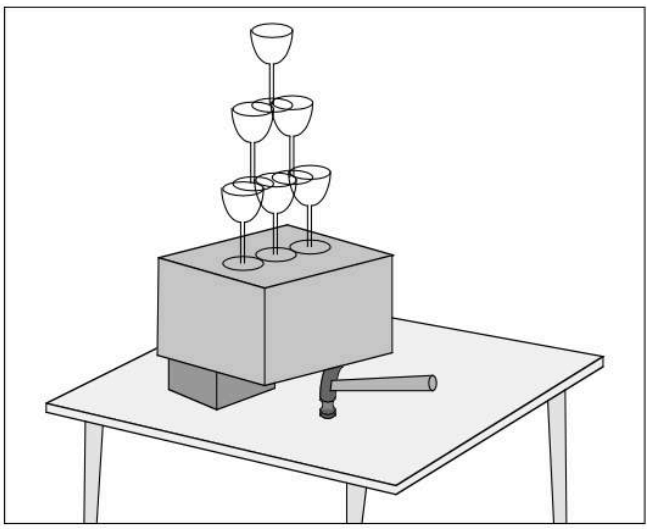

Figure 1: An example of visual reasoning in a novel context (Green & Hummel, 2004). Even if one has never seen this image before, it is obvious that moving the hammer is ill-advised.

Consider, for example, the arrangement depicted in Figure 1 (from Green & Hummel, 2004), and imagine oneself in need of the hammer. Upon a glance at the figure, it is clear that one should not simply pick up the hammer, as doing do would cause the wine glasses to fall and break. We can easily understand this property of Figure 1 in spite of the fact that, for most people, the arrangement in the figure is completely unfamiliar. To put the power of this inference into perspective, note that an associative response to Figure 1

(e.g., of the kind that would be learned by a deep net) might specify that there was something fragile in the scene, and it might even specify that a hammer as an object capable of breaking things, but would it would be incapable of even representing (much less inferring) a complex relational thought such as "moving the hammer is ill-advised because it would result in the wine glasses falling." Although the natural associative relation between hammers and breaking is to think of hammers as objects that break things, in the case of Figure 1, the hammer is *preventing* the glasses from being broken.

Making the appropriate inference about the arrangement in Figure 1 requires us to perceive the spatial relations between the hammer, the boxes and the wine glasses, and to infer from those relations what kinds of actions will and will not result in the glasses falling (Green & Hummel, 2004). Crucially, this inference depends much more on the relations between the objects than on the features or identities of the objects themselves: If we were to replace the wine glasses with a baby, the same relations would be in place, and the same inference would follow; the same is true if we replace the hammer with any other object of an appropriate size to support the box.

Similarly, even recognizing and reasoning about a novel instance of a known object class (for example, a new kind of coffeemaker), requires this kind of representational flexibility: the carafe of a coffeemaker may not always be perfectly cylindrical, especially if its designer was feeling creative, but it will always reside below the filter basket. The coffeemaker may even contain extra parts (e.g. thrown in for flourish) or have parts removed for a minimalist aesthetic, but barring extreme artistic license, it will still be recognizable as a coffeemaker.

In other words, visual inference, and even object recognition, depend on our ability to represent relations independently of the object/parts serving as arguments of the relations, and to simultaneously bind the objects/parts to their relational roles (Hummel & Biederman, 1992; Hummel & Holyoak, 1997, 2003a).

In summary, what is needed is a visual system capable of delivering relational (i.e., symbolic) representations of objects or scenes in terms of their constituent parts and the relations among them, and a cognitive architecture that is capable of using those representations in order to make flexible relational inferences.

Perceiving Relations with JIM and Reasoning About Them with LISA

Models of high-level vision that generate explicitly relational representations are comparatively rare. The examples with which we are familiar are Winston (1975), Lovett and Forbus (2017), and Hummel and Biederman's (1992; Hummel, 2001; Hummel & Stankiewicz, 1996, 1998) JIM. We will focus on JIM, a neural network that was originally developed as a model of object recognition, and in that context has accounted for, and successfully predicted, a very large number of findings in the literature on shape perception and object recognition (for a review, see Thoma & Davidoff, 2007). As such, JIM provides a psychologically and neurally plausible theory of the shape representations that can be derived from line drawings of objects. As elaborated shortly, the model is also useful as a basis for visual reasoning because it generates visual representations that are both explicitly relational and in a format that is directly usable by the LISA model of relational reasoning (Hummel & Holyoak, 1997, 2003a).

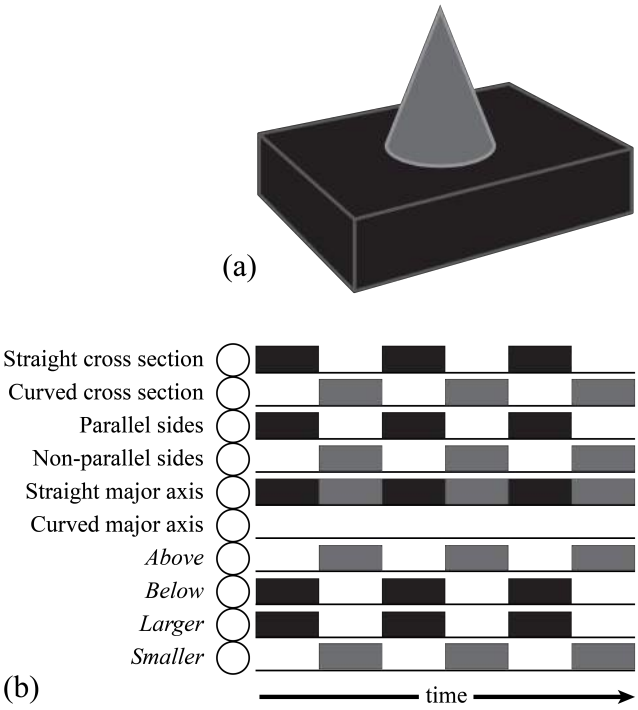

Figure 2: (a) A cone on top of a brick. (b) The JIM representation of a cone on top of a brick. Circles are units representing shape attributes. Bars indicate the activity of corresponding units over time, with black bars corresponding to the brick and gray to the cone.

JIM (Hummel & Biederman, 1992) represents objects as configurations of geons (basic volumetric shapes; Biederman, 1987) in specific spatial relations to one another. For example, the simple object in Figure 2a would be represented as a cone on-top-of, smaller-than and orthogonal-to a brick. The cone and brick are represented in JIM, not as atomic primitives, but as patterns of activation distributed over neuron-like units representing their shape attributes (Figure 2a). For example, the cone would be represented by units specifying that it has a curved cross section, a straight major axis, non-parallel sides, and a slightly elongated aspect ratio; the brick would be represented as having a straight cross section, a straight major axis, parallel sides, and a slightly elongated aspect ratio. The units representing the cone are bound to units representing its relational roles (here, *smaller* and *above*), and the units for the brick are bound to its roles (*larger* and *below*) by synchrony of firing: Units

representing the cone and its roles fire in synchrony with one another, and out of synchrony with the units representing the brick and its roles (Figure 2b). (These synchrony relations are established in the model's V1- and V2-like first layers, by lateral interactions between local units representing the geons' edges and the vertices where they coterminate; see Hummel & Biederman, 1992.)

The resulting representations (Figure 2b) are then matched to stored representations in JIM's long-term memory (LTM) for the purposes of object recognition. This representational format also happens to be identical to the format LISA (Hummel & Holyoak, 1997, 2003a) uses to represent role-argument bindings for the purposes of relational reasoning. In LISA, relational roles and their arguments are represented as patterns of activation over units representing their semantic content, and bound into complete propositions by synchrony of firing: Within a proposition, such as *on-top-of* (cone, brick) or *loves* (John, Mary), units for a relational role (e.g., *above*, *below*, *lover*, or *beloved*) fire in synchrony with the units representing the arguments to which they are bound (with *above* firing with *cone*, or *lover* firing with *John*) and out of synchrony with the units coding the proposition's other role bindings (*below+brick* or *beloved+Mary*).

Armed with these representations, LISA accounts for roughly 100 major empirical phenomena in relational reasoning, including its development (e.g., Doumas et al., 2008) and its decline with brain damage, normal aging, and frontotemporal dementia (for reviews, see Hummel & Holyoak, 2003b; Knowlton et al., 2012). As such, we take JIM and LISA as empirically well-grounded starting points for developing a model of visual thinking.

Although the kinds of representations JIM generates provide a natural basis for reasoning by LISA, the problem remains of adapting JIM-like representations for a LISA-like inference engine. That problem is the focus of the current modeling effort.

Object Files as a Basis for Visual Reasoning

Figure 2b illustrates the kind of distributed representation LISA uses to represent the semantic content of propositions in working memory (WM). To encode these representations into LTM, LISA uses a hierarchy of progressively more localist representations (Figure 3). At the bottom of the hierarchy, semantic units represent relational roles and their arguments in a distributed fashion (as in Figure 2b). *Argument* and *role* units (Figure 3) code arguments and relational roles in a localist fashion and share bidirectional excitatory connections with the corresponding semantic units. *Sub-proposition* (SP) units locally code role-filler bindings, such as *above+cone* and *below+brick*, and *proposition* units bind multiple role-filler bindings into complete propositions, such as *on-top-of* (cone, brick). Collections of related propositions are linked together with *group* (for our current purposes, *object file*) units. The resulting hierarchy of units serves both to represent propositions in LTM and as the basis for analogical mapping and the other functions LISA performs.

This hierarchy serves as a natural way to represent structural descriptions of objects and scenes (a very similar hierarchy encodes objects into LTM in JIM; Hummel & Biederman, 1992). For example, in order to represent an object, propositions would represent the spatial relations among the object's parts, and collections of such propositions would constitute a description of the complete object. Moreover, these descriptions can be nested hierarchically (with propositions taking other propositions as arguments; Hummel & Holyoak, 1997), making it possible to represent entire scenes as hierarchical collections of objects in various relations to each other.

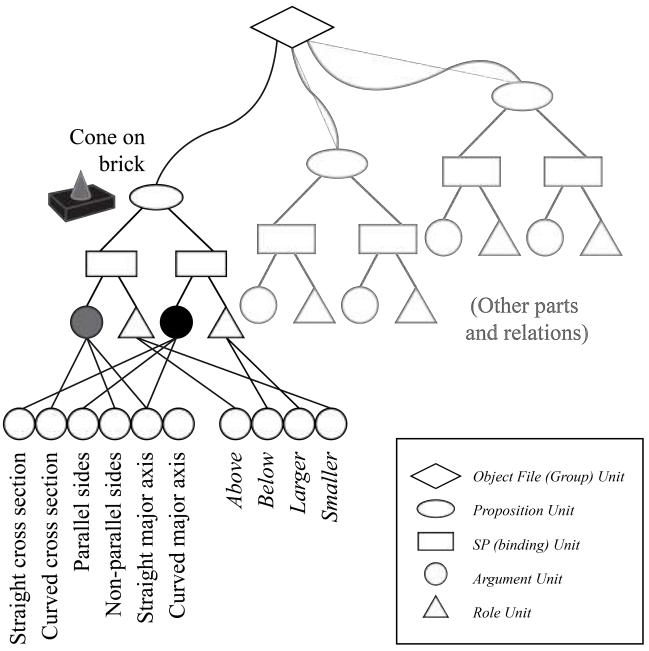

Figure 3. The LISAese representation of an object file. Left: representation of the proposition expressing the relations between the cone and the brick (roughly, *on-top-of-and-smaller-than* (cone, brick)). In light gray: other potential propositions in the object file.

Borrowing from Kahneman et al. (1992), we refer to collections of propositions encoding the properties of objects and/or scenes as *object files*. Importantly, the propositions composing an object file are assumed to encode (in the limit) everything visible about the object, including its shape, color, trajectory, and so forth. We also assume they are hierarchical, describing the properties of (and relations among) both whole objects and of individual object parts. In other words, we assume that the goal of early- and middle-vision, as well as visual attention, is to deliver a hierarchical description of the visual world. Although JIM provides an algorithmic basis for computing some of these properties and relations from object images, we assume that the visual input to the object files is much richer than any computational model is currently capable of providing. In the current effort, we therefore assume this visual input as a given to the model. Specifically,

we assume visual preprocessing that delivers descriptions of objects in terms of their properties (shape, color, etc.), spatial relations to one another, and the spatial relations among their parts. We assume that these descriptions are temporally bound into packages corresponding to bindings of relational roles to their arguments (e.g., Figure 2b; Hummel & Biederman, 1992), where the arguments can either be whole objects or object parts.

The Model

Given such a representation as a basic input, constructing an explicit object file from that input means encoding the propositions—i.e., collections of synchronized patterns of activation—into active memory (Cowan, 2001) so that they can be compared to the contents of LTM and reasoned about. The current model borrows and adapts elements of LISA's *self-supervised learning* algorithm (Hummel & Holyoak, 2003a) to accomplish this task. Like LISA and JIM, the current model uses synchrony of firing at multiple temporal scales in order to bind roles to their arguments, role-argument bindings into complete propositions, and collections of propositions into whole objects or scenes.

At the fastest temporal scale (i.e., the *phase*, which we assume to last about 25 ms; Hummel & Holyoak, 1997), units coding relational roles fire in synchrony with the units coding for the features of their arguments. At the next temporal scale (the *phase set*, corresponding to about 100 - 200 ms), mutually desynchronized role-filler bindings are grouped into complete propositions. And at the slowest temporal scale (corresponding to about 200 – 1000 ms), multiple propositions (phase sets) are grouped into complete units—either whole objects, or small groups of objects in specific relations (Green & Hummel, 2004). Each of these temporal scales corresponds to a specific kind of unit in the hierarchy in Figure 3, with the fastest corresponding to argument, role and SP units, the second slowest corresponding to proposition units, and the slowest to object file (group) units; units at each scale of the hierarchy integrate their inputs over corresponding temporal intervals (Hummel & Holyoak, 1997).

One at a time, patterns of activation corresponding to individual phases, i.e., parts or objects in specific relational roles, are presented to the model. These patterns correspond to packages being delivered by early to middle visual processing (e.g., in visual area LOC). In response to each such package, the model's task is twofold: One task is to encode new packages (phases), as they arrive into active memory, and integrate them into the representation of the emerging object file (Figure 3). This operation is performed by a simple kind of mapping-guided Hebbian learning (i.e., Hummel & Holyoak's, 2003a, self-supervised learning). At the same time, the model performs the parallel task of matching these incoming patterns to stored patterns in LTM (stored object files). That is, the model attempts to recognize each stimulus as an instance of a familiar object category at the same time as it encodes it into active memory as a new object file to be reasoned about.

By the time several phase sets have been processed, the object file will contain a collection of propositions describing (for example) the object's parts in terms of their spatial relations. If the object is familiar, the model will also have activated one or more existing object files in LTM, effectively recognizing/categorizing the object. The preceding describes the model in the language of visual cognition. In the language of analogical reasoning, the model will have encoded a new *target analog* (the object file) to be reasoned about, and it will have retrieved one or more *source analogs* (i.e., existing object files) to use in the service of reasoning about the target. Once this process is complete, the machinery of analogical reasoning (as embodied in LISA) can take over, mapping the target onto the source in order to identify corresponding elements and relations, using the source to drive inferences about the target, and inducing a more abstract schema capturing what the source and target have in common (Hummel & Holyoak, 2003a).

Token Formation

This very coarse description of the model's operation necessarily glosses over numerous implementation details, but all of these are standard to LISA's operation (see Hummel & Holyoak, 2003a, Appendix A). However, one aspect of the algorithm warrants discussion in greater detail. In LISA, argument, role, SP, proposition, and group units represent *tokens* of objects, roles, and so forth, in the context of the larger structure in which they reside. For example, the *cone* unit in Figure 3 represents a token of "cone" in the context of the specific object file depicted in the Figure; the abstract *type* "cone" is represented by the shape units (in LISA, "semantic units") to which the token is connected (Figure 2b). This type/token distinction becomes apparent in the case of scenes containing more than one instance of a given object or geon: If an image contains, say, two cones, then the resulting object file must contain separate argument units for each, even if those units are connected to otherwise identical shape units: Constructing an object file from an image requires the model to distinguish clearly between types ("a cone") and tokens of those types ("this cone").

Keeping this type/token distinction straight is complicated by the fact that a given token is likely to fire more than once in the output of visual processing: If the features of a cone fire at time *t*, and a cone also fired at time *t*-5, then how can we know whether the cone that is firing now is the same one (the same *token*) that fired 5 iterations ago? (In this respect, the object files created by the current model differ from those postulated by Kahneman et al., 1992, in that their object files were assumed to be unitary tokens for single objects. By contrast, the object files created here are hierarchical tokens that can, themselves, contain tokens for smaller parts.)

The current model solves this problem by exploiting the role of mappings in self-supervised learning (Hummel & Holyoak, 2003a). In brief, the current model, like LISA, knows when a new token is required by knowing the mappings between the tokens composing the source of an inference (here, an object file in LTM) and those composing

the target of that inference (the emerging object file): If an unmapped token fires in the source, then a new token is required in the target. The current model exploits a similar constraint by mapping each token in the emerging object file to the location of the corresponding part or object in the image: In essence, it knows whether the cone firing at time *t* is the same token as the one from time *t*-5 by knowing whether they occupy the same location. (This heuristic is admittedly too simple and will fail with, for instance, moving stimuli. In general, we assume that tokens are distinguished, not by locations in the image, but by spatiotemporal trajectories in 3-space.)

The model is still in an early stage of development—and is, itself, only a component of a much larger emerging model—but preliminary simulations provide an encouraging proof of concept.

Simulations

We ran four sets of simulations as basic tests the model's ability to rapidly encode object files from oscillatory visual inputs of the kind illustrated in Figure 2b. In each simulation, objects were presented and encoded in the model's LTM; subsequently, additional objects were presented to be encoded and categorized as one of the known objects. Objects were constructed by combining 14 parts, P1… P14, into arrangements by placing them in various two-place relations, with roles R1…R15. Each part was coded as a 10-dimensional feature vector, and each role of a relation was also coded as a 10-dimensional vector. In addition, 6 units served as location tags, L1…L6, which as discussed above, permit the model to solve the type-token problem. The full feature space was thus 26-dimensional (10 for parts, 10 for roles, and 6 for location tags). The binding of a given part, P_i, to a given relational role, R_j, was implemented as the concatenation of vector P_i with vector R_j and location vector L_k (synchrony of firing is equivalent to vector addition). We manipulated the relationships between the stored and stimulus objects by varying the parts of the objects, *P*, the relations, *R*, and the locations *L* in which they were instantiated. For clarity in what follows, we will refer to a given part in a given location as $P_{i,k}$. The assignment of features to part vectors *P*, role vectors, *R*, and location vectors *L* was randomized on every simulation.

Table 1 shows the library of objects used in all simulations. In the table, objects are denoted using the format (using object O_1 as an example):

$$[(P_{1,1}, R_1) + (P_{4,4}, R_2)], [(P_{1,2}, R_3) + (P_{4,4}, R_4)],$$

where $(P_{1,1}, R_1)$ denotes part P_1 in location L_1 bound to role R_1, and $(P_{4,4}, R_2)$ denotes P_4, in L_4, bound to R_2; and the square brackets around these expressions indicate that roles R_1 and R_2 form a single relation linking P_1 to P_4. Note that P_1 appears in two locations in O_1, L_1 and L_2, and thus instantiates two tokens of the same type in the representation of O_1.

Simulation 1 was the most basic test of the model's ability to encode and match objects. We encoded objects O_1-O_3 into the model's memory and then tested its ability recognize object O_1. Unsurprisingly, it recognized O_1 as O_1 on three of three simulation runs, in the sense that it activated the O_1 group unit more than the group units for O_2 or O_3 (roughly 0.7 versus 0.6 or less, respectively; objects O_2 and O_3 are as active as they are because there is no lateral inhibition between group [object file] units).

Simulation 2 tested the model's ability to recognize an object when it has an extra part. On three runs, the model was initially trained on objects O_1-O_3, and then tested with O_4. O_4 is the same as O_1, but with an extra part, P_3, in a new relation to P_4. In addition to encoding O_4 as a new object file, the model also recognized it as most similar to object O_1 with activation about 0.7, versus about 0.5 for O_2 and O_3. When the model was then tested with O_1 as a stimulus (after O_4 was encoded into memory), the model recognized O_1 as O_1 (about 0.7), but also activated O_4 as a close match (about 0.6 versus about 0.5 for O_2 and O_3).

Table 1: Object Library for Simulations

O_1	$[(P_{1,1}, R_1) + (P_{4,4}, R_2)], [(P_{1,2}, R_3) + (P_{4,4}, R_4)]$
O_2	$[(P_{5,5}, R_7) + (P_{11,11}, R_8)], [(P_{8,8}, R_9) + (P_{11,11}, R_{10})], [(P_{10,10}, R_{11}) + (P_{11,11}, R_{12})]$
O_3	$[(P_{13,13}, R_{14}) + (P_{4,4}, R_2)], [(P_{12,12}, R_{13}) + (P_{12,12}, R_{14})]$
O_4	$[(P_{1,1}, R_1) + (P_{4,4}, R_2)], [(P_{1,2}, R_3) + (P_{4,4}, R_4)], [(P_{3,3}, R_5) + (P_{4,4}, R_6)]$
O_5	$[(P_{5,5}, R_7) + (P_{11,11}, R_8)], [(P_{10,10}, R_{11}) + (P_{11,11}, R_{12})]$
O_6	$[(P_{6,6}, R_7) + (P_{11,11}, R_8)], [(P_{8,8}, R_9) + (P_{11,11}, R_{10})], [(P_{10,10}, R_{11}) + (P_{11,11}, R_{12})]$

Simulation 3 tested the model's ability to recognize an object with a missing part. In three runs, the model was again trained with O_1-O_3 and tested with O_5, which is like O_2, but missing part P_8. The model correctly recognized O_5 as most similar to O_2 on two out of the three runs. On the third run, the model classified O_5 as most similar to both O_2 and O_1 equally. We speculate that in this case the part and relation vectors randomly generated for O_1 happened to be similar to those of O_2, in which case this result would be an example of a neighborhood effect. However, in all simulations, when O_2 was re-presented after O_5 was encoded, the model recognized it as an instance of O_2, with O_5 as a close second (both near 0.7), preferentially activating both over O_1.

Finally, simulation 4 tested the effect of replacing one part with another. Again, in three runs, the model was trained on O_1-O_3, and then tested with O_6 (O_6 is like O_2, but with P_5 replaced by P_6). On two of three runs, the model recognized O_6 as most similar to O_2. On the third, the model slightly favored O_3. Once again, we speculate that this result is due to neighborhood effects created by the randomization of the vectors. In all runs, when O_2 was re-presented to the model, it activated O_2 (greater than 0.7), with O_6 as a close second.

Discussion

The online generation of object files from the output of middle-to-late vision is a crucial step in visual thinking. We

present a model that, starting with outputs of a JIM-like model of shape perception, generates representations that can be stored in memory for future recognition and can be used by a LISA-like inference engine to reason about those objects. Preliminary simulation results suggest that this approach provides a promising starting point for simulating both object recognition and the visual-cognitive interface.

Simulations demonstrated that the model can correctly recognize familiar objects (simulation 1) as well as new objects created by adding (simulation 2), deleting (simulation 3), and replacing (simulation 4) parts of familiar objects. All of these transformations pose problems for non-compositional (e.g. template-based) accounts of object recognition (Biederman, 1987), but they are commonplace in human interactions with objects. Parts are often deleted by occlusion or by modification of the physical object (e.g. as when a tire is removed from a car); added, as when new parts are added to objects to extend functional capabilities; or replaced (e.g., for styling reasons). These types of modifications are especially common in commercially designed objects, so our ability to recognize and reason about these objects depends on our ability to tolerate these types of modifications: The first time we see a new model of coffeemaker, we may decide that the styling is not to our liking, but we do not stare at it in confusion about what it is.

Crucially, the representations used by this model are not only useful for recognition, as shown by the simulations, but also lend themselves naturally to reasoning about the objects' function. In particular, these representations are already in "LISAese", the representational format used by the LISA model, and as such are available to the full inductive power of that inference engine. For example, given an object file describing a novel coffee maker, LISA is well-equipped to infer that the handle is where the pot should be grasped, the filter basket is where the ground coffee should be placed, and the carafe is where the brewed coffee will collect. Once the model is supplied with a JIM-like front-end, it should be in a position to start with object images and end with inferences about those objects.

Norms and the meaning of omissive enabling conditions

Abstract

People often reason about omissions. One line of research shows that people can distinguish between the semantics of omissive causes and omissive enabling conditions: for instance, not flunking out of college enabled you (but didn't cause you) to graduate. Another line of work shows that people rely on the normative status of omissive events in inferring their causal role: if the outcome came about because the omission violated some norm, reasoners are more likely to select that omission as a cause. We designed a novel paradigm that tests how norms interact with the semantics of omissive enabling conditions. The paradigm concerns the circuitry of a mechanical device that plays music. Two experiments used the paradigm to stipulate norms and present a distinct set of possibilities to participants. Participants chose which causal verb best described the operations of the machine. The studies revealed that participants' responses are best predicted by their tendency to consider the semantics of omissive relations. In contrast, norms had little to no effect in participants' responses. We conclude by marshaling the evidence and considering what role norms may play in people's understanding of omissions.

Keywords: omissive causes; enabling; allowing; modal semantics; norms; mental models

Introduction

A railway gatekeeper's job is to open and close a crossing gate that lets trains pass. In 1902, the gatekeeper for the Somerset and Dorset railway was found guilty of manslaughter because he failed to close the gate (R. v. Pittwood, 1902). While he was at lunch, a train passed through the open gate and crashed into a horse and cart, killing one man and injuring another. The case describes an omissive cause: the jury held that the gatekeeper's failure to close the gate caused the death of an innocent bystander.

Omissive causation is a controversial topic amongst philosophers, psychologists, and legal scholars (Moore, 2009; Bernstein, 2015; Henne, Pinillos, & De Brigard, 2017). People have little difficulty in distinguishing which event was causal from alternative events that are non-causal. But causes are often easy to establish when they occur in a particular place and at a particular time; for instance, throwing a switch at a particular time causes the particular gate to close, so it is easy to identify the intervening action as the cause. Since omissive causes—absences, failures to act, scarcities, etc.—do not occur in any spatial or temporal frame, they present unique difficulties for causal reasoning and theories of causation.

One proposal suggests that norm violations affect causal judgments and play a fundamental role in establishing what constitutes a cause (Hitchcock & Knobe, 2009; McGrath, 2005; Hart & Honoré, 1985). In the railway example, the gatekeeper was charged and found guilty because his occupation made it his responsibility to monitor the track. It may seem trivial that many other individuals—for instance, some passerby—also failed to close the gate, but previous philosophical treatments have difficulty explaining why only certain omissive causes are deemed relevant and not others (see McGrath, 2005; Bernstein, 2015). On the norm-based account, the passerby, unlike the gatekeeper, is not considered a cause, as there was no normative expectation for him to close the gate. The norm-based account provides an explanation for why people focus their attention on potential causes. Consistent with this view, recent studies show that reasoners view norm-violating omissions as causes but norm-preserving events as non-causes or as enablers (Henne et al., 2017; see also Clarke et al., 2013).

Nevertheless, some theorists question whether norms determine the meaning of omissive causal statements or whether norms simply bias causal judgments (Bernstein, 2014; 2017, p. 89-90). Consider the following statement:

1. The drought caused the famine.

Some argue that omissive causal statements as in (1) do not involve norms in any way, yet they are easy to comprehend. If norms were a central part of the meanings of causal relations, then the absence of any norm should render (1) uninterpretable (Bernstein, 2017). On such a view, norms may be relevant in *establishing* causal relations—such as in the train example—but they are not central to their meaning.

One clue for what it means to be a cause comes from the application of causal verbs: "causes," "enables," and "prevents." Each verb refers to a relation between two events, and those relations have stark differences in their semantics. Psychological accounts of causal reasoning identify differences in the way people understand causal verbs (e.g., Goldvarg & Johnson-Laird, 2001; Sloman, Barbey, & Hotaling, 2009; Wolff, 2007). Accordingly, a viable theory of how people understand and infer omissive relations must distinguish the semantics between them. Consider the following two statements:

2a. An absence of light *causes* a flower to die.
b. An absence of light *enables* a flower to die.

(2a) seems sensible, but (2b) does not, because (2b) implies that the flower can live without light. Likewise, in the following two statements:

3a. A lack of insecticides *causes* insects to thrive.
b. A lack of insecticides *enables* insects to thrive.

(3b) seems sensible, but (3a) does not, because (3a) inappropriately guarantees that insects will thrive once insecticides are eliminated. The distinctions may be compelling, but until recently, no theory of causal reasoning could explain them.

A recent theory of omissive causation differentiates omissive causes from omissive enablers (Khemlani, Wasylyshyn, Briggs, & Bello, 2018). The theory is based on the idea that people represent causal scenarios by constructing and manipulating a set of discrete possibilities, i.e., mental models (Goldvarg & Johnson-Laird, 2001). The model-based theory—the "model theory," for short—posits that omissive causes and omissive enabling conditions differ in the sets of possibilities to which they refer. On tasks that require reasoners to distinguish between the different relations, they should base their judgments on the semantics stipulated by the model theory (Khemlani et al., 2018). In contrast, if norms are central to the meaning of omissive relations, reasoners should base their decisions on norm-violations (Henne et al., 2017).

In what follows, we first delineate the predictions of the model theory and the norms hypotheses. We then describe an experimental paradigm that can test between the two predictions, and we present two novel experiments that test the competing predictions. The studies showed that reasoners separated omissive causes from omissive enabling conditions in a manner predicted by the model theory, and norm-violations had little effect on their behavior.

The model theory of causal reasoning

The mental model theory of human reasoning proposes that humans reason based on representing sets of possibilities (Johnson-Laird, 2006). The meanings of spatial relations, temporal relations, and causal relations refer to the sets of possibilities consistent with each relation (Goodwin & Johnson-Laird, 2005; Khemlani, Barbey, & Johnson-Laird, 2014). The model theory posits two systems of reasoning: a fast, intuitive system of reasoning constructs a single initial possibility—the "mental model"—to represent one or more assertions. Reasoners can formulate inferences rapidly by scanning that initial possibility, but those inferences are prone to error, because causal relations can be consistent with several possibilities. Errors can be corrected through deliberation, which is a process by which reasoners iteratively construct and consider alternative possibilities.

Khemlani and colleagues recently extended the model theory to account for reasoning about omissive causation (Bello et al., 2017; Khemlani et al., 2018). Their account explains why people distinguish different omissive relations (Table 1). It appeals to the idea that people rapidly construct initial mental models, and then flesh out those initial models into "fully explicit" models. On this view, a mental model is a privileged, default possibility to which an omissive causal relation refers, whereas fully explicit models represent all the possibilities consistent with the modal semantics of the relation. The following diagram depicts the mental model of the omissive causal relation described in (2a):

```
¬ light        death
```

where '¬' denotes the symbol for negation (Khemlani, Orenes, & Johnson-Laird, 2012). Here, the lack of light is interpreted as a negated event, and it arranges the two events in the same chronological order in which they would occur. Hence, the model represents a single iconic possibility. When reasoners deliberate, they can consider all of the possibilities that accord with the modal semantics of omissive causation (Table 1). They can accordingly build fully explicit models of (2a), which are depicted in this diagram:

```
¬ light        death
  light        death
  light      ¬ death
```

where each row represents a separate possibility. The bolded row represents the mental model. The latter two possibilities show that if the flower receives light, it may die anyway (for some other reason), or it may not die at all. But the theory predicts that reasoners should be less likely to think of these latter two possibilities at the outset because most reasoners only construct and reason with the mental model.

The theory posits that the mental model of omissive enabling conditions is the same as the mental model of omissive causation. Hence, the model of (3b) above is:

```
¬ insecticide   thrive
```

It predicts that reasoners who draw conclusions on the basis of mental models should often conflate the two assertions (e.g., Wolff, 2007; Frosch & Johnson-Laird, 2011). When reasoners distinguish between omissive causes and enabling conditions, they should do so on the basis of their modal semantics, i.e., on the fully explicit models of the relations. The fully explicit models of an omissive enabling condition are depicted in the following diagram:

```
¬ insecticide   thrive
¬ insecticide ¬ thrive
  insecticide ¬ thrive
```

Unlike omissive causes, omissive enabling conditions are consistent with the possibility in which both the cause and the effect do not hold, i.e., the situation in which insecticides are administered and insects subsequently do not thrive. Omissive enabling relations typically prohibit the possibility in which the cause and the effect both hold (A and B), e.g., the insects thrive even when they are sprayed with insecticide. But in some situations, omissive enabling relations can take on a weaker meaning and permit that possibility, as in, "The failure to cut the grass enabled it to grow." The statement permits the possibility in which the grass is cut and it grows anyway (Table 1).

The model theory accordingly makes the following general hypothesis about semantics of omissive relations:

Semantics hypothesis: On tasks that require reasoners to distinguish between alternative causal relations, they should discriminate between omissive causes and omissive enabling conditions on the basis of the possibilities unique to each relation.

In contrast, reasoners are often susceptible to norm violations that affect their causal judgments (Henne et al., 2017). Hence, norm-based accounts posit the following hypothesis:

Norms hypothesis: When norms are available, reasoners distinguish between causal relations by focusing on those candidate events that violate norms. Events that violate norms should be considered causes, whereas those that do not violate norms should be rejected as causes.

In the next section, we describe a novel paradigm developed to test between the two hypotheses.

A paradigm for testing semantics and norms

Many existing paradigms test the meanings of omissive causes, but they do not typically encourage reasoners to consider and track multiple possibilities that are thought to be essential to the meanings (Henne et al., 2016; Khemlani et al., 2018; Wolff, Barbey, & Hausknecht, 2010; cf., Bello et al., 2017; Experiment 2). To try to overcome this limitation, we developed a novel paradigm that could be used to investigate how people distinguish the meanings of causal relations.

The paradigm made use of diagrams akin to those shown in Table 2. The basic diagram depicts a machine with a speaker, a red battery, a safety switch (which appeared green or else black), a blue wire, and an unnamed yellow component. The diagram could vary in several ways in order to depict different possibilities. For instance, the speaker could be playing or not playing (depicted as a series of soundwaves or not); the blue wire could be connected to the red battery, or else not connected; and the safety is green when it is *on* and black when it is *off*. The safety switch allowed for the establishment of a norm: participants were taught that whenever the safety is on (colored green), the blue wire *is not supposed to touch* the battery. And when the safety is off (colored black), the blue wire *is supposed to touch* the battery. Hence, the machine could be depicted in 2 (sound or no sound) x 2 (wire connected or disconnected) x 2 (safety on or off) = 8 different configurations. Depending on the particular condition in the experiments, those various configurations either violated or preserved norms. And those various configurations were either compatible with a particular omissive causal relation or incompatible with it.

The paradigm allows to directly compare predictions made by both the semantics hypothesis and the norms hypothesis. Experiments 1 and 2 provided participants a single trial in which they received three different diagrams (Table 2). After studying three different diagrams, participants were given a sentence completion task that tested their understanding of the scenario depicted.

Experiment 1

Experiment 1 presented participants with three separate diagrams. Participants only received diagrams that were either possible or impossible given causal and enabling relations: diagrams depicting context-dependent contingencies were not used in the experiment (Tables 1 and 2). Half the participants saw a set of diagrams in which each diagram was compatible with the following omissive enabling relation:

4. The blue wire not touching the red battery *allows* the speaker to play music.

The other half saw a set of diagrams that were compatible with (4) and the following causal assertion (5):

5. The blue wire not touching the red battery *causes* the speaker to play music.

Because the experiment avoided context-dependent contingencies, the remaining diagrams compatible with (5) were also compatible with (4), so the set of diagrams were ambiguous: the model theory predicts that participants should treat them as depicting both omissive causes and omissive enabling conditions (Khemlani et al., 2018, Experiment 4).

Participants were given a sentence completion task in which they chose the causal verb ("causes" or "allows") to complete the following sentence:

> The blue wire not touching the battery _____ the speaker to play music.

Notably, for the purposes of the study, the verb "allows" was treated as equivalent to "enables". The experiment accordingly tested the prediction of the semantics hypothesis that reasoners should select the causal verb that matched the possibilities depicted. Hence, the semantics hypothesis predicts that reasoners should select "allows" more often for the enabling condition than the ambiguous condition. Experiment 1 also tested the norms hypothesis. Half the conditions in the study concerned abnormal situations in which the safety was off, and the other half concerned normal situations in which the safety was on, and participants were instructed that the blue wire is not supposed to touch the battery when the safety was on, and that it was supposed to touch the battery when the safety was off. The norms hypothesis predicts that people should be sensitive to norm violations, i.e., they should be more likely to select the verb "causes" to fill in the sentence provided for abnormal omissions compared to normal ones. In turn, normal omissions should be judged to be involved in enabling relations. The semantic hypothesis, however, posits that participants' responses should not vary as a function of whether the condition was abnormal or normal—only as a function of which set of possibilities participants considered.

	The four possible contingencies between A and B			
Omissive relation	¬A B	**¬A ¬B**	A ¬B	A B
The lack of A causes B.	Mental model	**Impossible**	Possible	Context-dependent
The lack of A enables B.	Mental model	**Possible**	Possible	Context-dependent

Table 1: The table outlines the semantics of omissive causes and omissive enabling conditions. The rows separate omissive causes and omissive enabling conditions. The cells in each column describe whether each contingency is possible given a particular omissive relation. The mental models are always possible. The bolded column denotes the contingency diagnostic of omissive enabling conditions.

Methods

Participants A total of 822 adults participated in this study on Amazon Mechanical Turk (AMT). Of these participants, 59 did not complete the study, and 26 were excluded for failing to pass two attention checks. Data were analyzed with the remaining 796 participants (M_{age} = 34, SD = 11.0, age range = [18-71], 43% females).

Design and procedure Participants were randomly assigned to one of four possible conditions in a 2 (enabling vs. ambiguous) x 2 (normal vs. abnormal) between-participants design. Participants were acquainted with the machine in Figure 1 and its various components. After viewing and responding to instructions, participants were presented with three diagrams of configurations of the machine. The diagrams appeared on the screen simultaneously. To check their comprehension of the machine and the three separate possibilities, they matched the possibilities with descriptions provided in a dropdown menu, i.e., they chose from the following options to describe each of the three diagrams: (1) "The blue wire touches the battery, and the speaker plays music," (2) "The blue wire touches the battery, and the speaker does not play music," (3) "The blue wire does not touch the battery, and the speaker plays music," and (4) "The blue wire does not touch the battery, and the speaker does not play music." The order in which the possibilities were presented was fixed. In the normal condition, the machine's safety was green, so the blue wire was not supposed to touch the battery. The blue wire not touching the battery is normal. In the abnormal condition, the machine's safety was black, so the blue wire is supposed to touch the battery. The blue wire not touching the battery is abnormal. Participants were explicitly instructed to attend to the color of the safety and what the blue wire was supposed to do. They were then asked to think back to their observations and then fill in the verb in the sentence: "The blue wire not touching the battery _____ the speaker to play music." Participants could choose between the verb "causes" or "allows" from a drop-down menu, and they could not proceed until a choice was made.

Post-experimental questionnaire Participants filled out a post-experimental questionnaire that asked them if they had paid attention and if they had taken the survey multiple times. Participants who reported affirmatively on either question were excluded.

Results and discussion

Figure 1 shows the proportion of participants who chose "allows" as a function of whether the condition was normal or not and as a function of whether the diagrams were consistent with the semantics for omissive enabling conditions or else ambiguous. Participants chose "allows" more often for diagrams consistent with enabling conditions than for ambiguous diagrams (74% vs. 54%; Mann-Whitney test, $z = 5.65$, $p < .0001$, Cliff's $\delta = .19$). Participants selected "allows" more often when the diagrams were presented in a normal rather than an abnormal context—although this result was not statistically significant (68% vs. 62%; Mann-Whitney test, $z = 1.72$, $p = .09$, Cliff's $\delta = .06$). A follow-up generalized logistical mixed-model (GLMM) regression further revealed that the difference in selection between the two conditions was inconsistent with a significant effect ($\beta = .00$, $p = .97$), as was the interaction between the two conditions ($\beta = .48$, $p = .12$). Nevertheless, a planned comparison revealed that for ambiguous diagrams, participants selected "allows" more often when the diagrams were presented in a normal context rather than an abnormal context (61% vs. 49%, Mann-Whitney test, $z = 2.35$, $p = .02$,

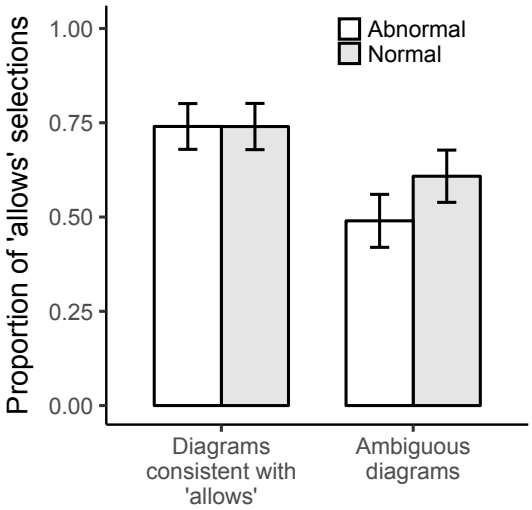

Figure 1: Proportion of participants who chose "allows" instead of "causes" in Experiment 1 as a function of whether participants saw normal or abnormal devices, and as a function of whether the diagrams were consistent with omissive enabling conditions only or consistent with both omissive causes and omissive enabling conditions. Error bars indicate 95% confidence intervals.

Condition	Diagrams presented to participants			
	¬wire music	¬wire ¬music	wire ¬music	wire music
Ambiguous	 (shown twice)	Not shown to participants		Not shown to participants
Enabling				Not shown to participants

Table 2: The three diagrams presented to participants in enabling and the ambiguous conditions. These diagrams all depict the normal conditions, i.e., the safety is on, so the blue wire is not supposed to touch the red battery. In Experiment 1, participants were not provided with written cues about the condition of the safety switch. In Experiment 2, those cues were provided (as in the diagrams above).

Cliff's δ = .12). All data and analysis code available at https://osf.io/jf36w/. The result provides some support for the norm hypothesis, which predicts that people should be more likely to select "causes" (and less likely to select "allows") for abnormal contexts. It also suggests that participants were sensitive to the norm manipulation: they comprehended the norms and took them into account in making their selections. If they had not, they would have shown no sensitivity to whether the diagrams were in normal or abnormal context. Yet, an analogous comparison for diagrams consistent with omissive enabling conditions was not reliable, and so the study revealed mixed support for the norms hypothesis.

Experiment 1 corroborated the prediction that reasoners interpret omissive causes and enabling conditions in accordance with the semantics outlined by the model theory. Reasoners in the enabling condition selected "allows" more often than those in the ambiguous condition. Moreover, participants' responses did not depend on whether a norm had been violated or not. If, as the norms hypothesis states, abnormal situations help reasoners choose which candidate events constitute causes, then those abnormalities appeared to have no effect on participants' tendencies to select appropriate causal relations.

One limitation of Experiment 1 is that reasoners may have simply failed to recognize abnormalities in the first place, i.e., they may not have encoded the black safety switch's color, which was designed to serve as a cue that a norm had been violated. Another limitation of the study is that participants evaluated only one set of three diagrams and only one causal relation. Experiment 2 corrected for both of these limitations.

Experiment 2

Because participants may not have picked up on the norm distinction between conditions in Experiment 1, we sought to ensure that the difference was salient in Experiment 2. Hence, rather than just identifying the color as the difference in norms, Experiment 2 added the verbal cues "SAFETY ON" and "SAFETY OFF" to the diagrams (see Table 2). Moreover, the study employed a within-participants design to further validate the findings from Experiment 1 supporting the semantics hypothesis. Hence, each participant saw four distinct sets of three diagrams.

Methods

Participants A total of 215 adults participated in this study on AMT. Of these, 21 participants were excluded for failing to pass two attention checks. Data were analyzed with the remaining 194 participants (M_{age} = 33.82, SD = 9.39, age range [18-68] 40% females).

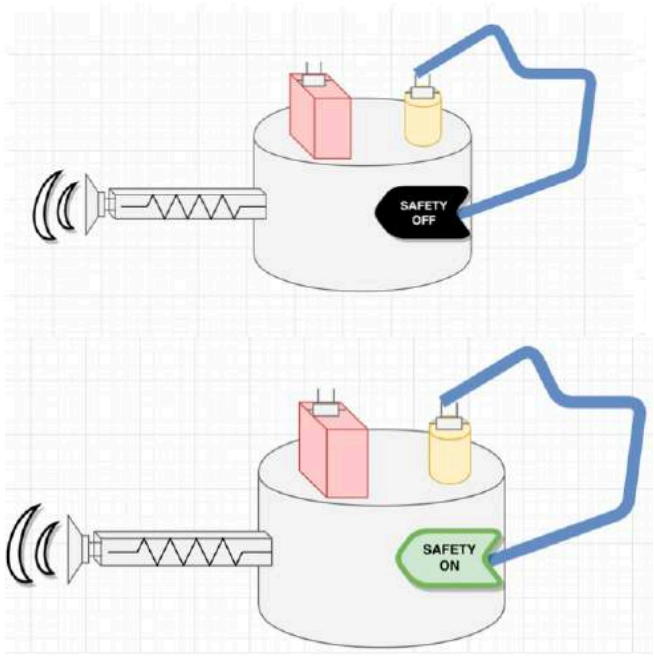

Figure 2: The stimuli used in Experiment 2. Participants in the abnormal condition saw the machine with the black safety i.e., in the off position (top diagram), and those in the normal condition saw the machine with the green safety, i.e., in the on position (bottom diagram).

Design and procedure Participants acted as their own controls and received all four possible conditions in a 2 (enabling vs. ambiguous) x 2 (normal vs. abnormal) within-participants design. As in Experiment 1, participants were acquainted with the machine and its various components. The model conditions were constructed just as they were in Experiment 1 (see Table 2). The stimuli were modified such that the normal and abnormal conditions were more salient by adding the words "SAFETY ON" and "SAFETY OFF" to the diagrams (Figure 2).

Results and discussion

Figure 3 shows the proportion of participants who chose "allows" as a function of whether the condition was normal or not and as a function of whether the diagrams were consistent with the semantics for omissive enabling conditions or else ambiguous. As in Experiment 1, participants selected "allows" more often when the diagrams depicted possibilities uniquely consistent with omissive allowing relations rather than ambiguous possibilities (77% vs. 53%; Mann-Whitney test, $z = 7.00$, $p < .0001$, Cliff's $\delta = .24$). They didn't reliably select "allows" more often for diagrams in an abnormal vs. a normal context (66% vs. 64%; Mann-Whitney test, $z = .83$, $p = .41$, Cliff's $\delta = .03$). GLMM regression analyses likewise corroborated the nonparametric analyses: it yielded an effect of whether the diagrams were ambiguous or consistent with omissive allowing conditions ($B = 1.14$, $p < .0001$), but no effect of normality ($B = .15$, $p = .54$) and no interaction ($B = .02$, $p = .95$).

A planned comparison revealed that for ambiguous diagrams, participants did not reliably select "allows" more often for abnormal than normal contexts (55% vs. 52%; Mann-Whitney test, $z = .61$, $p = .54$, Cliff's $\delta = .03$). Hence, overall, the results are not consistent with the norms hypothesis, which states that reasoners should be more likely to select "causes" (and less likely to select "allows") for abnormal vs. normal contexts.

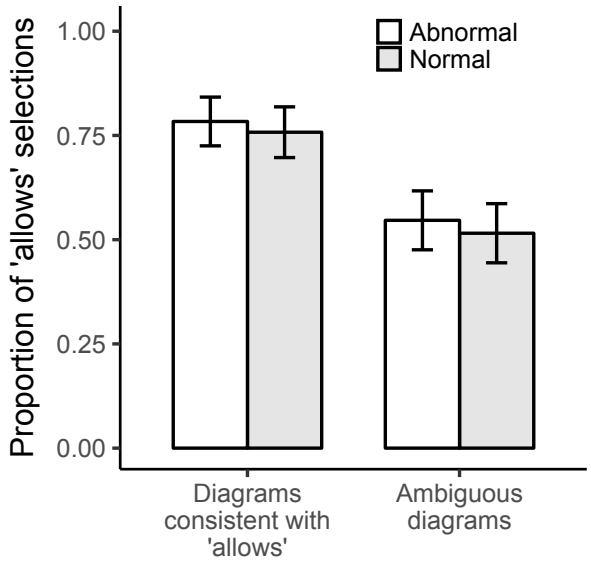

Figure 3: Proportion of participants who chose "allows" instead of "causes" in Experiment 2 as a function of whether participants saw normal or abnormal devices, and as a function of whether the diagrams were consistent with omissive enabling conditions only or ambiguous. Error bars indicate 95% confidence intervals.

Just as in Experiment 1, the results of Experiment 2 support the prediction of the model theory with respect to its predictions about the semantics of omissive enabling conditions. Reasoners in the enabling condition selected "allows" more often those in the ambiguous condition. Moreover, participants' responses did not depend on whether a norm had been violated or not.

General Discussion

Two experiments were designed to test how participants judge the causal effect omissive events have on outcomes. The experiments corroborated a recent theory of omissive causation, which predicts that reasoners should be able to distinguish omissive enabling conditions from other sorts of omissive relation (Khemlani et al., 2018). Moreover, the results showed that norm violations cannot explain the semantic difference between causes and enabling conditions.

The results of these studies can help refine the role that norms play in causal reasoning. As Henne and colleagues (2017) show, norms help select potential causes and distinguish them from irrelevant non-causes. The present studies, however, show that norms do not always explain the difference between causes and enablers. When reasoners consider the distinctive possibilities consistent with enabling conditions norms have little to no effect on causal judgment. When reasoners consider only the mental model, norms may have a more prominent effect on causal judgment. A more robust extension of the model theory, i.e., one that explains how norms are represented and how they modulate possibilities could potentially explain both the semantics between different causal verbs as well as how reasoners isolate potential causes from non-causes. Such a theory would also have to be contrasted with recent models of causal strength that could potentially explain the norm effects and the results predicted by the model theory (Icard, Kominsky, & Knobe, 2018).

Abstract

The learning and generalisation of grammatical regularities is fundamental to successful language acquisition and use. Research into statistical learning has started to consider how this process occurs through the implicit detection and assimilation of grammatical regularities. This study focuses on how adults and children generalise regularities and explores the role of explicit knowledge in this process. Across three experiments, adults and children learnt an artificial language containing two semantic categories denoted by a co-occurring determiner and suffix. Explicit knowledge of the regularities was associated with generalisation performance in adults but not children, even when adult word level knowledge was similar to children's. The implications of these results for developmental theories of grammatical generalisation are discussed.

Keywords: statistical learning, explicit knowledge, grammatical categories, artificial language, learning, generalisation.

Introduction

A key aspect of language acquisition and use is the ability to learn grammatical regularities that are present in the input, and generalise them to novel situations. Statistical learning (SL) has been suggested as one of the key mechanisms for the acquisition of grammatical regularities (Gómez & Gerken, 2000). For example, corpus studies of child directed speech have shown the presence of two statistical cues, which reliably indicate grammatical categories: phonological and distributional cues (e.g. Monaghan et al., 2005). Phonological cues consist of speech sounds which are associated with word class (e.g. in English, phoneme length can indicate a noun or a verb), and can be at the word, syllable or phoneme level. Distributional cues relate to the linguistic context within which a word usually sits, for instance where two co-occurring words (or morphemes) frame an interleaved word stem (e.g. '…is walking; Monaghan et al., 2005). Both adults and children use these cues in natural language learning and processing (e.g. Farmer et al., 2006; Lew-William & Fernald 2007; 2010). Research using artificial languages incorporating these types of cues has also shown that adults and children are able to utilise them when learning grammatical categories (e.g. Lany & Saffran, 2010; 2011; Mirković, Forest & Gaskell, 2011; Mirković & Gaskell, 2016; Frost, Monaghan & Christiansen, 2019). For example, Gómez (2002) found that both young infants (17-19 months old) and adults were able to detect and learn distributional cues and Hall, Horne and Farmer (2018) demonstrated the use of distributional cues in the learning and generalisation of grammatical categories in older children (6-9 years old).

The role of semantic cues has also been assessed. For example, in 20-month-old infants, the learning of semantic cues was supported by deterministic phonological and distributional cues for grammatical categories (Lany and Saffran, 2011), and to a lesser extent by probabilistic mappings between semantics and distributional cues (Lany, 2014). More recently, distributional cues have also been shown to enhance the learning of word-referent mappings in adults (Frost, Monaghan & Christiansen, 2019). Adults have also been shown to use semantic cues to generalise grammatical gender-like classes to previously unseen items, in a probabilistic artificial language (Mirkovic et al., 2011; Mirkovic & Gaskell, 2016).

In sum, the research on both adults and children and infants demonstrates that they can use SL to learn grammatical categories from statistical cues. Although not all studies assess generalisation of newly formed grammatical knowledge to previously unseen items, those that do show that both adults (e.g. Mirković et al., 2011) and children and infants (e.g. Lany & Saffran, 2010; 2011; Wonnacott et al., 2012) are able to do so. However, an important open question concerns the processes that support successful generalisation, and whether these processes differ in adults and children.

It is typically assumed that SL is an implicit (unconscious) process that is invariant across different ages (e.g. Aslin & Newport, 2012). However, more recent studies (Batterink et al., 2015; Franco et al, 2011; Conway & Christiansen, 2005) suggest that both implicit and explicit processes play a role in adult statistical learning. By drawing parallels between the implicit learning literature (e.g. Reber, 1967) and SL, these authors consider how 'implicit' implicit learning tasks really are in the context of SL.

To test the relative roles of implicit and explicit processes in SL, Batterink et al., (2015) incorporated on-line measures of implicit learning (reaction times and ERPs) into a word boundary SL task with adults (based on the paradigm used by Saffran et al., 1996). The results suggested that both implicit and explicit processes were involved in the detection of word boundaries. In a similar vein, Smalle et al. (2017) used a Hebb sequence-learning paradigm to examine the relative role of explicit/implicit processing in children as compared to adults. Although both adults and children showed evidence of explicit awareness of the learned sequences, there were some notable developmental differences: adults' explicit awareness emerged at an earlier point during learning than that of children. Furthermore, while explicit awareness was significantly associated with Hebb learning performance in adults, this association was not present in children. This suggests that adults were drawing on both explicit and implicit learning mechanisms during this task, while children relied on implicit learning (Smalle et al., 2017). These studies suggest that both explicit and implicit processes are involved in SL and that the relative contributions of these processes may differ between adults and children.

Current Study

The key aim of the current study was to examine the role of explicit knowledge in grammatical category generalisation, and whether this differs in children and adults. Across three experiments, participants were trained on an artificial language using phonological, distributional and semantic cues to create a grammatical gender-like noun class system (Mirkovic et al., 2011). We tested adult and school-aged child participants and examined the role of explicit knowledge in the generalisation of grammatical regularities to previously unseen items. We manipulated the type of training and the level of initial learning of the novel nouns.

The artificial language consisted of the noun "classes" based on semantic, phonological, and distributional cues. To create the semantic cues, two semantic categories were used: animals and artefacts. The phonological cues were incorporated using a "suffix" (e.g. mof*eem*). The distributional cues were incorporated as a co-occurrence of a "determiner" and a "suffix" (see Table 1 for examples). Each determiner and each suffix was paired with a semantic category (animals or artefacts). This provided an *a*X*b* structure for animals and *c*X*d* structure for artefacts, with X denoting the interleaving arbitrary stem, *a* and *c* the determiner and the *b* and *d* the suffix.

Across all studies participants were trained using a word learning task (with no reference to underpinning 'grammatical' regularities. After training, they were tested on three generalisation tasks focusing on the three different cues (explained below). Levels of emergent explicit knowledge were assessed at the end of the experiment. Experiment 1 included adults and children, while Experiments 2 and 3 included adults only. Across the three experiments, we manipulated two factors that we hypothesised would contribute to generalisation and the emergence of explicit knowledge: i) initial levels of word learning, and ii) type of training. In Experiment 1, participants were exposed to a fixed number of repetitions of the novel words at training using a word-picture matching task (WPM; Breitenstein et al., 2007), and a word repetition task. Experiments 2 and 3 used criterion learning, with adult participants matched in the level of initial word learning to the children in Experiment 1. We hypothesized that levels of initial word learning may influence generalisation performance and levels of explicit knowledge of the 'grammatical' regularities. In addition, we removed word-picture matching from the training procedure in Experiment 3, to test the hypothesis that explicit selection may contribute to the emergence of explicit knowledge of the 'grammatical' regularities. In all three experiments, we examined the extent to which generalisation performance was associated with the emergent explicit knowledge of the phonological, distributional, and semantic cues.

Table 1: Design of the noun classes

	Determiner	Suffix	Examples
animal	tib	eem	*tib* mof*eem* = dog *tib* zeap*eem* = duck
artefact	ked	ool	*ked* larsh*ool* = table *ked* snar*ool*=TV

Method

Participants

Experiment 1. Sixty-one participants took part: 31 adults with a mean age of 19.70 years (19.08-20.67 years; 1 male) and 30 children with a mean age of 10.21 years (9.67-10.82 years; 13 males). The adult sample was drawn from the undergraduate population at the University of York and received course credits for their participation. The child sample was drawn from primary schools in North Yorkshire.

Experiments 2 & 3. Thirty participants took part in Experiment 2 with a mean age of 20.77 years (18.17-32.58 years; 4 male), and thirty in Experiment 3 with a mean age of 21.09 years (18.25-31.58 years; 5 males). These two samples were drawn from the undergraduate population at the University of York and received course credits or payment for their participation.

Stimuli The training and testing tasks in all experiments used pictures drawn from Rossion and Purtois (2001) object database (281x173ppi) and artificial words created from the English database of pronounceable nonwords (Rastle et al., 2002). The artificial 'words' were constructed using the three elements described earlier (e.g. *a*X*b*) and were digitally recorded (produced by a native speaker of English). This process was based on the stimuli created by Mirković et al., (2011).

All arbitrary stem (X) elements consisted of one syllable with a CVC, CCVC or CVCC (C= Consonant, V = Vowel; 'CAT' = CVC) structure. An overall balance of CVC, CCVC

and CVCC words between the animal and artefact training words was controlled for. The stem onset phoneme did not match the onset phoneme of the English word for the animal/artefact it was paired with. The same training and generalisation sets were used in all three experiments.

Training Set: Thirty-two word-picture pairs were created (16 in each semantic category). Each word was paired with a picture, which denoted the assigned meaning of the word, providing the non-arbitrary semantic cue (see Table 1 for examples).

Generalisation Sets: Three different sets of 8 generalisation items were designed to test post-training performance on previously unseen items. Each set consisted of 4 items that were consistent with the trained regularities, and 4 items that were inconsistent. Higher endorsement rates for consistent vs inconsistent items was taken to indicate learning of the regularities.

Determiner and Suffix Generalisation. This task was designed to test learning of the mapping between the determiner and suffix, and the associated semantic category. Eight novel words were presented with novel picture pairings. The four consistent items conformed entirely to the regularities present in the training set. In the four inconsistent items, the structure of the word conformed to the training set (e.g. *tib darleem*), but it was presented with a picture from the 'wrong' semantic category (e.g. *tib darleem* was paired with an artefact, instead of an animal).

Suffix-Only Generalisation. This task tested learning of the co-occurrence between the semantic category and the suffix specifically; that is, the 'phonological' cue. The 8 novel words were presented with novel picture pairings; as before, the 4 consistent items conformed to the regularities in the training set. In the inconsistent items, the determiner 'matched' the picture, but the suffix did not match either the determiner or the picture (e.g.*tib* sen*ool* was paired with a picture of a goat; where the co-occurrence of 'tib' with the picture of an animal conformed to the training set, but the suffix 'ool' was inconsistent with both the determiner 'tib' and the semantic category of animal).

Phonological Form Generalisation. This task specifically tested learning of the co-occurrence of the determiner and suffix; that is, the 'distributional' cue. Eight novel words were presented without pictures. The 4 consistent items conformed to the regularities used in the training set. The 4 inconsistent items had a mismatch between the determiner and the suffix (e.g. *tib* jit*ool* and *ked* narp*eem*).

Procedure Participants completed all tasks in one session of approximately 40-60 minutes. Responses were recorded by the 'DMDX' programme (Forster & Forster, 2003) on a PC laptop computer. Participants were introduced to experimental tasks as a series of games involving 'alien' words introduced by a visiting extra-terrestrial. The training procedure varied across the three experiments, but they all used the same testing protocol.

Experiment 1 training:

Repetition: The thirty-two training stimuli were presented once within a block, for three blocks. Participants were instructed to look at the picture and listen to the 'alien' word and repeat the word aloud once. Participants completed this task twice.

WPM: Participants were presented with word-picture pairs and were instructed to judge if they thought the word and picture '*went well together'*. Participants were exposed to all 32 word-picture pairs once. In addition, 16 of the word items were presented again paired with a different picture from the same semantic category (mismatch trials) for the 'incorrect' response. The participant responded using keys on the computer keyboard: a "happy face" if they thought the picture and word went well together and a "sad face" if they did not. Participants completed this task twice.

Experiment 2 training:

Repetition and WPM: For this experiment, the repetition and WPM tasks were merged. In each block, participants were exposed to all 32 word-picture pairs once. In addition, 8 mismatch trials were included, in which the word items were paired with an incorrect picture from the same semantic category. Participants were instructed to look at the picture and listen to the 'alien' word and repeat it aloud once. They then pressed the space bar and then judged if the word and picture '*went well together'* using the same WPM response procedure from Experiment 1.

Each training block was followed by a word-learning test (described below). Training ended when the participant reached the same level of accuracy as that of the children in Experiment 1 (75%).

Experiment 3 training:

Repetition Only: The training set for Experiment 3 was the same as that for Experiment 2, including criterion learning. However, the training procedure was different in that it did not include WPM: participants had only to repeat the training items.

All Experiments: Testing

Word Learning –Two Alternative Forced Choice (2AFC): This task tested learning of the novel words. Each word was randomly presented once and was accompanied by the simultaneous presentation of two pictures (on either side of the screen), one of which was the correct trained picture. The 'foil' picture was drawn from the trained pictures and was from the same semantic category. Participants responded using keys on the computer keyboard which corresponded to the on-screen picture presentation position.

Generalisation: "Determiner and Suffix" and "Suffix Only" Generalisation. In both these tasks, participants were instructed to attend to 'alien*'* word and picture pairings (from the respective generalisation sets) and judge if they thought they '*went well together',* pressing the happy or sad face accordingly.

"Phonological Form": Participants were instructed to listen to the 'alien' words from the generalisation set and asked to judge if the words '*went well with'* the 'alien' language they

had been listening to, pressing the happy or sad face accordingly.

Explicit Knowledge Questionnaire: Once all tasks were completed, participants were asked *'Did you notice anything about the alien language? Did you use any kind of strategies or clues to decide whether the word and the picture matched?'* Answers were recorded manually and a score from 0-3 was given separately for determiner and suffix knowledge: 0 for no reference to the morpheme or semantic dependency, 1 for knowledge of the morpheme but not the dependent semantic cue, 2 for partial knowledge of the morpheme and semantic dependency and 3 for full knowledge.

Results and Discussion

Word Learning: We examined the level of word learning in the three experiments by analysing performance on the 2AFC task at the end of training. One-sample t-tests against chance (.5) showed that all groups learned the novel words. (Experiment 1 adults, $t(30)=28.93$, $p<.001$; children, $t(29)=9.10$, $p<.001$; Experiment 2 adults, $t(29)=21.17$, $p<.001$; Experiment 3 adults, $t(29)=21.83$, $p<.001$; Figure 1). Adult participants in Experiments 2 and 3 were trained to the criterion matching the levels of child word learning in Experiment 1. To confirm that the word learning across the three studies matched as intended, we ran two multiple regressions with 2AFC performance as the outcome variable and group as the predictor variable coded using Helmert contrasts. The first set of contrasts showed that, as expected, adults learned more words in Experiment 1 (Adults1) than in Experiments 2 (Adults2) and 3 (Adults3; $\beta=0.68$, $p<.001$), and that there was no difference between the latter two ($p=.293$). The second set of contrasts showed that Adults2 ($p=.341$) and Adults3 ($p=.757$) learnt an equivalent number of words to the children in Experiment 1 (Children1). These findings show that all participants demonstrated word learning. Crucially, these results indicate that criterion learning method used in Experiments 2 and 3 was successful at reducing the level of adult participants' word-learning to that of the child participants in Experiment 1.

Generalisation Tasks To analyse performance in the generalisation tasks, we derived an A' metric based on the endorsement rates for consistent and inconsistent trials (Pallier, 2002). A' scores above 0.5 were taken as indication that a participant could reliably endorse consistent trials more often than inconsistent trials, demonstrating learning of the regularities.

"Determiner and Suffix": Figure 2 shows levels of generalisation performance for all groups on this task. One-sample t-tests showed that only Adults1 performed significantly above 0.5 ($t(30)=6.13$, $p<.001$). Thus, only this group demonstrated learning and generalisation of the mapping between the determiner and suffix, and the semantic category.

Using the same set of contrasts as in the analysis of word learning, with A' performance as the outcome variable and group contrasts as the predictor variables, group comparisons further confirmed that Adults1 were significantly better at generalising this regularity than Adults2 and Adults3 ($\beta=0.30$, $p<.004$). There was no difference between the Adults2 and Adults3 ($p=.703$), nor between Children1 and Adults2 ($p=.451$) or Adults3 ($p=.916$).

"Suffix Only": Figure 3 shows generalisation performance for all groups on this task. One-sample t-tests demonstrated that Adults1 ($t(30)=3.45$, $p<.001$) and Adults2 ($t(29)=1.97$, $p=.029$) performed significantly above an A' of 0.5. Children1 ($p=.762$) and Adults3 ($p=.500$) did not. Therefore, only Adults1 and Adults2 showed learning and generalisation of the mapping between the semantic category and the suffix (the phonological cue).

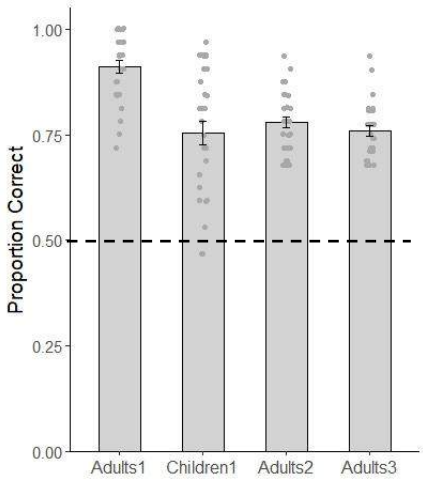

Figure 1: Word Learning: Accuracy on the 2AFC task at the end of training.

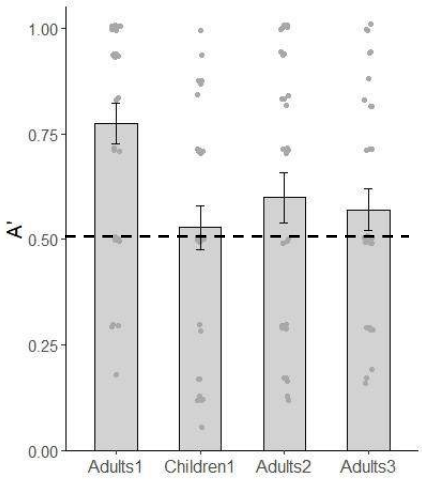

Figure 2: Performance on the "Determiner & Suffix" Generalisation Task

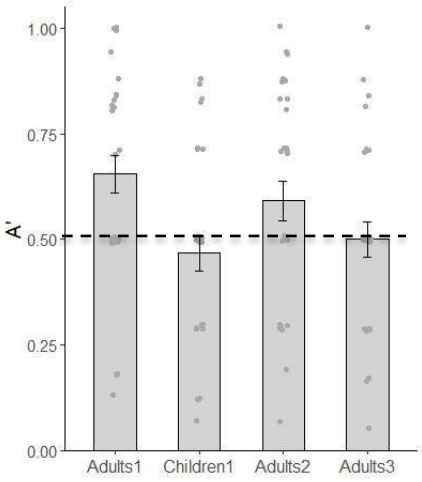

Figure 3: Performance on the Suffix Only Generalisation Task

Group comparisons showed differences between Adults 1 compared to Adults2 and Adults3 (β=0.25, p=.044) and between Children1 and adults 2 (β=0.35, p<.044). There was no difference between Adults 2 and 3 (p=.148) or between Children1 and Adults3 (p=.581).

"Phonological Form": As illustrated in Figure 4, participants in all groups and experiments performed at a similar level. One-sample t-tests demonstrated that only Adults1 performed significantly above 0.5 (t(30)=2.93, p<.001). Thus, only this group showed evidence of learning and generalising the co-occurrence between the determiner and the suffix (the distributional cue).

The group comparisons showed there was no evidence of a differences in generalisation across the three experiments, or between adults and children (Adults1 vs. Adults2&3, p=.083; Adults2 vs. Adults3, p=.294; Children1 vs. Adults2, p=.513;

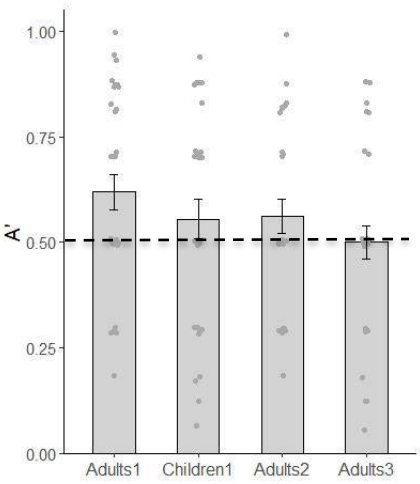

Figure 4: Performance on the "Phonological Form" Generalisation Task

Children1 vs. Adults3, p=.268). These results show only weak evidence for the learning and generalisation of the determiner + suffix co-occurrence in this paradigm.

In summary, only adults in Experiment 1 demonstrated the ability to utilise all three statistical cues to generalise newly formed grammatical knowledge. Their performance was reliably different from that of children, and of adults in Experiments 2 and 3, when generalising the trained cues to novel exemplars.

Given that Adults2 and Adults3 show the same level of word learning as Children1, this result suggests that the level of word learning may be a driver of grammatical generalisation and as such may explain some of the difference seen between adults and children in Experiment 1. This finding aligns with Bates and Goodman's (1997) lexicalist theory, which proposes that the emergence of grammar depends on lexical learning.

Although the lack of generalisation in children found here is in contrast to some previous studies in the literature (e.g. Hall et al., 2018; Lany & Saffran, 2010; 2011), this may be due to a number of factors, including the nature of the training and the structure and complexity of the regularities. In the current study, the training tasks always included simultaneous presentation of the referent with the novel words, unlike e.g. Lany and Saffran (2010; 2011) and Lany (2014), who trained participants on the phonological word form before introducing the referent, and Hall et al., (2018), who trained participants on a language that did not include a referent. Moreover, the simultaneous presentation of all noun class cues (phonological, distributional, and semantic) in the current study may have increased the complexity of the task, and affected the relative salience of the cues. Thus, further research exploring these methodological differences would help to clarify the role of semantic cues, and the effects of sequential vs simultaneous presentation of different type of cue.

Explicit Knowledge: Contributions to Generalisation

Table 2 shows the explicit knowledge scores for each group, presented separately for each morpheme. These scores suggest greater explicit knowledge for determiners than for suffixes across all groups/experiments.

A key aim in the current study was to assess the extent to which explicit knowledge contributes to generalisation performance, and whether this contribution differs in children and adults. We were specifically interested not in the group differences between children and adults (as children may be less able to verbalise their knowledge), but in the extent to which individual variation in the levels of explicit knowledge

Table 2: Descriptive Statistics for Explicit Knowledge Scores

	Determiner		Suffix	
	M	*SD*	*M*	*SD*
Adults1	2.39	1.02	0.58	1.03
Children1	0.70	1.11	0.10	0.31
Adults2	1.20	1.19	0.33	0.76
Adults3	1.50	1.17	0.23	0.63

within each group contributes to generalisation performance. To address these questions, multiple regressions were carried out for each generalisation task. The outcome variable in each regression was the A' score, while explicit knowledge scores for the relevant morpheme(s) were the predictor(s). For example, in the "phonological form" and "suffix only" generalisation tasks, only knowledge of the suffix was necessary for successful performance, so only suffix knowledge was used as a predictor, while for the "determiner and suffix" task, knowledge of both determiner and suffix was relevant.

As illustrated in Table 3, for adults in Experiment 1 explicit knowledge of the regularities was a significant predictor of generalisation performance in the "determiner & suffix" and "suffix only" tasks, but not in the "phonological form" task. Explicit knowledge of the relevant morpheme facilitated performance in the generalisation tasks. The strongest effect was for knowledge of the determiner-semantic mapping, which accounted for 27% of the variance in the 'determiner & suffix' task. In contrast to the adults, explicit knowledge of the regularities in children did not significantly predict performance in any of the generalisation tasks.

The pattern of results in Experiment 2 provides an informative comparison because the adults in this group showed low levels of generalisation (comparable to children), and intermediate levels of explicit awareness. Nonetheless, variability in generalisation within this group was significantly predicted by explicit awareness of the relevant morphemes. As with adults in Experiment 1, the strongest effect was for knowledge of the determiner-semantic mapping, which in this case accounted for an even larger proportion (38%) of the variance in the 'determiner & suffix' task. Finally, the adults in Experiment 3, showed low levels of generalisation as well as low levels of explicit knowledge. In this case, and similarly to the children in Experiment 1, there was no clear evidence of facilitatory effect of explicit knowledge on generalisation performance. This may suggest that the use of the WPM training task could prompt the emergence and correct use of explicit knowledge, at least in adults.

Overall these results suggest a partial role for explicit knowledge in grammatical generalisation for adults but not children. This still seems to hold when adults demonstrate similar levels of word learning and generalisation to children, suggesting that there may be differences in the extent to which adults and children draw on explicit processes when generalising in a grammatical SL task.

Conclusion

The current set of experiments demonstrates that explicit knowledge plays a role in grammatical category generalisation in adults but not children. This may be partially due to children's lower level of word knowledge, given the lower level of generalisation performance in adults when levels of word knowledge were matched to those of children. However, adults with a lower level of word knowledge still demonstrated a partial involvement of explicit knowledge in the generalisation tasks. This suggests the possibility of developmental differences between adults and children in the role of explicit and implicit processes when generalising in SL tasks. In future studies, more sensitive measures that do not rely on verbal reports would provide further insights into the contributions of explicit knowledge in implicit learning tasks across development.

Table 3: Multiple Regressions for the Role of Explicit Morpheme Knowledge on Generalisation Performance.

Abstract

Speech-acts can have literal meaning as well as pragmatic meaning, but these both involve consequences typically *intended* by a speaker. Speech-acts can also have *unintentional meaning*, in which what is conveyed goes above and beyond what was intended. Here, we present a Bayesian analysis of how, to a listener, the meaning of an utterance can significantly differ from a speaker's intended meaning. Our model emphasizes how comprehending the intentional *and* unintentional meaning of speech-acts requires listeners to engage in sophisticated model-based perspective-taking and reasoning about the *history* of the state of the world, each other's actions, and each other's observations. To test our model, we have human participants make judgments about vignettes where speakers make utterances that could be interpreted as intentional insults or unintentional *faux pas*. In elucidating the mechanics of speech-acts with unintentional meanings, our account provides insight into how communication both functions and malfunctions.

Keywords: Bayesian modeling, social cognition, common ground, speech-act theory, faux pas, theory of mind

Introduction

People sometimes communicate things that they did not intend or expect. Consider the following vignette, adapted from Baron-Cohen et al. (1999):

> **Curtains** Paul had just moved into a new apartment. Paul went shopping and bought some new curtains for his bedroom. After he returned from shopping and had put up the new curtains in the bedroom, his best friend, Lisa, came over. Paul gave her a tour of the apartment and asked, "How do you like my bedroom?"
>
> "Those curtains are horrible," Lisa said. "I hope you're going to get some new ones!"

Clearly, Lisa committed a social blunder or *faux pas* with her remark. What happened here? When Lisa says, "Those curtains look horrible," she is merely stating her private aesthetic experience of the curtains. The *literal* meaning is straightforward: The curtains look bad. And the *intended* or *expected* meaning of her utterance is largely captured by this literal meaning. However, to Paul, the utterance means more. Specifically, what Lisa is *really* saying is that *he* chose horrible curtains. Of course, Lisa did not "really" say that Paul's choice in curtains was horrible—she had no intention of conveying such an idea. Paul might even realize this. Nonetheless, the remark stings. Why? Lisa and Paul each possess a piece of a puzzle, and when put together, they entail that Paul has awful taste in curtains. At the outset, neither one knew that they each had a piece of a puzzle. But once Lisa makes her remark, she inadvertently completes the puzzle, at least from Paul's perspective.

Standard models of communication (Grice, 1957; Sperber & Wilson, 1986) tend to focus on how people use language successfully. For example, people can imply more than they literally mean (Carston, 2002), convey subtle distinctions via metaphor (Tendahl & Gibbs Jr, 2008), and manage their own and others' public face using politeness (Levinson, Brown, Levinson, & Levinson, 1987; Yoon, Frank, Tessler, & Goodman, 2018). But things do not always go smoothly, as Paul and Lisa's situation indicates. Sometimes people find themselves having inadvertently stepped on conversational landmines, meaning things that they never anticipated meaning. Notably, because such situations present complex dilemmas of mutual perspective-taking against a backdrop of divergent knowledge, they can serve as advanced tests of theory of mind (Baron-Cohen et al., 1999; Zalla, Sav, Stopin, Ahade, & Leboyer, 2009; Korman, Zalla, & Malle, 2017). But how do people reason about such dilemmas? And how can this be understood computationally? Disentangling unintentional meaning can shed light on how communication works in a broader social context as well as inform the design of artificial intelligences that interact with people.

Here, we develop a rational, cognitive account of interpreting unintentional speech-acts that builds on existing Bayesian models of language (e.g., Rational Speech Act [RSA] models [Goodman & Frank, 2016]). To do this, we analyze the general epistemic structure of social interactions such as the one described above and model listeners engaging in *model-based perspective-taking*. In particular, our model explains how the same utterance could be interpreted as either an (unintentional) *faux pas* or an *intentional insult* depending on the context of a listener and speaker's interaction. We then test several model predictions in an experiment with human participants. In the following sections, we outline our computational model, experimental results, and their implications.

A Bayesian Account of Unintentional Meaning

During social interactions, people reason about the world as well as each other's perspective on the world (Brown-Schmidt & Heller, 2018). Thus, our account has two components, which we formulate as probabilistic models. First, we specify a *world model* that captures common-sense relationships between world states, actions, and events. Second, we define *agent models* of a speaker and listener reasoning about the world and one another.

World Model

We model the interaction as a partially observable stochastic game (POSG), a generalization of Markov Decision Processes (MDPs) with multiple agents with private observations (Kuhn, 1953). Formally, a world model $\mathcal{W} = \langle I, \mathcal{S}, \mathcal{A}, \mathcal{Z}, \mathcal{T} \rangle$ where:

- I is a set of n agents indexed $1, ..., n$;
- $\mathcal{S}$ is a set of possible states of the world, where each state $s \in \mathcal{S}$ is an assignment to k variables, $s = (x_0, x_1, ..., x_k)$;
- $\mathcal{A} = \times_{i \in I} \mathcal{A}^i$ is the set of joint actions, i.e., every combination of each agent i's actions, $\mathcal{A}^i$ (including utterances);
- $\mathcal{Z} = \times_{i \in I} \mathcal{Z}^i$ is the set of joint private observations, which is every possible combination of each individual agent i's private observation set, $\mathcal{Z}^i$; and
- $\mathcal{T} = P(z, s' \mid s, a)$ is a transition function representing the probability of a joint observation z and next state s' given a previous state $s \in \mathcal{S}$ and joint action $a \in \mathcal{A}$ was taken.

In **Curtains**, the initial state, s_0, includes Paul with the old curtains in the apartment and Lisa elsewhere. There is also a latent state feature of interest: whether Paul has good or bad taste. At $t = 0$, Paul's action, a_0^{Paul}, is choosing new curtains, while Lisa's action, a_0^{Lisa}, is going to the apartment. The joint action, $a_0 = (a_0^{\text{Paul}}, a_0^{\text{Lisa}})$, results in a new state, s_1, with them both in the apartment, the curtains either good or bad, and Paul's taste. Paul's observation, z_0^{Paul}, but not Lisa's, z_0^{Lisa}, includes Paul having put up the curtains. These relationships between world states (e.g. Paul and Lisa's locations), actions (e.g. Lisa walking to Paul's apartment), and observations (e.g. Paul observing himself put up the curtains) are formally encoded in the transition function $\mathcal{T}$. The sequence of states, joint actions and observations resulting from such interactions constitute the *history* up to a point t, $\vec{h}_t = (s_0, a_0, z_0, ..., s_{t-1}, a_{t-1}, z_{t-1}, s_t)$.

Agent Models

Agents are modeled as Bayesian decision-makers (Bernardo & Smith, 1994) who can reason about the world and other agents as well as take actions—including making utterances.

Interactive Belief State Agents' beliefs are probability distributions over variables that represent aspects of the current state, previous states, or each other's beliefs. The configuration of these first- and higher-order, recursive beliefs constitute their *interactive belief state* (Gmytrasiewicz & Doshi, 2005). We refer to an agent i's beliefs as b^i. For example, if we denote Paul's taste as the variable T^{Paul}, then Paul's belief that his taste is good is $b^{\text{Paul}}(T^{\text{Paul}} = \texttt{Good})$. Higher-order beliefs can also be represented. For instance, we can calculate Paul's *expectation* of Lisa's belief in his taste as $\mathbb{E}_{b^{\text{Paul}}}[b^{\text{Lisa}}](T^{\text{Paul}}) = \sum_{b^{\text{Lisa}}} b^{\text{Paul}}(b^{\text{Lisa}}(T^{\text{Paul}}))$.

An agent i's beliefs are a function of their prior, model of the world, model of other agents, and *observation history* up to time t, $\vec{z}_t^{\,i}$. Note that $\vec{z}_t^{\,i}$ can include observations that are completely private to i (e.g., Lisa's personal aesthetic experience) as well as public actions and utterances (e.g., Lisa's remark to Paul). Thus, we denote Paul's belief about his taste at a time t as $b_t^{\text{Paul}}(T^{\text{Paul}}) = b^{\text{Paul}}(T^{\text{Paul}} \mid \vec{z}_t^{\text{Paul}})$. Given a sequence of observations, $\vec{z}_t^{\,i}$, posterior beliefs about a variable X are updated via Bayes' rule:

$$b(X \mid \vec{z}_t^{\,i}) \propto b(\vec{z}_t^{\,i} \mid X) b(X) \tag{1}$$

$$= \sum_{\vec{h}_t} b(\vec{z}_t^{\,i} \mid \vec{h}_t) b(\vec{h}_t, X) \tag{2}$$

The capacity to reason about higher-order beliefs (e.g., Paul's beliefs about Lisa's belief in his taste), along with Equation 2 express agents' joint inferences about events and model-based perspective-taking.

Speaker Model Speakers have beliefs and goals. When choosing what to say, they may have beliefs and goals with respect to the listener's beliefs and goals. In our example, Lisa may care about being informative about how she sees the curtains, but may also think Paul cares about having good taste in curtains and care whether she hurts his feelings. Following previous work (e.g., Franke, 2009), we model speakers as reasoning about changes in *belief states*. Here, we are interested in how a speaker can intend to mean one thing but inadvertently mean another. Thus, we distinguish between state variables that the speaker wants to be *informative* about, X^{Info} (e.g., how Lisa sees the curtains), and *evaluative* variables, X^{Eval}, that the listener wants to take on a specific value $x^{\text{Eval}*}$ (e.g., Paul's taste being good). The speaker then cares about the changes in those quantities. Formally:

$$\Delta_t^{\text{L-Info}} = b_{t+1}^L(X^{\text{Info}} = x^{\text{Info}}) - b_t^L(X^{\text{Info}} = x^{\text{Info}}), \tag{3}$$

where x^{Info} is given by $\vec{h}_t$; and,

$$\Delta_t^{\text{L-Eval}} = b_{t+1}^L(X^{\text{Eval}} = x^{\text{Eval}*}) - b_t^L(X^{\text{Eval}} = x^{\text{Eval}*}). \tag{4}$$

A speaker who is interested in what the listener thinks about X^{Info} and X^{Eval} will, at a minimum, anticipate how their utterances will influence $\Delta_t^{\text{L-Info}}$ and $\Delta_t^{\text{L-Eval}}$. A speaker would then have a reward function defined as:

$$R^{\text{S}}(a_t^S, \vec{z}_{t+1}^L) = \theta^{\text{L-Info}} \Delta_t^{\text{L-Info}} + \theta^{\text{L-Eval}} \Delta_t^{\text{L-Eval}} \tag{5}$$

where the θ terms correspond to how the speaker values certain outcomes in the listener's mental state. For instance, if $\theta^{\text{L-Eval}} < 0$, the speaker *wants* to insult the speaker.

Given Equation 5, a speaker can take utterances based on expected future utility/rewards (or *value* [Sutton & Barto,

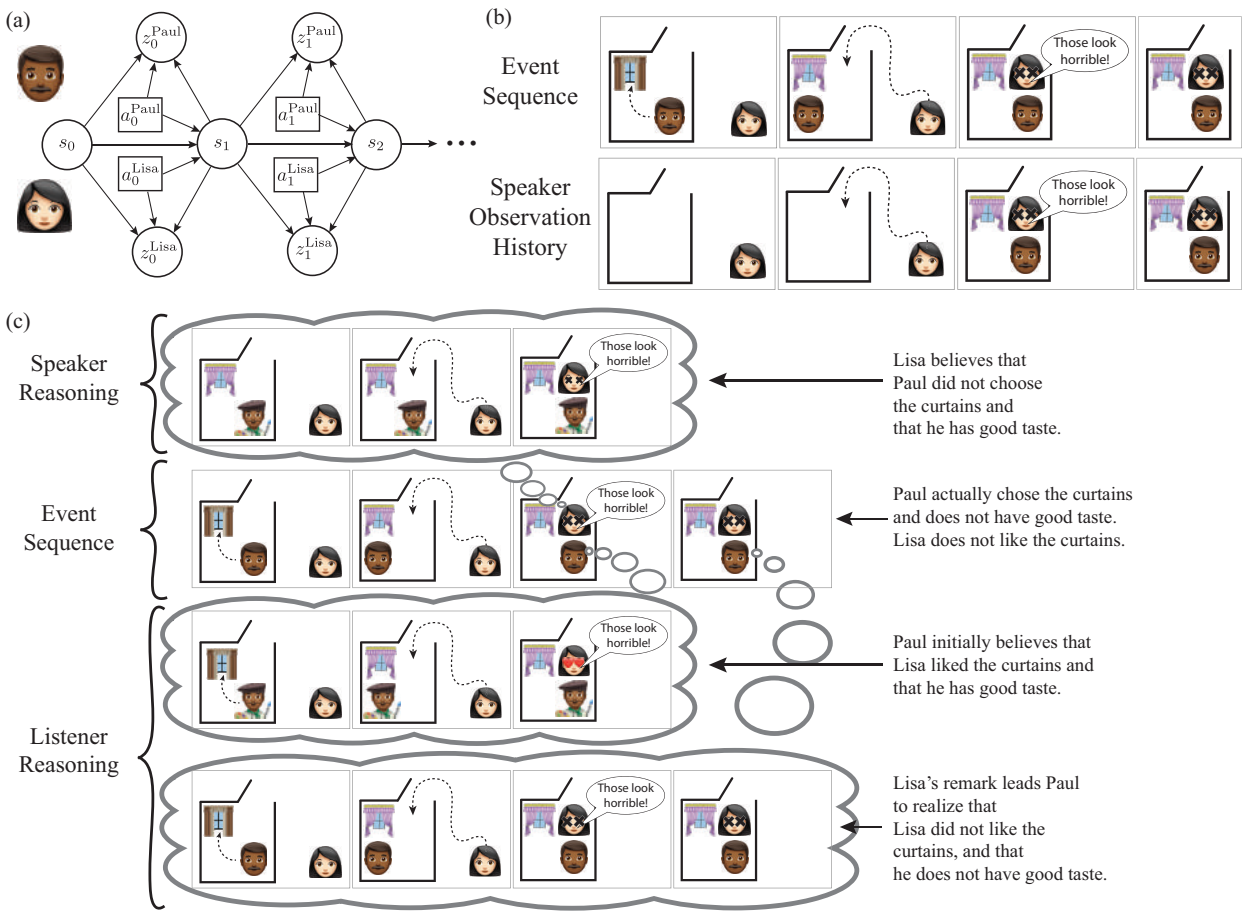

Figure 1: Model and example of unintentional meaning. (a) Influence diagram with state, action, and observation dependencies. Circles correspond to world state (e.g., s_t) and observation (e.g., z_t^i) variables; squares correspond to agent action variables (including utterances) (e.g., a_t^i). (b) Event sequence in **Curtains** (top) and speaker observation history (bottom). Lisa does not observe Paul choose the curtains. Only Lisa experiences whether the curtains look good or bad and comments on this experience. (c) Diagram of interactive belief state over time in **Curtains**.

1998]), where the expectation is taken with respect to the speaker's beliefs, b_t^S. That is, given observations $\vec{z}_t^S$, the value of a_t^S is $V^S(a_t^S; \vec{z}_t^S) = \mathbb{E}_{b_t^S}\left[R^S(a_t^S, \vec{z}_{t+1}^L)\right]$, and an action is chosen using a Luce choice rule (Luce, 1959).

Listener Inference Our goal is to characterize how a listener's interpretation of an utterance can differ from a speaker's intended meaning, which requires specifying listener inferences. We start with a simple listener that understands the literal meanings of words when spoken. Following previous models (Franke, 2009; Goodman & Frank, 2016), the literal meaning of an utterance a^S is determined by its truth-functional denotation, which maps histories to Boolean truth values, $[\![a^S]\!] : \vec{h}_t \mapsto y$, $y \in \{\texttt{True}, \texttt{False}\}$. A literal listener's model of speaker utterances is:

$$b(a^S \mid \vec{h}_t) \propto \begin{cases} 1-\varepsilon & \text{if } [\![a^S]\!](\vec{h}_t) \\ \varepsilon & \text{if } \neg[\![a^S]\!](\vec{h}_t) \end{cases}$$

where ε is a small probability of a^S being said even if it happens to be false.

We can also posit a more sophisticated listener who, rather than assuming utterances literally reflect reality, reason about how a speaker's beliefs and goals mediate their use of language. This type of listener draws inferences based on an *intentional* model of a speaker that track the quantities in Equations 3 and 4 as well as maximize the expected rewards. These inferences, however, occur while the listener is also reasoning about the actual sequence of events $\vec{h}_t$, making it possible to draw inferences based on utterances that the speaker did not anticipate.

Model Simulations

In the original **Curtains** scenario, Lisa was not present when Paul put up the curtains. As a result, Lisa's comment ("Those curtains are horrible") is interpreted in a *diverging* observation history context. But what if Lisa had been present when Paul put up the curtains and made the same utterance? Given a *shared* observation history, Lisa's utterance is still offensive, but now Lisa has all the information needed to realize it would be offensive. Put simply, in the *diverging history* con-

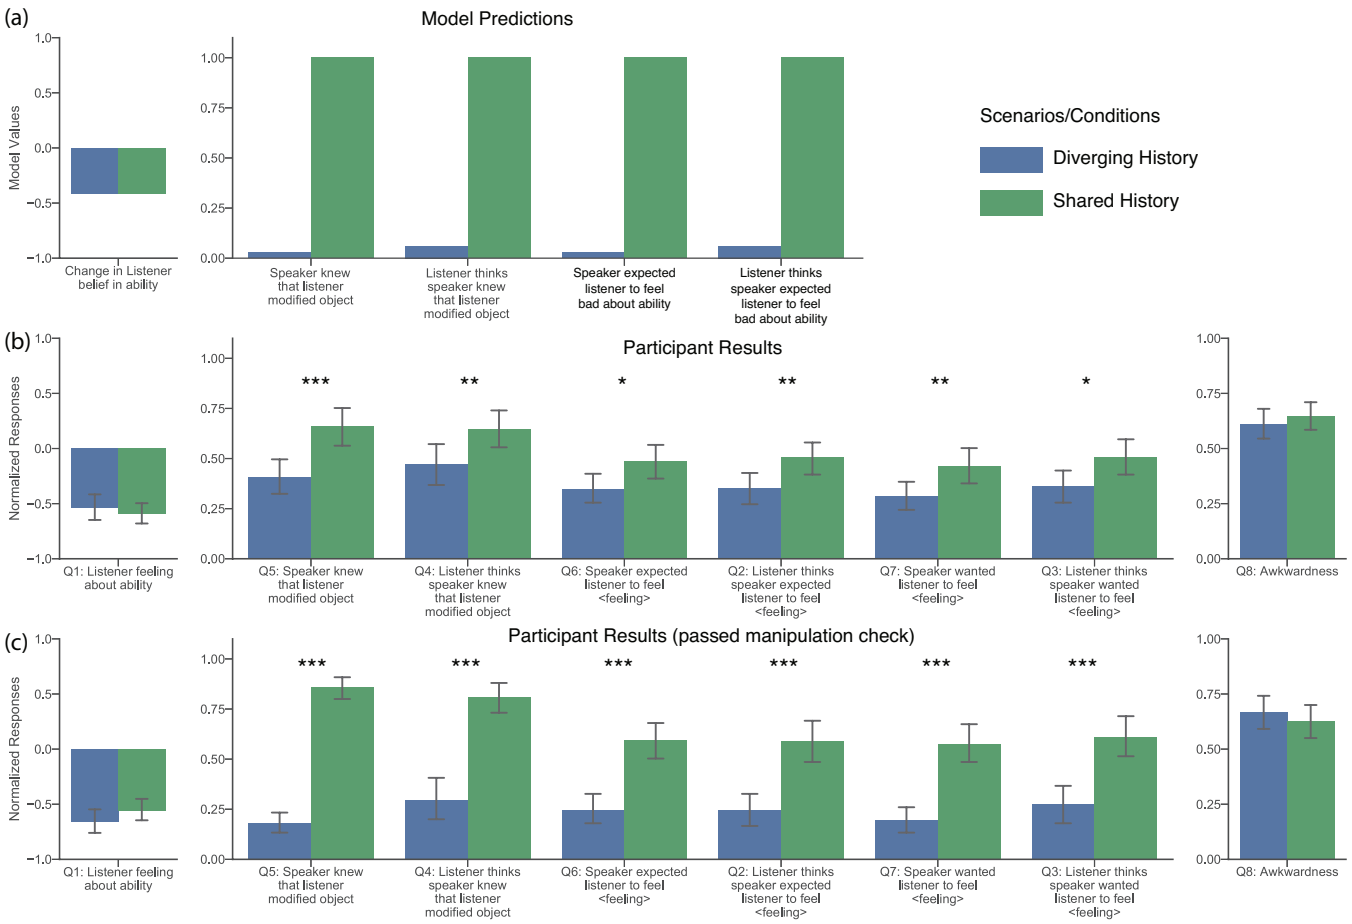

Figure 2: (a) Model predictions. The model predicts that the listener's change in belief in the evaluative variable ($\Delta_t^{\text{L-Eval}}$) is equally negative in the diverging and shared history scenarios. However, whether the speaker anticipated the offensiveness of their comment differs between the two scenarios, as do the listener's beliefs about the speaker's anticipation. (b) Judgments from all participants by question. Responses were normalized depending on whether response scales were valanced (Q1), likelihood (Q2-Q7), or qualitative (Q8). (c) Judgments from participants who correctly identified whether the speaker knew the listener modified the object. * : $p < .05$, ** : $p < .01$, *** : $p < .001$.

text, the utterance is a faux pas, whereas in the *shared history* context, it is an intentional insult.

In this section, we discuss how our model can be used to make these intuitive predictions precise and explain how they arise from agents' interactions and model-based perspective-taking within a shared environment. We implemented our model in WebPPL (Goodman & Stuhlmüller, 2014), a programming language that can express stochastic processes like POSGs as well as Bayesian inference.

Generative Model

To model a scenario like **Curtains**, we define agents, objects, and features assigned to them. These are the curtains, which have a location (inside Paul's apartment); the speaker (Lisa), who has a location (inside or outside Paul's apartment) and a perception of the curtains (good or bad); and the listener (Paul), who has a location (inside or outside) and ability to choose curtains (high or low). Additionally, the listener can either act on the curtains or not, while the speaker can enter the apartment and make an utterance about the curtains ("the curtains look good", "the curtains look bad", or `<nothing>`). The truth-conditional semantics of the utterances map onto world features in a standard manner, and we set $\varepsilon = .05$.

Observations depend on whether agents and objects are co-located and are defined as subsets of state and action variables. For instance, if Paul and Lisa are both inside the house and Paul modifies the curtains, they both observe that Paul acted on the curtains, but only Lisa directly knows whether they look good to her. Finally, we define a state and action prior for both agents such that the listener's ability is initially high ($p = 0.90$), the speaker's perception of the object is initially random ($p = 0.50$), and the listener has a low probability of modifying the object ($p = 0.05$).

Model Predictions

Given the generative model, we can provide scenarios and calculate aspects of the resulting interactive belief state (the listener and speaker's beliefs about the world and each other's

beliefs). In particular, we compare the results of a *shared history* with those of a *diverging history*. In the shared history, the speaker and listener are both present when the listener modifies the object, whereas in the diverging history, the speaker is not present when the listener acts on the object. Otherwise, the two scenarios are the same and the speaker comments on the curtains being bad. Figure 2a displays the results of the simulation when given each of the two histories. In both histories, the listener learns that their ability when modifying the object, X^{Eval}, is low (i.e., $\Delta_t^{\text{L-Eval}} < 0$). They also learn about the informative variable (i.e., $\Delta_t^{\text{L-Info}} > 0$).

However, the resulting interactive belief states differ in important ways. For example, in the diverging history, although the listener concludes that the evaluative variable is *low*, the speaker thinks the evaluative variable is *high*. Relatedly, the speaker thinks the utterance was informative ($\mathbb{E}_{b^S}[\Delta^{\text{L-Info}}] > 0$) but not offensive ($\mathbb{E}_{b^S}[\Delta^{\text{L-Eval}}] = 0$). Moreover, the listener knows the speaker believes that their comment was expected to be informative and not offensive. In the shared history, this is not the case: The listener and speaker both believe the evaluative variable is low, and they both know the resulting informational and evaluative effects. Because they were both present when the listener modified the object, they share expectations about the utterance's meaning.

Put intuitively, whereas the shared history leads to an *expected insult*, the diverging history leads to a *faux pas*. Our model explains this difference in terms of differential transformations of the listener and speaker's interactive belief state.

Experiment

Our model explains how different observation histories result in interactive belief states, which can produce unintentional meaning. To test whether this accurately describes people's capacity to reason about unintentional meaning, we had people read vignettes that described scenarios involving shared or diverging observation histories. The underlying logical structure of all the vignettes mirrored that of **Curtains**, and so the model predictions described in the previous section apply to all of them. Participants then provided judgments corresponding to predicted differences in listener/speaker beliefs. The study's main hypotheses were preregistered on the Open Science Framework platform (`https://osf.io/84wqn`). Overall, we find that our model captures key qualitative features of people's inferences.

Materials

We developed a set of vignettes that included interactions in different contexts as well as different histories of interaction. Each vignette involved a listener (e.g., Paul) who could potentially interact with an object (e.g., curtains) as well as a speaker (e.g., Lisa) who makes an utterance about their negative aesthetic experience of the object (e.g., "The curtains look horrible"). In the shared history versions of the vignettes, the two agents were described as being both present when the listener acted on an object. In the diverging history versions of the vignettes, the speaker was not present when the listener interacted with the object. Each vignette involved one of five contexts: *Curtain*, *Story-Prize*, *Wine-bottle*, *Cupcakes*, and *Parking*. Thus there were a total of ten items (Diverging/Shared history $\times$ 5 contexts). All items used in the experiment are available on the primary author's website.

Procedure

One-hundred participants were recruited via MTurk to participate in our experiment using PsiTurk (Gureckis et al., 2016). Each participant read one of the ten context-history items, and then answered the following questions in order:

- Q1: At this point, how does `<listener>` feel about their ability to `<action>`? [6 point scale ranging "Very Bad" to "Very Good" with no neutral option]
- Q2: `<listener>` thinks that `<speaker>` expected that their remark would make them feel `<Q1_response>`.
- Q3: `<listener>` thinks that in making the remark, `<speaker>` wanted to make them feel `<Q1_response>`.
- Q4: `<listener>` thinks that `<speaker>` thinks that `<listener>` `<action>`.
- Q5: `<speaker>` knew that `<listener>` `<action>`.
- Q6: In making the remark, `<speaker>` expected `<listener>` to feel `<Q1_response>`.
- Q7: In making the remark, `<speaker>` wanted `<listener>` to feel `<Q1_response>`.
- Q8: How awkward is this situation? [5 point scale ranging "Not at all" to "Extremely"

The values for `<listener>`, `<speaker>`, and `<action>`were specified parametrically based on the context, while the value for `<Q1_response>` was filled in based on the answer to the first question. The response scale for questions 2-7 was a six-point scale ranging from "Definitely Not" to "Definitely", with no neutral point. We included question 8 because previous work studying faux pas have focused on this question (Zalla et al., 2009). Participants were also given free response boxes to elaborate on their interpretation of the situation and answered demographic questions.

Experimental Results

Manipulation check To assess whether the Diverging/Shared history manipulation worked, we examined responses to Q5 (whether the speaker knew the listener acted on the object). A comparison in which the responses were coded

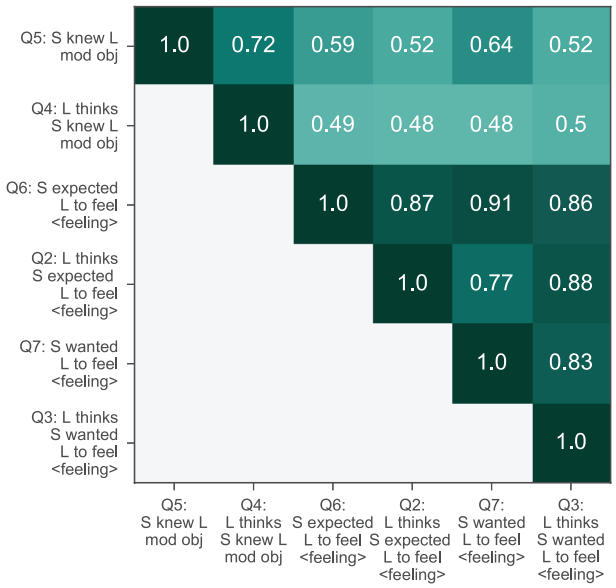

Figure 3: Judgment correlations (Pearson's r).

as Yes or No (i.e., above or below the middle of the response scale) showed that it was effective ($\chi^2(1) = 7.92, p < .01$). However, a number of participants (15 of 50 in Shared; 20 of 50 in Diverging) did not pass this manipulation check and gave opposite answers than implied by the stories. Whether their responses are included does not affect our qualitative results, and in our analyses we use the full data set. Figure 2c plots the results for those who passed this check.

Judgment differences Responses paralleled the model predictions for the Shared versus Diverging history versions of the vignettes (Figure 2b). For each judgment, we fit mixed-effects linear models with context intercepts as a random effect and history as a fixed effect. Table shows tests of significance on the Diverging/Shared history parameters. Judgments about the listener's feelings (Q1) were negative and not significantly different, indicating that people perceived the psychological impact (at least with respect to ability) of the utterance as roughly equivalent. In contrast, questions about the interactive belief state—the listener and speaker's beliefs about the world and each other's beliefs (Q2-Q7)—differed as predicted by the model. In particular, participants thought that the speaker neither expected that their utterance would hurt the listener's feelings, nor that they wanted to do so. Participants judged that the listener recognized this as well.

Judgment correlations Judgments among questions about higher order mental states were strongly correlated, while those between the higher order mental states and the listener's action were weaker (Figure 3). Specifically, those about speaker mental states (Q6, Q7) and listener beliefs about speaker mental states (Q2, Q3) were all highly correlated (all $r \in [0.77, 0.91], p < .001$). In contrast, questions about knowledge of the object being modified (Q4, Q5) were only moderately correlated with those about anticipated effects (Q2, Q3, Q6, Q7) (all $r \in [0.48, 0.64], p < .001$).

Discussion

People's actions can have unexpected consequences, and speech-acts are no different. To understand unintentional meaning though, we need to characterize how a communicative act can lead to unanticipated epistemic consequences. Sometimes, a listener can learn something from an utterance that a speaker did not intend to convey or may not even believe (e.g., as in **Curtains**). Here, we have presented a Bayesian model and experiments testing how people reason about scenarios involving unintentional speech acts. Specifically, our account treats speech-acts as actions taken by a speaker that influence a shared interactive belief state—the beliefs each agent has about the world and each other's beliefs. In doing so, we can capture the inferences that underlie unintentional meaning.

The current work raises important empirical and theoretical questions about how people reason about interactive beliefs and unintentional meaning. For instance, our experiments focus on third-party judgments about how a listener interprets the unintended meanings of utterances, but further work would be needed to assess how listeners do this (e.g., when the victim of an offhand comment) or even how speakers can recognize this (e.g., realizing one has put their foot in their mouth). Additionally, we have presented a Bayesian account of unintentional meaning in which agents reason about a large but finite set of possible histories of interaction. In everyday conversation, the space of possible histories can be much larger or even infinite. It is thus an open question how people can approximate the recursive inferences needed to make sense of unintentional meaning.

A rigorous characterization of unintentional meaning can deepen our understanding of how communication works in a broader social context. For example, attempts to build common ground through shared experience (Clark & Marshall, 1981; McKinley, Brown-Schmidt, & Benjamin, 2017) or manage face with polite speech (Levinson et al., 1987; Yoon et al., 2018) could be understood, in part, as strategies for forestalling unintentional meaning. And given that intentionality plays a key role in judgments of blame (Baird & Astington, 2004), phenomena like plausible deniability could be understood as people leveraging the possibility of unintentional meaning to covertly accomplish communicative goals (Pinker, Nowak, & Lee, 2008). Although further investigation is needed to test the extent to which people can track and influence interactive belief states (as well as how artificial agents can do so), this work provides a point of departure for computationally investigating these social and cognitive aspects of communication.

Abstract

Previous studies have shown that people can make adaptive inferences based on memory-based simple heuristics such as recognition, fluency, or familiarity heuristic. In the present study, we discussed the adaptive nature of memory-based simple heuristics in a group decision making setting. In particular, we examined how the diversity of memory affected group decision making when group members were assumed to make inferences based on the familiarity heuristic. We predicted that, when the group members' memories were diverse, group decision making would become more accurate. To examine this prediction, we conducted a behavioral experiment and computer simulations, and our results generally supported the prediction. We discuss the role of diverse memories in generating adaptive group decision making.

Keywords: group decision making; heuristics; ecological rationality; diversity

Introduction

In research on human judgments and decisions, one of the most studied topics has been the heuristics people use. Previous studies have shown that, although heuristics can produce biases (e.g., Tversky & Kahneman, 1974), they generally result in adaptive judgments and decisions (e.g., Gigerenzer, Todd, & The ABC Research Group, 1999). Some heuristics, such as the availability (Tverky & Kahneman, 1973) or recognition heuristic (Goldstein & Gigerenzer, 2002), are highly related to the nature of an individual's memory. We shall discuss the adaptive nature of memory-based simple heuristics in terms of group decision making.

How do memory-based simple heuristics work in a group decision making setting? Given that individuals can make adaptive judgments and decisions in general based on the memory-based simple heuristics, when each member relies on such heuristics and the group makes a collective decision by, for example, simple majority rule, the group may be able to make good decisions in general. However, as described above, heuristics produce biases. For some situations, biased inferences are enhanced, and group performance may be deteriorated. Thus, although memory-based simple heuristics will enhance group decision making in general, they will also enhance biased group decision making in some cases. Fujisaki, Honda, and Ueda (2018) used computer simulations to show that a group does not always perform well when group members use strategies, which are regarded as generally adaptive in individual usage, because of biases generated by the strategies.

How, then, can the biases of memory-based simple heuristics in a group decision making setting be resolved? Recently, research has discussed how groups can achieve good performance such as wisdom-of-crowds or collective intelligence in terms of group diversity (e.g., Fujisaki et al., 2018; Jönsson, Hahn, & Olsson, 2015; Lorenz, Rauhut, Schweitzer, & Helbing, 2011; Luan, Katsikopoulos, & Reimer, 2012; Mavrodiev, Tessone, & Schweitzer, 2013). In group decision making based on members who use memory-based simple heuristics, if members' memories vary (i.e., memories in group members are diverse), biases generated by heuristics may be resolved.

In the present study, we examined how the diversity of memories in group members works for group decision-making with the following methods. First, we conducted a behavioral experiment about memories of city names. Using these data (i.e., actual memory data), we examined the accuracies of inferences made by hypothetical people who made inferences based on a memory-based simple heuristic. As an inference task, we used binary choice inference problems about population sizes (e.g., "Which city has a greater population size, Tokyo or Chiba?"). For this task, people tend to rely on memory-based simple heuristics such as recognition (Goldstein & Gigerenzer, 2002), fluency (Hertwig, Herzog, Schooler, & Reimer, 2008), or familiarity (Honda, Abe, Matsuka, & Yamagishi, 2011; Honda, Matsuka, & Ueda, 2017; Xu, González-Vallejo, Weinhardt, Chimeli, & Karadogan, 2018). Thus, people's memories will affect the inference processes for this kind of problem. Finally, we

constructed a group of such hypothetical people and examined the performance of group decision making.

How can memory diversity be generated? Given that the present study used city names as stimuli, we predicted that constructed memories about city names (e.g., recognitions of or familiarities with city names) were more dissimilar (i.e., diverse) between people in different areas than between those in the same area. Based on this consideration, we recruited participants from two areas (Tokyo and Osaka).

In the following section, we shall report two studies: a behavioral experiment and a computer simulation.

Study 1: Behavioral experiment

We conducted a behavioral experiment about memories of 30 cities in Japan. We examined whether recognitions and familiarities regarding the 30 cities differed depending on the area participants lived in and analyzed the memory diversity.

Method

Participants We recruited participants in their 30s and 50s from two areas, Tokyo and Osaka, with the following definitions: first, they were born in Tokyo (or Osaka); second, they had lived in Tokyo (or Osaka) for more than 20 years in total; and third, they had been living in Tokyo (or Osaka) during the past five years. As a result, we recruited 99 people in their 30s in the Tokyo area (M_{age} = 35.48, SD_{age} = 2.76, n_{female} = 49), 101 people in their 50s in the Tokyo area (M_{age} = 54.74, SD_{age} = 2.51, n_{female} = 50), 99 people in their 30s in the Osaka area (M_{age} = 35.15, SD_{age} = 2.92, n_{female} = 50), and 101 people in their 50s in the Osaka area (M_{age} = 53.92, SD_{age} = 2.89, n_{female} = 51). In total, 400 Japanese participated in the experiment.

Tasks, materials, and procedure We conducted a recognition task and measurement of familiarity. In the recognition task, participants were presented with a city name and answered whether they knew the city. When participants knew the presented city, they were also asked about their level of familiarity with the city. They answered this question using a scale labeled "I know only the name" on the far left and "I know a lot" on the far right. This rating was recorded with 100 points ranging from 1 (I know only the name) to 100 (I know a lot) depending on the familiarity level. In these two tasks, we used 30 Japanese cities based on Honda et al. (2017). 15 of the 30 cities were from the difficult list, and the other 15 were from the easy list (see Appendix for the specific city names). The definition of "difficulty" for the list lies in the difficulty of binary choice inferences about population size (Honda et al., 2017). Since memory-based heuristics in group decision making can work differently depending on the inference problems (see Fujisaki et al., 2018), we used these 30 cities. We conducted the two tasks on the Internet. Each city name was presented individually. The presentation order of the 30 cities was randomized for each participant.

Results and discussion

First, we examined the similarities of memories. In this examination, we calculated Spearman's correlation coefficient for familiarity ratings between two participants. We used the correlation coefficient as the criterion of similarity for memories between the two participants. We examined the differences in similarities as functions of area and age. As Table 1 shows, we examined the distributions of correlation coefficients in 10 pairs of participants each for easy and difficult lists. For example, in the "Tokyo30s–Tokyo30s" pair, since there were 99 participants in their 30s in the Tokyo area, there were 4851 (99 × 98 / 2) pairs at most. In some cases (14 out of 800[400 participants × 2 lists]), participants provided the same familiarity ratings for 15 cities in a list. For this case, we excluded the data since we could not calculate correlation coefficients.

Table 1 shows the distributions of correlation coefficients as a function of pair type. For each pair, we estimated a 95% confidence interval of the mean based on bootstrapping using 5000 simulations. Familiarity ratings between two participants became more similar in pairs of individuals from the same area than different areas, supporting our prediction. In contrast, we did not find a specific trend of similarity in terms of the age difference.

Next, we analyzed the similarity of memories in terms of ecological rationality (Gigerenzer & Todd, 1999). In this analysis, a participant was assumed to make inferences based on her/his memory as follows: s/he was presented with a pair of cities and made binary choice inference about population size (i.e., inferred which city had a greater population size). In making inferences, s/he used memory-based simple heuristics. We assumed that s/he used the familiarity heuristic (Honda, et al, 2011, 2017; Xu, et al., 2018). In this heuristic, s/he inferred that the more familiar city had the larger population size. In Honda et al. (2017), for the inference in pair x, person i's decision (D) is defined as follows:

$$D_i(x) = c_i(FA_{iL} - FA_{iS}) \quad (1)$$

where FA_{iL} and FA_{iS} represent familiarities for the larger and smaller cities in pair x, and c_i represents the scaling parameter. This scaling parameter for each person was selected so that the maximum or minimum value of D became 1 or −1. This model predicts that, when $D(x)$ is larger than 0 and satisfies the decision threshold (i.e., $D[x]$ > decision threshold), person i infers that the larger city has the larger population and that, when it is smaller than 0 and satisfies the decision threshold (i.e., $-D[x]$ > decision threshold), person i infers that the smaller city has the larger population. In pairs in which participants could recognize only the larger (or smaller) city, $D(x)$ was set as 1 (or −1) so that they choose the larger (or smaller) city. This choice is consistent with the recognition heuristic (Goldstein & Gigerenzer, 2002), indicating that the familiarity heuristic model can explain inference patterns predicted by the recognition heuristic.

We then examined how accurate people's memory-based inferences were and discussed the diversity of memory from this perspective. In this examination, we set two criteria, validity and discrimination rates (Gigerenzer & Todd, 1999). The validity rate is defined as follows:

$$V = \frac{H_c}{H_c + H_i} \quad (2)$$

where H_c (or H_i) denotes the number of pairs for which a person can use heuristic (i.e., $D[x]$ exceeds the decision threshold) and heuristic-based inference resulted in the correct (or incorrect) inference. That is, the validity rate means the accuracy of the familiarity heuristic. In contrast, the discrimination rate means the proportion of pairs in which a person can use the familiarity heuristic.

We calculated the validity and discrimination rates for all 105 pairs in difficult and easy lists for each participant. In this calculation, we set the decision threshold as 0.3 based on the empirical findings in Honda et al. (2017). Figure 1 shows the distributions of validity and discrimination rates for the two lists. We conducted 2 (area; Tokyo and Osaka) × 2 (age; 30s and 50s) ANOVA for the two criteria (i.e., validity and discrimination rates) and the two lists, respectively.

As for the validity rate, in the difficult list, a significant main effect of area was observed [$F(1, 388) = 111.49$, $p < .001$, $\eta^2 = 0.223$], indicating that the familiarity heuristic by participants from the Tokyo area would have led to more accurate inferences ($M_{Tokyo} = 0.680$, $M_{Osaka} = 0.488$). No significant main effect of age [$F(1, 388) = 0.09$, $p = .77$, $\eta^2 = 0.00$] or interaction [$F(1, 388) = 0.95$, $p = .33$, $\eta^2 = 0.00$] was observed. In the easy list, a significant main effect of area was observed [$F(1, 382) = 8.09$, $p = .005$, $\eta^2 = 0.223$], indicating that the familiarity heuristic by participants from the Osaka

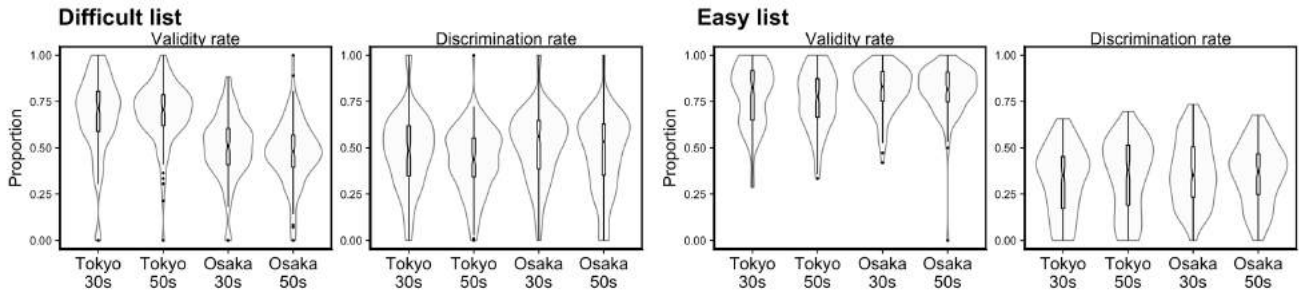

Figure 1. Validity and discrimination rates of the familiarity heuristic.

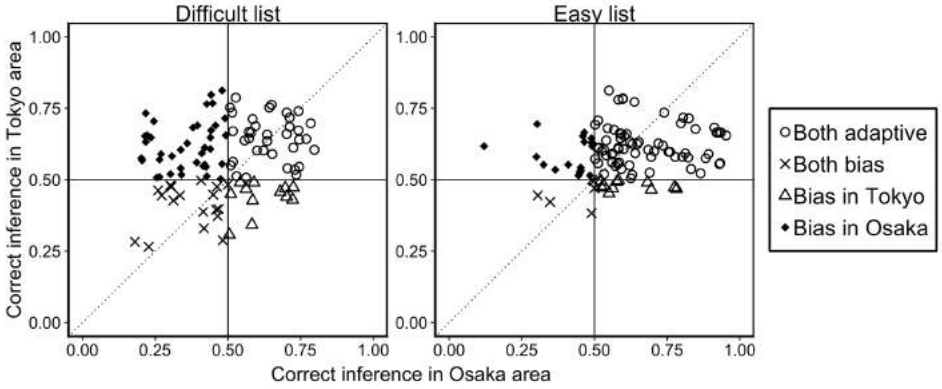

Figure 2. Proportions of correct inferences for Osaka's and Tokyo's participants. Each point denotes the proportion of correct inferences for each inference problem [i.e., there are 105 (15 × 14 / 2) points in each list].

area would have led to more accurate inferences (M_{Tokyo}= 0.771, M_{Osaka} = 0.814). No significant main effect of age [F(1, 382) = 0.99, p = .32, η^2 = 0.00] or interaction [F(1, 382) = 0.32, p = .57, η^2 = 0.00] was observed.

As for the discrimination rate, in the difficult list, a significant main effect of age was observed [F(1, 396) = 5.32, p = .02, η^2 = 0.01], indicating participants in 30s could have potentially used familiarity heuristic more often than those in 50s (M_{30s}= 0.499, M_{50s} = 0.454). No significant main effect of area [F(1, 396) = 3.30, p = .07, η^2 = 0.01] or interaction [F(1, 388) = 0.02, p = .89, η^2 = 0.00] was observed. In the easy list, no significant effects were observed [main effect of age, F(1, 396) = 0.11, p = .75, η^2 = 0.00; main effect of area, F(1, 396) = 1.76, p = .19, η^2 = 0.00; interaction, F(1, 388) = 1.01, p = .32, η^2 = 0.00].

The above analyses indicated that, although similarities of familiarity ratings and the nature of ecological rationality differed depending on the areas, ages were not generally related. Thus, in the following analyses, we merged the data between the two generations.

Next, we analyzed the accuracy of the familiarity heuristic for each inference problem. Figure 2 shows the relationship of correct inference between the two areas. Each figure includes 105 points, each of which shows the proportion of correct inference for each problem. Depending on the relationships about inference adaptivity (i.e., proportions of correct inferences were above the chance level [0.5] or not), we named pairs "Both adaptive," "Both bias," "Bias in Tokyo," and "Bias in Osaka." If the participants in the two areas show the same adaptivity or bias, each point will lie on the diagonal line (i.e., proportions of correct inferences correspond with each other). However, as is apparent in the figure, this was not true; the proportions of correct inferences varied depending on the areas, and the relationship of correct inferences between the two areas was not strong (in the difficult list, r = 0.18, p = .07; in the easy list, r = 0.19, p = .05). Furthermore, there were nonnegligible cases of "Bias in Tokyo" or "Bias in Osaka," indicating that participants in each area showed opposite direction of inference accuracy.

Altogether, we found that accuracy of the familiarity heuristic varied depending on the participants' profiles. In particular, the area (i.e., Tokyo or Osaka) was highly related to the accuracy of the familiarity heuristic, indicating that ecological rationality of memory differed depending on the area participants were from. Thus, constructed memory in the two areas were diverse.

Study 2: Computer simulations

We conducted computer simulations about group decision making based on the behavioral experiment data. We constructed hypothetical groups that comprised participants in the behavioral experiment, and the groups made inferences about population. Then, we compared group performance in terms of diversity of group members (i.e., members from only Tokyo or Osaka or members from a mixture of Tokyo and Osaka).

Method

Group construction We set group size at 5, 10, 20, or 50. In constructing a group, we randomly selected group members from participants in the behavioral experiment. Groups were constructed from a single area (i.e., participants from only Tokyo or Osaka) and both two areas (i.e., mixture of participants from Tokyo and Osaka).

Group decision making We set the following hypothetical group decision making situation. Group members made binary choice inferences about population size. They were presented with a pair of cities and made binary choice inference about population size (i.e., inferred which city had a greater population size). Here, each member was assumed to make inferences based on the familiarity heuristic, and the group made decisions based on simple majority rule (Hastie & Kameda, 2005; Sorkin, Hays, & West, 2001). According to previous assumptions (Fujisaki et al., 2018), when a member could not make an inference (i.e., her/his inference did not exceed the decision threshold), s/he did not participate in the group decision making. Furthermore, when a group could not make decisions (i.e., an equal number of members chose different cities), the group randomly chose one city.

Procedure The group made decisions for all 105 inference problems for the two lists. For each parameter setting (i.e., group size or diversity of group members), we constructed, in total, 5000 different groups based on random selection of members. We regarded the average of proportion of correct inference in the 5000 groups as the group performance in each parameter setting.

Results and discussion

First, we examined the performance in the single-area group (i.e., group members comprised participants from only Tokyo or Osaka). Figure 3 shows results of computer simulations. This shows the proportion of correct inferences for 105 inference problems each in the difficult and easy lists. Our findings can be summarized with the following three points. First, when individuals showed accurate inferences on average (i.e., proportion of correct inferences exceeded the chance level), group decision making enhanced accurate inferences. Second, when individual inference showed biases on average (i.e., proportion of correct inferences fell below the chance level), group decision making deteriorated accurate inferences (see Osaka performance in the difficult list). Third, and most importantly, individual performance did not always predict the better boost of group decision making. See the group performance in the easy list. At the individual level, members in Osaka showed more accurate inferences than those in Tokyo (see group size 1 in Figure 3). Intuitively, the group that comprises Osaka members seemed to show better group performance than that comprising Tokyo members since participants in Osaka showed more accurate inferences at the individual level. However, this was not true, and the group of participants from Tokyo performed better than the group of participants from Osaka. This counter-intuitive phenomenon may occur because of the biases (Fujisaki et al., 2018). Regarding the problems wherein people have bias (i.e., mean

proportion of correct inference lies below the chance level [0.5] at the individual level), group decisions deteriorate accurate inferences, and the mean proportion of correct inferences reaches 0 as the number in the group increases. Actually, out of the 105 problems on the easy list, the proportion of biased problems for participants in Osaka was 0.234, and that for participants in Tokyo was 0.162. Thus, although participants in Osaka showed more accurate inferences on average, they also showed more biases. Thus, in group decision-making, inaccurate inferences were enhanced for more inference problems in Osaka than in Tokyo, and a counter-intuitive phenomenon occurred.

Next, we examined the performance of decisions in groups whose members were diverse (i.e., mixture of participants). Figure 4 shows the performance of decisions for these groups. The x-axis indicates the proportion of members from Tokyo (i.e., 1 – the proportion is the proportion of members from Osaka). Thus, the values 0 and 1 indicate that the group includes members from only a single area (i.e., the values correspond to those in Figure 3 in each parameter setting). On the difficult list, the proportion of correct inferences in groups was boosted as the proportion of members from Tokyo increased. Since individual inferences in participants from Osaka were not accurate (i.e., their inferences were almost chance level), members from Tokyo boosted accurate inferences. On the easy list, the findings were highly intriguing. The peak of the group performance did not lie in the endpoint (i.e., group comprised members from a single area) but in the group that comprised members from the two areas. That is, when the group included diverse members, the group reached the highest performance.

In sum, we found that, when memories of group members were diverse, collective decisions by the group could be more accurate in some decision situations (e.g., when making collective decisions for the inference problems on the easy list).

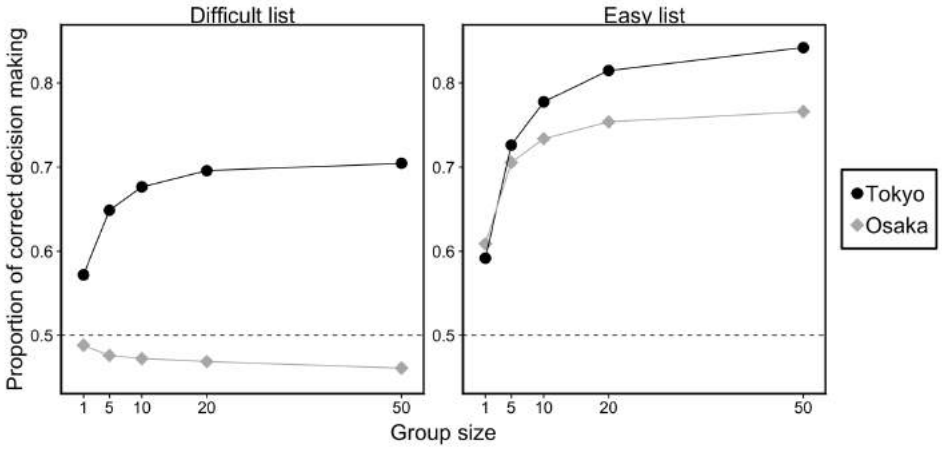

Figure 3. Performance of group decision making (i.e., proportions of correct inferences for 105 inference problems on the difficult and easy lists) in the group whose members were from a single area (i.e., Tokyo or Osaka). Group size 1 indicates the mean proportions of correct inferences in individual inferences. The dotted line indicates the chance level of inferences.

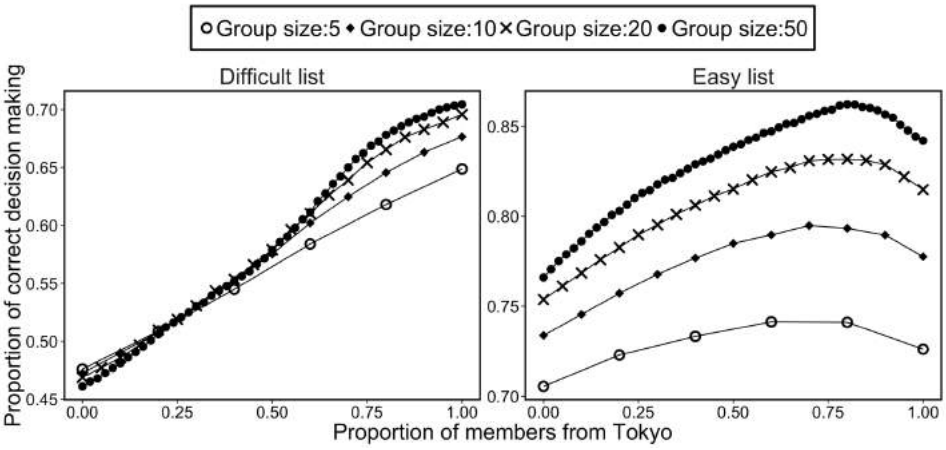

Figure 4. Performance of group decision making (i.e., proportions of correct inferences for 105 inference problems on the difficult and easy lists) in the group whose members were from two areas (i.e., Tokyo or Osaka).

General discussion

Through a behavioral experiment and computer simulations, we found that diverse memories in group members enhanced accurate group decision making.

How was the effect of member diversity generated? The key was the biases. As Figure 2 shows, participants in each area had unique biases (i.e., "Bias in Tokyo" and "Bias in Osaka" in Figure 2). In the mixed group, these biases could be improved by members from different areas, leading to accurate inferences.

Finally, we note the following two points about the difference in the adaptive nature of inferences between individual and group decision making levels. First, adaptive heuristics at the individual level do not indicate that such heuristics also boost accurate inferences in group decision making (see Figure 3 regarding the easy list) since adaptive heuristics are accompanied by some biases. That is, group decision making can boost both accurate and inaccurate inferences. Second, such problems in group decision making can be resolved by the diversity of inferences. In the present study, we showed that diversity in memories could remedy individual biases. Diverse memories can produce different inferences even when people use the same heuristic. That is, people make inferences using superficially "different" strategies. This is basically consistent with previous findings that diverse inference strategies used by group members can boost group decision making (Fujisaki et al., 2018). These findings suggest that diversity in inferences plays a key role in improving biases produced by individual inferences.

Abstract

Humans readily form social impressions of faces at a glance, whether assessing trustworthiness, attractiveness, or dominance. However, little is understood about how such computations are carried out neurally. Here, we leverage a computational model of human face perception to quantify and characterize the extent to which macaque monkey face patch neurons encode information relevant for social trait perception. Specifically, we use a social trait prediction model to estimate the social trait ratings for face stimuli viewed by monkeys during a neural recording experiment. We find that, while the monkey face patch neurons are linearly tuned to facial features different from those used by humans to make social judgments, the subspace spanned by the face patch neurons and the subspace spanned by the facial features supporting human social perception are highly overlapping. This result implies that the information present in the monkey face patch neurons are largely sufficient, after *linear decoding*, to support human social perception, thus shedding light on the biological origin of human social processing of faces.

Keywords: face perception; social perception; representation; neural recording; face modeling

Introduction

Face processing plays a special role in human life, as it underpins social interactions essential for survival and reproductive success (Olivola, Funk, & Todorov, 2014). Psychological studies have shown that humans effortlessly and consistently derive social characteristics (social, demographic, emotional traits) from the appearance of faces of strangers (Willis & Todorov, 2006). However, little is known about how such assessments are represented or computed in the brain. In this work, we leverage a computational model of human face perception (Guan, Ryali, & Yu, 2018) to quantify and characterize the extent to which face patch neurons in the macaque monkey brain (Freiwald & Tsao, 2010) encode information relevant for human social perception of faces.

One challenge for studying the relationship between neural responses and human face perception is that human face images are high dimensional and vary among each other in complex ways. To parameterize the space of human face images, we adapt a popular computer vision algorithm, the Active Appearance Model (AAM) (Cootes, Edwards, & Taylor, 2001; Valentine, 1991). AAM provides a vector space representation of face images with several desirable properties. Firstly, this representation is sufficiently rich such that each face image corresponds to a unique point in this space. Secondly, AAM is capable of generating realistic face images, helping to visualize the features encoded by neurons or group of neurons. Thirdly, recent neural data suggest that face patch neurons encode facial features similar to those in AAM (Chang & Tsao, 2017). Here, we train our own version of the AAM model (Guan et al., 2018) using a publicly available face dataset (Bainbridge, Isola, & Oliva, 2013). This dataset also contains human ratings along 20 social trait dimensions, which we model linearly by regressing the trait ratings against AAM latent features. Similarly, we linearly model the classification of gender and age based on human judgments of these qualities on the same face dataset (Bainbridge et al., 2013).

The neural data we analyze are single cell recordings from the face patch areas of the macaque monkey, recorded while the animals viewed 37 human face images (Freiwald & Tsao, 2010) (the original dataset contained 41 face images, in 4 of which the person's eyes are fully or partially closed – these 4 are excluded from our analyses). The face patch areas of the monkey inferotemporal (IT) cortex have been shown to contain neurons that are highly selective for faces (Freiwald & Tsao, 2010). Although face images used in the monkey experiment have not been rated by human subjects for social traits, we can predict the ratings by projecting the face stimuli to our AAM model, and then use the pre-trained regression models to predict the social ratings (Guan et al., 2018).

In the following, we first define and compute each neuron's Linear Response Axis (LRA), the linear axis within AAM that best captures the tuning selectivity of a neuron. We then characterize the properties of the LRA's both individually and as a population. Finally, we compare the facial features encoded by the neuronal LRA's versus those necessary for human social perception.

Results

Predicting Social Trait Perception

In order to predict human social perception of the faces seen by the monkeys, we utilize a model we recently developed based on the Active Appearance Model (AAM) (Guan et al., 2018). The model obtains a latent vector space representation of face images, consisting of combined principal components of shape and texture features (see Methods). We then use linear regression to model how latent features of a face give rise to trait ratings (20 social traits as in (Bainbridge et al., 2013),

plus the demographic traits gender and age, see Methods). We find that this approach predicts human social ratings on a *novel face* better than other humans' rating on the *same face*; it also achieves comparable performance to the state-of-the-art convolutional deep neural network, but has the advantage of having better interpretability (Guan et al., 2018).

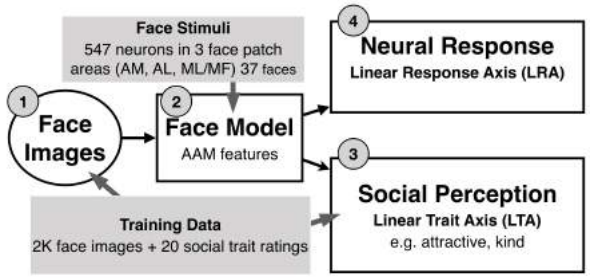

Figure 1: The face model is a vector space representation, whose axes represent the facial features that vary among face images, and the mean of the training dataset sample is centered at the origin (by design). We utilize the publicly available dataset (Bainbridge et al., 2013) (1) to train the AAM face model (2), obtaining 60 facial features. Using the same datasets, we model human social perception (3), and estimate the facial information encoded by each neuron (4).

Here, we can predict the human social ratings of the faces viewed by the monkeys by projecting these face images into the pre-trained AAM model. We first obtain the landmarks of the face stimuli using the free software Face++ (https://www.faceplusplus.com), then projecting them into the pre-trained AAM model (Guan et al., 2018) (Figure 1). Each face stimulus is a point in a 60-dimensional latent space. Figure 2 shows an example face image viewed by monkeys. We then obtain the predicted social perception of each face stimulus using the pre-trained Linear Trait Axes or LTA's (see Methods). The LTA of a trait represents the linear combination of facial features that maximally modulates human perception of this trait (a similar variation in facial feature along any other axis will induce a smaller change in average human perception). For example, the face in Figure 2A is predicted to be slightly more than 1 standard deviation more attractive than the average face (in the training data); Figure 2C shows predicted social ratings a number of traits.

One question we want to answer is how much information related to each social trait is encoded in the neural responses of the monkey face patch neurons. To have sufficient statistical power to assess this, we first need to make sure that the 37 face images span a substantial portion of the predicted trait ratings. This is indeed the case, as can be seen in Figure 3 for "happy" and "attractive." Figure 3A.ii visualizes a pair of face images seen by the monkeys that are predicted by the model to be less (left) or more (right) happy, and another pair (Figure 3B.ii) that is predicted to be less (left) or more (right) attractive. They are consistent with visual intuition.

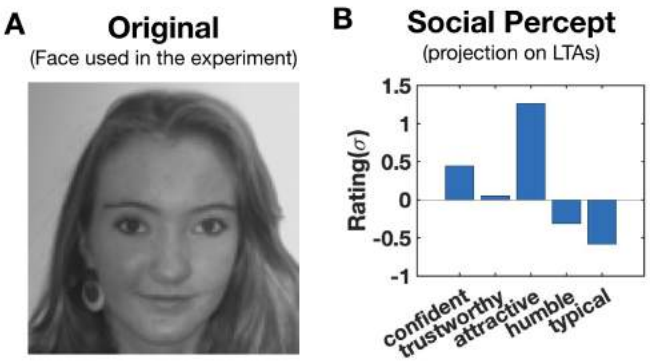

Figure 2: Face representation and social trait estimation. (A) An example face image viewed by the monkeys. (B) 5 examples (out of 20) of predicted social trait ratings for the same face.

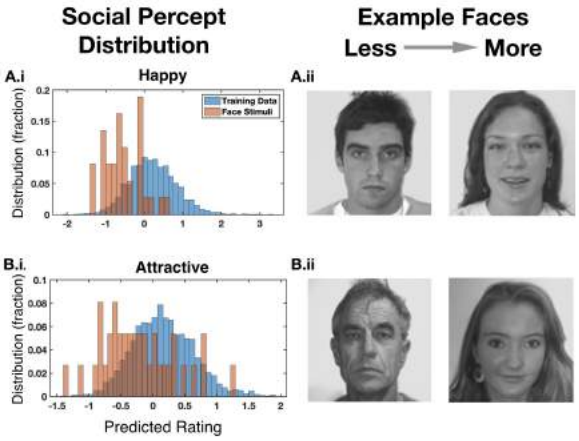

Figure 3: Social trait rating prediction. The histograms (left) of predicted social traits and two face stimuli (right) that are predicted by the model to vary in (A) happiness and (B) attractiveness. Distribution of predicted "happy" rating (A.i) for the 37 face stimuli (red) and training data (blue).

To quantify the information related to human social perception encoded by the macaque face patch neurons, we compute the correlation coefficient between each neuron's mean firing rate for each face (see Methods) and the predicted trait rating of each face. A neuron is deemed to significantly encode a trait if its correlation coefficient has a p-value < 0.05. We find that 19 out of 22 traits are encoded by a significant fraction of the neural population (Figure 4).

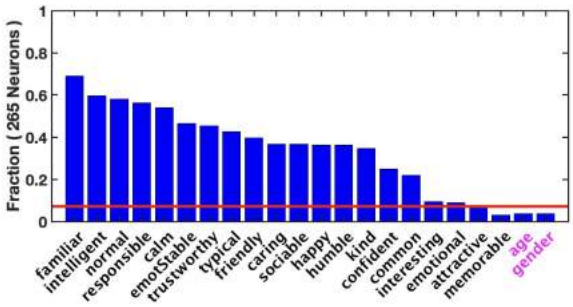

Figure 4: Proportion of neurons significantly encoding various social and demographic traits. A neuron is considered to significantly encode a trait if its MFR has significant correlation ($p < 0.05$, corrected for multiple comparison) with predicted ratings of viewed faces for that trait. The red line indicates the threshold for determining whether a significant (non-zero) fraction of neurons encode a trait at the significance level of $\alpha = 0.05$). This analysis only consists of the 265 neurons whose responses we can statistically reliably model (see subsection on Linear Response Axis)

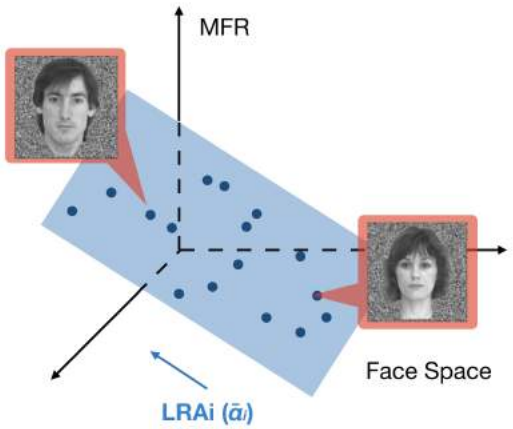

Figure 5: Schematic illustration of Linear response axis (LRA). The blue dots represent MFR of a neuron for different face images. The blue hyper-plane is the best linear fit of the neuron's response to those face stimuli. LRA gives the axis in the face space that yields the largest linear gradient for this neuron's MFR.

Linear Response Axis

To quantify the featural selectivity of each face patch neuron, we first define and compute the Linear Response Axis (LRA) of each neuron (see Figure 5A), which is just the normalized regression coefficient vector. Each LRA is obtained by regressing each neuron's mean firing rate (MFR) against the first $k = 13$ latent features of each image in the AAM space. k is chosen to be 13 in order to maximize the number of neurons whose response we can reliably estimate (i.e. significant correlation between model-predicted MFR and observed MFR on held-out faces, see Methods). For $k = 13$, we find that we can reliably estimate the LRA of 265 neurons – unless otherwise noted, all subsequent LRA-based analyses are performed using only these 265 neurons. The LRA specifies the linear axis that maximally accounts for variations in the neural response. We find that the average neural response along the LRA is not only monotonically increasing, as found in (Chang & Tsao, 2017), but in fact highly linear in this data set; and like in (Chang & Tsao, 2017), the neural response to the principal axis is completely flat. This replicates the finding in (Chang & Tsao, 2017) that monkey face patch neurons encode single axes in the AAM latent feature space.

While Figure 3 quantifies the relationship between social traits and individual neuron's MFR, we are also interested in characterizing the facial features encoded by the neural population as a whole. Naively, we might do so by applying principal component analysis (PCA) to the LRA's. However, the LRA's compose a special sort of data, namely unit-length vectors that lie on a hypersphere. If the LRA's lie in a completely balanced manner (by balanced, we mean that for each LRA, there is an "opposite" LRA that points approximately in the opposite direction, so that the two neurons encode the same AAM axis but have opposite preferences), then PCA would pull out the main directions encoded by neural LRA's; but if they are highly imbalanced, then PCA would instead pull out something like the tangent subspace and yield something uninterpretable. We therefore add an *opposite* LRA to each estimated LRA, to artificially balance the LRA's, and then apply PCA. We find that PC 1 alone explain 48.2% of the total variance among the LRA's, and the first 9 PC's explain 95% of the variance among the LRA's (Figure 6). Relative to the other features, the first PC plays an outsized role in terms of the features that the neurons linearly encode.

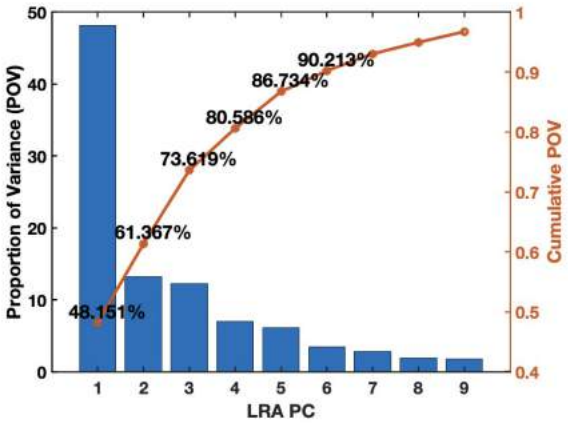

Figure 6: Incremental and cumulative proportion of variance explained by the PCs of neural LRAs. The histogram indicate the explained variance by each LRA PC and the plot for the accumulated explained variance.

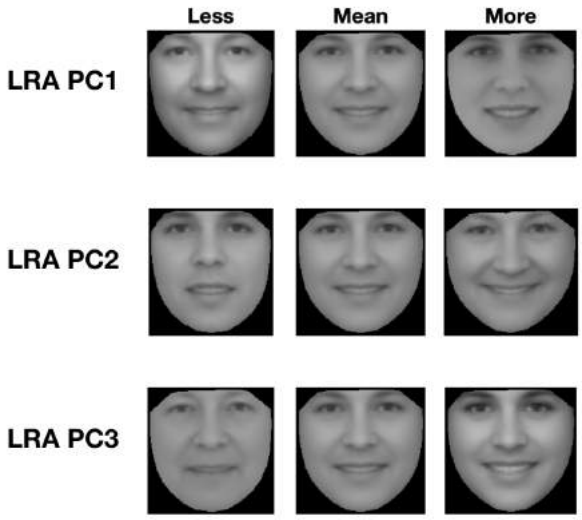

Figure 7: Synthetic face images along the top three LRA PC's. Each row shows how the mean face changes when positive (right) and negative (left) values are added to the mean face along each PC.

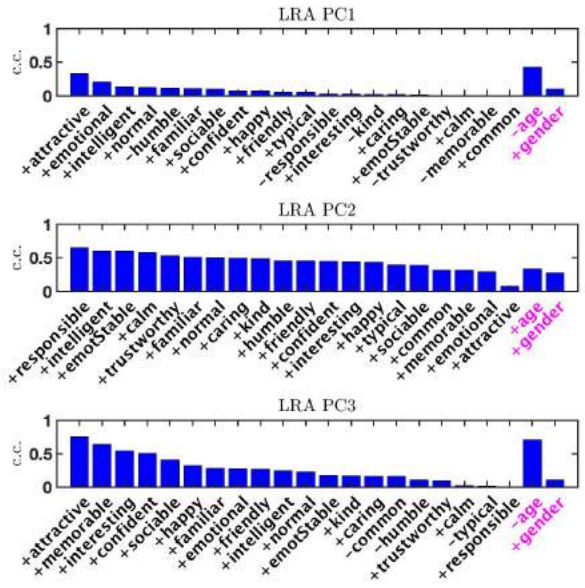

Figure 8: Expected correlation (i.e. dot product) between neural LRA PC's and social trait LTA's. Each row indicate expected c.c. for the various traits for each PC (blue: social trait, magenta: demographic trait). The bars indicate the absolute value of the correlation coefficients while the sign of the correlation is represented by + and - sign in front of the name of traits on x-axis. The traits are ordered in descending order of expected c.c., separately for social and demographic trait.

To get a sense for the primary featural axes that face patch neurons encode, we generate synthetic faces along each of the first three PC's (Figure 7). The first row of Figure 7 shows how the middle face changes as it gains more positive (right face) or more negative (left face) value along the first LRA PC; the next two rows show the same for LRA PC 2 and PC 3, respectively. The faces undergo interesting holistic changes along each of the first three PC's, consisting of some age- and gender-related changes but also other harder-to-verbalize structural changes.

To gain a more quantitative understanding of what the major features the face patch neurons encode as a population, we compute the expected correlation between each LRA PC and social trait (Figure 8), which is just the dot product between each LTA and LRA PC (they are both unit lengths). We find that all three LRA PCs significantly correlate with age. The expected correlation coefficient (dot product) between age LTA and each of LRA PC1, PC2, and PC3 ρ=.48, ρ=-.32, ρ=.67, respectively. In addition, PC1 and PC3 are correlated with attractiveness (PC1: ρ=.35, PC2: ρ=.75), and PC2 correlated with responsible (ρ=.67). This shows that while the neural population as a whole encode features that are highly correlated with those important for human social perception, the most important featural dimension (PC 1) has a poor correlation with any of the human social traits that we considered.

Figure 9 illustrates yet another way to visualize the relationship between neural LRA's and human LTA's. It shows a scatterplot of all the neural LRA's (red), the "pposite LRA's" (gray), and the social LTA's (green) projected into the subspace spanned by the Attractive and Responsible LTA's, the two traits that neurons as a population linearly encoded the most information about. We see that, first of all, that most of the social LTA's are fairly close to unit length within this subspace, indicating that most of them point in a direction very close to this 2D subspace. The neural LRA's show a range of distances from the origin, with the majority lying close to the origin, indicating they primarily point in a direction far away from this 2D plane that is quite important for human social perception. The neurons that do have LRA's pointing close to this subspace (distance close to 1 from the origin) are mostly pointing in the direction of traits such as familiar, intelligent, and normal – the traits that have the greatest number of significant correlation with neurons (Figure 4).

Conversely, we can also visualize all the projected LTA's and LRA's in the subspace spanned by LRA PC 1 and PC 2 (Figure 10). Here, we see that the neural LRA's are highly imbalanced, with most LRA having a positive projection along PC 1. We also see that most human LTA's point in a direction far away from PC 1, but have a fairly large component pointing in the direction of PC 2 (the exception is Attractive, which has the opposite pattern).

Similarly, we can also visualize all the projected LTA's and LRA's in the subspace spanned by LRA PC 1 and PC 3 (Fig-

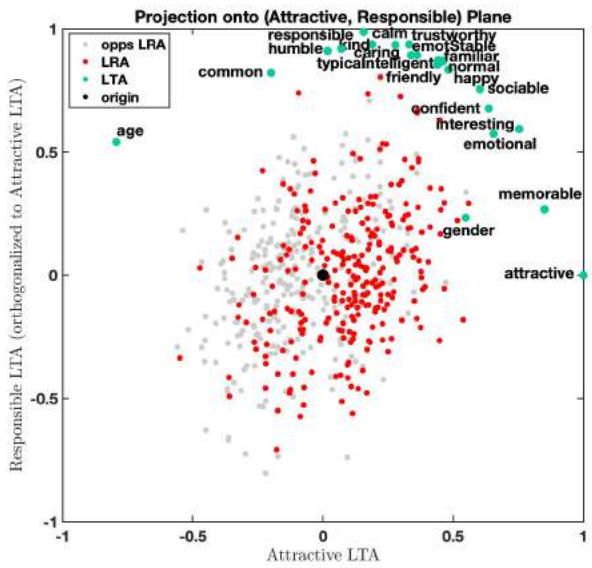

Figure 9: Projection of LRA's and LTA's onto the plane spanned by Attractive and Responsible LTA's. Red dots are projections of LRA's (gray for "opposite" LRA's). Green dots are projections of LTAs'. The label next to each green dot indicates the trait.

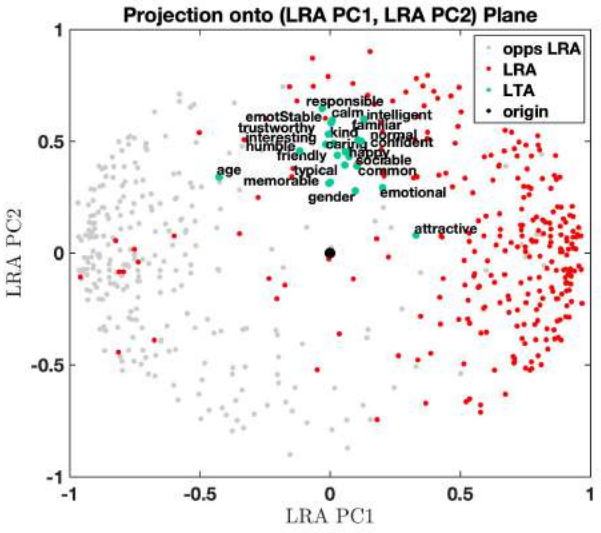

Figure 10: Projection of LRA's and LTA's onto LRA PC1 and LRA PC2. Similar formatting as Figure 9.

ure 10). It is apparent that Attractive and Age have fairly large components pointing along PC 3, along with traits such as memorable, interesting, and confident.

Subspace Comparison

While the previous analyses suggest that there is some overlap in the facial features that are encoded by monkey face patch neurons, and those that matter for human social trait perception, here we quantify their overlap in a different way. We compute how well (model-predicted) human social perception can be computed from the information present in the monkey face patch neurons (via simple linear decoding), and vice versa. As shown in Figure 12, the LTA-predicted ratings of the 22 social traits can be almost perfectly recovered from the LRA-predicted neural response (265 neurons) to face images (R^2 very close to 1); conversely, we find that the LRA-predicted response of all 265 neurons can be perfectly recovered from the LTA-predicted social trait ratings (22 traits), where $R^2 = 1$ in every case. This result suggests that facial featural information present in the macaque face patch areas is largely the same as those necessary for human social perception.

Methods

The Face Model: AAM

The Face model is an instantiation of the Active Appearance Model (Cootes et al., 2001; Guan et al., 2018). Each face image has shape and texture features. The shape features consist of the (x, y) coordinates of a set of landmarks that are consistently defined across faces. The texture features are the pixel values (grayscale) of each face image after warping it to have the same landmark locations as the averaged face. To reduce the dimensionality and remove correlation between shape and texture features, we perform additional Principal Component Analysis (PCA) on shape and texture features and retain the first 60 PC's, resulting in a 60-dimensional AAM feature space. AAM features form the basis of the Face Model that jointly describes the variations of shape and texture of the faces.

Social Trait Perception: Linear Trait Axis (LTA)

The Linear Trait Axis (LTA) $\tilde{\beta}$ for each social trait is computed as the normalized regression coefficients of ratings regressed against AAM features:

$$y = \beta\vec{x} + \varepsilon$$

where y is the standardized ratings for the trait, $\vec{x}$ is the AAM features, and β is the vector of regression coefficients. The linear trait axis (LTA) is defined as

$$\tilde{\beta} = \frac{\beta}{||\beta||}$$

The LTA specifies a direction in the face space that would (linearly) maximally alter the perception of the trait.

Predicted social perception A novel face images can be projected into the trained face model, resulting in a 60-dimensional representation $\vec{x}$. The predicted rating of a face image is then given by

$$\hat{y} = \beta\vec{x}$$

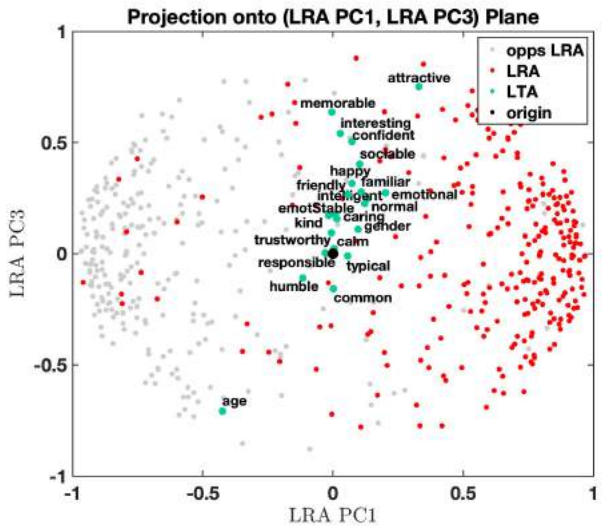

Figure 11: Projection of LRA's and LTA's onto LRA PC 1 and LRA PC 3. Similar formatting as Figure 9.

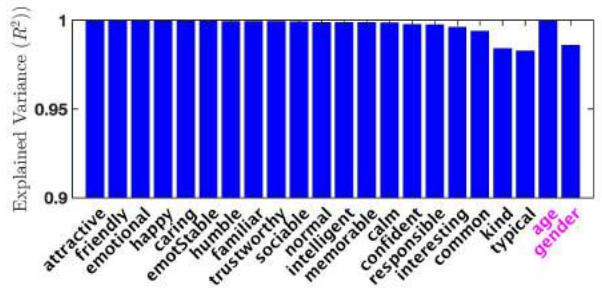

Figure 12: Comparison between LRA subspace and social LTA subspace. The bars (blue: social trait, magenta: demographic trait) represent the amount of variance in LTA explained by LRA, measured in terms of R^2.

with $\vec{x}$ as the 60-dim representation in the face model, and β the regression coefficients for the target trait.

Neuron Encoding - Linear Response Axis (LRA)

Similar to LTA, the Linear Trait Axis (LRA) $\tilde{\alpha}$ for each neuron is the normalized regression coefficients of neurons mean fire rate (MFR) regressed against AAM features.

$$r = \alpha\vec{x} + \varepsilon$$

$$\tilde{\alpha} = \frac{\alpha}{||\alpha||}$$

where r is the neurons MFR, $\vec{x}$ is the AAM features, and α is the vector of regression coefficients. $\tilde{\alpha}$ is the axis in the Face Model that drives maximal (linear) variation of the neurons response. Consistent with existing literature (Chang & Tsao, 2017), we find that MFR (averaged across neurons) increases monotonically along the LRA, and is flat along the principal orthogonal axis (data not shown).

Cross-validation is implemented to evaluate the reliability of LRA estimation. When estimating the LRA for a neuron, its true response to one stimulus is held out as test data. Using the LRA fitted on the remaining faces, we can compare the model-predicted MFR with the actual MFR on the held-out data point. For each neuron, the same process is repeated for every face image (as the test data point). We then the correlation coefficient between the true MFR and model-predicted MFR across all held-out data. The neuron is retained for further analysis if the correlation is significant ($p < 0.05$).

Subspace Comparison

For two vector spaces A and B, let $\{a_1, a_2, \ldots a_n\}$ be a set of vectors in A. The explanatory strength of space B for vector a_1 is determined by the percentage of variance of data from space A explained by the best linear combination of Bs basis vectors:

$$R^2 = 1 - \frac{\sum_i (z_i - z_{approx})^2}{\sum_i (z_i - \bar{z})^2},$$

where z_i is the data projection on vector a_1, $\bar{z}$ is the mean, and z_{approx} is the projection to space B.

Discussion

Our results indicate that, while macaque face patch neurons are primarily tuned to combinations of facial features that are rather different from those most important for human social trait perception, one can easily go back and forth using a simple linear operation (linear decoding scheme). There is no particular reason to expect that monkey face patch neurons, or monkeys themselves should particularly care about social trait perception of human faces. However, our results suggest that human social perception of faces may arise simply as linear decoding of featural information in a neural representational system that humans and monkeys share with each other, and with our common primate ancestors.

Leveraging computational modeling, our work represents a novel way to *retroactively* analyze social perceptual information or other face-related cognitive or perceptual information in monkey neural recording data, even if no social ratings are collected for the face images that the monkeys actually saw. We can also easily extend this framework to other kinds of animal neural data, or to human neural recording (or neuroimaging) data, obtained while experimental participants viewed face images. Technologically, this approach presents a promising approach for extracting much more information out of neural data about the neural basis of face processing, than has been hitherto possible.

Acknowledgments

We thank Doris Tsao and Winrich Freiwald for sharing the monkey neural data, Samer Sabri for helpful advice with the writing, and the UCSD CRES program for partial funding.

Abstract

We examined if using meta-memory judgments to control restudy choices has a positive impact on undergraduate students' memory performance, or whether simply making meta-memory judgments improved memory performance. 72 undergraduates at the University of Exeter were randomly divided into three groups. Participants in group A, had a chance to make meta-memory judgments and restudied the words they chose (self- selection). Participants in group B, also made meta-memory judgments, but restudy for this group was matched to that of Group A (control 1). Group C did not have a chance to make meta-memory judgments and were also matched to Group A for restudy opportunities (control 2). The results indicated that making meta-memory judgments had a positive overall impact on memory performance if undergraduates were allowed to control their restudy opportunities. Groups B and C showed no differences in memory performance, which means that making meta-memory judgments did not automatically improve memory performance. Group A restudied more of the words that they had rated as least well learned, and there were no significant differences between groups on test for the restudied words.

Keywords: Meta-memory Judgment (MJ), Restudy Choices, Learning, Memory.

Introduction

Meta-memory judgments rely on an individual's knowledge about how her or his memory processes affect their memory performance (Flavell, 1999; Hanczakowski, Zawadzka, & Cockcroft-McKay, 2014; Nelson, Dunlosky, Graf, & Narens, 1994). Efficient learning not only requires one to recognize information from memory, but also to be able to judge their level of confidence in material that they have previously learned and studied (Nelson, 1990; Nelson et al., 1994). One of the key reasons for studying meta-memory judgments is because it serves two functions: monitoring of memory processes and control over study behaviour (Nelson, 1990). The relationship between these functions is direct: people use memory monitoring, especially metamemory judgments, to decide which items need to be restudied and the length of time to be spent on them (Dunlosky & Hertzog, 1997; Kornell & Metcalfe, 2006). The central question addressed here is, do meta-memory judgments lead to effective study decisions? To test this experimentally, this study assumed that there would be positive effects on memory performance when participants are able to monitor their learning and are also able to use it to control their restudy opportunities.

Monitoring Accuracy: Studying cue-target word pairs is the most common approach used to investigate monitoring accuracy (Kimball, Smith, & Muntean, 2012; Nelson et al., 1994; Pyc, Rawson, & Aschenbrenner, 2014; Robey, Dougherty, & Buttaccio, 2017; Thiede & Dunlosky, 1994). This study design typically involves participants studying the word pairs, then making a Meta-memory judgment (MJ) to rate their ability to recall the target word when a cue is presented in the final test. Finally, participants take recall and recognition tests, which allow the researchers to assess how MJ can predict memory performance (Hughes, Taylor, & Thomas, 2018). Meta-memory judgments can be made immediately after the word pairs are studied, or delayed and made to the cue word alone. According to Nelson and Dunlosky (1991) the most important difference between immediate and delayed MJ lies in the amount of information available to participants when they judge their level of confidence. Participants who have made an immediate MJ have their target information in working memory, by contrast, this target is not available in working memory for a delayed MJ. Participants instead need to retrieve it from long-term memory. Several studies have investigated whether immediate MJ is more accurate than delayed MJ (Kimball et al., 2012; Nelson & Dunlosky, 1991; Pyc et al., 2014; Robey et al., 2017; Thiede & Dunlosky, 1994). While this study does not intend to assess the accuracy difference between these two processes, it uses the immediate MJ. The reason for choosing immediate MJ is provided by Hughes et al. (2018) who found that monitoring accuracy increases with immediate MJ when participants review material as a means of controlling repeated study or study- test practice. This study assumes that better meta-memory monitoring will lead to better restudy decisions, and also assumes that our main interest is in controlling restudy decisions at the time of study, rather than during later revision of the material.

Effectiveness of self-regulation: Effective learning involves two skills as stated earlier: monitoring learning and controlling study based on that monitoring (Kornell & Metcalfe, 2006; Nelson, 1990). Giving participants the opportunity to have control over their choices of which words to restudy allows them to be more engaged with their learning and improves their performance in the final memory tests. Begg, Martin & Needham (1992) and Hager & Hasselhorn (1992) concluded that self-memory monitoring is of no value to memory performance if participants did not control their study as well. In addition, Kornell & Metcalfe (2006) and Tullis & Benjamin (2012) tested the effectiveness of self-selection on using metacognitive judgements to control learning and memory performance. They found that allowing

participants to control their learning had a positive effect on memory performance, long term learning and restudy choices. Methodologically, these researchers have used different ways to test the effectiveness of self-regulation on memory performance. Some of these ways involve comparing memory performance between groups: an experimental group (allowed to choose) versus a control group (choices made for them) (e.g. Begg et al., 1992; Kimball et al., 2012; Kornell & Metcalfe, 2006), as well as establishing comparisons on the basis of the best learned or worst learned restudied items (Nelson et al., 1994), or items rated as most difficult by participants (Thiede & Dunlosky, 1994). In this study, memory performance will be compared between all items, including those selected for restudy **or** unselected items across groups (experimental and control; Begg et al., 1992; Kimball et al., 2012; Kornell & Metcalfe, 2006). Several studies have shown that when allowing participants to judge their confidence and use that judgment to control their restudy decisions, the final memory performance was better than controls (Begg et al., 1992; Kimball et al., 2012; Kornell & Metcalfe, 2006; Nelson et al., 1994; Tullis & Benjamin, 2012). The first aim of this research is to test if using meta-memory judgment to control restudy choices has a positive impact on undergraduate students' memory performance, or whether simply making meta-memory judgments improved memory performance.

Method

Summary of the task: Forty concrete Arabic nouns with their pronunciations and translations were used to create two lists of word pairs, twenty in each list. Words were limited to be between four to eight letters. The words were randomly selected to serve as practice (first list) and study (second list) word pairs. Each phase of the experiment (practice followed by main study) started with instructions, then each item from the appropriate word list was presented on the screen for ten seconds on a white background. After each word, participants in Groups A (self-selection) and B had to judge their confidence of remembering the word in the future by rating their confidence from 1 to 9 (1=low confidence, 9= high confidence). Participants in Group C had to make a rating of how similar the Arabic word was to its English translation. Participants in Group A were then also asked if they needed to restudy the word just seen or not. Recall and recognition tests were given at the end of experiment.

Experiment design: The experiment used a between-subject design with three groups: Group A, who both made meta-memory judgments and could choose whether or not to restudy words (self-selection), control Group B, who made meta-memory judgments of their learning and experienced the same restudy opportunities as their counterpart in Group A (they were yoked to them), and control Group C, who did not make meta-memory judgments ratings but made similarity ratings instead, and were also yoked (in terms of restudy) to their counterpart in Group A. After seeing a word pair, participants first made their MJ to rate their meta-memory confidence of remembering the word later. Then, in Group A, each participant was able to request a restudy opportunity for any word. If they did, they then also made a meta-memory judgment after restudy as well. In Group B, each participant made a MJ, then got the same restudy opportunities as one of the participants in Group A but had no choice in the matter. If they were given a restudy opportunity, then they also made a second MJ to that word pair. For Group C, each participant had a chance to study the Arabic words, however they did not make a MJ during the task, but did get the restudy opportunities of one of the participants in Group A, and made a second similarity judgement after any restudy opportunity.

Participants: In this pilot study, random sampling was used. The participants of the study were 72 undergraduates from the University of Exeter; 24 in the meta-memory judgments and re-study (experimental group A), 24 in the MJ (control group B) and 24 in the No MJ (control group C) were random selected. The sample of the current study included 54 female and 18 male participants aged between 18 to 35 years, who did not speak the Arabic language and were enrolled in a variety of different subject disciplines. They were recruited via posters, email advertising and through the University of Exeter's Psychology Research Participation System. Participants were rewarded with a single payment of £5 or one credit on completion of the experiment, questionnaires and interview.

Procedure: All stimuli were presented with Superlab on a PC. The outline of the procedure for the study is summarised diagrammatically in Figure 1.

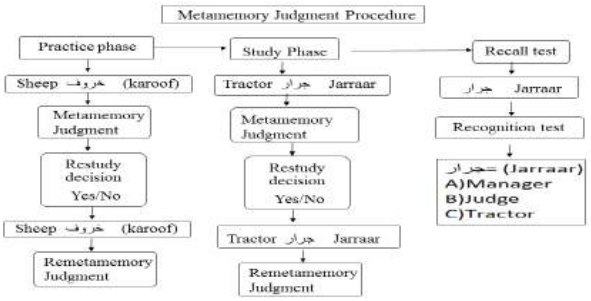

Figure 1 visual representation of the procedure.

Participants first completed a practice phase, which included 20 Arabic words with their translations and pronunciations in English. Then, participants in groups A and B made a judgment of how confident they were in their learning (selected number between 1 to 9). Whereas participants in group C made a judgment of how similar the English translation was to the Arabic pronunciation (again, a 1 to 9 rating, the purpose of this instruction was to have the same procedure across groups). After this, participants in group A were asked whether they would restudy this word if given the opportunity. Participants in group B and C were told that there was chance of repeating some words. Participants in groups A and B again made a meta-memory judgment after restudying words, whereas participants in group C again rated the similarity of the English translation word to the Arabic pronunciation. The same procedure was repeated in the study

phase, but this included 20 new Arabic words. In the last phase, participants were asked to recall all the English translations cued by the Arabic words from the study phase in a random order. After this there was a recognition test provided for each word. One Arabic word with three English translations appeared on the screen, one of which was the right translation; participants had to choose that one. The following sections now give details of our procedure.

In the practice phase. Twenty Arabic words were presented in the middle of the screen between their translation and their pronunciation in English, with a font size of 16. A fixation stimulus was presented before the word pair and a blank screen after the word pair for 1 second. All participants studied the same word pairs (but in a random order), and all the word pairs were presented for ten seconds.

Meta-memory judgment: Participants in the meta-memory judgment A and B groups responded to the following instruction "Please select your level of confidence that you can remember this word pair by pressing the appropriate key from 1 to 9". Participants in group C in the non-meta-memory judgment did not make meta-memory judgments, but were asked the following question "Please rate the similarity of the English translation of this Arabic word to its Arabic pronunciation by pressing a key from 1 (very low) to 9 (very high)".

Restudy judgment. After making their meta-memory judgment, Participants in group A were asked "Would you like to re-study that Arabic to English translation? Press "y" for yes, "n" for no. If you've already re-studied once, then pressing either key will move you to the next trial". Participants in group B and group C were told "Note that there is a chance that the word pair you have just studied will be repeated. Press "y" to move on to the next trial". We arranged for participants in control group B and control group C to restudy the words determined by the matched participants in the experimental group A.

Second meta-memory judgment. After restudying a word, participants repeated the judgement appropriate for the group they were in.

Study Phase. In the main study phase, twenty new Arabic words with their translations and pronunciations in English were presented on the screen in a random order in a similar manner to the practice phase, and participants studied the pairs in order to remember them in the final recall test and recognise them in the final recognition test at the end of the experiment. All participants studied the same word pairs, and all the word pairs were presented for ten seconds at a font size of 16. They were then given meta-memory or similarity judgments and re-study opportunities as before.

Final test. After participants had completed the practice phase and study phase for all the 40 words, they completed a final recall test followed by a recognition test. More specifically, they were asked to recall the English translations of all the words from the study phase (i.e. all 20 words in that phase). They were given their Arabic form and pronunciations in English on the screen in a random order as a cue, and participants were asked to provide the English translation by typing their responses on the keyboard within 30 seconds. After all the words were tested in this way, a recognition test was given for each word. One Arabic word and English pronunciation with three English translations appeared on the screen, one of which was the right translation; participants had to choose this one. Another of the three translations was randomly taken from the practice phase, so that each practice word was used as a distractor once during this test phase. The other incorrect distractor word was novel, and would not have appeared before. None of the words used in a given test trial was repeated in any other test trial. Again, 30 seconds were given to do this, and once a word was selected they moved on to the next trial.

Results

74 participants were run on this experiment. Two participants were excluded because they did not complete the recall test. The results for the remaining 72 participants are as follows:

The first issue we looked at was to determine if either of our control groups differed on either recall or recognition performance (the means for these groups are shown in Figure 2 below). They did not, both Fs<1, so we collapsed B and C into one overall control group and Compared this to A. An independent t- test used to examine the difference in the overall score between Experimental group A and this combined control group at recall gives a statistically significant difference between experimental group (M= 10, SD= 4.81) and control group (M=7.1, SD=3.78), t (70) = 2.727, p<.001, the eta squared statistic ($\eta 2$=.1) indicates a large effect size A similar test used to examine the difference in the overall score for recognition also revealed a statistically significant difference, t = (70) = 2.558, p=.013. The effect size, calculated using eta squared, was close to large ($\eta 2$=0.09). This implies that simply making a MJ does not automatically confer a significant benefit, but in combination with being able to choose which words to restudy it is effective in enhancing memory.

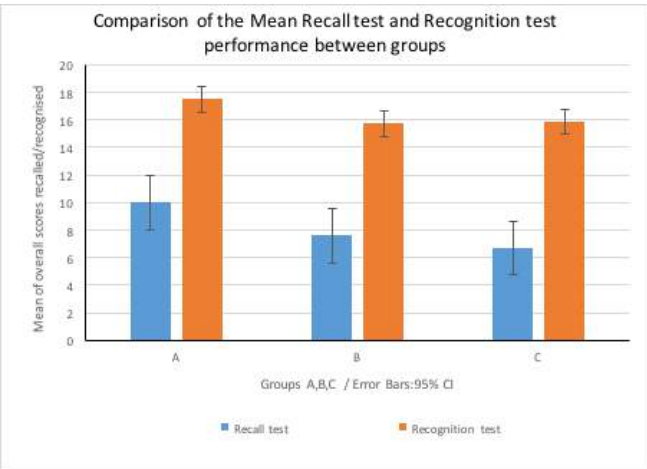

Fig. 2. This shows the difference between groups in their performance on the recall test and Recognition test.

The similar effects for recall and recognition suggest that both simply reflect memory for the word pairs, and this impression is confirmed by a correlational analysis. A Spearman rho test found a strong positive correlation at the 0.005 level (1-tailed) between the two variables, rho=.740.

Our next question was whether there was the expected relationship between the average MJ given to a word pair and performance on the recall and recognition tests? Obviously, we would expect higher average MJ to result in better performance on test. Correlations across participants failed to reveal any significant effects. When we compute this correlation across words, it failed to reveal a positive correlation between the MJ to a word pair and the recall test score for that word (r = .207, p=.079, n=48 1- tailed), but on the recognition test there was a significant and positive correlation between average MJ and performance (r= .439, p< .001, n=48, 1- tailed) with 19 % of the variance in recognition explained by this judgement. These results mean we have some evidence that some words are easier to learn than others.

In addition, as illustrated in Figure 3, there were differences in the MJ given before and after restudy for the restudied words, and also differences in the MJ given to non-restudied words. We analyzed this by performing two separate ANOVAs. The first was used to compare the MJ to the restudied and non-restudied words using the first judgement given in both cases (this would be the only judgement in the case of the non-restudied words). Group (A vs. B) was also included as a factor. The interaction between the groups factor (A, B) and the study factor (non-restudy, restudy) was significant, F (1, 46) = 7.100, p=.011. If we look at Figure 3, we can see that the MJs for Group A are higher than those for Group B for the non-restudied words, but lower for the words that were chosen by Group A for restudy. This is what is driving the interaction. An independent t- test showed that there was a statistically significant difference in the MJ between groups for the non- restudied words in favour of group A, t (46)= 3.073, p<.001, with large effect size (η^2=.3). The difference for the restudied words is not significant. It would appear, then, that Group A selected words that they found particularly difficult for restudy, leaving the easier words, and that this selection was somewhat specific to them, even though the Group B participants obviously show considerable agreement in what are the easier and harder words. This last point is reinforced by the main effect of study in this analysis, with the MJ for non-restudied words being much higher than that for the restudied words, F (1, 46) =40.69, p<.001.

The second ANOVA that we ran compared MJs to the restudied words before and after restudy. The interaction between groups (A, B) and study factor (before restudy and after) was just significant, F (1, 46) = 4.415, p=.041. Obviously, the effect of the factor of Study is stronger than this, the change from before to after is clear in Figure 3. The main effect for the type of MJ (before and after restudy) gave an F (1, 46) =35.197, p<.001, indicating that all participants show improved levels of confidence after restudying words. The interaction suggests that Group A improved more than Group B. Therefore, we have some evidence that restudy really helps participants to improve their level of confidence to remember the words in the final tests, and that effect was greatest when allowing participants to control their restudy opportunity.

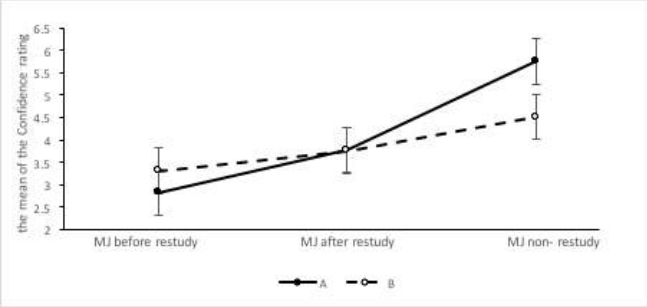

Fig 3. MJ before and after restudy and MJ for non-restudied words for groups A and B, Error Bars: 95%CI.

Turning now to a correlational analysis across participants, a Spearman rho test revealed a strong negative correlation between the mean of the initial MJ made by a participant and the number of requests for restudy in Group A, rho=.-.747 n=24, p<.001 (1-tailed). This correlation means that people who tended to give a lower MJ on average also tended to ask to restudy more. In essence, it could be taken to suggest that people have some sense of whether they are finding the task easy or hard, and adjust their study strategy accordingly. Another Spearman rho test gives a statistically significant and large positive correlation between frequency of restudy for a participant and their recall performance. That is, the more times people restudy (on average) the better their ability to retrieve words in the recall test, rho= .661 n=72, p<.001. There is a similar effect with recognition, a significant large positive correlation between frequency of study and recognition test performance, rho=.610, n=72, p<.001. It is not hard to see why this would be the case. The more restudy, the more practice of the items one gets, and if that helps then the better he or she performs. But this then leaves us with a slightly paradoxical situation, where the participants that we would argue are finding the task hardest (as signaled by a low MJ on average) are actually the ones performing the best. Perhaps the low average MJs may actually reflect better self-knowledge (i.e. a form of meta-memory) rather than ability as such. These are the people who know that they need to restudy, and do so, and benefit from it. Those with higher average MJs may be confident but may be mistaken in their confidence. It's also worth pointing out that the correlation between restudy request frequency and performance includes participants in Groups B and C who had no control over restudy. In some sense, the restudy manipulation was simply one imposed on them, and the result that more restudy benefitted performance is not surprising in that context. Finally, the correlations between MJ and test performance across subjects were not significant, so actually the paradox is not present in our data, just a potential feature of our theory.

After looking at the MJ data for the restudied and non-restudied words, we quite naturally would like to know how performance differed for those word types, and whether it differed across groups. Having collapsed B and C into one group as they do not differ on these measures, there was a main effect on recall for the type of words F (1, 69) =20.284, p=<.001. Participants performed better on non-restudied words than on restudied words. An independent t- test found statistically significant differences between the experimental group A (M= .504, SD= .240) and the combined control group (M=.360, SD=.192) for non- restudied words, t (70) = 2.734, p= <.001. The eta squared statistic (η^2= .1) indicated a large effect size. Whereas the difference between experimental group A (M= .301, SD= .368) and the control group (M=.222, SD=.315) for restudied words was not significant t (70) = .940, p=.350. The fact that overall, participants recalled more words when they were not restudied we take to simply reflect the fact that these were the easier word pairs. The fact that Group A was better than the combined control on these words again suggests an item specific advantage based on Group A participants selecting the words. Whilst the words were generally the easier ones (hence the main effect), the agreement on this between Group A and controls was not complete.

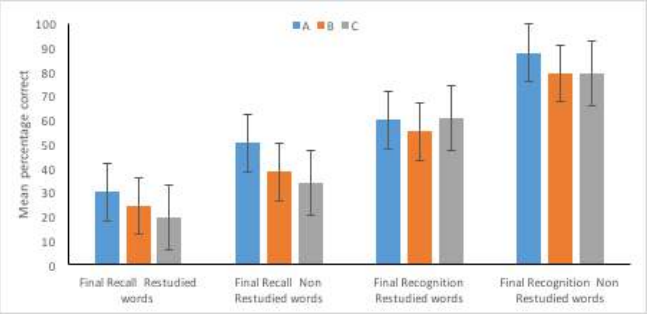

Fig. 4. Mean percentage of Final Recall and Recognition tests between restudied and non-restudied between groups A, B and C. Error Bars: 95%CI.

Turning now to the recognition test, once again participants recognise more words from the non-restudied words than the restudied words, F (1, 69) =20.783, p<.001. After collapsing B and C into one control group, an independent t- test showed there was a statistically significant difference between the experimental group (M= .878, SD= .111) and control group (M=.791, SD=.148) for the non- restudied words, t (70) = 2.515, p= =.014. The effect size, calculated using eta squared, was large (η^2= .1). However, the difference between the experimental group (M= .599, SD= .463) and control group (M=.579, SD=.423) for restudied words was not significant t (70) = .184, p=.854. (See Figure 4). Just as before, we can attribute some of this advantage on test to Group A's effective selection of the non-restudied words as the easier items, and that selection not transferring completely to the other groups. As a result, Groups B and C find these items harder on average and score lower on test. But the overall averages indicate general agreement about which are the more difficult items, as the overall means for the non-restudied words are much higher than for the restudied ones.

Discussion

In this experiment, we have found a significant advantage for Group A over the other two groups in terms of performance on the tests used to assess memory, with no significant differences between Groups B and C. It can be concluded that using meta-memory judgments and allowing control of restudy has a positive impact on participant's memory performance. The question now is why does this happen? Is it that the use of meta-memory allows our participants to select items that they find particularly difficult for restudy, thus improving performance? Or is it a more general effect? We can envisage two possibilities here. One is that people know how good their memories are and can make use of that knowledge to guide restudy. Another is that that giving people control over their choice of restudy items improves their motivation and engagement with the task. As we have seen and will see, there is evidence for both explanations, but what we can say is that simply "exercising" meta-memory, by giving a MJ to an item, is not in itself a significant factor in improving performance, otherwise there would be a significant difference between Groups B and C.

These results are in line with those of previous studies Begg, Martin, & Needham (1992) and Hager & Hasselhorn (1992) who concluded that self-memory monitoring has no value for memory performance if participants did not also have control of their study. In addition, these results are in agreement with those obtained by Kornell & Metcalfe (2006) and Jonathan G. Tullis & Benjamin (2012) who tested the effectiveness of self-selection on the use of metacognitive control over learning and memory performance. They found that allowing participants to control their learning had a positive effect on memory performance, long term learning and restudy choices.

This study found that there was a significant difference on MJ between non-restudy words and restudy words, and one possible explanation for this is that meta-memory monitoring helped participants in groups A and B to make their meta-memory judgments so as to discriminate between items which were more difficult and items that were easy and really sufficiently learned. These result are in line with those of previous studies who found that young subjects use their metacognition monitoring to distinguish between more difficult items (Li et al., 2018; Tullis & Benjamin, 2012; Tullis, Fiechter, & Benjamin, 2018; Zawadzka et al., 2018). Another significant finding was that meta-memory judgments could, to some extent, predict a participant's restudy frequency. Participants in group A, requested restudy more often for items that they had judged as least well – learned. This finding supports the work of other studies in this area (e.g. Dunlosky & Hertzog, 1997; Li et al., 2018; Nelson et al., 1994; Jonathan G. Tullis & Benjamin, 2012). Equally, participants in group A and B show significant improvement in their MJ after restudying words. These results agree with the finding of other study such as

Zawadzka et al. (2018) who demonstrate that repeated learning in the same environment improved learning, and metacognition monitoring. Obviously we are unable to comment on the effect of restudying a word on learning here because we do not know what performance on the restudied words would have been if they had not been restudied, but the positive correlation between frequency of restudying and test performance does fit in with the results cited. We intend to gather data that bears directly on this issue.

We can interpret some of the correlational results very simply as meaning that higher confidence about learning translates into better memory performance later. This would fit well with an item-specific effect of meta-memory on these tasks, whereby items judged as hard by Group A participants were given a low MJ, and this was used to trigger a restudy request. The effect of this was to improve performance on these items, back up to the level shown by the controls, while the advantage on the items not chosen for restudy because they were easy was greater in Group A again because they were able to make the right choices for them. Whilst there is general agreement about which are the easy and hard word pairs across groups (as shown by the correlations by word for MJ and test performance reported earlier) there is enough disagreement for the control groups to not gain as much benefit from the restudy offered, and so Group A does better. This is one possible explanation for our results.

But there may be more to this. Note that the MJ was, on average, higher in Group A than Group B, and, as we have seen, Group A performs better on test than Group B and C combined. The higher MJ in Group A could reflect increased confidence due to having control over which items are restudied, but this could be a general motivational effect rather than one based on meta-memory. To be clear, it could be that both the high MJ and better memory in Group A are both due to increased motivation due to their being in control of their restudy choices, in which case it would not be correct to say that the high MJ had some causal role in improving performance for Group A relative to Group B. Further research will be needed to disentangle the relationship between these variables.

Abstract

The present study explores the impact of including social media messages on learning from television programs that broadcast pseudoscientific claims. Seventy-seven university students were allocated to one of three experimental conditions: viewing television content with messages supporting the claim, with opposing messages, or without any messages presented. Memory retention did not differ among the conditions. However, social media messages influenced validation of the arguments claimed in the video. The participants who watched the video with opposing messages showed significant decrease in positive attitude toward the pseudoscientific technology that claimed to be effective in the video. Additionally, the participants who watched the video with supporting messages made fewer critical comments and showed willingness to donate more to the activity using the pseudoscientific technology. The impact of including social media messages and the process of attitude change are discussed.

Keywords: social media messages; learning from television programs; incorrect arguments; validation of argument; attitudes; retention.

Introduction

Learning from television programs with social media messages

One of the major sources for everyday learning is television. Since television programs are designed with various styles, it is not easy to define the processes of learning from television in general. Thus, we begin by focusing on a relatively simple program that broadcasts experts' explanations. Although the style is simple, we can find many examples of the type of television programs in which experts like scholars and scientists explain topics of interests such as politics, technology, and science.

The present study investigates how social media messages impact learning from the "experts' explanation" type of show. It is shown that people often access social media while watching television. It is also getting popular to include social media posts on the screen during such programs (Inuzuka, Tanaka, & Tsubakimoto, 2017; Barra & Scaglioni, 2014). In this case, the social media messages, which typically include hashtags, are searched and presented. (See Figure 1 for an example of how these feeds may be presented.) The programs usually include messages that consist mainly of text, such as posts on Twitter. Although the relationships between social media and viewing television programs have begun to be explored widely (e.g., Anstead & O'Loughlin, 2011; Ceron & Splendore, 2018; Miao, 2018; Waddell & Bailey, 2019), few studies investigate their impact on cognitive processes (e.g., Cameron & Geidner, 2014; Maruyama, Robertson, Douglas, Semaan, & Fucett, 2014; Maruyama, Robertson, Douglas, & Raine, 2017). Thus, we still lack evidence to discuss their effects on learning.

In the present study, we focus on the impacts of social media messages on validation as well as memory retention. Validation is one type of integration process that requires activation of one's prior knowledge and unfolding a logical argument (e.g., Halldorson & Singer, 2002; Lea, Mulligan, & Walton, 2005; Singer, Halldorson, Lear, & Andrusiak, 1992). The inclusion of social media messages may impact the validation process of the viewers; the messages can activate viewers' knowledge or provide new information that is effective for appropriate validation. These social media messages, however, cannot always be effective for validation. The messages contain various opinions (D'heer & Verdegem, 2015), and irrelevant and inappropriate messages can be included as well as helpful ones. Previous studies failed to investigate how qualitatively different messages impact viewers' learning. Thus, the present study investigates the effects of different types of social media messages on viewers' memory retention and validation of arguments provided in television programs.

Learning from multimedia sources and the effects of including social media messages

While the "experts' explanation" type of television program may seem simpler than other styles, the situation can be

described as learning from multimedia materials. Watching the program, the viewers integrate the information presented in the speech and other visually presented materials such as graphs and illustrations. When social media messages are incorporated into the program, the viewers must integrate more information presented visually in the text of social media messages.

The literature on multimedia learning suggests that the inclusion of social media messages may interfere with viewer comprehension since the messages may contain incoherent information. Mayer (2009) suggested a "coherent principle" in which learners understand a topic better when irrelevant and seductive elements are removed from the learning materials. The coherence principle can be explained by the split-attention effect theory; a multimedia resource results in less learning when it splits learners' attention (Sweller & Chandler, 1996). This attention split is more likely to occur when the resource contains information sharing the same modality and when it is not coherent with the other information presented (Mayer, 2009; Mayer & Moreno, 1998).

Consideration of the coherence principle led us to assume that the presentation of messages interferes with learning since these messages are not consistent with the main information of the contents. Inuzuka, Tanaka, and Tsubakimoto (2017, 2018), however, suggested that the effects of presenting social media messages on memory retention were limited. They compared the memory retention scores of participants who watched video material including and not including social media messages. Participants paid attention to the messages when presented but showed no significant difference in retention scores between the two groups.

The gap between the coherent principal and the results of Inuzuka et al. (2017, 2018) can be interpreted from the standpoint of the difference in the level of comprehension. Research on multimedia learning suggested that violation of the coherent principal mainly influences the integration of learning materials and the learner's knowledge (Mayer, 2009). Thus, we can assume that Inuzuka et al. (2017, 2018) showed no significant effects of including social media messages since they examined memory retention, which did not require integration of the knowledge.

The validation of false arguments

Viewers activate their prior knowledge, integrate the information presented, and validate the arguments (e.g., Halldorson & Singer, 2002; Lea, Mulligan, & Walton, 2005). Validation of an argument is especially important when it comes to learning from television programs since the issues tackled in television programs are often relevant to viewers' lives and require them to decide what to believe and what to do. Additionally, and more importantly, the media do not always provide fair and correct arguments. Consideration and validation of potentially biased information are among the most important practices in surviving the information age.

Research shows that people display difficulty rejecting information even when the texts they read are inconsistent with prior knowledge and even patently false (e.g., Gilbert, Krull, & Malone, 1990; Gilbert, Tafarodi, & Malone, 1993). Gerrig and Prentice (1991) revealed that it took longer to vilify a false statement as "incorrect" when participants read the statement discussed as truth in a narrative text. These studies suggest that learners accept what they have processed as truth first and resolve the validation afterwards. Rapp (2008) suggested that, when providing fake information within a context that casts doubt on correct information, the verification becomes even more difficult for learners.

To extend the above discussion, it is necessary to note that the above studies employed information regarding which the correctness of the arguments was apparent to the learners. Television programs, however, usually focus on issues on which learners do not possess much prior knowledge. In this case, the validation of incorrect argument becomes a more difficult and complex task that demands more deliberate consideration. Thus, we must employ an index other than reaction time. Consideration of new ambiguous topics should and can be measured more qualitatively using participants' attitudes toward the topic, decision making, and the explanation of the situation related to the issue.

The impacts of presenting social media messages

We can predict that the presentation of social media messages changes the way viewers validate presented arguments. Maruyama et al. (2017) investigated the effects of referring to social media messages when watching a discussion on the television. They revealed that viewers' attitudes were different in the direction of the social media messages. Similarly, Cameron and Geidner (2014) explored the effects of social media feeds on viewers' opinion formation. They indicated that participants' opinions were found to conform to the majority opinion presented in the messages. These studies suggest that conformity process in which viewers may follow the majority of the people.

The above studies are limited, however, as they did not investigate the situation in which learners are required to validate incorrect arguments. When watching a discussion in which both sides of the argument can equally be justified, the viewers' consideration and decision making would depend on what the majority says. Thus, conformity can best describe the impacts of social media messages, as depicted by Maruyama et al. (2017). However, the same may not be true when the argument claimed by the specialist on the television program is incorrect. Thus, this study aimed to examine whether the impacts of social media messages are valid when new and incorrect information is presented and to explore if the impacts are caused by conformity.

Aim of the study

The present study focused on how the incorporation of social media into television programs affects memory retention and

validation of incorrect arguments. More specifically, we examined the effects of social media messages by presenting either opposing or supporting messages for the pseudoscientific claims. We hypothesized the following:

(1) The presentation of the social media messages does not interfere with memory retention that does not require integration of knowledge.

(2) The presentation of social media messages impacts viewers' validation of pseudoscientific claims. Namely, the viewers change their attitudes in the direction of the social media messages, and the viewers react differently to the situation in which they must make some decision.

Method

Participants

Seventy-seven undergraduates participated in this study after providing informed consent and were assigned to one of three conditions: Supporting, Opposing, and Without message. As a reward for their participation, they received a 500 Japanese yen (approximately $4.50) cash voucher.

Materials

Fake television program The video material used by Inuzuka et al. (2017) was edited for the purpose of the present study (Figure 1). The original video was produced to mimic a scientific talk show. We omitted some parts of the video so that only the claim of one scientist (an actor) remained. Following the procedure above, the video material used in the present study was approximately eight minutes long. The scientist stated that "Effective Microorganisms" (EM) are effective for improving water quality. "EM" is a pseudoscience based on the idea that a particular collection of microorganisms can solve virtually all health and environmental problems. We chose the topic because it is relevant to participants' lives and yet unfamiliar to them.

Fake social media messages We included fake social media messages that simulated Twitter posts in the video material presented to the participants in the Supporting and Opposing message conditions. The messages consisted of text with each containing one or two short sentences. We designed three types of messages: opposing, supporting, and neutral (Table 1). Neutral messages were developed for when neither supporting nor opposing messages were appropriate. Neutral messages were, therefore, included in both Opposing and Supporting conditions and were presented at the same time in both conditions. Opposing and supporting messages were included in the corresponding conditions, and each message was inserted at the bottom of the screen (Figure 1) approximately five seconds after the relevant topic was mentioned by the scientist. The participants assigned to the Without messages condition watched the video not including the messages.

Retention test A retention test was developed with six quiz items (e.g., "What was the name of the two rivers that Scientist A claimed that EM cleaned up?"). The tests were administered after participants had watched the video.

Attitude questionnaire To assess the participants' validation of the video contents, whether the participants agreed with the effectiveness of EM was measured using a questionnaire. The attitude questionnaire was administered before and after the participants watched the fake video. It consisted of two subscales with three items each: positive attitude (e.g., "I think EM will somehow do some good") and careful attitude (e.g., "We need more investigation on the effectiveness of EM"). The participants were asked to answer the items on seven-point Likert scales.

Figure 1. A frame from the video material that mimics the television program displaying a social media feed saying, "*So, the 'power of nature' means using microorganisms. Right?"*

Table 1. Examples of fake social messages used in the study.

	Example
Supporting (33)	It is important to use an enriched compound of specific types of organic matter. I understand.
Opposing (33)	After all, I think EM is condensed organic matter. If so, there might be a risk of causing more pollution.
Neutral (21)	I agree that it is important to discuss in a scientific way.

Note: The numbers in parentheses are the numbers of each type of message. Supporting messages were presented only to the participants in the Supporting condition and opposing messages to those in the Opposing condition.

Explanation and decision-making task Additionally, we developed a test in which a short story was introduced to qualitatively assess the consideration and validation of the argument. In that story, the following scenes were introduced: "You are considering making a donation, and a man comes and explains that NGOs are planning water quality-improvement activities using EM." The participants were asked to decide how much they would donate to that NGO (0–5000 JPY, approximately 40 USD). Participants were also asked to write comments and questions for the man in the story.

Evaluations of the messages The participants in the Opposing and Supporting message conditions rated three questionnaire items on an 11-point scale: (1) the extent to which the social media messages were against the claim, (2) how much attention they paid to the messages, and (3) how much they considered the contents of the messages.

Procedures

Each participant was tested individually in a laboratory. Each session lasted approximately 30 minutes. After participants had signed a consent form, the experimenter introduced the video, explaining, "The video is a digest of a television program. In the program, a scientist will explain how they try to clear water pollution." The experimenter then instructed the participants to watch the television show and learn from it. Each participant was randomly assigned to one of the three conditions: Supporting, Opposing, and Without messages. No instruction regarding the social media messages was given, so the participants were not aware of the differences among the conditions. After watching the video, participants responded to the retention test and attitude questionnaire. There was no time limit for completing the questionnaires, but participants did so within 10–15 minutes.

Results

The evaluation of messages

Three participants were excluded from the following analysis since they reported that they knew about EM in advance. To confirm that the different types of social media messages were delivered to the participants, we employed the participants' rating for the extent to which the social media messages were against the claim. The difference between conditions was significant, $t(45) = 10.0$, $p < .001$, $d = 2.97$. The mean scores were significantly higher than the neutral score ($t(22) = 9.56$, $p < .001$) in the Opposing condition and lower than the neutral score ($t(22) = -5.31$, $p < .001$) in the Supporting condition.

Additionally, the participants' rating for the extent of attention ($t(45) = 2.13$, $p < .05$, $d = 0.63$) and consideration ($t(45) = 3.82$, $p < .001$, $d = 1.136$) of the messages also differed between two groups, indicating that the participants assigned to the Opposing condition rated themselves as paying more attention and considered the messages.

The effects of message presentation on retention test

Each retention test item was scored with two points, and the total was used as the retention test score (Table 3). Fully correct answers were given two points, and partially correct answers, such as giving only one name of a river when two should be named, were given one point. The difference in retention test score among the conditions was analyzed with a one-way ANOVA. The result indicated no significant difference among the experimental conditions, $F(2,70) = 1.45$.

The effects of message presentation on attitude

For the analysis of attitude change, we used the average scores of positive and careful attitude questionnaire items. The mean scores for each subscale are shown in Table 3. The impact of message presentation was analyzed with two-way mixed ANOVAs. The dependent variables were positive and careful attitude scores, and the independent variables were conditions (Opposing, Supporting, and Without messages), time of measurement (pretest and posttest), and the interaction effect of two independent variables.

The results of careful attitude score showed no significant main effects of experimental condition ($F(2,71)= 1.78$) and time ($F(1,71)= 0.421$), and there was no significant interaction effect either ($F(2,71) = 0.745$).

On the other hand, the analysis of positive attitude revealed significant results. The main effect of time was significant ($F(1,71) = 9.37$, $p < .01$, $\eta_p = .117$), showing a decreasing tendency, while the main effect of condition was not significant ($F(2,71) = 1.58$). More importantly, the interaction effect of condition and time reached a significant level (Figure 2, $F(2,71) = 10.22$, $p < .001$, $\eta_p = .224$). Subsequent analysis of simple effect revealed that positive attitude was decreased significantly only in the Opposing condition, $F(1,71) = 27.26$, $p < .001$, $\eta_p = .532$). The change in other conditions did not reach a significant level ($F(1,71) = 1.42$ for the Without condition and $F(1,71) = 1.21$ for the Supporting message condition). The effects of conditions were significant only at the posttest ($F(2,142) = 8.36$, $p < .001$, $\eta_p = .191$), showing a significant difference between Opposing and Without message conditions ($t(142) = 2.35$, $p < .05$, $d = 0.943$) and between Opposing and Supporting message conditions ($t(142)= -4.07$, $p < .001$, $d = 1.62$). The difference between Without and Supporting message conditions was not significant, $t(142)=1.68$.

The results of one-way ANOVA conducted on the explanation score showed a significant effect of condition ($F(2,71) = 3.50$, $p < .05$, $\eta_p = .090$), and the following multiple comparison (Holm) revealed that the difference between Supporting and Opposing message conditions was significant ($t(71) = 2.55$, $p < .05$, $d = 0.710$) with higher scores for the participants in the Opposing message condition.

Table 2. Average scores for evaluation of the messages

	Supporting	Opposing
The messages against the claim	3.86 (1.96)	9.25 (1.51)
Attention paid to the messages	7.25 (2.80)	8.75 (1.56)
Consideration of the message contents	5.46 (2.78)	8.05 (1.31)

Note: The numbers in parentheses are standard deviations.

Table 3. Average scores on the retention test, change in attitude, and critical thinking disposition scales for each experimental condition

	Supporting	Opposing	Without
Retention test	7.71 (2.31)	8.44 (3.17)	7.42 (2.39)
Positive attitude			
Pretest	3.63 (0.58)	3.91 (0.64)	3.68 (0.54)
Posttest	3.84 (1.04)	2.29 (0.79)	3.44 (1.15)
Careful attitude			
Pretest	3.64 (0.43)	3.76 (0.67)	3.75 (0.15)
Posttest	3.64 (0.41)	3.92 (0.41)	3.72 (0.52)
Explanation score	0.72 (1.44)	1.32 (1.41)	0.88 (1.41)
Donation amount (yen)	1750.00 (1161.00)	916.00 (1086.16)	1071.67 (1075.965)

Note: The numbers in parentheses are standard deviations.

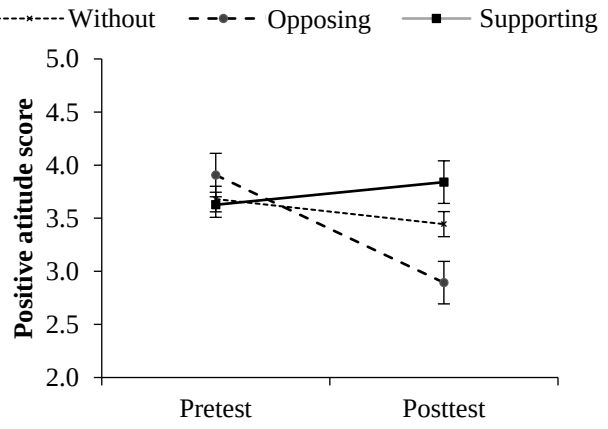

Figure 2. Changes in positive attitude as a function of message presentation. Error bars represent standardized errors.

Explanation and decision-making task

The explanation score was calculated based on the number of critical points included in the answer to the explanation and decision-making task. The participants were given one point each when referring to the following points: (1) suspicious effects of EM, (2) the lack of clear explanations for the mechanism, (3) the lack of consideration of side effects, (4) the need for solid data. Thus, the explanation score for each participant was in the range of 0–4. The donation amount indicated by the participants was also used as an index for the validation. The average scores and SDs are shown in Table 3.

Additionally, the amount of money the participants were willing to donate for the activity using EM was compared among the conditions. One-way ANOVA revealed a significant effect of experimental condition ($F(2,70) = 3.89$, $p < .001$, $\eta_p = .100$). Multiple comparison (Holm) was conducted and showed significant difference between Supporting and Opposing message conditions ($t(70) = -2.64$, $p < .05$, $d = -0.741$). The participants in the Supporting message condition tended to donate more than those who watched the same video with opposing messages.

Discussion

The present study investigated the effects of including social media messages in a television program on which incorrect arguments were claimed. As predicted in Hypothesis 1, the results demonstrated no significant difference in retention. The result was consistent with previous studies using a similar method (Inuzuka et al., 2017; 2018) and with studies of multimedia learning (Mayer, 2009), suggesting that the incorporation of social media messages would not interfere with the memory of what had been discussed in the program. The results for attitude changes and explanation and decision-making tasks also supported our hypothesis about the impact of social media messages on validation of the arguments (Hypothesis 2). The participants who watched opposing messages became less positive about the effectiveness of EM, the pseudoscientific technology. The participants' explanation and decision also showed that those who watched supporting messages were relatively uncritical about using the pseudoscientific technology.

The results of the present study suggested that showing counterarguments in text messages may support the viewers to consider and validate the information shown in the television programs more appropriately. Considering research showing that rejecting incorrect text is difficult for readers (Gerrig & Prentice, 1991; Gilbert et al., 1990; Gilbert et al., 1993; Rapp, 2008), it may be beneficial to incorporate these counter-messages for viewers.

However, it should be noted that the messages included in the study were biased, either supporting or opposing the explanation of the expert in the program. Actual social media messages are supposed to be more varied including both appropriate and inappropriate arguments. As Inuzuka (2017)

showed that presenting varied messages did not significantly change the viewers' attitude, the impacts of appropriate counterarguments may be wiped out when combined with inappropriate messages.

While previous studies (Cameron & Geidner, 2014; Maruyama et al., 2014, 2017) suggested conformity as the mechanism underlying the effects of social media messages on the viewers' attitude change, the present study brought up another possibility. The conformity hypothesis should predict that both opposing and supporting messages will have similar impacts on participants' validation process. However, we found smaller attitude changes in the Supporting condition in the present study. The unequal results in our two conditions may be caused by the qualitative difference in the messages presented. The ratings of the consideration of messages showed that the participants in the Opposing condition considered the messages more than those in the Supporting condition (Table 2.).

The difference may be caused by the effectiveness of the messages; the messages in the Opposing condition provided other perspectives from the expert's explanation while the messages of the Supporting condition provided rephrasing and supplemental information. Thus, the participants may consider the messages of the Opposing condition to be more informative. If the above consideration stands, it can be said that the information contained in the messages is used in the process of deliberation rather than merely conformity. The next step of the research, therefore, should be to clarify if the impacts are caused by the conformity of deliberate consideration.

The results also showed that the attention change led to decision-making in a more realistic situation. The participants in the Supporting condition tended to donate more with fewer questions about the appropriateness of the activity. Although the present study is based on a laboratory examination using a fake television program, the results provided eligible data to discuss the effects of showing biased information. Presenting biased information without counterargument may result in an actual disadvantage.

The present study makes meaningful contributions toward understanding how we learn from a new type of media. The first is the suggestion that incorporation of social media messages affects individuals. The results of the present study broaden the previous studies on social media and television programs by showing that incorporation of meaningful messages would help viewers more appropriately validate the information. The second is the expansion of the research on validation of incorrect information to broader learning contexts. Previous studies mainly focused on information presented in texts and information the participants already knew. The present study highlights information that participants newly learn and suggests that using different media may be an effective way to present counterarguments.

We should note, however, some limitations of the study. First, the instruction for the participants should be less instructive. We instructed the participants to learn from the television program to make sure they focused on the program, but the instruction may have influenced their attitude and caused better memory retention while they may have spared more attention for the social media messages if not for the instruction. Although we repeatedly found small effects of the social media messages on memory for detailed facts, it is important to test the impacts of those in more natural settings.

Secondly, a more thorough comprehension test should be administered. In the experiment, we used a quiz to test the participants' memory retention. The quiz mainly tapped detailed memory of the program contents. Open-ended questions and analysis of the structure of their memory would enable us to understand the impacts of social media messages on memory in more detail.

Finally, the mechanism of the impacts of message presentation should be investigated in future studies. The impacts of social media messages shown in the present study supported the hypothesis that social media messages provide support for deliberate consideration or evaluation of information. Since the present study does not provide direct evidence to discuss the process of attitude change, there remains one alternative interpretation: conformity (c.f., Maruyama et al., 2017). However, relatively weak impacts of supporting messages suggest that the effects of messages may not be caused by conformity alone. If the participants reacted to the messages in the direction these messages suggest, the participants should change their attitude equivalently in both Supporting and Opposing conditions. The future direction of the study is more detailed investigation of the process of validation: conformity or deliberate consideration.

Abstract

Speech input is often noisy and ambiguous. Yet listeners usually do not have difficulties understanding it. A key hypothesis is that in speech processing acoustic-phonetic bottom-up processing is complemented by top-down contextual information. This context effect is larger when the ambiguous word is only separated from a disambiguating word by a few syllables compared to many syllables, suggesting that there is a limited time window for processing acoustic-phonetic information with the help of context. Here, we argue that the relative weight of bottom-up and top-down processes may be different for languages that have different phonological properties. We report an experiment comparing two closely related languages, Danish and Norwegian. We show that Danish speakers do indeed rely on context more than Norwegian speakers do. These results highlight the importance of investigating cross-linguistic differences in speech processing, suggesting that speakers of different languages may develop different language processing strategies.

Keywords: categorical perception; speech perception; Danish; Norwegian, cross-linguistic studies

Introduction

Speech is often ambiguous and noisy. Yet most of the time listeners show remarkable skills in understanding what is being said. A possible explanation is that the imperfect acoustic-phonetic input is integrated with contextual information. Thus, to understand speech, listeners combine bottom-up acoustic-phonetic cues with top-down lexical-semantic and pragmatic contextual information. This context effect might be particularly apparent when the acoustic-phonetic information is unclear or noisy (e.g., Borsky, Tuller & Shapiro, 1998; Gaskell & Marslen-Wilson, 2001; Marslen-Wilson & Welsh, 1978; Samuel, 1981).

Despite the variability of the acoustic properties of individual sounds and the noisiness of the acoustic-phonetic input, the perception of speech sounds is *categorical* (Liberman et al., 1957). This means that a certain sound is usually perceived unambiguously (e.g., either as a /b/ or as a /p/); listeners ignore within-category acoustic differences while easily perceiving across-category acoustic differences of the same magnitude.

Both within-word and sentential context facilitate sound categorization when the acoustic-phonetic information is ambiguous (Brown-Schmidt & Toscano, 2017; Bushong & Jaeger, 2017; Connine, Blasko & Hall, 1991; McMurray, Tanenhaus & Aslin, 2009; Szostak & Pitt, 2013). In a phoneme identification study, Connine et al. (1991) manipulated the onset of the target words *dent/tent* on a continuum from a clear [d] to a clear [t^h] with three intermediate steps. The listeners were presented with sentences biased either towards *dent* (*After the _ent corroded, they patched it*) or towards *tent* (*After the _ent collapsed, we went home*). Connine et al. (1991) showed that listeners often relied on the biasing word at the end of the sentence to disambiguate the target word, when the target word had an ambiguous onset, whereas they were not biased by the context (biasing word), when the target word had a phonetically clear onset. They concluded that top-down inference from the context is given more weight when the target input is ambiguous than when it is clear.

In the same study, Connine et al. (1991) showed that the contextual biasing effect was present when the target word was separated from the disambiguating word by a small number of syllables (NEAR condition) but not when there was a larger number of syllables (FAR condition). The response time data, however, showed that in the FAR

condition, most of the time, the decision was being made prior to the availability of the disambiguating information, suggesting that there was an approximately 1 s window to make a decision based on acoustic-phonetic information prior to its decay.

In an eye-tracking study, Brown-Schmidt & Toscano (2017) showed a context bias effect even when the ambiguous word is separated from the biasing context by six-seven syllables. In fact, prior to disambiguation, the listeners fixated on the interpretation of the word that did not match the context but shifted their gaze only after having heard the biasing context. Similarly, Szostak and Pitt (2013) replicated the contextual biasing effects on ambiguous-sounding phoneme identification. Although smaller than in the NEAR condition, they also observed a biasing effect in the FAR condition. The authors suggested that the temporal window for disambiguating unclear acoustic-phonetic information may not be completely fixed, as suggested by Connine et al. (1991), but rather influenced by other factors, such as syntactic complexity or experience with language use.

Another factor that could affect the temporal window may be the typological characteristics of a given language. However, so far, language processing studies have mainly focused on English, therefore making it difficult to generalize the findings to other languages. In fact, it is debated whether all languages are processed in the same way and thus findings in one are generalizable to the others (Pinker, 1994), or whether each language has its unique characteristics, shaped by language users (Evans & Levinson, 2009). In the current study we address the question of whether individual languages are all processed in the same way or afford different processing strategies. Specifically, we investigate potential differences in the processing of the two languages—Danish and Norwegian—which are closely related but differ substantially in their phonological structure.

The Case of Danish and Norwegian

The relative weight that context is given in speech comprehension may vary from language to language, depending on the typological characteristics of a given language. We hypothesized that Danish may be a language, where top-down contextual processes is given larger weight than bottom-up acoustic-phonetic cues, compared to its close linguistic neighbors, Swedish and Norwegian. In terms of cross-linguistic comparisons, Danish and Norwegian thus allow for a well-controlled natural experiment. Denmark and Norway have a long common history, and have strong similarities in culture, education, politics, and other extra-linguistic factors. The two languages also have very similar grammars, morphology, and vocabulary—but differ in their phonology: Danish has a much more opaque phonology than Norwegian.

The sound structure of Danish is quite unique. Apart from having an unusually high number of vowels and vowel-like consonants, there is also a higher degree of syllabic reduction and assimilation of both vowels and consonants, compared to its close relatives Norwegian and Swedish (Basbøll, 2005). As a result, Danish is more difficult to acquire as a native language than Swedish and Norwegian (Bleses, Basbøll & Vach, 2011). There is also evidence that out of these three mutually intelligible Scandinavian languages, Danish is the most difficult to understand (Gooskens et al., 2010; Hilton, Schüppert & Gooskens, 2011). This may be due to the fact that there is generally a higher degree of syllabic reduction in Danish than in Norwegian and Swedish. Moreover, due to phonological reduction in Danish, some words sound identical to each other (Basbøll, 2005). In general, Danish speakers are thus exposed to a more imperfect and unclear acoustic-phonetic input compared to their Scandinavian neighbors. And, as a result, Danish speakers may rely on top-down processes to a larger extent than Norwegian and Swedish speakers.

In the current study, we adapted the paradigms used by Connine et al. (1991) and Szostak and Pitt (2013) to test the hypothesis that Danish speakers, due to the phonological peculiarities of the language, rely more on top-down processes than Norwegian speakers do. We predicted that when presented with ambiguous sounding words, Danish speakers would rely more on contextual cues compared to Norwegian speakers. In fact, for Danish speakers, we expected this effect to be present not only in the NEAR condition but also in the FAR condition, indicating that the acoustic-phonetic bottom-up input is given relatively less weight by Danish speakers than by Norwegian speakers. Moreover, we predicted that Danish speakers would be more inclined to wait until the end of the sentence to respond than Norwegian speakers (H1: language main effect). Following the findings for English by Szostak and Pitt (2013) and Connine et al. (1991), we expected that both Danish and Norwegian speakers would be affected by contextual bias (H2: contextual bias main effect) and that the effect would be stronger in the NEAR condition (H3: bias by distance interaction). Additionally, given the processing differences between Danish and Norwegian, we expected the bias effect to be stronger in Danish (H4: bias by language interaction) and the bias by distance interaction stronger in Norwegian (H5: bias by distance by language interaction).

To test these hypotheses, we fitted our experimental data to a drift diffusion model (Ratcliff, 1978), which jointly takes into account responses and response times as dependent variables and allowed us to separate the time preceding the decision making process (non-decision time), the rate at which evidence is accumulated (drift rate) and the amount of evidence needed to make a decision (boundary separation, see Methods for details). We expected to observe a longer non-decision time in Danish speakers than Norwegian speakers (H1). We expected the evidence accumulation rate to be affected by contextual bias (faster in congruent contexts, H2). We expected both drift rate and boundary separation to be affected by contextual bias in a way that is modulated by distance (stronger effect for the shorter distance, H3), and by language (Danish speakers being more sensitive to context, H4). Finally, we expected both drift rate and boundary separation to follow H5: Norwegian speakers

will show a stronger bias by distance interaction, that is, the way distance modulates contextual bias will be more marked for them (H5).

Method

Participants

Thirty-two Danish (22 female, age = 19 - 36 years, median = 23, sd = 3.3) and 34 Norwegian (13 female, age = 19 - 28 years, median = 22, sd = 2.5) right-handed native speakers participated in the study. The participants did not report a history of neurological or psychiatric disorders. The Danish speakers were tested at the Cognitive and Behavior Lab at Aarhus University in Denmark, while the Norwegian speakers were tested at the Faculty of Humanities at the University of Bergen in Norway. All participants received a monetary compensation for their participation.

Materials

We constructed 16 pairs of carrier sentences, half of which were biased towards the target word *sendt,* as shown in (1a) (Danish) and (1b) (Norwegian) and the other half towards *tændt* in Danish (2a) or *tent* in Norwegian (2b). In 8 pairs, the distance between the target and the disambiguating word was one syllable (NEAR condition); and in the remaining 8 pairs, it was 5-7 syllables (FAR condition). Importantly, in normal speech, except for the difference in the initial phoneme, the two target words have similar (rhyme) endings in both languages.

(1a) *Hun har **sendt** en (imponerende klar) mail.*
[ˈhun ˈhɑ ˈ**sɛntˢ** eˀn (empoˈneˀʌnə klɑˀ) ˈmɛjl]
'She has **sent** an (impressively clear) email.'
(1b) *Hun har **sendt** en (imponerende klar) mail.*
[ˈhʉn ˈhɑr ˈ**sɛnt** en (empoˈnerʌnə klɑr) ˈmɛjl]
(2a) *Hun har **tændt** en (imponerende klar) lampe.*
[ˈhun ˈhɑ ˈ**tˢɛntˢ** eˀn (empoˈneˀʌnə ˈklɑˀ) ˈlɑmbə]
(2b) *Hun har **tent** en (imponerende klar) lampe.*
[ˈhʉn ˈhɑr ˈ**tɛnt** en (empoˈnerʌnə klɑr) ˈlɑmpə]
'She has **turned-on** a(n) (impressively clear) lamp.'

Both the Danish and the Norwegian stimuli were recorded by a native male speaker of the respective languages. The recorded Danish [s] and [t^s] sounds in the target words *sendt* and *tændt* differed primarily according to the duration of the frication noise, the rise time of the noise, and the duration of the silent interval between noise offset and onset of the following vowel. The same was true for the Norwegian target words' [s] and [t^h] sounds, which in addition differed in intensity. A ten-step s-t continuum was generated for each language by interpolating between the endpoints according to the above-mentioned acoustic differences and splicing the resultant sounds to a single token of *tændt/tent*. The continua had a clear [s] at one end and a clear [t^s] (Danish) or [t^h] (Norwegian) at the other end and with eight intermediate steps.

We then piloted the two continua (forced choice identification). Based on the identification functions we chose steps 4, 5 and 6 as they straddled the mean category boundaries in each language. These three intermediate steps and the endpoints were used in the experiment. Thus, there were 160 trial sentences in total. The experiment was programmed and carried out in PsychoPy2 v1.90.1. (Peirce & MacAskill, 2018).

Procedure

Prior to the experiment, the participants received detailed instructions on the screen in their native languages. They were told to indicate which word they thought they heard and they were warned that sometimes this would not be easy. The participants were also instructed that they could use any information in the sentence that may help them to make their decision (cf. Connine et al., 1991; Szostak & Pitt, 2013). Following the instructions, the participants completed a practice trial and then the real experiment began. The target words *sendt* and *tændt/tent* were presented in boxes in the upper left and right corners of the screen while the target sentences were played back through headphones. The participants responded by clicking on the appropriate word with the mouse. They were allowed to respond at any point during and after the sentence playback (cf. Connine et al., 1991). There was a pause of 1.5 s between each trial, during which a blank screen was presented. The 160 stimuli were presented in a pseudorandomized order across four blocks of 40 trials. The first two items of the experiment contained the endpoints [s] and [t^s]/[t^h], respectively, in a congruent context. After each block, the participants had a self-paced short break. The whole experiment took 15 – 20 minutes. Responses and response times (RTs) were recorded as dependent variables. RTs were measured from the onset of the target word until the mouse click.

Data Analysis

Mouse clicks outside the boxes were recorded as missing values and were removed from the analysis. Further, responses corresponding to RTs higher than 3 standard deviations from the mean (> 8s) were also excluded from the analysis (2% of the total number of data points).

We fitted a Bayesian multilevel drift diffusion model (DDM) to the response and RT data. DDM is a sequential sampling model that explains cognitive processes underlying decision-making in 2-choice discrimination tasks (Ratcliff & McKoon, 2008). Decisions are described by the following parameters: the drift rate (δ) is the average rate of evidence accumulation; the boundary separation (α) is the evidence necessary to make a decision; the starting point (β) is the initial bias towards one of the response boundaries; and non-decision time (τ) is the part of the response time that is not involved in evidence accumulation (e.g., motor response execution). We conditioned drift rate and boundary separation on language, contextual bias (congruent/ incongruent), distance (NEAR/FAR) and continuum step as fixed effects, including their interactions, and participants as

varying effects, including varying slopes for bias, distance and step. We assumed no biased preference for a specific response and conditioned non-decision time on language and contextual bias only due to convergence issues. PSIS-LOO model comparison was used to select the relevant predictors to include (Vehtari, Gelman & Gabry, 2017), which led us to exclude step. We set weakly informative priors for δ (mean = 0, *sd* = 0.5), α (mean = 1.5, *sd* = 1) and τ (mean = 0.2, *sd* = 0.1). Model quality was thoroughly assessed via predictive prior and posterior checks, Rhat and divergence diagnostics. The model presented no divergences, and all chains mixed well and produced comparable estimates (Rhat < 1.01). In order to assess the evidence in favor or against our hypotheses, we used Evidence Ratio (ER, a generalization of Bayes factors allowing for directional hypotheses). An ER above 3 indicates moderate to substantial evidence for our hypothesis, below 0.3 indicates moderate to substantial evidence for the null hypothesis, and anything in between is inconclusive evidence (Morey, Rouder & Jamil, 2014). The models were implemented through the *brms* (Bürkner, 2017) and *RWiener* (Wabersich & Vandekerckhove, 2014) packages in RStudio v1.1.46, following the procedures of the tutorial written by Singmann (2017).

Results

Descriptive statistics are presented in Table 1. Full parameter estimates by condition are presented in Table 2.

Table 1: Mean reaction times ± standard deviations (in seconds) and *tændt/tent* response mean proportions ± standard deviations for Danish and Norwegian and NEAR and FAR distances with the context biased towards *sendt* or *tændt/tent*.

Language	Distance	Context bias	RT (s)	Response *tændt/ tent* (%)
Danish	NEAR	sendt	2.08 ± 0.82	66 ± 12
		tændt	2.15 ± 0.90	72 ± 8
	FAR	sendt	2.70 ± 1.07	66 ± 12
		tændt	2.71 ± 1.10	69 ± 10
Norwegian	NEAR	sendt	2.49 ± 0.98	34 ± 16
		tent	2.56 ± 1.02	50 ± 24
	FAR	sendt	3.38 ± 1.26	32 ± 18
		tent	3.35 ± 1.22	48 ± 22

As predicted by H1, we observed substantial evidence for non-decision time being longer in Danish than in Norwegian in congruent context ($\Delta\tau = 0.11 \pm 0.02$, ER > 1000), indicating that Danish speakers waited longer before starting to make a decision.

As per H2, we found substantial evidence for contextual bias affecting Danish speakers in the NEAR condition. When the response (i.e., *tændt*) matched the contextual bias (biased towards *tændt*, congruent context), evidence accumulation was faster ($\Delta\delta = 0.21 \pm 0.1$, ER = 45.5), than when the context did not match (biased towards *sendt,* incongruent context). There was also evidence that the boundary separation was larger for congruent context than for incongruent context ($\Delta\alpha = 0.98 \pm 0.29$, ER > 1000). Contrary to our expectations, however, there was no evidence that Norwegian speakers were affected by contextual bias ($\Delta\delta$ = -0.06 ± 0.12, ER = 0.46; $\Delta\alpha$ = -0.2 ± 0.36, ER = 0.41).

As expected (H4), we found substantial evidence for the bias effect being larger for Danish than for Norwegian speakers ($\Delta\Delta\delta = 0.27 \pm 0.12$, ER = 89.9, $\Delta\Delta\alpha = 1.18 \pm 0.39$, ER = 999). In other words, Danish speakers relied more on contextual evidence: matching context sped up their evidence accumulation more than for Norwegian speakers.

Table 2: The estimates of the diffusion drift model parameters per condition Bias (congruent/incongruent), Language (Danish/Norwegian) and Distance (NEAR/FAR). The parameters are drift rate (δ), boundary separation (α) and non-decision time (τ).

δ	estimate	95% CI
congruent:Danish:NEAR	2.12	1.94 - 2.31
incongruent:Danish:NEAR	1.91	1.75 - 2.07
congruent:Norwegian:NEAR	1.92	1.72 - 2.12
incongruent:Norwegian:NEAR	1.98	1.80 - 2.16
congruent:Danish:FAR	1.79	1.59 - 1.98
incongruent:Danish:FAR	1.74	1.56 - 1.93
congruent:Norwegian:FAR	1.70	1.47 - 1.92
incongruent:Norwegian:FAR	1.63	1.43 - 1.84
α		
congruent:Danish:NEAR	3.90	3.00 - 4.72
incongruent:Danish:NEAR	2.92	2.13 - 3.64
congruent:Norwegian:NEAR	4.31	3.27 - 5.29
incongruent:Norwegian:NEAR	4.52	3.58 - 5.41
congruent:Danish:FAR	3.25	1.94 - 4.48
incongruent:Danish:FAR	2.63	1.36 - 3.86
congruent:Norwegian:FAR	4.09	2.69 - 5.47
incongruent:Norwegian:FAR	3.55	2.16 - 4.98
τ		
congruent:Danish	0.57	0.54 - 0.6
incongruent:Danish	0.71	0.68 - 0.73
congruent:Norwegian	0.46	0.43 - 0.49
incongruent:Norwegian	0.50	0.46 - 0.54

We found moderate evidence that the drift rate was affected by contextual bias more in the NEAR condition than in the FAR condition in Danish speakers (H3: bias by distance interaction, $\Delta\Delta\delta = 0.15 \pm 0.17$, ER = 6.1). There was, however, no substantial evidence for boundary separation being affected by contextual bias differently according to distance ($\Delta\Delta\alpha = 0.37 \pm 0.58$, ER = 2.9). As for Norwegian speakers, there was no evidence either for drift rate ($\Delta\Delta\delta$ = -0.12 ± 0.17, ER = 0.3) or boundary separation ($\Delta\Delta\alpha$ = -0.75 ± 0.68, ER = 0.16) being affected more in the NEAR than in the FAR condition (against H3). Finally, as predicted, distance did not affect Norwegian speakers as much as

Danish speakers (H5, $\Delta\Delta\Delta\delta$ = -0.29 ± 0.18, ER = 16.7; $\Delta\Delta\Delta\alpha$ = -1.11 ± 0.71, ER = 15.7). This is likely to be due to the absence of bias effect in Norwegian altogether. The DDM simulations per each condition are depicted in Figure 1.

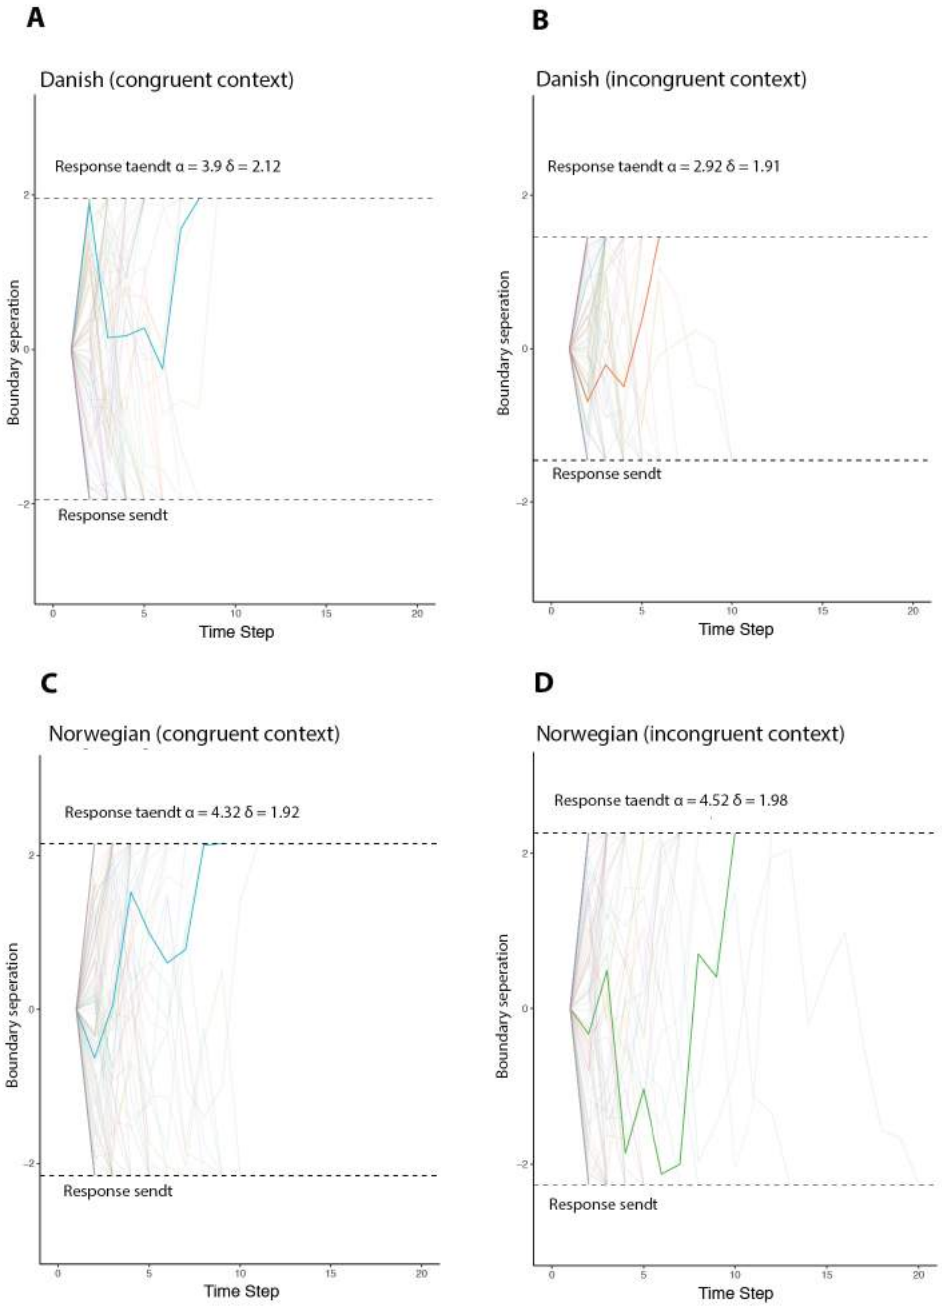

Figure 1: Simulation of the drift diffusion model for distance NEAR and congruent context (i.e. *tændt* bias) in A) Danish and C) Norwegian, and incongruent context (i.e. *sendt* bias) in B) Danish and D) Norwegian. The upper decision boundary is for the response *tændt* and the lower decision boundary is for the response *sendt*. The distance between the two boundaries is the boundary separation (α) and the evidence accumulation speed is the drift rate (δ). While there is no credible difference in drift rate between congruent and incongruent contexts for Norwegian, there is evidence that the drift rate is smaller in the incongruent context than in the congruent context in Danish. Thus, when the context is incongruent, evidence is accumulated slower to make a decision about *tændt*. The highlighted line is an example of the decision process in each condition.

Discussion

In the current study, we investigated whether contextual bias has a different effect on word recognition across the two related languages, Danish and Norwegian, and whether the distance between the target word and the disambiguating word affected word recognition across the two languages. We fitted our data to a drift diffusion model to obtain more subtle evidence about the cognitive processes underlying word recognition.

We found strong evidence that contextual bias affected the drift rate (the speed with which evidence is accumulated) in the NEAR condition in Danish. This indicates that acoustic-phonetic information alone is insufficient to make a decision and thus that additional evidence, such as contextual cues are integrated to support top-down processes of word comprehension. These findings are in line with previous evidence by Szostak and Pitt (2013) as well as Connine et al. (1991).

Surprisingly, we did not find evidence for contextual bias effects in Norwegian, which contradicts the previous evidence for English (Brown-Schmidt & Toscano, 2017; Bushong & Jaeger, 2017; Connine et al., 1991; McMurray et al., 2009; Szostak & Pitt, 2013). It is possible that this is because top-down contextual information is assigned even less weight in speech processing in Norwegian than in English or Danish. Moreover, Norwegian speakers may have responded prior to hearing the biasing context, thus not having the opportunity of using contextual information. In line with this, we found that Danish speakers generally wait longer to respond than Norwegian speakers (longer non-decision time in Danish compared to Norwegian, H1), which may be additional evidence that Danish speakers weight top-down contextual information more than bottom-up acoustic-phonetic information compared to Norwegians.

In line with our hypotheses, we found that Danish speakers were more affected by contextual biases than Norwegian speakers (H4), and that the contextual bias was stronger for Danish speakers in the NEAR condition than in the FAR condition, compared to Norwegian speakers (H5). However, importantly, the H3 interaction results held only for Danish, likely due to the lack of a contextual bias effect in Norwegian.

There was also some evidence that the bias effect on drift rate was stronger in the NEAR condition than in the FAR condition for Danish speakers but there was no credible evidence of the same effect on boundary separation. It is possible that a similar amount of information is necessary to make a decision about an ambiguous target word, as the nature of the information does not change across NEAR and FAR distances (i.e., the acoustic-phonetic cues are equally ambiguous and the disambiguating words remain the same). However, the speed at which this information is accumulated changes slightly. As Szostak and Pitt (2013) and Connine et al. (1991) suggested, there is a short temporal window to make a decision about the acoustic-phonetic information. Thus, in the NEAR condition, due to a higher drift rate in Danish speakers, it takes shorter time to choose a response that is congruent with the contextual bias (i.e., to respond *tændt* in a *tændt*-biased context).

The above-mentioned effect on drift rate was stronger for Danish than for Norwegian, indicating that the temporal window suggested by Szostak and Pitt (2013) may indeed vary due to different factors, in this particular case, phonological differences between languages. We interpret this evidence as suggesting that top-down contextual inferences are more important for Danish speakers compared to Norwegian speakers, when faced with acoustic-phonetically ambiguous stimulus. This may be because of the unique sound structure of Danish, which results in relatively more ambiguity in Danish speech than in other Scandinavian languages (Basbøll, 2005; Hilton et al., 2011; Gooskens et al., 2010). Thus, in line with first language acquisition studies (Bleses et al., 2008; 2011), we provide evidence that Danish is processed differently also by adult native speakers, compared to native Norwegian speakers.

It is possible that allowing participants to respond at any time during a trial may also have affected our results. Using the Connine et al. (1991) paradigm, Bushong & Jaeger (2017) showed that the context effect was smaller in the FAR condition, when the listeners could respond whenever they wanted. However, there was no difference between the NEAR and FAR conditions, when the listeners were forced to wait until hearing the biasing word to respond. In fact, the observation that participants change their response profile when forced to wait to the sentence offset, as shown by Brown-Schmidt & Toscano (2017), indicates that indeed free and forced responses may influence the decisions that listeners make. Thus, a future study comparing forced and free responses may shed light on the different strategies Danish and Norwegian speakers may be using when completing the task.

The current study, however, has one important limitation: the steps of the [s]-[t^s]/[t^h] continuum were not included in the DDM model. Step is a crucial feature and it could provide more nuanced information not only about the contextual bias and distance effect on word recognition processes but also how these processes vary cross-linguistically. Future work should include a nuanced modeling of step (e.g., as a monotonic but not necessarily a linear function) to assess whether step can be meaningfully included and help better explain the data. We anticipate that such analyses might provide a more detailed picture of the points in the continuum at which information is accumulated faster and at which more information is needed. Thus, a more complex drift diffusion model with the steps of the continuum as one of the fixed effect variables would shed further light on the cognitive processes underlying spoken word recognition when the acoustic-phonetic cues are ambiguous.

Despite these limitations, our study suggests that Danish is processed differently compared to Norwegian. When exposed to ambiguous stimuli, Danish speakers rely more on top-down processes than Norwegian speakers. Contrary to the standard view that all languages are equally easy to learn and use (e.g., Pinker, 1994), we provide evidence that

languages can differ in how they are processed, as suggested, for instance, by Evans and Levinson (2009)— and that there may be a continuum of reliance on top-down processes, where English could be lying somewhere between Danish and Norwegian. However, future cross-linguistic studies are necessary to confirm this assumption.

Abstract

How can people learn to make better decisions and become more far-sighted? To make the underlying learning mechanisms more accessible to scientific inquiry, we develop a computational method for measuring the time course of experience-dependent changes in people's planning strategies. We validated our method on simulated and empirical data: on simulated data its inferences were significantly more accurate than simpler approaches, and when evaluated on human data it correctly detected the plasticity-enhancing effect of performance feedback. Having validated our method, we illustrate how it can be used to gain new insights into the time course and nature of cognitive plasticity. Future work will leverage our method to i) reverse-engineer the learning mechanisms enabling people to acquire complex cognitive skills such as planning and problem-solving and ii) measure individual differences in cognitive plasticity.

Keywords: cognitive plasticity; planning; decision-making; process-tracing; statistical methods

Introduction

One of the most remarkable features of the human mind is its ability to continuously improve itself. As helpless babies develop into mature adults, their brains do not only acquire impressive perceptual and sensory-motor skills and knowledge about the world but they also learn to think, to make better decisions, to learn, and to monitor and adaptively regulate themselves. These phenomena are collectively known as *cognitive plasticity*. Just like the acquisition of perceptual skills (Hubel & Wiesel, 1970), the acquisition of cognitive skills requires specific experiences and practice (van Lehn, 1996; Ericsson, Krampe, & Tesch-Römer, 1993).

Despite initial research on how people acquire cognitive skills (van Lehn, 1996; Shrager & Siegler, 1998; Krueger, Lieder, & Griffiths, 2017), the underlying learning mechanisms are still largely unknown. Reverse-engineering how people learn how to think and how to decide is very challenging because we can neither observe people's cognitive strategies, nor how they change with experience – let alone the underlying learning mechanisms. Instead, cognitive plasticity has to be inferred from observable changes in behavior. This is difficult because each observed behavior could have been generated by many possible cognitive mechanisms. This problem is pertinent to all areas of cognition. As a first step towards a more general solution, we develop a computational method for measuring how people's planning strategies change depending on the person's experience. Initial work suggested that metacognitive reinforcement learning might play an important role in how people come to plan farther ahead (Krueger et al., 2017) and which strategies they use (Lieder & Griffiths, 2017) but the postulated mechanisms are difficult to investigate because cognitive plasticity has remained unobservable.

Our approach combines a recently developed process-tracing paradigm that renders people's behavior highly diagnostic of their planning strategies with probabilistic models of planning and learning that constrain the space of potential cognitive mechanisms and exploit temporal dependencies among subsequent planning strategies. Critically, our measurement model can be inverted to infer the sequence of people's planning strategies from the clicks they make in the process tracing paradigm. Our computational method makes it possible to observe how people's planning strategies change from each decision to the next. This sheds new light on the time course and the nature of metacognitive learning. Future work will reverse-engineer the learning mechanisms that generate the cognitive plasticity our approach is bringing to light.

The plan for this paper is as follows: we start by developing a computational method for measuring experience-dependent changes in people's planning strategies. Next, we validate it on synthetic data and human data. We then illustrate the utility of our method by measuring the time course of how people learn how to plan, characterizing the revealed learning trajectories, and testing hypotheses about cognitive plasticity. In closing, we discuss directions for future work.

Methods

Process-tracing using the Mouselab-MDP paradigm

Planning, like all cognitive processes, cannot be observed directly but has to be inferred from observable behavior. This is generally an ill-posed problem. To address this challenge, researchers have developed *process-tracing* methods that elicit and record behavioral signatures of latent cognitive processes; for instance decision strategies can be traced by recording the order in which people inspect the payoffs of different gambles (Payne, Bettman, & Johnson, 1993). While these behavioral signatures are still indirect measures of cognitive processes, they do provide additional information about

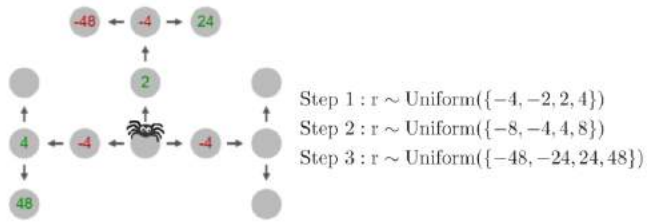

Figure 1: Illustration of the Mouselab-MDP paradigm. Rewards are revealed by clicking, prior to selecting a path with the arrow keys. The distribution of rewards underlying each node at a given step is shown on the right.

what the underlying cognitive strategy might be.

Here, we employ a process-tracing paradigm that externalizes people's beliefs and planning operations as observable states and actions (Callaway, Lieder, Krueger, & Griffiths, 2017; Callaway et al., 2018). Inspired by the Mouselab paradigm (Payne et al., 1993), the Mouselab-MDP paradigm uses people's mouse-clicking as a window into their planning.

The Mouselab-MDP paradigm illustrated in Figure 1 presents a series of route planning problems where each location (the gray circles), harbors a gain or loss. These potential gains and losses are initially occluded, corresponding to a highly uncertain belief state. The participant can reveal each location's reward by clicking on it and paying a fee. This is similar to looking at a map to plan a road trip. Clicking on a circle corresponds to thinking about a potential destination, evaluating how enjoyable it would be to go there, and adjusting one's assessment of candidate routes accordingly.

Measurement model

To develop an efficient computational method for inferring the temporal evolution of people's planning strategies, we make the simplifying assumption that the trial-by-trial sequence of peoples' cognitive strategies $(S_1, S_2, \cdots, S_{31})$ forms a Markov chain whose hidden states emit the observed process tracing data collect on each trial $(\mathbf{d}_1, \cdots, \mathbf{d}_{31})$. This hidden Markov model requires additional methodological assumptions about i) how cognitive strategies manifest in process-tracing data, ii) the space of cognitive mechanisms that can be learned, and iii) the nature and amount of cognitive plasticity that might occur. The following paragraphs detail our assumptions about each of these three components in turn.

Observation model. To plan in the Mouselab-MDP paradigm participants have to gather information by making a sequence of clicks. Our observation model thus specifies the probability of of observing a sequence of clicks $\mathbf{d_t}$ on trial t if the strategy was S_t (i.e., $P(\mathbf{d_t}|S_t)$).

To achieve this, we quantify each planning strategy's propensity to generate a click c (or stop collecting information) given the already observed rewards encoded in belief state b by a weighted sum of 29 features $(f_1(b,c), \cdots, f_{29}(b,c))$. The features describe the click c relative to this information (e.g., by the value of the largest reward that can be collected from the inspected location) and in terms of the action it gathers information about (e.g., whether it pertains to the first, second, or third step)[1]. The *depth* feature, for instance, describes each click by whether it looks 1, 2, or 3 steps into the future. The features and weights jointly determine the strategy's propensity to make click c in belief state b according to

$$P(\mathbf{d_t}|S_t) = \prod_{i=1}^{|\mathbf{d_t}|} \frac{\exp\left(\frac{1}{\tau} \cdot \sum_{k=1}^{|w^{(S)}|} w_k^{(S)} \cdot f_k^{(S)}(c_{t,i}, b_{t,i})\right)}{\sum_{c \in \mathcal{C}_{b_t}} \exp\left(\frac{1}{\tau} \cdot \sum_{k=1}^{|w^{(S)}|} w_k^{(S)} \cdot f_k^{(S)}(c, b_{t,i})\right)}, \quad (1)$$

where $d_{t,i}$ is the i$^{\text{th}}$ click the participant made on trial t (or the decision to stop clicking and take action), the decision temperature τ was set to 0.5 to match the variability of people's click sequences, and $w^{(S)}$ is the weight vector of strategy S.

Space of cognitive mechanisms. We formulated a set of 38 strategies $(\mathcal{S})$[1] to describe the process tracing data from Lieder (2018). These strategies include the optimal goal-setting strategy (Callaway et al., 2018) that starts by inspecting the possible final destinations and search-based planning algorithms such as breadth-first search, depth-first search, and best-first search (Russell & Norvig, 2016). 76.7% of the click sequences were the most likely instantiation of one of the 38 strategies. The clicks of the remaining 23.3% of the sequences were, at worst, second most likely under the best fitting strategy. These strategies differ in how much information they consider (ranging from none to all), which information they focus on, and in the order in which they collect it.

Building on the observation model in Equation 1, we represent each strategy by a weight vector $\mathbf{w} = (w_1, \cdots, w_{29})$ that specifies the strategy's preference for more vs. less planning, considering immediate vs. long-term consequences, satisficing vs. maximizing, avoiding losses (cf. Huys et al., 2012), and other desiderata. These weights span a high-dimensional continuous space with many intermediate strategies and mixtures of strategies. Cognitive plasticity could be measured by tracking how those weights change over time. But this would be a very difficult ill-defined inference problem whose solution would depend on our somewhat arbitrary choice of features. As a first approximation, our method therefore simplifies the problem of measuring cognitive plasticity to inferring a time-series of discrete strategies.

To understand what types of strategies people use, we grouped our 38 strategies using hierarchical clustering. This requires measuring the similarity between strategies. Since the strategies are probabilistic, we defined the distance metric $\Delta(s_1, s_2)$ between strategy s_1 and s_2 as the Jensen-Shannon

[1] A detailed description of the features and strategies is available at https://osf.io/y58d3/?view_only=fa2f89de3aa04d4d87af3d050bb1a64c

divergence (Lin, 1991) between the distributions of click sequences and belief states induced by strategies s_1 and s_2 respectively, that is

$$\Delta(s_1, s_2) = \mathrm{JS}\left[p(\mathbf{d}|s_1), p(\mathbf{d}|s_2)\right], \tag{2}$$

and approximate it using Monte-Carlo integration.

Applying Ward's hierarchical clustering method (Ward Jr, 1963) to the resulting distances suggested 11 types of planning strategies: acting impulsively without any planning, finding a goal and immediately moving towards it, inspecting both immediate and final outcomes (but no intermediate ones), overly frugal goal setting strategies, goal setting strategies that plan towards potential goals even when it is wasteful, exhaustive backward planning strategies that inspect all of the states, other far-sighted strategies that inspect all potential final states, forward-planning strategies similar to depth-first search, forward-planning strategies similar to best-first search, strategies similar to breadth-first search, and strategies that focus on the course of action that has received the most consideration so far.

Prior on strategy sequences. Inferring a strategy from a single click sequence could be unreliable. Our method therefore exploits temporal dependencies between subsequent strategies to smooth out its inferences. Transitions from one strategy to the next can be grouped into three types: repetitions, gradual changes, and abrupt changes. While most neuroscientific and reinforcement-learning perspectives emphasize gradual learning (e.g., Hebb, 1949; Mercado III, 2008; Lieder, Shenhav, Musslick, & Griffiths, 2018), others suggest that animals change their strategy abruptly when they detect a change in the environment (Gershman, Blei, & Niv, 2010). Symbolic models and stage theories of cognitive development also assume abrupt changes (e.g., Piaget, 1971; Shrager & Siegler, 1998), and it seems plausible that both types of mechanisms might coexist. To accommodate these different perspectives, we consider three prior distributions on participants' trial-by-trial sequence of cognitive strategies.

The *gradual learning prior* (m_{gradual} in Equation 3) assumes that strategies changes gradually, that is

$$P(S_{t+1} = s|S_t, m_{\text{gradual}}) = \frac{\exp(-\frac{1}{\tau} \cdot \Delta(s, S_t))}{\sum_{s' \in \mathcal{S}} \exp(-\frac{1}{\tau} \cdot \Delta(s', S_t))}, \tag{3}$$

where $\mathcal{S}$ is the set of strategies, $|\mathcal{S}|$ is the number of strategies, and the temperature parameter τ was set to achieve a 50% chance of a strategy change. By contrast, the *abrupt changes prior* (m_{abrupt} in Equation 4) assumes that transitions are either repetitions or jumps.

$$\begin{aligned} &P(S_{t+1} = s|S_t, m_{\text{abrupt}}) = \\ &\quad p_{\text{stay}} \cdot \mathbb{I}(S_{t+1} = S_t) + (1 - p_{\text{stay}}) \cdot \frac{\mathbb{I}(s \neq S_t)}{|\mathcal{S}|-1}, \end{aligned} \tag{4}$$

Finally, the *mixed prior* (m_{mixed} in Equation 5) assumes that both types of changes coexist.

$$\begin{aligned} &P(S_{t+1} = s|S_t, m_{\text{mixed}}) = \\ &\quad p_{\text{gradual}} \cdot P(S_{t+1} = s|S_t, m_{\text{gradual}}) \\ &\quad + (1 - p_{\text{gradual}}) \cdot P(S_{t+1} = s|S_t, m_{\text{abrupt}}). \end{aligned} \tag{5}$$

In each of these three cases, we model the probability of the first strategy as a uniform distribution over the space of decision strategies (i.e., $P(S_1) = \frac{1}{|\mathcal{S}|}$).

Together with the observation model and the strategy space described above each of these priors defines a generative model of a participant's process tracing data $\mathbf{d}$; this model has the following form:

$$P(\mathbf{d}, S_1, \cdots, S_T) = \frac{1}{|\mathcal{S}|} \cdot \prod_{t=2}^{T} P(S_t|S_{t-1}, m) \cdot P(\mathbf{d_t}|S_t). \tag{6}$$

The three measurement models differ in the identity of $m \in \{m_{\text{gradual}}, m_{\text{abrupt}}, m_{\text{mixed}}\}$. Inverting these models gives rise to a computational method for measuring an important aspect of cognitive plasticity.

Inference on cognitive plasticity

The models above describe how changes in cognitive strategies manifest in process-tracing data. To measure those cognitive changes, we have to reason backwards from the process tracing data $\mathbf{d}$ to the unobservable cognitive strategies $S_1, \cdots, S_T$ that generated it. To achieve this, we leverage the Viterbi algorithm (Forney, 1973) to compute maximum a posteriori (MAP) estimates of the hidden sequence of planning strategies $S_1, \cdots, S_T$ given the observed process tracing data $\mathbf{d}$, the measurement model m, and its parameters (p_{stay} for m_{abrupt} and p_{gradual} and p_{stay} for m_{mixed}). To estimate the model parameters we perform grid search with a resolution of 0.02 over $p_{\text{stay}} \in [0, 1]$ for m_{abrupt} and $(p_{\text{stay}}, p_{\text{gradual}}) \in [0, 1] \times [0, 1]$ for m_{mixed}.

Inferring the hidden sequence of cognitive strategies in this way lets us see otherwise unobservable aspects of cognitive plasticity through the lens of a computational microscope.

Validating the computational microscope

Validation on synthetic data

To validate our "computational microscope" for looking at cognitive plasticity, we apply it to simulated process tracing data. To avoid bias towards any one of the three measurement models, we used each of them to generate a data set with 100 simulated participants completing 31 trials each. We then combined the resulting three data sets into a single data set from 300 simulated participants.

We then inverted the three measurement models on each of the simulated trials ($\mathbf{d}$) and compared the maximum a posteriori estimate of each strategy sequence ($\hat{\mathbf{S}}$) against the ground truth (S) in terms of the proportion of correctly inferred strategies and the distance between the inferred strategies and the ground truth. To measure the distance between

two sequences of n planning strategies we define $\Delta(\mathbf{v},\mathbf{w})$ as $\frac{1}{n}\cdot\sum_{i=1}^{n}\Delta(v_i,w_i)$. For better interpretability, the relative distance $\Delta_{\text{rel}}(s_1,s_2)=\Delta(s_1,s_2)/\bar{\Delta}$ normalizes $\Delta(s_1,s_2)$ by the average distance between any strategy and its closest neighbour.

As a baseline, we evaluated the computational method that inverts the observation model in Equation 1 on each click sequences independently. This simple approach was sufficient to infer the correct strategy about 81% of the time (95% confidence interval: $[80.2\%,81.8\%]$). The average distance from the inferred strategy to the true one was only 21% of the average distance from each strategy to its closest neighbor ($\Delta_{\text{rel}}(\hat{\mathbf{s}}^{\text{baseline}},\mathbf{s})=0.215$, 95% confidence interval: $[0.20,0.23]$). This shows that the simulated click sequences were highly diagnostic of the strategies that generated them.

We found that exploiting the temporal dependencies among subsequent strategies by using either of the three measurement models significantly improved the proportion of correctly inferred strategies to 88.5%, 88.3%, and 88.5% for m_{gradual}, m_{abrupt}, and m_{mixed} respectively (all $p<0.0001$) and decreased the average distance between the inferred strategies and the ground truth by more than 40% ($\Delta_{\text{rel}}(\hat{\mathbf{s}}^{\text{gradual}},\mathbf{s})=0.124$, $\Delta_{\text{rel}}(\hat{\mathbf{s}}^{\text{mixed}},\mathbf{s})=0.124$, and $\Delta_{\text{rel}}(\hat{\mathbf{s}}^{\text{abrupt}},\mathbf{s})=0.127$, all $p<0.0001$). The minor differences between the accuracies and distances achieved with the three measurement models were not statistically significant ($\chi^2(2)=0.36$, $p=0.8373$ and $F(2,897)=0.06$, $p=0.942$ respectively). These results suggest that – under reasonable, theory-agnostic assumptions about what cognitive plasticity might be like – our computational microscopes for looking at cognitive plasticity can be expected to produce more accurate measurements than simpler methods.

Which measurement model is most suitable depends on whether the measured changes are mostly gradual, mostly abrupt, or a combination of both. This may vary across tasks and participants. We therefore invert all three measurement models on each participant's data and select the most appropriate measurement model for each participant according to the Akaike Information Criterion (Akaike, 1974). We then interpret the inferences obtained from inverting the selected model as the measurement of our computational microscope.

Validation on empirical data

To validate our computational microscope on empirical data, we applied it to the Mouselab-MDP process-tracing data from Experiments 1–3 by Lieder (2018) where 176 participants solved 31 different 3-step planning problems of the form shown in Figure 1. Concretely, we asked if our computational microscope can detect the effect of an experimental manipulation expected to promote cognitive plasticity, namely the feedback participants in the second condition of Experiment 1 received on the (sub)optimality of their chosen actions. This performance feedback stated whether the chosen move was sub-optimal and included a delay penalty whose duration was proportional to the difference between the expected returns of the optimal move versus the chose one.

Our computational microscope successfully detected the effect of this manipulation. As shown in Figure 2, the inferred learning-induced changes were significantly larger in the feedback condition than in the control condition in the first 15 trials and in trials 21–25 ($p\leq 0.012$ for each 5-trial bin) and nearly significant in trials 15–20 ($p=0.08$) and trials 25–30 ($p=0.06$). Furthermore, Figure 2 also shows that cognitive plasticity slowed down over time as participants adapted to experiment's stationary decision environment.

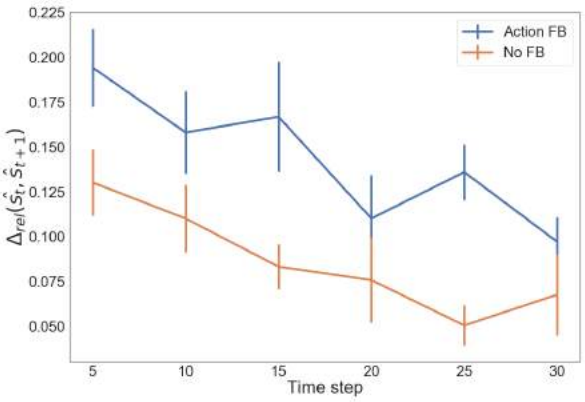

Figure 2: Feedback accelerates cognitive plasticity. This figure shows that feedback increased the amount of cognitive plasticity at the beginning of learning.

Next, we performed χ^2-tests with the Sidak correction for multiple comparisons to compare the frequencies of all possible strategy transitions (i.e., $P(S_{t+1}|S_t)$) between the experimental condition with action feedback versus the control condition. We found that action feedback selectively increased the probability of eight performance-increasing transitions from a strategy with a lower average performance (S_t) to a strategy with a higher average performance (S_{t+1}) and significantly decreased the probability of five performance-decreasing transitions and five strategy repetitions ($S_{t+1}=S_t$). By contrast, the feedback decreased the frequency of only one performance-increasing strategy-transition and increased the frequency of only two performance-decreasing strategy transitions.

Our method's ability to detect the plasticity-enhancing effects of feedback suggests that its inferences provide a valid measure of cognitive plasticity.

Shedding light on cognitive plasticity

Having validated our computational microscope on both simulated and empirical data, we now leverage it to measure how people learn how to plan by applying it to the process tracing data from the control conditions of Experiment 1 and the training phases of the control conditions of Experiments 2 and 3 from Lieder (2018). In the following, we illustrate how our computational microscope can be used to i) measure how people's propensity to use different cognitive strate-

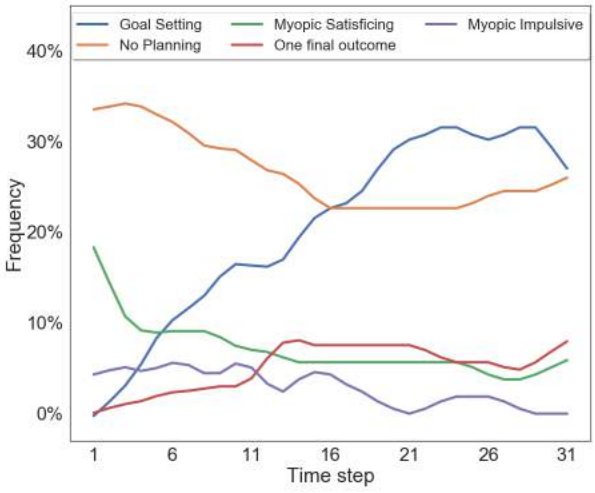

Figure 3: Time course of strategy usage frequencies of the five most common strategies.

gies evolves over time, ii) test theories of cognitive development and cognitive plasticity, and iii) characterize people's metacognitive learning trajectories.

Temporal evolution of strategy frequencies. As shown in Figure 3, we found that the most common initial strategy was to act impulsively without any planning (*No Planning*). The prevalence of this strategy decreased gradually over time from about 34% on average across the first five trials to about 25% on average across the last five trials ($\chi^2(1) = 7.95$, $p = 0.0048$).[2]. Conversely, the frequency of the near-optimal *Goal Setting* strategy increased from about 4% to 30% ($\chi^2(1) = 148.85, p < 0.0001$). The frequencies of the two maladaptive strategies that decide based on immediate rewards (*Myopic Satisficing* and *Myopic Impulsive*) dropped from about 11% and 4% respectively to about 5% ($\chi^2(1) = 11.74, p = 0.0006$) and 0.6% ($\chi^2(1) = 11.62, p = 0.0006$) respectively, whereas the frequency of the strategy *One Final Outcome* that prioritizes long-term consequences increased from about 1% to about 6% ($\chi^2(1) = 20.22, p < 0.0001$). Jointly these strategies accounted for about 53%–72% of our participants' planning across the different trials of our experiment.

Testing hypotheses about the nature of cognitive plasticity. Prominent theories of cognitive development disagree about whether it proceeds in discrete stages (Piaget, 1971) with abrupt transitions or continuous gradual change (Siegler, 1996). Inspired by these theories, we asked to which extent learning how to plan in the Mouselab-MDP paradigm proceeds through gradual changes versus abrupt transitions. Our computational microscope suggested that cognitive plasticity includes both gradual and abrupt strategy changes. We observed that the data from $63.0\% \pm 4.9\%$ of our participants was best captured by the abrupt model, while the data from $29.8\% \pm 4.6\%$ of the participants were best captured by the gradual model, and the data from $7.2\% \pm 2.6\%$ were best captured by the mixed model. A more fine-grained analysis of the individual inferred transitions revealed that the majority of strategy changes was gradual (i.e., 59.1%, $\chi^2(1) = 56.8$, $p < 0.0001$) but there was also a non-negligible percentage of abrupt changes (i.e., 40.9%). In total those different types of strategy changes constituted 22.8% of all transitions; that is 77.2% of the inferred transitions were strategy repetitions.

Siegler's overlapping waves theory (Siegler, 1996) asserts that multiple cognitive strategies are being used in parallel at each time during cognitive development. It further asserts that the relative frequencies of these strategies shift towards increasingly more adaptive strategies and that there are intermediary strategies whose frequency waxes and vanes. Under the strong assumption that the underlying plasticity mechanisms are the same as those that drive learning in the Mouselab-MDP paradigm, we predicted that the same patterns should also occur in the participants' strategy sequences. To test the first prediction, we performed χ^2-tests on the strategies' frequencies in all bins of 5 consecutive trials. In support of the hypothesis that multiple different strategies are used at each point in time throughout the learning process we found that on average 2.16 strategies were each used by significantly more than 5% of our participants in any given trial of the experiment (95% confidence interval: $[2.02, 2.30]$). Consistent with the prediction that high-performing strategies become more prevalent over time whereas low-performing strategies become less prevalent over time we found a significant rank correlation between each strategies' average performance and the change in their frequency from the first trial to the last trial (Spearman's $\rho(37) = 0.39$, $p = 0.0154$). On the population level, we did not find any evidence for intermediary strategies whose average frequency across participants initially increases and later decreases again. That is, there was no strategy whose frequency was higher in the middle two time bins than in both the first two time bins and the last two time bins. Yet, overall the measurements we obtained with our computational microscope suggest that learning in the Mouselab-MDP paradigm is better described by the overlapping waves theory than by stage theories of cognitive development.

Learning trajectories. To identify the most common learning trajectories, we categorized each inferred strategy as belonging to one of the 11 types of strategies described earlier. We then extracted the order in which different strategy types appeared in the inferred sequences. Using this analysis, we found that there were almost as many unique learning trajectories as there were learners: The 110 participants

[2] All χ^2-tests in this paragraph compare the average frequency in the first five trials against the average frequency in the last five trials.

who changed their strategy at least once displayed 94 unique learning trajectories; that is 85.4% of the learning trajectories were unique and the remaining trajectories were exhibited by only 2–4 learners each. Zooming in on the 49 participants who learned the near-optimal goal setting strategy, we found that they reached the near-optimal goal setting strategy via 38 unique learning trajectories. Consistent with the overlapping waves theory, we found that 84.2% of these learning trajectories included at least one intermediary strategy between the initial strategy and the final strategy. Most importantly, our analysis revealed three dominant gateways to optimal planning: 35% of the penultimate strategies inspected all potential final states – whereas the optimal strategy stops searching for better final states once it encounters the best possible outcome – and sometimes planned backwards from undesirable states; 27% of the penultimate strategies inspected the potential final states in a manner akin to the optimal strategy but additionally and wastefully inspected paths towards undesirable final outcomes, and 21% of the penultimate strategies inspected both immediate and final outcomes while ignoring the intermediate states. This suggests that participants discovered the optimal goal setting strategy via intermediate strategies that perform gratuitous planning. Furthermore, we found that about 42% of participants who succeeded to learn a near-optimal goal setting strategy started with strategies that inspect both immediate and final outcomes without looking at intermediate ones. In addition to the 110 participants who changed their initial strategy, 66 participants (37.5%) never changed their strategy. The majority of those participants always acted impulsively without any planning (21% of all participants). Consistent with the interpretation that those participants were less engaged in the experiment and had not paid close attention to the instructions, we found that they performed substantially worse on the four attention check questions at the end of the experiment than participants who had demonstrated learning (1.7 errors vs. 0.8 errors on average; $t(111) = -5.80, p < .0001$). In addition, 9% of all participants always inspected immediate and final outcomes while ignoring intermediate rewards, 4% always focused exclusively on final outcomes, and 3.5% used other types of strategies.

Discussion

We have successfully validated our method on both synthetic and human data. The results suggest that our computational microscope can measure cognitive plasticity in terms of the temporal evolution of people's cognitive strategies.

Our findings suggest that this method has great potential for helping cognitive scientists uncover the mechanisms of cognitive plasticity and how they are impacted by the learning environment, individual differences, time pressure, motivation, and interventions – including feedback, instructions, and reflection prompts.

We are optimistic that computational microscopes will become useful tools for reverse-engineering the learning mechanisms that enable people to acquire complex cognitive skills and shape the way we think and decide. To make this possible, we will extend the proposed measurement model to continuous strategy spaces, a wider range of tasks and strategies, and learning at the timescale of individual cognitive operations. In addition, future work will also leverage our computational microscope to elucidate individual differences in cognitive plasticity within and across psychiatric conditions and different age groups.

The tentative conclusions we obtained with our first prototype of a computational microscope for measuring cognitive plasticity should be taken with a grain of salt because more psychologically plausible distance metrics and more realistic strategy representations could lead to different conclusions about the nature of cognitive plasticity. In this first step, we determined the similarity between strategies based on their behavior. But two strategies that look very different could result from similar mechanisms. Future work will identify a low-dimensional continuous strategy space by decomposing each strategy into its Pavlovian, habitual, and model-based components (van der Meer, Kurth-Nelson, & Redish, 2012). This more realistic representation will allows us to measure the similarity between strategies by comparing the underlying neurocomputational mechanisms. In addition, we will seek to validate the robustness of our computational microscope by measuring its performance on data generated from more realistic models of cognitive plasticity (e.g., Krueger et al., 2017; Lieder et al., 2018).

The approach developed in this paper makes it possible to more directly observe the previously hidden phenomenon of cognitive plasticity in many of its facets – ranging from skill acquisition, learning to think differently, reflective learning, cognitive decline, self-improvement, changes in cognitive dispositions, and the onset, progression, and recovery from psychiatric symptoms and mental disorders. This will make it easier to reverse-engineer people's ability to discover and continuously refine their own algorithms.

Abstract

So-called insight problems are believed to tap into sudden, creative thinking that is crucial for real problems. In contrast, recent findings suggest that solving insight problems depends on the same cognitive mechanisms that underpin systematic, analytical thinking. However, existing studies may have low ecological validity, because insight problems were usually presented in static formats (on paper, computer screen) which allowed no physical interaction with the problem elements. This study administered 8 established insight problems either in the static or interactive variants. It also probed two markers of analytical thinking: working memory capacity and reasoning ability. Virtually no difference in performance was observed between the static and interactive variants of insight problems with regard to (1) solution rate, (2) subjective experience of suddenness, pleasure, and relief accompanying the solutions, as well as (3) correlations with the working memory capacity and analytical reasoning tests. These results suggest that externalized/embodied/situated factors play no substantial role in insight problem solving and the crucial parts of this process seem to occur in the mind of a solver.

Keywords: insight problem solving; analytical thinking; working memory; interactivity.

Introduction

An important category of problems investigated in the problem solving literature is so-called insight problems. Such problems are defined in the vague and misleading way that suggests a typical but wrong problem representation, so following this representation often results in an impasse. The correct solution can be found only when the problem is viewed from a novel perspective and can be appropriately restructured. Especially difficult are problems that require rejecting one strongly believed and subjectively obvious assumption that, however, is not implicated by the problem description (Knöblich, Ohlsson, Haider, & Renius, 1999). For example, when instructed to transform an incorrect equation including Roman numerals made of matchsticks: "VI = VI + VI" into a correct equation by moving just one matchstick (without adding or removing any matchsticks), people must realize that equations do not necessarily include only one equation sign and that two such signs can also be allowed, here resulting in the tautology "VI = VI = VI". Insight problems have been studied intensively in cognitive science and psychology because many authors believe that they tap into mental processes that also play a role in "full-blown" creative cognition, leading to great masterpieces, discoveries, and inventions (Ohlsson, 2011).

The crucial controversy is whether the processing underpinning insight problem solving is distinct from solving so-called analytical problems, such as complex but typical arithmetic equations, which are defined in a more precise way, and require more systematic construction of the problem representation, while including no tricky obstacles. Some evidence suggested that insight problem solving involves idiosyncratic processes: constraint relaxation, defocusing attention, and uncontrolled spread of activation in memory (Knöblich et al., 1999; Kounios & Beeman, 2014), and so relies minimally on cognitive resources such as executive control and working memory capacity that typically determine success on analytical problems (see Wiley & Jarosz, 2012). Other evidence highlighted a large overlap of attentional, control, memory, reasoning, and imagery processes for insight and non-insight problems (MacGregor, Ormerod, & Chronicle, 2001; Weisberg, 2015). Specifically, two recent meta-analyses suggested that individual success on insight problems is strongly correlated with performance on analytical problems as well as with executive control and working memory tasks (Chuderski & Jastrzębski, 2018a; Gilhooly & Webb, 2018).

However, such a similarity of insight and analytical thinking might result from the fact that most of the experiments to date presented insight problems in a static format, usually printed on a paper sheet or shown on a computer screen, and participants were not allowed to interact with the problem by manipulating its elements. For instance, in a typically administered matchstick arithmetic problem, there are no actual matchsticks to be manipulated; all transformations of the equation must proceed in the mind, and the potential solution has to be written down. This lack of interaction with the problem may to some extent impede more spontaneous, "fuzzy" cognition that might be crucial for creative solutions. Participants, forced to represent and explore the problem space solely in the mind, might be prone to using more systematic, gradual problem solving strategies typical for analytical problems, while in the contexts that are

more externalized/embodied/situated they switch to less systematic strategies, such as trial-and-error, remote associations, etc. Obviously, the former strategies are more strictly constrained by available attentional resources and working memory capacity, while cognitive load might be largely reduced when artefacts can be used. Also, as many real-life problems seem to be situated to a large extent (see Clark and Chalmers, 1998; Cowley & Vallée-Tourangeau, 2010), investigating insight problem solving using non-interactive paradigms may yield low ecological validity.

Interactive insight problem solving

Indeed, a few studies by F. Vallée-Tourangeau, who applied insight problems in such a way that problems elements could be manipulated, as compared to static variants, have shown that solutions occur more frequently when the problem can be interacted with. Substantial effects, reaching the doubled solution rates, have been reported for the well-known insight problems such as the cheap necklace (Henok, Vallée-Tourangeau, & Vallée-Tourangeau, 2018; see also Fioratou & Cowley, 2009), the triangle of coins (Vallée-Tourangeau, 2017), the anagrams (Vallée-Tourangeau & Wrightman, 2011), the animals in pens (Vallée-Tourangeau, Steffensen, Vallée-Tourangeau, & Sirota, 2016), Luchins' water jars (Vallée-Tourangeau, Euden, & Hearn, 2011), and matchstick arithmetic (Weller, Villejoubert, & Vallée-Tourangeau, 2011). Also, some studies reported no difference in working memory capacity between solvers and non-solvers in the situated context. All this suggests that cognitive processing may change substantially in the embodied/situated contexts.

Besides the fact that virtually all these data (except for Fioratou & Cowley, 2009) come from one and the same lab, and thus require independent replication, existing evidence needs to be extended for at least three reasons. First, each study examined a single insight problem, applied either in the computerized/paper format or in the interactive format. As different samples of participants were used in consecutive studies, it is not possible to compare across the problems the size of presumed benefit from interactivity. (Do all problems benefit equally?) Second, recent studies (Danek, Wiley, & Öllinger, 2016; Fleck & Weisberg, 2013) probed experience during solution (asked how sudden and surprising it was), and suggested that many insight problems, originally designed to require sudden restructuring, by some participants could be solved in a fully systematic, gradual way. Thus, probably no insight problem always elicits "pure" insight. Unfortunately, so far subjective measures of insight have not been combined with examination of interactivity. Examining if interactivity can affect the subjective experience of insight might reveal mechanisms facilitating solutions. Finally, because to date, single problems were studied, the resulting binary dependent variables prohibited a proper analysis of correlations between performance on insight problems, analytical problems, and working memory tests. (Do interactive variants correlate with cognitive aptitude more weakly than the static variants?) All these research goals have important ramifications for our understanding of insight problem solving.

To tackle these three goals, the present study applied 8 popular insight problems. They were organized in 4 pairs of comparable problems. In each pair, one problem was shown in a typical, paper-and-pencil format, while the other problem was applied in a way that allowed manipulating the artifacts comprising this problem. Which problem from each pair was applied in the static format, and which was applied in the interactive way, was randomized across the sample. This fact allowed the within-subjects manipulation of the presentation format that gave control over group differences in general performance. Moreover, the size of the expected interactivity effect could be compared across the problems, in order to see if the problems differ in how strongly they benefit from externalizing. Additionally, after each solution given to an insight problem, the four-dimensional scale that probed the subjective experience of suddenness, pleasure, relief, and certainty accompanying the solution, was applied in order to see if the surplus solutions, which were expected to occur in the interactive problem format, would consist primarily of solutions assessed subjectively as the Aha! experience. Finally, an established working memory test and a hallmark analytic reasoning test were applied in order to compare whether the correlations of these two measures with the interactive variants could really be weaker than the respective correlations with the static variants, the latter presumed to load more substantially on cognitive resources.

The study

Participants

The total sample included 64 people (34 females; aged 19 to 39, M = 25.8 y, SD = 5.3 y). All participants were recruited from the general population via internet adverts and paid an equivalent of 12 USD in local currency. They signed a written consent to participate, were screened for normal or corrected-to-normal vision and no history of neurological problems, and were informed that they could stop the experiment and leave the lab at will. Data were anonymized. All other procedural aspects of the study conformed to the WMA's Declaration of Helsinki.

Insight problems

Matchstick arithmetic. Two matchstick arithmetic problems consisted of incorrect arithmetic equations written using Roman numerals. One problem was the above described "VI + VI = VI" equation. The second problem (I = II – II) required introducing a negative number (not a typical Roman numeral) by changing one of the sticks into the minus sign. The instructions were: "This equation consists of Roman numerals made of sticks. Unfortunately, the equation is wrong! Move exactly one stick so that the equation becomes correct. The allowed operations are „–," „+" and „=." You can't remove any stick. Upright sticks and tilted sticks are not

interchangeable („|/" is not „\/")." In order to familiarize the participants with the Roman numerals, the instruction contained also a table linking each Arabic number with its Roman equivalent, up to number ten. In the interactive format, the equations were constructed out of plastic sticks.

Triangle of coins/Eight coins. In the first problem, the participants were presented with a triangle facing upwards composed of 10 coins, and their task was to "Move exactly 3 coins to make the triangle point downward." In the eight coins problem, the participants were presented with a figure composed of 8 coins, and they had to "Move exactly 2 coins so that each of the 8 coins touches exactly 3 coins," which requires realizing that the coins have to form 3D piles. Both configurations require breaking constraints (of the X-axis rotation and 2D solution, respectively). In the interactive formats of the two tasks, the initial configurations were composed of real coins that could be manipulated freely. In the triangle problem, the response included presenting to the research assistant all the steps that had led to the solution.

Sheep in pens/Nine dots. In the first problem, the task was to "Close the 11 sheep in 4 pens so that in each pen there is an odd number of sheep." In the interactive format, the participants were given 11 small cloth figures of sheep and 4 pieces of string. As it is impossible to divide the number 11 into any combination of 4 odd numbers, the solution required embedding at least one of the pens inside another pen. In the nine dots problem, a 3×3 array of dots was presented and the task was to "Connect all the 9 dots with a broken line composed of 4 straight lines so that each following straight line begins at the end of the preceding line." In the correct solution, the lines should extend beyond the square shape of the array, but most people constrain themselves to explore only lines that fit within the array. In the interactive format, the participants were given tacks, 4 pieces of string, and a piece of paper with 9 dots printed.

Card split/Figure split. In the first task, participants were instructed to "Cut a hole in the card so that you can put your head through." In the figure split, problem participants were presented with an L-shape figure and the task was to "Divide the figure into four identical parts." Both problems require non-standard topological solutions. In the interactive formats of the tasks, participants were given scissors and several card/L-shape figures made of thick paper to experiment with.

Problems administration. In all the 8 problems, there was an identical instruction for each variant, and the variants differed only in the presentation method and response format. In the static variant, problems were given on a sheet of paper, with a blank space for making notes and drawings, and for providing a solution using a pen. In the interactive variants, the participants were given a cardboard box with respective objects placed on it, but were not provided with anything to write with, so they had to physically manipulate the objects provided. Participants were tested in individual cabins. The time limit for each problem was 5 minutes.

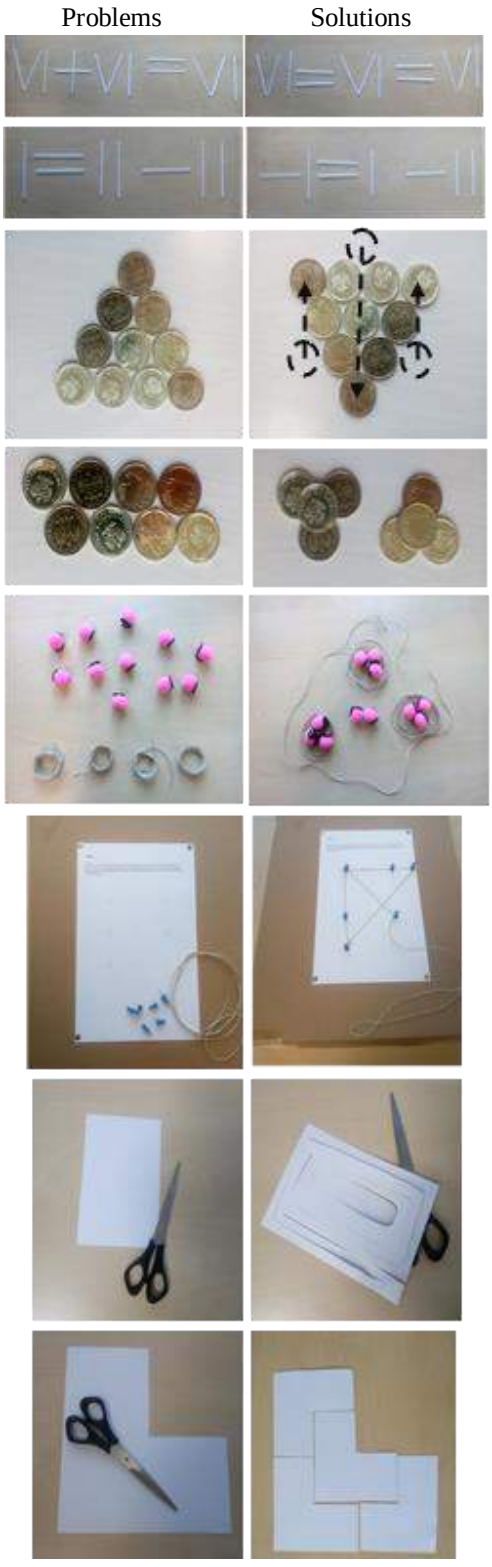

Fig. 1: The eight problems in initial configurations presented to the participants in the interactive format (left column) together with the sample correct solutions (right column). In the static format (not depicted) each problem elements were printed on a paper sheet, and a solution had to be drawn.

Subjective experience scale

The scale was modelled after Danek and Wiley (2016), who tested which dimensions of subjective experience best predict correct solutions to insight problems (suddenness, pleasure, relief, certainty). Here, the instruction was "Please describe your subjective experience at the moment when you found the solution to this problem", and the four questions were:
"The solution came to me…" (Gradually – Suddenly)
"At the moment of finding the solution my feelings were…" (Unpleasant – Pleasant),
"When I realised the solution I felt…" (Tension – Relief)
"My feeling that the solution was correct was…" (Uncertain – Certain)
Ratings were recorded on a 19-point graphical scale (line of cells) for which the contradicting words (e.g. Unpleasant – Pleasant) occupied the extremes. Point "10" was marked with the text "Don't know", and served for inconclusive cases.

Working memory task

The letter complex span required memorizing 4, 6, or 8 letters, which were drawn from 9 possible stimuli and were presented using a computer for 1.2 s apiece. After each letter presentation, participants indicated with a mouse button if a simple arithmetic equation (e.g., 2 × 3 – 1 = 5?) was correct. Then, they were to recall the letters in proper order. Five trials for each set size (in increasing order) were presented. The response procedure employed as many 3×3 matrices as was a particular set size. Each matrix contained all possible letters. Those letters that had been presented in a sequence should be selected in the matrices in the correct order. There was no time limit for responding. The dependent variable was the proportion of correctly selected letters.

Reasoning test

Raven Advanced Progressive Matrices (RAPM; Raven, Court, & Raven, 1983) consists of items that include a 3×3 matrix of figural patterns which is missing the bottom-right pattern, and 8 response options presenting the potentially matching patterns. The goal was to discover the rules that govern the distribution of patterns and to choose the response option including the correct pattern that completed the matrix according to these rules. The 18 odd-numbered items were given with the 20-min. time limit.

Procedure

Participants were tested in groups of 5 to 9 people. They first undertook RAPM and the letter complex span (as well as several other cognitive tests unrelated to the present study). Then, they attempted the 8 insight problems in the fixed order. A random half of the sample attempted the odd-numbered problems in the interactive variant and the even-numbered problems in the paper-and-pencil variant. The other half used the paper and pencil for the odd-numbered problems and the interactive formats for the even-numbered problems. The entire session lasted about 2 hours.

Results

No one was able to solve correctly the Card split and Letter split problems, so the analysis pertained to the 6 remaining problems. Participants admitted familiarity with 11 out of 384 problems applied, and these 11 problems were excluded from further analysis. Fig. 2 presents the number of correct solutions for each problem, for the static versus interactive format, separately. The Triangle of coins problem was the easiest one, solved by 37.5% of participants. In contrast, the 8 coins and the 9 dots problems were most difficult, solved only by 7.8% of the sample. These solution rates matched some existing data for the same problems (e.g., Chuderski & Jastrzębski, 2018b, 2018c). Importantly, for no problem the difference between the static and the interactive format was statistically significant. The largest numerical difference was observed for the Triangle of coins problem, which was solved by 15 people (out of 32) in the static format, and by 9 (out of 32) in the interactive format, but even this difference was far from reaching statistical significance, $\chi^2(1) = 1.50$, $p = .220$. Overall, 41 problems were solved with the paper and pencil, while 37 problems were solved in the interactive way, which is a totally non-significant difference.

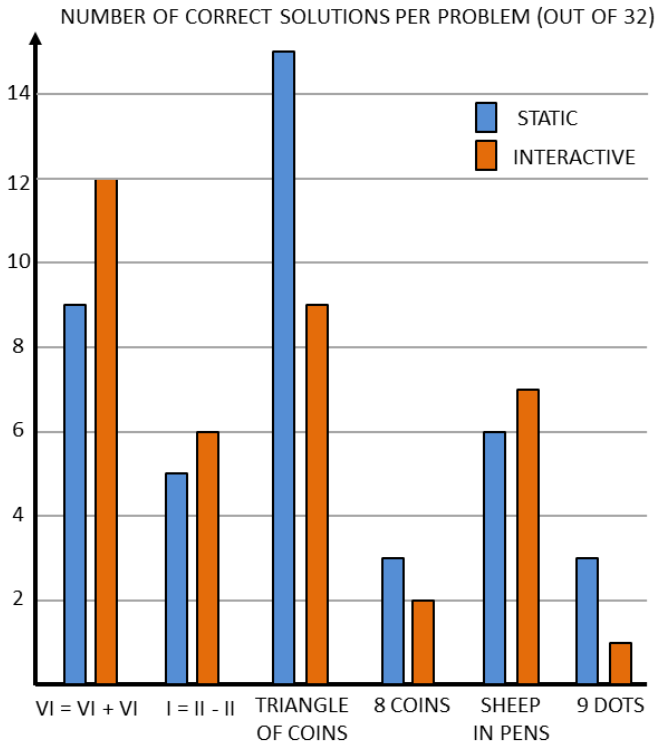

Fig.2: Number of insight problems (only those reported by the participants to be unfamiliar to them) correctly solved by the group who attempted a given problem in the static format (blue bars) vs. the group who undertook it in the interactive format (red bars). For no problem the difference between the conditions was significant at the $p < .05$ level.

Next, as it was possible that even though overall problem solving accuracy was not affected by the problem format, but it changed the way of processing the problems (at least the way subjectively experienced, and later reported, by the participants). Fig. 3 presents mean ratings for 4 indicators of insight: suddenness, pleasure, relief, and certainty, for 41 problems solved in the static format versus 37 interactive problems. Mean ratings ranging from 11 to 16 suggest that solutions yielded experience more typical for insight than for gradual, analytical processing. These ratings were submitted to MANOVA, with the problem variant (static vs. interactive) as a factor. Wilks' $\lambda = 0.917$ suggested no significant multivariate difference in experience between problem variants, $p = .173$. Second, single ratings were compared, with the Tukey correction for multiple comparisons. The only significant difference between the problem variants was noted for certainty, $F(1, 76) = 4.45$, $p = .038$, $\eta^2 = .06$, with interactive variants yielding 20% higher certainty of the correctness of the solution, as compared to the static variants. For the single problems, only the "VI = VI + VI" and the Triangle of coins problems yielded enough solutions (>20) so the accompanying reports could be compared meaningfully. For the former problem, significantly higher ratings in the interactive variant were observed for pleasure, $F(1, 20) = 7.58$, $p = .012$, $\eta^2 = .27$. No significant difference in ratings between variants was observed for the latter problem.

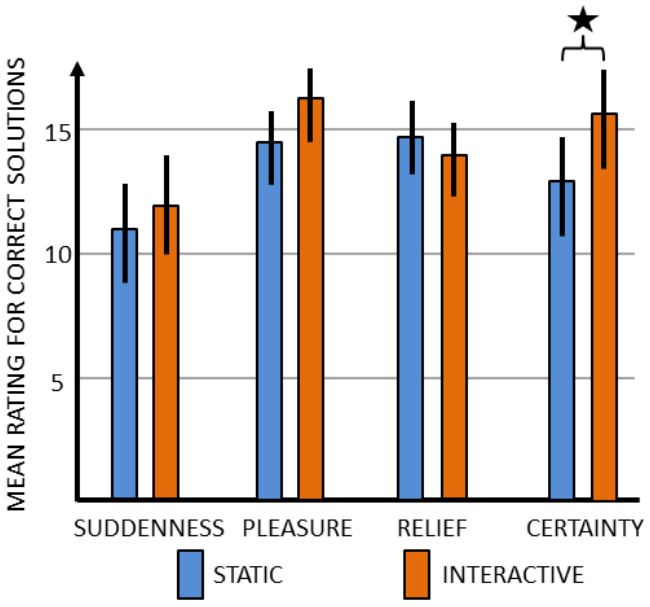

Fig. 3: Mean ratings for the reported subjective experience of suddenness, pleasure, relief, and certainty during correct solutions of insight problems, separately for the 41 problems in static variants versus the 37 problems in interactive variants. The star indicates a weak difference significant at the $p < .05$ level (for the experience of certainty). The three other differences were non-significant.

Finally, for each participant her or his score on all the 6 problems, the 3 problems applied in the static format, and the 3 problems applied in the interactive formats were calculated. The Spearman rank correlation was computed to assess the relationship between the number of problems solved and the letter complex span and RAPM scores. The resulting correlations are presented in the Table.

Table: Matrix of Spearman correlations between variables

Variable	1.	2.	3.	4.
1.All 6 problems	1			
2.Static variants	.756	1		
3.Interactive variants	.765	.195	1	
4.Complex span	.404	.316	.282	1
5.RAPM	.640	.520	.465	.353

Note. $N = 64$. All correlations significant at $p < .05$ except for the correlation between static and interactive variants.

Overall, correlations between the insight problem scores and the complex span (*rhos* ≈ .3) and RAPM (*rhos* ≈ .5) were substantial. However, the difference in correlation with the complex span between the scores on static versus interactive variants equaled only $\Delta rho = .034$ that was far not significant. The analogical difference for RAPM equaled $\Delta rho = .055$, which was not significant, either.

Discussion

The present study aimed to examine the role of interactivity in the process of insight problem solving. More specifically, it aimed to test (1) whether insight problems could be more frequently solved when presented in the interactive format allowing physical manipulation of the problem elements, as compared to the static format; (2) whether solutions in the former format could yield different subjective experience of suddenness, pleasure, relief, and certainty than yielded by solutions in the static format; and (3) how much performance on the interactive variants depended on cognitive resources, in comparison to the static variants.

A variety of established insight problems were used, which ranged in difficulty from a complete floor up to over one-third of correct solutions. Given existing evidence, the present results were quite surprising. There was virtually no difference in problem solving accuracy, regardless of the format used. Subjective experience reported, especially the suddenness of solution, linked closely to actual insight, was comparable for both problem formats. One exception was slightly increased certainty in interactive problem variants, which might have resulted from the fact that interactively delivered solutions were more concrete, so they could be more directly evaluated than the solutions written on paper. Importantly, both the static and the interactive problem variants substantially depended on working memory capacity and analytic reasoning and did it in a fully comparable way. Consequently, no evidence was found for any substantial

effects of interactivity on the process of insight problem solving on the sample of diverse and established insight problems. As both static and interactive conditions substantially relied on working memory/reasoning ability, no evidence was found for the decreased role of analytic thinking in the interactive format. Thus, it seems that physically manipulating problem elements did not substantially decrease cognitive load or affect the use of strategies in the process of problem solving.

On the other hand, it may be arguable to what extent the paper-and-pencil format, at least in case of some particular problems, is fully static, i.e. it does not provide any external support that may help in the process of solving. For example, making drawings and sketches may help to test hypotheses, keep track of the progress and perform simple trial-and-error strategies compared to problem solving without any external support provided. Thus, comparing interactive, static paper-and-pencil and the "pure" static format at the same time should be considered in future studies.

We cannot fully exclude the possibility that the null effects observed in the present study resulted from the selection of the particular problems or the specific way the interactive format was implemented in the given problems. If interactivity substantially affects only specific insight problems under some specific conditions it would be valuable to identify the characteristics of such problems that moderate this effect. Also, one limitation of the present study is that although no substantial effects of interactivity were observed, the relatively low statistical power prevented the detection of any potential small effects. However, if the effects of interactivity are negligible or observed only in very specific problems or circumstances, it would be questionable whether the role of interactivity in the process of insight problem solving is an important research topic at all.

Summing up, no evidence was found that manipulating physically problem elements when solving problems presumably involving insight helps to reach the correct solution. Neither the influence on the course of the problem solving process (the extent of its suddenness) nor on its affective consequences (pleasure, relief) were observed. Interactivity did not decrease a substantial reliance of the problem solving process on working memory capacity and reasoning ability, either. The only observed effect was a small increase in certainty about the solution (a meta-cognitive consequence). Thus, at least for the problems applied in the present study, externalized/embodied/situated factors played no substantial role in finding solutions, and the results are in line with the key role of analytic reasoning in solving insight problems. Still, more research is needed to comprehensively examine the potential role of interactivity in the process of insight problem solving.

Abstract

Scientists seek to discover truths that are interesting and important. We characterized these notions by asking laypeople to assess the importance, interestingness, surprisingness, practical value, scientific impact, and comprehensibility of research reported in the journals *Science* and *Psychological Science*. These judgments were interrelated in both samples, with interest predicted by practical value, surprisingness, and comprehensibility, and importance predicted mainly by practical value. However, these judgments poorly tracked the academic impact of the research, measured by citation counts three and seven years later. These results suggest that although people have internally reliable notions of what makes science interesting and important, these notions do not track scientific findings' actual impact.

Keywords: Folk science; science methodology; interest; philosophy of science; scientometrics

Introduction

The scientific enterprise aims to uncover eternal truths, and psychological science seeks to understand the most fundamental aspects of the human condition. From our modern vantage point, we can see clearly which scientific theories and results have stood the test of time, as truly foundational scientific achievements—Euclid's explication of geometry, Newton's laws of motion, Smith's insights about economic activity, Darwin's theory of evolution are among the timeless truths that clarify the structure of the natural and social worlds. But as scientists in the trenches, it is much more difficult for us to know what research is truly significant. Mendel's insights into genetics were ignored in his day, revolutionizing biology only decades later. The full significance of Bayes' contributions to statistics long eluded the profession.

Given these difficulties, scientists are likely to develop heuristics to evaluate scientific importance (Kahneman & Frederick, 2002). One particularly plausible heuristic is the *counterintuitiveness* or *surprisingness* of the research finding. For example, research on cultural narratives finds that minimally counterintuitive myths (relying mainly on intuitive concepts, peppered with a few counterintuitive ones) are most likely to be remembered and passed on (Norenzayan et al., 2006). Indeed, at a very general level, learning is likeliest to occur when the difference between expectations and reality (i.e., prediction error) is largest (Rescorla & Wagner, 1972).

Surprise is often a good criterion for scientific importance. We might consider a scientific result to be important when it falsifies an element of a theory (Popper, 1959/1934) or requires us to reconceptualize a topic of inquiry altogether (Kuhn, 1962). In Bayesian terms, a result is highly diagnostic when it is highly improbable on most theories but highly probable on another (i.e., $P(E|H)$ is high but $P(E)$ is low). As heuristics go, the extent to which a result encourages theory change is an excellent proxy for scientific importance.

But often, this heuristic can lead us astray. This is because even practicing scientists have scientific theories and intuitive theories that co-exist in their minds (Goldberg & Thompson-Schill, 2009; Shtulman & Varcarcel, 2012). Thus, although the disagreement between a result and existing *scientific* theory is a plausible proxy for scientific importance, disagreement with one's *lay* theory is not, if it is superseded by one's scientific understanding. For example, suppose that a psychologist believes that our behavior is guided by the unconscious activation of stereotypes, as suggested in the social priming literature. These original effects are highly counterintuitive, and if true, of great scientific significance. However, even though conceptual replications of these priming effects (e.g., using different stereotypes) would no longer contradict *scientific theory* (assuming we accept the initial demonstration), they would remain counterintuitive relative to our *folk theory*. Thus, this creates a misalignment between the scientific and lay surprisingness of a particular finding. To the extent that scientists rely on their folk theories rather than their scientific understanding for evaluating whether a finding is surprising, they may share this misalignment.

Regardless of the normative importance of counterintuitiveness, there is no question that many scientists prize it highly. Scientists, particularly during training, are often advised to seek out counterintuitive results. For example, one guide to doing "interesting" research advises (Gray & Wegner, 2013; pg. 550):

> One concrete test for evaluating ideas is to imagine the most surprising outcome possible (i.e., the best case scenario). If results were exactly as predicted, would they be interesting? If not, you should dream bigger when hypothesizing or perhaps consider the opposite of your hypothesis—if one way is intuitive, the opposite may be surprising.

Whose intuitions are we trying to contradict? "Grandmothers, not scientists," note the authors: "Ideally, research should counter both scientists' and laypeople's intuitions, but we emphasize the latter" (pg. 550). It is

hard to disagree with this as career advice, but it nonetheless raises uncomfortable concerns about replicability. After all, results with low prior probability are less likely to be true. Indeed, surprisingness is among the factors most associated with failure to replicate (Open Science Collaboration, 2012). It is presumably for this reason that the submission guidelines for *Psychological Science* now distinguish explicitly between "theoretical significance" (which is an acceptance criterion) and "surprising novelty" (which is not).

In this paper, we test two sets of issues, with Study 1 examining the folk science surrounding psychological research and Study 2 examining the natural sciences.

First, we ask what factors drive laypeople's judgments of how interesting and important scientific findings are. The opinions of laypeople, while likely divergent from experts, are important for two reasons. One reason is that scientists are laypeople in all fields aside from their own, and even in their own field may have lay intuitions that conflict with their scientific understanding of the field (Goldberg & Thompson-Schill, 2009). Thus, lay intuitions can creep into scientists' evaluations of research. A second reason is that the opinions of laypeople directly impact what scientific research is conducted, since laypeople are the ultimate consumers of taxpayer-funded research and since many scientists prioritize newsworthiness (to laypeople) in choosing topics to investigate. We study, therefore, the relative importance of surprisingness, perceived scientific impact, perceived practical value, and comprehensibility in guiding judgments of importance and interest.

Second, we ask how well these judgments track the objective academic impact of scientific findings, as quantified by their citations. Is the advice quoted above—to prioritize counterintuitiveness to laypeople—sound, if one's goal is to generate citations? Gray and Wegner (2013) suggest that it may be counterintuitiveness to scientists that drives citations in the short term, but to laypeople that drives citations in the longer term. We begin to examine this issue by looking separately at citation counts 4- and 7-years post-publication, testing whether lay judgments predict such measures of impact.

Study 1

In our first study, we looked at the factors influencing judgments of interest and importance, as well as citation counts, for articles published in *Psychological Science*.

Method

Participants. We recruited 60 participants from Amazon Mechanical Turk. Across our two studies, 57% of participants were female, 42% had completed at least a 4-year college degree, and the average age was 35. Only 8% of participants had doctoral-level training in any field, so the vast majority of participants were laypeople in the specific fields featured in our studies.

Participants were excluded if they incorrectly answered more than 30% of a set of 20 check questions ($N = 8$).

Materials. The materials were derived from abstracts of 40 articles appearing in the journal *Psychological Science* in the January, February, and March 2012 issues. A power analysis, treating item as the unit of analysis (like our main analysis below), revealed that 40 items is sufficient to detect correlations of $r > .41$ with 80% power.

For each abstract, a short summary was developed by the second author. For example, the actual abstract of one article (Frankenstein et al., 2012) read:

> We examined how a highly familiar environmental space—one's city of residence—is represented in memory. Twenty-six participants faced a photo-realistic virtual model of their hometown and completed a task in which they pointed to familiar target locations from various orientations. Each participant's performance was most accurate when he or she was facing north, and errors increased as participants' deviation from a north-facing orientation increased. Pointing errors and latencies were not related to the distance between participants' initial locations and the target locations. Our results are inconsistent with accounts of orientation-free memory and with theories assuming that the storage of spatial knowledge depends on local reference frames. Although participants recognized familiar local views in their initial locations, their strategy for pointing relied on a single, north-oriented reference frame that was likely acquired from maps rather than experience from daily exploration. Even though participants had spent significantly more time navigating the city than looking at maps, their pointing behavior seemed to rely on a north-oriented mental map.

We anticipated that real scientific abstracts like this one would be too long, syntactically complex, and jargon-filled to be comprehensible by most laypeople. Therefore, our summary version read:

> When presented with a virtual model of their hometown, people are able to more accurately point to familiar target locations when the people were oriented north and become progressively less accurate as they were oriented away from north. This suggests that people rely on a mental map that is oriented northward when trying to locate familiar places.

Comparable summaries were constructed for all 40 abstracts. Summaries were written at a minimum Flesch–Kincaid grade level of 12 and were of similar length.

We conducted pretests to ensure as strong of a perceived correspondence between the real abstract and summary as possible. In an initial pretest, each participant was assigned to read 10 of the abstracts along with their summaries, and rated their correspondence on a 0 ("A very poor match") to 10 ("An excellent match") scale. Any abstract with a score below 7 was targeted for revision and re-normed in a second pretest. All correspondences were rated above the scale midpoint in the second pretest (except one item which was omitted due to a coding error).

As an objective measure of academic impact, we obtained the Google Scholar citation counts for each article approximately 4 years (on 26 March 2016) and 7

years post-publication (on 29 January 2019) (on the pros and cons of Google Scholar versus other bibliometric databases, see Harzing & Alakangas, 2016). These were square root transformed, to account for the skewness of citation data.

Procedure. Participants each viewed 10 of the 40 summaries (balanced across participants). For each finding, participants first read the summary and then, on subsequent pages, made six ratings:

Interest. How interesting are these findings to you?

Importance. How important do you think these findings are?

Surprise. How surprising do you think these findings are?

Scientific impact. How much do you think these findings will change the way scientists think about this topic?

Practical value. How useful do you think this finding is on a practical level?

Comprehensibility. How well do you think that you understand the description of this finding?

These ratings were all made on scales from 0 ("Not at all…") to 10 ("Very…"). Each rating was made on a separate page, with the summary repeated at the top of each page. The order of the interest and importance questions was counterbalanced across participants, and the other ratings were always made in the order above.

After the main task, participants checked off, from a list of 20 concepts, those that had appeared in the summaries. Participants incorrectly answering more than 30% of these check questions were excluded to decrease noise due to inattentiveness.

Results

Overall, participants' judgments were internally reliable, with significant correlations among many of our measures. However, these scores had little external predictive power: Citations 4 and 7 years later were not predicted by any judgment except comprehensibility.

First-order correlations. We averaged, for each item, across participants' ratings, and used these item-level means for our analyses. The first-order Pearson correlations among all measures are summarized in Table 1. Before probing these associations more carefully using regression models, we make two observations.

First, judgments of importance and interest were highly correlated, $r(38) = .59$, $p < .001$. Since these results are observational, this is consistent with several causal orders. It could be that importance is the more fundamental judgment, and these appraisals feed into interest. This would be consistent with the fact that usefulness judgments were even more strongly associated with importance, $r = .79$, than with interest, $r = .61$. Alternatively, interest could be the more fundamental judgment, with importance less natural to judge and confabulated in line with personal interest. Finally, these two assessments could be relatively independent, depending on a mix of the same factors (such as usefulness) and differentiating factors (such as comprehensibility, which is only associated with interest).

Note. Entries are first-order correlations among interest (In), importance (Im), surprise (Su), scientific impact (SI), practical value (PV), and comprehensibility (Co).

Table 1: First-order correlations (Study 1).

Second, in preparation for modeling interest and importance, we note that some of the other variables are strongly correlated, which can lead to a multicollinearity problem. Variance Inflation Factors were acceptable (VIF < 1.5 for the Step 1 models in Tables 2 and 6) for models that did not simultaneously include both surprise and scientific impact, which were correlated very highly, $r = .76$. This very high correlation suggests, perhaps not itself surprisingly, that laypeople tend to substitute the difficult question of what evidence tends to change scientists' theories with the easier question of what they personally find surprising (Kahneman & Frederick, 2002). To address this problem, we omitted the scientific impact variable from the models. We included surprise rather than scientific impact since this seems to be the more natural assessment, but the results are similar if we instead include scientific impact or the average of the two.

Predictors of interest and importance. Table 2 shows the regression coefficients predicting judgments of interest. The Step 1 model uses surprise, practical value, and comprehensibility to model interest, and the Step 2 model adds importance to capture any added value.

As shown in the regression table, the strongest predictor of interest was comprehensibility, followed by practical value, followed by surprise, but all three predictors were highly significant, making independent contributions to interest. Together, these factors accounted for 80% of the variance in interest across items. Adding importance did not add any predictive power.

Table 2: Regression models (Study 1)

The bottom panel of Table 2 shows the results of parallel regressions predicting importance. Comparably to the results of Table 1, adding interest has little predictive power beyond the other predictors. In this case, however, it is practical value that is doing nearly all of the predictive work: A 1 point increase on practical value is associated with a 0.67 point increase in importance. Surprise was weakly predictive in the Step 1, but not the Step 2, model. Overall, these variables predicted about 68% of the variance in perceived importance across items.

Co	.35*	.38*

Note. Entries are first-order correlations with citations (square-root transformed) approximately 4 years and 7 years post-publication.

Table 3: Correlations with citations (Study 1)

Predictors of citation count. Table 3 presents the first-order correlations between citation count 4 and 7 years post-publication (square-root transformed) and the six measures collected in Study 1. Various regression specifications produce similar conclusions, so we focus here on the simple correlations as they avoid the multicollinearity issues mentioned above.

At both time points, neither interest nor perceived importance significantly predict citation counts, nor did judgments of surprise, scientific impact, or practical value. The only significant predictor was comprehensibility, $r(38) = .35$, $p = .028$ and $r(38) = .38$, $p = .017$ at 4 and 7 years, respectively.

Discussion

Several results pop out in these data. First, judgments of interest and importance are fairly independent: They depend on different factors and do not predict one another once one adjusts for those other factors. Comprehensibility was the most important guide to interest, but had no impact on perceived importance (see Oppenheimer, 2006 for related findings). Practical value was the most important determinant of perceived importance, and also had a large effect on interest. Surprisingness was correlated with interest but not perceived importance. Second, these judgments had little predictive power for citation rates, either in the shorter- or longer-term. Comprehensibility had a moderately high correlation with citations, but no other factor did.

Study 2

The Study 1 results could very well be specific to psychology. For instance, people have much more detailed intuitive theories of psychology, since they can introspect about their own psychology, and therefore surprisingness could be seen as an especially strong cue to scientific impact. Study 2 repeated this procedure on natural science findings from *Science* magazine.

Method

We recruited 60 participants from Mechanical Turk. Participants were excluded using the same criterion as Study 1 ($N = 14$).

The materials were the "editor's summaries" of 40 articles published in the January 6, January 13, and January 20, 2012 issues of *Science* magazine. These summaries are written by the editorial staff of the journal, rather than by us, eliminating the possibility of experimenter bias. We lightly edited the summaries to match the format of our Study 1 materials (replacing the authors' names with "Researchers"). For example, the editor's summary of one article (Fermi LAT Collaboration, 2012) read:

> Binary star systems that contain a neutron star or a black hole are expected to emit gamma rays. These gamma-ray binaries are a rare class of objects, which are also expected to emit x-rays. Indeed, several such systems were initially detected through their x-ray emission. Researchers have reported the detection of a gamma-ray binary that was previously unknown as an x-ray source. Follow-up observations reveal that the system is also a source of x-rays and that the companion star is a class O star, a type that is very hot and very luminous.

Participants read 10 of the 40 descriptions

(counterbalanced across participants), making the same six judgments as in Study 1, using a similar procedure.

Citation counts were obtained using the same procedure as Study 1, on 17 August 2016 and 30 January 2019.

Results

Most of the key results from Study 1 were replicated. Surprisingness, practical value, and comprehensibility all predicted judgments of interest, while only practical value robustly predicted judgments of importance. Citations were marginally predicted by comprehensibility, as in Study 1, but also by judgments of practical value.

Differences in means across studies. Table 4 presents the descriptive statistics for each judgment across each set of summaries. We compared the means on each measure across studies, using the false discovery rate procedure to adjust *p*-values for multiple comparisons (Benjamini & Hochberg, 1995). Overall, the natural science findings in Study 2 were viewed as less interesting than the psychology findings, $t(78) = 3.51$, $p = .002$, $d = 0.78$, 95% CI[0.41,1.48], but as more important than the psychology findings, $t(78) = 2.82$, $p = .009$, $d = 0.63$, 95% CI[0.18,1.06]. The natural science findings were also viewed as more surprising, $t(78) = 2.68$, $p = .011$, $d = 0.60$, 95% CI[0.15,1.04], and more scientifically impactful, $t(78) = 3.84$, $p < .001$, $d = 0.86$, 95% CI[0.37,1.15], but of similar practical value, $t(78) = 0.67$, $p = .51$, $d = 0.15$, 95% CI[–0.33,0.66]. Finally, the psychology findings were much easier to understand, $t(78) = 9.39$, $p < .001$, $d = 2.10$, 95% CI[2.52,3.87].

	Study 1 (Psychology)	Study 2 (Natural Science)

Co	7.80 (1.08)	4.60 (1.86)

Note. Entries are means (SDs) across items.

Table 4: Descriptive Statistics across Studies

First-order correlations. Table 5 shows the first-order correlations for Study 2, analogous to Table 1.

Like Study 1, there was a significant correlation between interest and importance, $r(38) = .39$, $p = .013$, although of more modest magnitude. The correlation between surprise and perceived scientific impact was also more modest. This weaker correlation, relative to Study 1, may have resulted from participants' lesser ability to rely on intuitive theories of the natural sciences than of psychology, given introspective access to one's own mental states.

	In	Im	Su	SI	PV
Im	.39*	—

Co	.89***	.22	.18	.18	.35*

Table 5: First-order correlations (Study 2).

Predictors of interest and importance. Table 6 shows the regression coefficients predicting interest and importance judgments, analogously to Table 2.

The results are similar to Study 1. For interest judgments, we find that surprise, practical value, and comprehensibility are all significant predictors, with comprehensibility the strongest predictor, just like Study 1. (However, surprise was a stronger predictor than practical value in Study 1, whereas the converse was true in Study 2.) Like Study 1, importance does not have any added predictive power; in this case, its collinearity with practical value leads both to be non-significant when entered simultaneously.

	DV: Interest

Note. Entries are unstandardized bs *and* SEs

Table 6: Regression models (Study 2)

For importance judgments, we find, just as in Study 1, that the key predictor is practical value, with a possible additional role for surprise. Given the high correlation

between scientific impact and practical value in Study 2, however (see Table 5), replacing surprise with scientific impact in the regression leads to a reversal of the coefficient magnitudes: Scientific impact is then a more robust predictor of importance than practical value, although both are significant in either model. (This is not true for Study 1, where scientific impact and surprise are basically interchangeable in the models.)

	Year 4	Year 7
In	.16	.18
Im	.16	.18
Su	–.23	–.25
SI	.03	.04
PV	.43**	.45**
Co	.27º	.28º

Note. Entries are first-order correlations with citations (square-root transformed) approximately 4 years and 7 years post-publication.

Table 7: Correlations with citations (Study 2)

Predictors of citation count. Table 7 presents the correlations of our six judgment variables with citation counts approximately 4 and 7 years post-publication. Comprehensibility was a marginally significant predictor at both time points, $r(38) = .27$, $p = .098$ and $r(38) = .28$, $p = .076$, which is consistent with the predictive power of comprehensibility for citations in Study 1. Unlike Study 1, however, practical value also predicted citation counts at both time points, $r(38) = .43$, $p = .006$ and $r(38) = .45$, $p = .004$. Thus, laypeople do appear to be able to extract some information that is predictive of the academic impact of scientific findings, but it is not necessarily reflected in their own judgments of importance.

Discussion

Study 2 replicated the main results of Study 1: Comprehensibility was a powerful cue to interest but not importance, although only a marginal predictor of citations in Study 2. Surprisingness was only a robust predictor of interest, but not importance, while practical value strongly predicted both. Unlike Study 1, practical value was a fairly strong predictor of citations, even though perceived importance was not.

General Discussion

Lay intuitions about scientific importance are, well, important. They impact our choices of research topics indirectly, as we try to appeal to laypeople's interests, and directly, as we all have a layperson inside of us (Goldberg & Thompson-Schill, 2009). What scientific findings do laypeople consider interesting and important? How much do these judgments track objective scientific importance?

Overall, comprehensibility is the most important predictor of interest. It is unclear whether this is because writing quality itself provokes interest, or because interesting findings are easier to explain clearly—quite possibly both. Scientists who wish to appeal to public interest ought to keep this demand for clarity in mind, rather than obscuring their work in jargon (see Oppenheimer, 2006).

Perceived practical value was the most robust predictor of importance, although perceived scientific impact was also highly predictive in Study 2 (and difficult to distinguish from practical value). Surprisingness appears to be less predictive. This is, ironically, quite a counterintuitive result! Guides to doing "interesting research" (Gray & Wegner, 2013) and our professional intuitions point to the importance of surprising the reader. But laypeople may well be growing weary of surprising findings, as they encounter increasing levels of "click bait" reporting and all-too-frequent reversals of conventional wisdom (are we, or are we not, supposed to eat eggs now?). Future research might investigate the factors underpinning and moderating this relationship between surprise (e.g., Maguire, Maguire, & Keane, 2011) and judgments of interest and importance.

Finally, these results suggest caution regarding our ability to predict the impact of scientific research based on its relationship with our intuitive theories. Surprise had no impact on citations, but neither did interest or judgments of importance or scientific impact. The only factors impacting citation were comprehensibility (in both studies) and perceived practical value (in Study 2).

It is important to understand how laypeople think about science because scientific progress tracks social priorities—scientists serve at the pleasure of society. To the extent that laypeople have systematic misconceptions about science, we must understand how those misconceptions might thwart the dissemination of science to the public, or even scientific progress itself. To the extent that laypeople have irreducible preferences over the kind of science they like to see, we must understand how those preferences might be reflected in the kind of research produced by scientific institutions.

Several other research programs contribute to this broad goal. For example, people favor reductionist explanations (e.g., referring to smaller parts or component processes) even when the reductionist information makes no logical contribution to the explanation (e.g., Hopkins, Weisberg, & Taylor, 2016; Weisberg, Keil, Goodstein, Rawson, & Gray, 2008). As a second example, people have consistent intuitions about the limits of science, particularly of psychology (Gottlieb & Lombrozo, 2018), believing that phenomena are scientifically explainable to the extent that scientists can make falsifiable and reductionist claims about those phenomena (Johnson, Kim, & Keil, 2016).

These research areas—characterizing what scientific explanations people find compelling and what scientific questions people find tractable—are valuable because they contribute to our understanding of how the lay public

interfaces with the scientific community. If people have an unjustified preference for neuroscientific explanations or an ill-founded belief that psychological phenomena are beyond the limits of science to comprehend, these may lead to society-wide distortions in our scientific priorities.

Our work complements these approaches. While these other lines of research hint at what the public's scientific priorities might be by characterizing folk scientific beliefs, the current studies take a more direct approach by asking what research people find interesting and important. If we believe that laypeople's standards (e.g., regarding practically valuable findings as more important) are reasonable, then this is all to the better. To the extent that we find lay preferences more questionable (e.g., favoring counterintuitive findings as more interesting), this should catalyze a discussion about how society prioritizes research questions, how journals select research findings, and how scientists choose research topics.

Scientists get into the business because they want to have an impact—maybe even to change the world. We may be less able than we believe to predict successfully what scientific innovations are indeed important. Doing so successfully may require us to step back and reconsider our habits of thought.

Abstract

Research using short-term chess training programs has indicated an enhancement of cognitive functioning among children. The aim of the study was to investigate the effect of 1-year systematic chess training on the creativity and intelligence of children. A pretestposttest with control group design was used. Children who were studying in two government schools and two private schools (grades 39) were selected randomly. They were then randomly assigned to experimental and control groups, with 88 (50 boys, 38 girls) children in the experimental group and 90 (57 boys, 33 girls) children in the control group. The experimental group underwent weekly 1-hour chess training for 1 year, while the control group was actively involved in extracurricular activities offered by the school during the same period. Creativity was measured by WallachKogan Creativity Test (Indian adaptation) and intelligence was measured by subtests of Wechsler Intelligence Scale for Children: Fourth edition (WISC-IV), India. Analysis of covariance (ANCOVA) revealed significant improvement in total creativity and Full Scale Intelligence Quotient (FSIQ) for experimental group compared to the control group. Chess training as part of school activities appears to have a wide spectrum of outcomes.

Exploring informal science interventions to promote children's understanding of natural categories

Abstract

Categories carve up the world in a structured way, allowing people to inductively reason about the properties of novel exemplars. Children are still in the process of learning category structure, and often fail to leverage the inductive power of these representations to their advantage. For example, young children generally fail to recognize the value of sampling diverse exemplars to support category-wide generalization. This study investigates whether teaching children the structure within a natural category increases diversity-based inductive reasoning. In an informal science learning environment, we presented 259 children aged 5 to 8 years with exemplars of the three main types of birds: raptors, songbirds, and waterbirds. After a short dialogue pointing out the various within-type similarities and between-type differences, children's diversity-based inductive reasoning did not significantly improve, despite them evidencing a better understanding of the category's structure. Instead, children tended to avoid sampling waterbirds, the least typical cluster of birds. These patterns suggest that children's neglect of sample diversity is unlikely to be solely due to their relative ignorance of category structure.

Keywords: category induction; diversity-based reasoning; category learning; conceptual development

Introduction

Categories give us a way out of the infant's problem of "feel[ing] it all as one great blooming, buzzing confusion" (James, 1890), allowing us to carve our sensations of the world into classes that are distinguished by relevant properties. By picking out shared features while ignoring superficial differences, categories enable us to learn inductively (Rips, 1975), and allow us to reason about unseen properties. For example, having learned that one cat's fur is soft, we might generalize this to all cats, and proceed to seek out and pet all cats. Assuming that categories are homogeneous, in that the exemplars share many observable and unobservable features, offers further inductive power (Gelman, 1988), but can also lead to serious errors: your house cat may be amenable to petting, but a cougar may not be. Learning how to account for such within-category variation while engaging in category-based inductive reasoning is a nontrivial problem for children.

There is considerable evidence that adults take within-category variability into account when evaluating the inductive power of evidence. For example, when making inferences about general properties of a category, adults view some samples of exemplars from a category as more informative than others (Rips, 1975; Osherson, Smith, Wilkie, Lopez, & Shafir, 1990). Sample diversity is one feature adults attend to when evaluating evidential strength, with more diverse samples (e.g., a lion and a house cat) being viewed as more informative than nondiverse samples (two house cats) (Heit, 2000). Adults' preference for diverse samples indicates that they assume that observable variability across exemplars in a category is often correlated with variance in the hidden features, and it is thus informative to sample from diverse areas of the distribution.

Adults find diverse samples more informative both when choosing evidence to sample (Kim & Keil, 2003; Lopez, 1995; Rhodes, Brickman, & Gelman, 2008; Rhodes & Gelman, 2008) and when rating the strength of inductive arguments (Osherson et al., 1990). In contrast, children below the age of nine often fail to consider sample diversity (Gutheil & Gelman, 1997; Rhodes & Gelman, 2008; Rhodes et al., 2008). For example, before age 9, children are equally likely to choose to examine an eagle and a robin as two robins to see whether all birds have a given property (Rhodes et al., 2008; Rhodes & Gelman, 2008). One reason why this might be the case is that young children often assume categories to be more homogeneous than adults do (Gelman, 2003). For instance, preschool-aged children infer more readily than adults that a property seen in one exemplar is true for the whole category (Rhodes & Gelman, 2008). Moreover, preschool-aged children believe that everyday categories identify an objective natural reality to a greater extent than adults do (Kalish, 1998). Directly linking this tendency to assume that categories are homogeneous to diversity-based reasoning, 7-year-olds reliably chose diverse samples over nondiverse samples after they were primed with an example highlighting within-category variability (Rhodes & Brickman, 2010). This finding supports the idea that young children may default to a strong within-category homogeneity assumption, and also shows that they sometimes recognize the value of diverse samples when such an assumption is violated. Here, we tested whether a more abstract variation prime–distinguishing structured clusters within a category–induces a preference for diversity-based reasoning.

The present study

Imagine that you are trying to determine whether a novel, hidden property is true of all birds (e.g., "Do all birds have *scutella*?"). Adults deem it better grounds for generalization to the entire category when two dissimilar birds (e.g., an eagle and a robin) are both found to have the hidden property,

rather than two more similar birds (e.g., a robin and a swallow). In the model proposed by Osherson et al. (1990), the greater strength of the argument based on dissimilar birds is a result not of the similarity of the premise categories to the conclusion category, but of their similarity to the lowest-level category that covers both the premise and conclusion categories—that is, birds. If on the other hand, one were asked to determine if all songbirds have *scutella*, the robin and swallow premises would offer a better match to the inductive target, since the songbird cluster is the lowest-level category covering both the premises and the target.

The goal of this study was to teach children more about the heterogeneous structure of one natural category–birds–to determine whether that knowledge improves their inductive reasoning about that category. Specifically, this study taught young children (ages 5-8) that the bird category is clustered into songbirds, waterbirds, and raptors, and that birds within each cluster share many visible (e.g., talon and beak shape) and hidden properties. The didactic dialogue and displays (see Figures 1 and 2) used to teach the clusters will also highlight some of the variability within each cluster, and some cross-cluster similarities. Our hypothesis was that teaching children the clustered structure of the bird category may encourage them to represent the category more heterogeneously (i.e., with clusters instead of a single prototype), and thus may improve their diversity-based inductive reasoning—both for induction to a cluster, and to the entire category of birds. This study was conducted in the context of the American Museum of Natural History's Discovery Room with an interest in developing more effective exhibits.

Experiment

The purpose of the experiment is to investigate whether teaching children the clustered structure of a natural category (birds) improves their ability to do diversity-based inductive reasoning. Specifically, after measuring children's knowledge of the bird category through pile sorting, we tested two interventions–display cases (e.g., Figure 2) vs. poster-based (e.g., Figure 1), presented along with a didactic dialogue meant to demonstrate that birds can be subcategorized into three clusters: raptors, songbirds, and waterbirds. The dialogue first highlights the variability of the category (e.g., "Some are big, some are small; some have bright colors..." and then defines the three main clusters, emphasizing correlated features and their causal relationships (e.g., "Most water birds have webbed feet–see? That helps them swim.") After highlighting a few distinctive features for each cluster and naming four examples of birds in each, children were given a series of inductive sampling questions to generalize to either a given cluster, or to the entire bird category. Finally, we again measured children's knowledge of birds by pile sorting.

Methods

Participants Participants in this experiment were 265 children between the ages of 5 and 8 years old who were recruited at the American Museum of Natural History's Discovery Room. Of the 265 children recruited (per intervention: 99 in None, 94 in Exhibit, and 66 in Poster), we analyzed the data from 259 children (60 5-year-olds, 73 6-year-olds, 68 7-year-olds, and 58 8-year-olds) who completed the study.

Stimuli This task was designed to fit thematically with the content of the AMNH Discovery Room activities, which emphasize the varying features between species of birds, among other animals. Eight diverse birds from each cluster were selected to be used as stimuli. Songbirds[1] included were the robin, swallow, starling, oriole, redwing blackbird, blue jay, sparrow, and cardinal. Raptors included were the barred owl, falcon, vulture, kestrel, barn owl, red-tailed hawk, bald eagle, and kite. Water birds included were the tern, mallard duck, puffin, sea gull, harlequin duck, flamingo, goose, and anhinga. For the intervention conditions, four birds from each cluster were selected to be shown either on a poster, shown in Figure 1, or in display cases as in Figure 2. The same exemplars were used in both intervention conditions. For the sorting task, each of the 24 birds was printed in color on a single 8.5 x 11" sheet of paper, with the size of each bird being according to their real-world scale. These birds appeared in different combinations during the sampling questions, as well. All materials and the protocol are available online.[2]

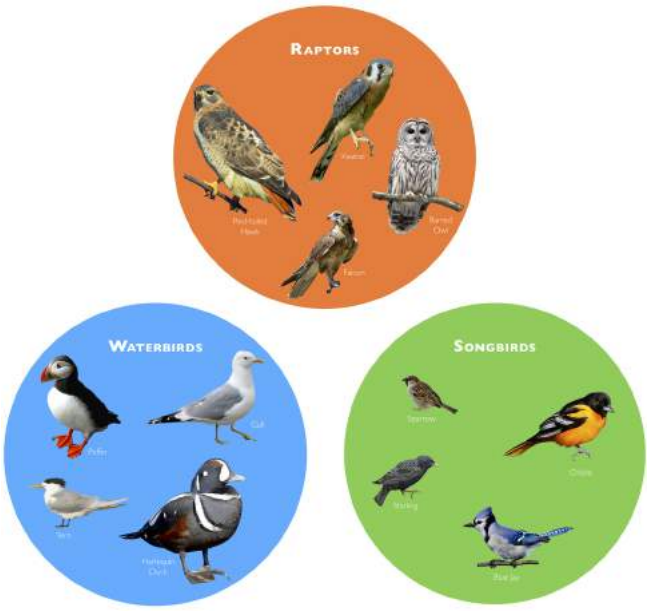

Figure 1: The experiment used four birds from each cluster as stimuli. The poster intervention used this arrangement.

Procedure Children participated in the experiment during individual sessions with trained undergraduate research assistants in a corner of the AMNH Discovery Room. Participants were randomly assigned to one of three intervention condi-

[1]Blue jays are not songbirds, so this cluster is more accurately described as passerines. Colloquially, all are songbirds.

Figure 2: The display cases in the American Museum of Natural History's Discovery Room, with the 12 bird specimens used in the intervention.

tions: Poster, Exhibit, or None. Participants were first asked to list all of the birds they could name, as a means of establishing rapport. Second, they were asked to sort 24 bird cards (8 water birds, 8 raptors, and 8 songbirds) into piles "that go together by nature." They were given three baskets, but were not explicitly told to form three piles—nor instructed to if they asked. This sorting task offered a simple way of measuring their knowledge of the category structure, and was repeated at the end of the experiment to measure changes in their representation of the category. After each sort, participants were asked to describe each of the piles they made.

In addition to a control condition with no dialogue or visual intervention (None), there were two intervention conditions, using either a Poster (see Figure 1) or an Exhibit of display cases (see Figure 2) showing four birds from each cluster. In the intervention conditions, the experimenter showed the poster or display cases while giving a 2-minute dialogue that stressed the diversity of birds (e.g., color, size, and beak and talon shapes), while linking the distinguishing features of each cluster to their habitat and food sources (e.g., "water birds swim in the water with webbed feet and eat fish").

After the dialogue, children were given a series of 18 2-alternative forced choice induction sampling trials, an example of which is shown in Figure 3. Each trial offered two pairs of birds, and one bird was always shared across the two pairs (i.e., the harlequin duck in Figure 3). Each trial always offered a same-cluster pair (e.g., two waterbirds) and a between-cluster pair (e.g., a waterbird and a raptor, as in Figure 3). Children were told they were scientists trying to determine whether all birds (on category induction trials) or all birds of a given type (e.g., all raptors; cluster induction trials) had some property (e.g., 'podotheca'). They were asked to choose which pair of birds (left or right) they would like to test in order to make that determination. The first 9 sampling trials had questions targeting induction to the entire bird category, of the form: "You are a scientist who wants to find out if BIRDS have podotheca. Which set of birds do you want to look at to learn about BIRDS?" Three of these category-induction trials were easy, in that the same-cluster pair of birds on each trial would be two exemplars of the same species (e.g., photos of two puffin exemplars). The other six were difficult, in that the same-cluster pair showed birds of different species (e.g., a duck and a puffin, in Figure 3). The final 9 sampling trials had questions targeting each cluster (3 per cluster), of the form: "Here are two sets of birds. You are a scientist who wants to find out if RAPTORS have cancella. Which set of birds do you want to look at to learn about RAPTORS?" For each cluster, one of the cluster-induction trials was easy (i.e., the same-cluster pair showed two birds of the same species), while the other two per cluster were difficult, with the same-cluster pair comprised of different species.

The same 12 exemplar birds were shown in the poster as in the exhibit, and were also represented among the 24 cards for sorting, and in the induction sampling trials. Thus, a total of 24 bird species (8 per cluster) were introduced in the experiment, 12 of which were used in the interventions, and all of which appeared in both the pile sorting and sampling trials.

Figure 3: Example of a difficult induction sampling trial. Participants might be asked to choose which sample of birds (left pair or right pair) they would like to test to determine whether all birds (on category induction trials) or, e.g., all water birds (on cluster induction trials) have a property (e.g., 'scutella'). For category induction, the right sample should be chosen for testing, as it is more diverse, containing a water bird and a raptor. For cluster (water bird) induction, the left sample should be chosen, as it contains two water birds (harlequin duck and puffin). On easy trials, one sample would contain two identical birds (e.g., two puffins).

Pre-Intervention Sort	*Post-Intervention Sort*

Table 1: Categories of participants' pile sort explanations.

Results

Results were analyzed for 259 participants: 94 in the Exhibit condition (24 aged-5, 26 aged-6, 20 aged-7, and 24 aged-8), 66 in the Poster condition (16 aged-5, 15 aged-6, 22 aged-7, 13 aged-8), and 99 in the None condition (23 aged-5, 32 aged-6, 24 aged-7, 20 aged-8). Data from 8 other participants were eliminated due to failure to complete the experiment or experimenter error.

Bird Sorts Participants' sorts of the 24 birds were first examined according to the descriptions that they gave their piles. Experimenters sanitized and aggregated the pile sort descriptions, and attempted to assign a single label to the scheme by which each participant carried out their first (pre-intervention) and second (post-intervention) sorts. Participants' aggregated pile sort explanations are shown in Table 1. In some cases, participants gave no interpretable description (*none*), or gave a *mix* of features (e.g., color and size for one pile, habitat for another). It is clear that many participants, both pre- and post-intervention, sorted according to a single salient dimension such as size (111 first sort; 67 second), a physical feature (24 first; 21 second) or color (20 first; 15 second). However, cluster-based sorting is the only strategy that saw a marked increase from the first to the second sort (25 to 120 participants), with most single-dimension strategies seeing corresponding decreases (e.g., size: 111 to 67; habitat: 35 to 11). In terms of their qualitative descriptions, participants have largely shifted from single-dimension sorting strategies to a cluster-based strategy. Next, we quantified the degree to which participants' sorts improve in each intervention condition with respect to the ground truth.

To measure the quality of participants' sorts, we compared the piles from each participant's first and second sorts to the objectively correct cluster sort (three piles: 8 raptors, 8 songbirds, and 8 waterbirds). The similarity between a participant's sort and the correct cluster sort was measured with the adjusted Rand Index (Rand, 1971), which counts the number of pairs of elements in S (the cards) that are in the same subset in partition X (a participant's piles) and in the same subset in Y (the 3-pile objective), as well as the number of pairs of elements in S that are in different subsets in X and that are in different subsets in Y. These agreements between sort X and sort Y are divided by the number of all possible pairs (agreements + disagreements), and thus the Rand index is 0 when two sorts do not agree on any pair of cards, and 1 when sorts are exactly the same. The adjusted Rand Index corrects for chance using the expected similarity of all pair-wise comparisons between clusterings specified by a random model, and can thus on occasion have negative values if the index is less than expected by chance (Hubert & Arabie, 1985).

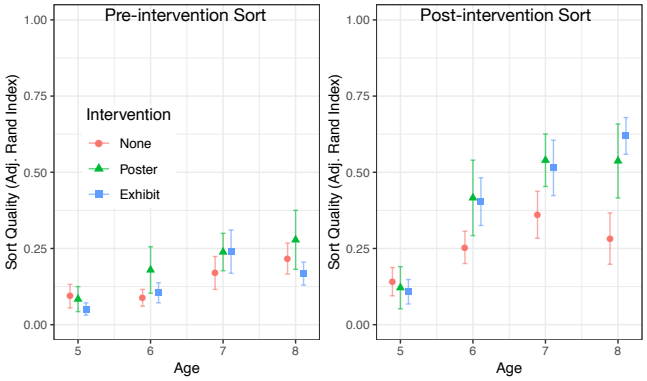

Figure 4: Mean pre-intervention sort quality (left panel) and post-intervention sort quality (right panel) by age and intervention condition. Error bars show +/-1SE.

The adjusted Rand Index of participants' sorts and the correct clustering (i.e., sort quality) were subjected to a repeated measures ANCOVA with sort (pre-/post-intervention) as the repeated measure, age (5.00-8.93 years) as covariate, and intervention condition (poster, exhibit, or none) as a between-subjects factor. Sort quality improved more in the intervention conditions (from pre- to post-intervention) than in the control condition (as evidenced by an interaction of intervention and sort ($F(2,253)=4.45$, $p = .01$); there were also subsumed main effects of sort (pre- to post-intervention $F(1,253)=97.42$, $p < .001$) and intervention condition ($F(2,253)=3.49$, $p = 0.03$). Participants in the two intervention conditions showed more improvement in sort quality ($M = .25$) than participants receiving no intervention (Welch's $t(245.7)=2.93$, $p = 0.004$). Sort quality also improved more for older children than younger children (interaction of age and sort ($F(1,253)=13.75$, $p < .001$), with a subsumed main effect of age ($F(1,253)=35.22$, $p < .001$). Figure 4 shows participants' mean sort quality on the pre- (first; left panel) and post-intervention (second; right panel) sorts by age and condition. Having shown that the interventions helped improve children's understanding of the clustered structure of the bird category, we turned to the induction sampling choices to determine if diversity-based reasoning also improved, using the quality of their second sort as a covariate.

Induction Sampling Choices We separately analyze the sampling trials that were targeted at inducing to a specific cluster, and the sampling trials that were targeted at inducing to the entire category. On the cluster induction trials, partici-

pants should choose the pair of birds from the targeted cluster, rather than the diverse pair. In contrast, on the category induction trials, participants should choose the diverse pair, with birds representing two different clusters. Thus, to analyze the cluster induction trials, participants' binomial choices for each trial (0=choosing the diverse pair, 1=choosing the cluster pair) were subjected to a logistic mixed-effects regression with intervention condition as a between-subjects factor and trial difficulty (easy or difficult) as a within-subjects factor, and age and quality of second sort as covariates[3].

On the cluster trials, there was no significant main effect of intervention ($F(2,243.5)=0.70$, $p = .50$), nor any significant interactive effects involving intervention, as shown in Figure 5 (left). Children were more likely to select samples containing only members of the cluster that they were trying to learn about (the more informative samples in this case) with age, ($F(1,244.2)=20.39$, $p < .001$), and they were also more likely to do so if they had more accurate representations of the category structure as indicated by their post-intervention category sort ($F(1,246.1)=27.15$, $p < .001$). There was a significant interaction of age and second sort quality ($F(1,241.5)=5.57$, $p = .02$). Shown in Figure 6, children with high-quality (4th quartile: ARI$>$ .65) second sorts are near-ceiling at correctly choosing the within-cluster sample for induction–even the 5- and 6-year-olds. The cluster pair was chosen significantly less often on difficult trials ($M = 0.69$) than on easy trials ($M = 0.77$, $F(1,255.2)=19.05$, $p < .001$). All other effects were not significant.

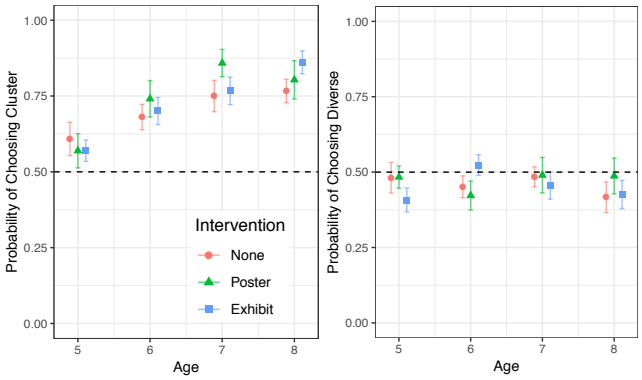

Figure 5: Mean proportion of correct sampling choice–nondiverse for cluster induction (left), and diverse for category induction (right)–by age group and intervention condition. Error bars show +/-1SE, and dotted lines show chance.

To analyze the category induction trials, participants' binomial choices for each trial (0=choosing the non-diverse pair, 1=choosing the diverse pair) were subjected to a logistic mixed-effects regression with intervention condition as a between-subjects factor and trial difficulty (easy or difficult) as a within-subjects factor, age and second sort quality, scaled and centered, as covariates. As seen in Figure 5 (right), there was no significant main effect of intervention ($F(2,266.0)=0.08$, $p = .93$), nor any significant interactive effects involving intervention: participants of all ages were near-chance at correctly choosing the diverse pair ($F(1,267.1)=0.00$, $p = .98$). There was no significant main effect of second sort quality ($F(1,269.6)=0.02$, $p = .88$). Easy trials had marginally higher performance than difficult trials ($F(1,1384.6)=3.67$, $p = .06$). There was once again a significant interaction of age and second sort quality ($F(1,262.8)=5.61$, $p = .02$), shown in Figure 6 (right). Children with 4th quartile post-intervention sorts were picking the diverse pair at close to chance rates at all ages, while 8-year-olds with lower-quality sorts preferred the less informative, nondiverse samples. All other effects were not significant.

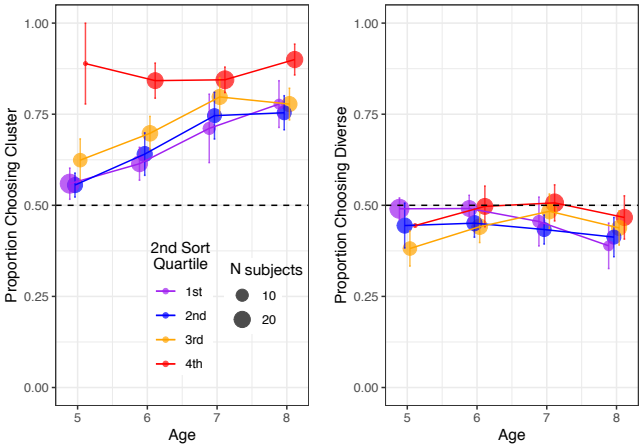

Figure 6: Mean proportion of correct sampling choice for induction (left: nondiverse for cluster, right: diverse for category) as a function of age and quartile of 2nd sort's quality. Error bars show +/-1SE, and dotted lines show chance.

Given that participants were at best choosing the diverse sample at as often as expected by chance on category induction trials, we investigated whether they showed any systematic sampling strategies on these items. As a reminder, each sampling trial presented three birds: one appearing in both samples, one from the same cluster, and one from a different cluster. We considered the possibility that, among the two varying birds per trial, children preferred to sample some types (i.e. clusters) of birds over others. Table 2 shows, for each type of sampling trial (category vs. each cluster), the proportion of trials on which participants chose a sample containing a bird of a given cluster. For category induction trials, participants avoided choosing samples with waterbirds, choosing them only 21% of the time, significantly different than the 40% raptors and 39% songbirds chosen ($\chi^2(2, N = 2,373) = 162.7$, $p < .001$). Indeed, this bias against sampling waterbirds extended to the cluster induction trials: participants had lower rates of choosing a waterbird to induce to all waterbirds (48%) than of choosing a raptor to induce to all raptors (80%), or than choosing a songbird to induce to all songbirds (71%). For incorrect answers, waterbird was the least popular choice (0% for songbird trials

[3]Covariates scaled and zero-centered.

	Chosen:		
Induce To:	Raptor	Songbird	Waterbird
All Birds	0.40	0.39	0.21
Raptors	0.80	0.13	0.08
Songbirds	0.29	0.71	0.00
Waterbirds	0.36	0.16	0.48

Table 2: Participant's choices on induction trials.

and 8% for raptor trials). It may be that participants avoid waterbirds because it is the cluster that they find least typical of birds. To verify this, we asked 13 adults to rate the typicality (1-7; 1=atypical, 7=very typical) of the 8 waterbirds, 8 raptors, and 8 songbirds used in this experiment. They were shown the same unlabeled pictures as children saw, in a randomized order. On average, participants found songbirds the most typical ($M = 5.92$), followed by raptors ($M = 4.41$), and waterbirds ($M = 3.54$).

General Discussion

The present study investigated whether teaching children about the clustered structure of the bird category would increase the diversity of their sampling choices in a category induction task. The didactic dialogue and intervention displays significantly shifted children's representation of the bird category, as evidenced by a shift from them sorting birds into piles according to single dimensions (e.g., size or color), to them predominantly sorting by cluster (songbird, waterbird, and raptor) after the intervention. Moreover, children's pile sorts post-intervention were much closer to the actual cluster structure, as measured by adjusted Rand index. Despite this shift in children's representation of the bird category, we found no evidence that either intervention display improved their category induction sampling choices. Children of all ages were near-chance at choosing the diverse sample when inducing to the category. Yet, the quality of children category's representations was indeed related to their sampling behavior in some cases. Younger children with more accurate category representations chose more informative samples on the cluster-induction trials. Also, older children with more accurate category representations chose diverse samples more often than their age-matched peers with less accurate category representations, although even these children did not choose diverse samples more often than expected by chance.

Given that the intervention conditions increased the accuracy of children's category representations, and category representations were somewhat related to children's sampling decisions, it is surprising that the intervention was not powerful enough to increase the efficiency of children's sampling strategies. One possibility is that children simply apply a different standard for evaluating the informativeness of samples. For instance, Foster-Hanson et al. (2019) found that young children prefer to examine highly prototypical examples instead of samples that cover variation. This tendency might have been behind children's decisions in the present study to avoid sampling waterbirds–the least typical birds presented according to adult raters. From this perspective, although the intervention made children more aware of the structured variability that exists within the category, perhaps it did not lead them to view that variation as informative because they prefer to rely on separate criteria (typicality) for evaluating samples of evidence.

We conclude that it is unlikely that simply knowing the clustered structure of a natural category is sufficient for children to realize the inductive power of choosing diverse samples. There is certainly merit to learning the structure of natural categories beyond any benefit to diversity-based reasoning, but future interventions seeking to increase appreciation for diverse sampling strategies may wish to demonstrate to children the value of choosing diverse samples more directly.

Does Children's Shape Knowledge Contribute to Age-Related Improvements in Selective Sustained Attention Measured in a TrackIt Task?

Abstract

The ability to maintain attentive state over a period of time (i.e., Selective Sustained Attention) is important for higher-order cognition but challenging to assess in preschool-age children. The TrackIt task was developed to address this challenge and has been argued to be sensitive to age-related differences in selective sustained attention in 3- to 5-year-old children. However, it remains unclear whether this improvement with age also (or predominantly) reflects improvement in children's knowledge of different shapes used as stimuli in this task in prior studies. The current study addressed this possibility. Consistent with prior studies, we found clear age-related improvement in performance on TrackIt. However, we did not find evidence that shape knowledge played a role in TrackIt performance for children aged 2 to 5, suggesting that increased knowledge of geometric shapes is not sufficient to explain age-related improvement in performance and helping to validate TrackIt as an assessment of Selective Sustained Attention.

Keywords: selective sustained attention; TrackIt

Introduction

The ability to maintain attentive state over a period of time (often referred to as Focused or Selective Sustained Attention) is important for higher-order cognition, including learning (e.g., Fisher & Kloos, 2016; Oakes, Kannass, & Shaddy, 2002). This ability undergoes marked development during the preschool years as shown by the increased time that children spend in this state during free play assessments of selective sustained attention (Ruff & Lawson, 1990; Sarid & Breznitz, 1997); however, few experimental paradigms capture usable data for children in this age range (for review see Fisher & Kloos, 2016).

The TrackIt paradigm was designed to address this measurement gap. In the TrackIt task, participants visually track a target object moving along a random trajectory on a grid, while simultaneously ignoring distractor objects. At the conclusion of the trial, the objects disappear and the participant indicates the final location of the target on the grid. Prior studies suggest that nearly all preschool-age children can complete and provide usable data on this task (in contrast to other assessments, such as downward extension of the Continuous Performance Test; see Fisher & Kloos, 2016). Performance on this task shows considerable age-related improvement between 3 and 5 years of age (Fisher et al., 2013) showing that the task is developmentally sensitive. Importantly to this paper, the target and distractor objects in the TrackIt task are usually selected from a set of geometric forms (circle, diamond, square, triangle, pentagon) and iconic shapes (crescent, cross, arrow, semi-circle).

Age-related improvement in performance on the TrackIt task during the preschool period has been interpreted as improvement in selective sustained attention (Brueggemann & Gable, 2018; Erickson et al., 2015; Fisher et al., 2013). However, shape knowledge is also known to improve during the preschool period (e.g., Clements et al., 1999; Verdine et al., 2016) and could be an important element of successful completion of the TrackIt task. Therefore, it remains unclear whether increased shape knowledge may account for the age-related improvement in performance on the TrackIt task. This finding would challenge prior interpretations that age-related changes in TrackIt performance primarily reflect improvement in selective sustained attention.

Shape knowledge may play a role in the task in the following way. When distractors are unique from each other and from the target, all objects in the task are comparable in salience (Fisher et al., 2013). Therefore, participants need to encode the identity of the target object in order to successfully complete the task. Children may encode the identity of the target object by maintaining its visual representation in working memory and by using labels to refer to object shape. Younger children whose shape knowledge is still developing may encode the identity of the target object less robustly than older children with greater shape knowledge.

There is indirect evidence to support this possibility. Vales and Smith (2015) provided evidence that object labels help children maintain precise representations of objects in working memory during a visual search task. Consistent with this explanation, Doebel et al. (2018) showed that preschool children were better at a modified TrackIt task with novel shapes (for which children did not have consistent labels) when experimenters provided labels. This result was found even though children were able to identify the shape from a set of choices after the task was complete (i.e., a memory check). Thus, although children completing TrackIt with geometric forms have demonstrated memory check accuracy that is well above chance, the encoding necessary to recognize the target object after the trial may be insufficient to support accuracy on the main task. Instead, children's own knowledge of shape names may facilitate their performance on the TrackIt task when the experimenter does not provide labels for the target objects (as is the standard procedure on the TrackIt task) by enabling the children to self-generate labels of the targets.

It is possible that children may use non-canonical names for shapes when they do not know the proper labels. For example, when asked to describe geometric forms, Clements et al. (1999) found that young children tended to invoke visual descriptions of geometric forms (e.g., "pointy," "round", or "skinny"). However, such visual descriptions comprise non-unique labels (e.g., both a diamond and a triangle could fit the visual description "pointy"). Therefore, if younger children generate visual descriptor labels when they do not know the canonical labels, these visual descriptor labels may still be less helpful for encoding the target identity than canonical labels that are more likely to be known (and self-generated) by older children.

In the current study we examined the possibility that age-related improvement in performance on the TrackIt task may be attributed, at least partially, to age-related increase in shape knowledge.

Experiment 1

Method

Participants 90 two- to five-year old children (*M* = 3.89 years, *SD* = 9.4 months, range 2.58 to 5.77 years) participated in the study. Participants were drawn from public and private preschool and kindergarten programs. The data reported are part of a larger cross-sectional study for which data collection is in progress, that has a final intended sample size of 240 participants aged 2-7 years. That larger study is preregistered at aspredicted.org, and the anonymized preregistration is available here. The target shape analyses reported in this paper were not pre-registered. Of the 90 participants recruited for this study, 3 participants were excluded from the analysis because they refused or otherwise failed to complete ten trials or due to experimenter error.

Materials and Apparatus The TrackIt task (freely available at http://www.psy.cmu.edu/~trackit) was presented on a Lenovo laptop screen with physical dimensions 19.1 cm x 34.2 cm and pixel dimensions 1920x1080 pixels. Participants were seated at a desk facing the screen with their heads about 12 inches away from the screen. For each trial, the target and distractor objects were randomly picked without replacement from a set of unique objects spanning 9 different shapes with 9 different color possibilities (81objects in total). See Figure 1 for examples.

We expect that young children have differential knowledge of the shape stimuli used in the TrackIt task (i.e., children are likely to know some, but not all, of the nine shapes and their associated labels). Because encoding the identity of the target object is necessary to complete the TrackIt task, greater knowledge of a target shape may result in better accuracy on trials with that target shape relative to trials with a less familiar shape. To represent the relative familiarity of the target shapes to one another, we assessed the frequency of the stimuli using ChildFreq (Bååth, 2010), a tool that extracts word frequencies from the American and British parts of the Childes database (MacWhinney, 2010). In particular, we found the frequency of the canonical names for the nine shapes over the for the age range 12-35 months (see Table 1). As is shown in Table 1, there was considerable variability in the frequency of the stimuli, ranging from 1 to 273 occurrences per million words.

Table 1: Frequency of Stimuli in the Childes Database

Stimuli	**Occurrences per 1,000,000 Words**
Circle	273
Triangle	165
Square	126
Cross	91
Diamond	26
Pentagon	11
Arrow	1
Crescent	1
Semicircle	1

Procedures The experimenter administered the TrackIt task to participants in a quiet room or hallway. In the TrackIt task, participants were asked to visually track a single target object as it moved on a grid among moving distractor objects. At the beginning of each trial, the objects appeared on the grid, centered in distinct grid cells, and the target object was indicated by a red circle around it. The initial positions of the objects were randomized. At the beginning of the task, participants were told that: 1) the objects will start moving around the grid when the experimenter presses a button; 2) the goal is to follow the target object with their eyes; 3) at some point the objects will suddenly disappear, and their job is to point to where the target object was when it disappeared.

The experimenter started each trial with a button press after ensuring the participant was ready to begin. Upon starting the trial, the red circle disappeared, and the objects

began to move in curvilinear trajectories from grid cell to grid cell at a constant speed. At the end of each trial, all objects disappeared from the screen, and the participants were asked to indicate with their finger (on the touch screen) which grid cell the target object was last in before it disappeared. Each trial was followed by a memory check screen and a smiley face. Participants were told that the smile did not indicate a correct answer and rather that we were happy they were playing our game. See Figure 1 for a diagram of the task sequence.

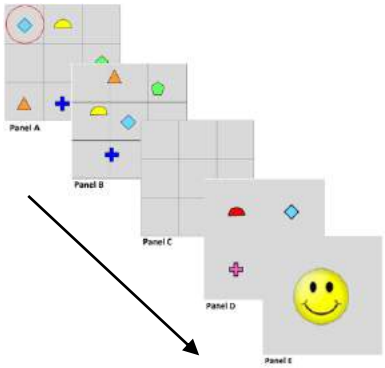

Figure 1: The TrackIt task pipeline. Panel A: static display of the stimuli before the trial starts; Panel B: the stimuli move along random trajectories during the trial; Panel C: response screen after the moving shapes disappear; Panel D: memory check; Panel E: a smiley face at the end of the trial.

Participants completed 11 trials of the task. The first trial was a practice trial and was completed with assistance from the experimenter who traced the moving target with their index finger. The first trial was accordingly omitted from analysis. Participants were then told that they would need to complete the rest of the task by themselves, tracking the target with their eyes only.

Design The sequence of positions in the path of each of the objects was randomized. Object motion display was set to 30 frames per second. The minimum trial length was set to 10 milliseconds. The parameters—grid size, number of distractors, and speed of objects—were determined by prior testing in TrackIt with a separate group of 3- to 5-year old children (Kim et al., 2017) and via pilot testing with two-year-olds. The parameters were organized according to participant age and difficulty level as seen in Table 2.

Table 2: TrackIt parameter combination used in each difficulty level

Difficulty	Age Group (years)	Grid Size	# of Distractors	Object Speed (pix/s)
Level 1	2-4	2x2	2	300
Level 2	3-5	4x4	4	500

Note: pix/s = pixels/second

Separate groups of participants were tested in each difficulty level. We did not complete testing for age and level combinations that were likely to produce floor or ceiling effects. The final sample size per age and difficulty level is presented in Table 3.

Table 3: Sample sizes and age statistics for each age group, for each difficulty level

Age (years)	Difficulty Level 1		Difficulty Level 2	
	n/m/f	Age Mean (Std)	n/m/f	Age Mean (Std)
2 y.o.	13/8/5	2.89 (0.12)	--	--
3	19/7/12	3.53 (0.27)	20/12/8	3.56 (0.24)
4	14/7/7	4.39 (0.26)	12/5/6 (1 not reported)	4.31 (0.15)
5	--	--	9/4/5	5.48 (0.22)

Note: n/m/f = sample size / # male/ # female.

Results and Discussion

Age and Task Level For each participant, we calculated an average accuracy score i.e., the proportion of ten trials for which the participant correctly identified the grid cell in which the target object disappeared. To investigate possible effects of participant age and task difficulty level, accuracy scores were submitted to a 2-way analysis of variance (ANOVA) with age and difficulty level as between-subject factors. This analysis indicated main effects of age (F (3, 81) = 11.40, p < .001) and difficulty level (F (1, 81) = 19.16, p < .001), but no age-by-difficulty interaction (F (1, 81) = 1.65, p = .20) (See Figure 2).

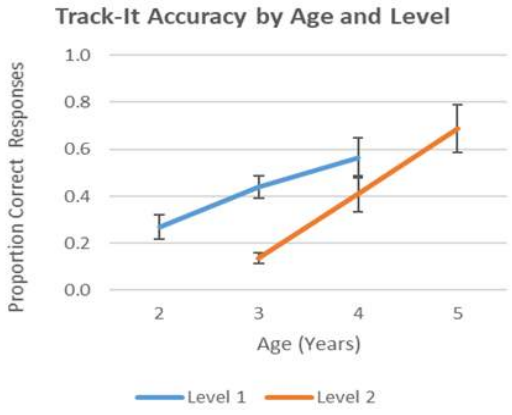

Figure 2: TrackIt accuracy improved with age for participants tested in Levels 1 and 2.

Post-hoc Tukey's tests showed that, for Level 1, the tracking accuracy of 4-year olds was significantly above that of 2-year olds (adjusted p = .02) but not 3-year olds (adjusted p = .44). For Level 2, the tracking accuracy of 4-year olds was significantly above that of 3-year olds (adjusted p = .03). However, the tracking accuracy of 5-year olds was not significantly above that of 4-year olds (adjusted p = .10). Nonetheless, there is an emergence of developmental trends that are consistent with Fisher et al. 2013 and Kim et al. 2017 and further, planned data collection (i.e., to bring the number of participants in each cell to 20) will shed light on any further age-related differences. Post-hoc Tukey's tests also showed that 3-year olds performed significantly better in Difficulty Level 1 than in Difficulty Level 2 (p < .01). Surprisingly, 4-year-olds did not show a significant difference in performance at Difficulty Levels 1 and 2 (adjusted p = .64).

For all combinations of difficulty level and age group, TrackIt accuracy was above chance (25% given four response options in Level 1 and 6.25% given 16 response options in Level 2, all one-sample t s > 3.62, p s < .001), except for two-year-old children completing Difficulty Level 1 (one-sample t (12) = 0.63, p = .54). This result indicates that two-year-olds did not differ from chance performance on the TrackIt task.

Shape Frequency Next we assessed the possibility that the frequency of a target shape influenced children's performance on trials with that target shape. The average proportion of correct trials, sorted by target shape, ranged from 0.32 (diamond) to 0.44 (crescent). To determine whether TrackIt performance varied significantly by shape frequency, we conducted a logistic regression using shape frequency to predict accurate TrackIt responses while controlling for participant age and task difficulty level. Results of the regression indicated that participant age and task difficulty level, but not frequency of target shape, were associated with TrackIt performance (see Table 4).

Table 4. Results from the logistic regression analysis: target shape frequency, difficulty level, and participant age as predictors of correct answer on a trial of TrackIt

Predictor	*B*	*SE B*	Wald	*P*	*df*
Shape Frequency	-0.00	0.00	-6.68	.89	868
Difficulty Level	-0.54	0.08	-0.14	<.001	868
Participant Age	0.98	0.10	-6.45	<.001	868

Similarly, results of a Pearson correlation did not indicate an association between frequency of a target shape and children's average TrackIt accuracy on trials of that target (r = -0.01, p = .72). See Figure 3.

Based on these results, it does not appear that shape knowledge can account for any variability in TrackIt performance, a finding that helps to validate TrackIt as a measure of selective sustained attention. However, there are several cautions in using frequency data as a proxy for shape knowledge. Some of these concerns are grammatical/technical in nature e.g., given the nature of the data, it is unknown what proportion of word utterances co-occurred with a concrete or pictorial referent, and this co-occurrence structure might matter for the encoding of the referent shapes.

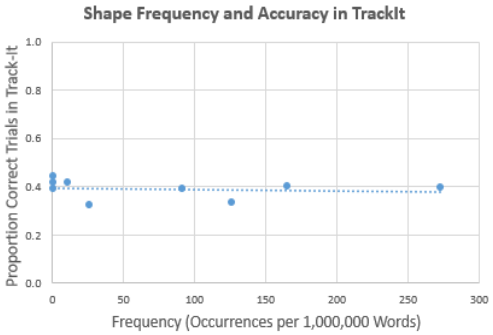

Figure 3: Corpus frequency of target shapes did not account for variability in TrackIt performance.

Relatedly, some of the stimuli names (see column 1 of Table 1) can be used as verbs with semantically-related meanings to the shapes whose names they share (e.g., circle, cross) and/or adjectives with meanings unrelated to the shapes whose name they share (e.g., cross). Some stimuli are both the nominal and adjectival form of the shape name (e.g., square); whereas, other shapes have a morphologically related but distinct adjective form (e.g., circular, triangular). These nuances might bias to the number of occurrences of each target shape in the ChildFreq database. Perhaps more critically, the nature of interactions captured in the Childes database may be biased toward free-play and informal interactions, rather than formal educational experiences. Accordingly, it might underestimate the frequency of less-common shape names, to which children might be exposed in other, more explicitly educational interactions not captured in the data.

Nonetheless, we posit that—for this age group—the relative frequencies observed likely comprise reasonable approximations of shape familiarity i.e., circle, triangle and square are the most common and early-emerging shape names in our stimuli set, with crescent and semi-circle being significantly less frequent. However, to address the concerns about using relative frequencies as a proxy for children's shape knowledge, in Experiment 2 we directly assessed the shape knowledge of three- to five-year-old children, as described below.

Experiment 2

Method

Participants We tested 32 participants to assess children's knowledge of the shapes (M = 4.47 years, SD = 9.3 months, range 3.24 to 5.84 years). Participants were drawn from preschool and kindergarten programs. 16 of these children

were also participants in Experiment 1 (M = 4.29 years, *SD* = 8.7 months, range 3.35 to 5.70 years) and completed the shape knowledge task an average of 9.7 weeks after the TrackIt task. It is unlikely that participation in the TrackIt task affected children's performance on the shape knowledge task. The total sample for Experiment 2 included 11 three-year-olds (8 females, *M* = 3.56 years, *SD* = 1.9 months); 11 four-year-olds (6 females, *M* = 4.52 years, *SD* = 3.0 months); and 10 five-year-olds (7 females, *M* = 5.40 years, *SD* = 2.7 months).

Given that (1) two-year-olds were at chance in identifying the last location visited by the target shape in Experiment 1 and (2) pilot testing indicated that two-year-old children had difficulty producing verbal responses on the shape knowledge assessment, we did not include this age group in Experiment 2.

Materials and Apparatus The physical equipment and child seating position is identical to those of Experiment 1. Shapes presented were the set of TrackIt stimuli, made identical in color and equated for overall size (see Figure 4).

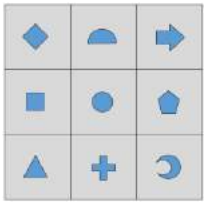

Figure 4**:** The set of geometric forms and iconic shapes comprising the TrackIt stimuli, presented on a single grid.

Procedures Shapes were displayed one at a time in the center of a gray screen. Children were instructed to provide verbally the name of each shape and prompted to "make their best guess" as necessary. No feedback was provided on the accuracy of children's responses. The experimenter demonstrated the task across 6 practice trials that presented the stimuli star, heart, and oval two times each. The nine stimuli were sampled without replacement, after which the block of nine was repeated two more times for a total of 27 trials (3 presentations of each of the 9 target shapes).

Results and Discussion

As expected based on the ChildFreq statistics, children demonstrated superior knowledge of high-frequency shape names (e.g., circle, triangle) relative to low-frequency shape names (e.g., crescent, semicircle). Results of the Pearson correlation indicated that there was a positive association between shape frequency and children's shape knowledge, (r = .82, p < .01) (Figure 5). Accordingly, we have put forth two complementary approaches for assessing shape familiarity for the TrackIt stimuli.

To assess possible age-related changes in shape knowledge, we conducted an ANOVA on children's shape

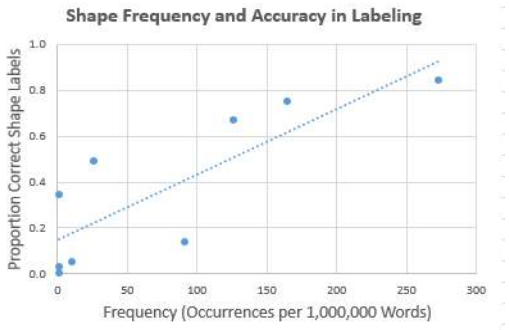

Figure 5: Children's accuracy in labeling shapes positively correlated with the frequency of those names in the corpus.

knowledge using participant age and shape frequency predictors. This analysis indicated main effects of age (F (1, 284) = 19.85, p < .001) and shape frequency (F (1, 284) = 147.40, p < .001).

Despite finding better shape knowledge in older children than in younger children, we did not find a relationship between children's knowledge of shapes and average performance on TrackIt trials with that target shape (see Figure 6 for a visualization).

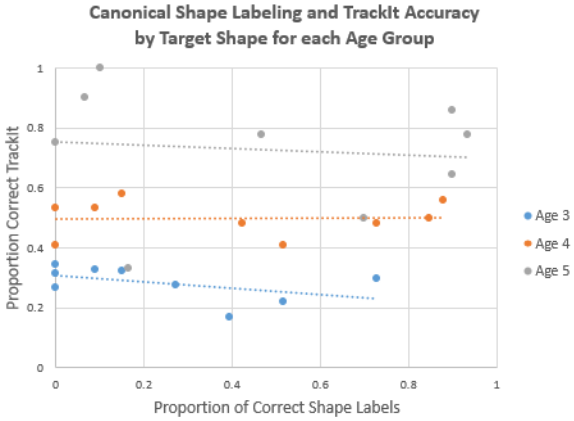

Figure 6: Children's accuracy in shape labeling and on TrackIt trials with that target shape, by age.

We further assessed this relationship using a logistic regression on trial accuracy by proportion correct shape labels with a control for difficulty level (Table 5).

Table 5. Results from the logistic regression analysis: proportion correct shape labels and difficulty level as predictors of producing a correct answer on a trial of TrackIt

Predictor	*B*	*SE B*	Wald	*P*	*df*
Shape Label	-0.26	0.23	-1.15	.25	868
Difficulty Level	-0.35	0.14	-2.48	.01	868

Similarly, results of a Pearson correlation did not indicate an association between average ability to name a target shape and accuracy on trials of that target (r = -0.04, p = .24).

Other Names The results above are based on children's productive shape knowledge of a single canonical name for each target shape (see column 1 of Table 1). We additionally assessed the extent to which the findings held when allowing for other valid names for the target shapes. Ten adult graduate students who were blind to the hypothesis (M = 28.62 years, SD = 6.33 years, range 25.15 to 46.08 years) assigned each shape-label match generated by children in Experiment 2 no credit, half credit, or full credit. Adults rated all canonical names as full-credit responses. When indicated by consensus agreement (80 percent) non-canonical names were assigned full-credit (e.g., "moon" for crescent, "plus" for cross) or half-credit (e.g., "ball" for circle, "right" for arrow).

Using this coding scheme to represent children's shape knowledge, there remained a positive association between shape frequency in the ChildFreq statistics and children's shape knowledge (r = .82, p = .03). In addition, we still found evidence for age-related changes in shape knowledge: an ANOVA on children's shape knowledge using participant age and shape frequency as predictors indicated main effects of age (F (1, 284) = 27.89, p < .001) and shape frequency (F (1, 284) = 81.48, p < .001). Importantly, we did not find a relationship between children's knowledge of shapes and average performance on TrackIt trials with that target shape (see Figure 7).

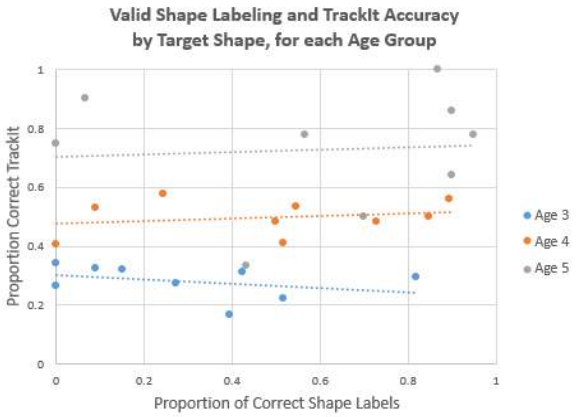

Figure 7: Children's accuracy in shape labeling and on TrackIt trials with that target shape, by age, when allowing for non-canonical labels judged valid by adult participants.

General Discussion

Consistent with prior research, we found effects of age and task difficulty level on performance in the TrackIt task in Experiment 1 (Fisher et al., 2013; Kim et al., 2017). In Experiment 2, we also found that indeed children's shape knowledge was related to age, with older children showing better shape knowledge of shape labels than younger children. We also found that across age, children showed better knowledge of shape labels for more frequently occurring labels. However, across Experiments 1-2 we did not find evidence that shape knowledge or frequency can account for age-related improvement in performance on the TrackIt task. Specifically, we did not find evidence that the frequency of a target shape, as derived from the ChildFreq database, was related to children's performance on TrackIt trials using that target shape. Similarly, we did not find a significant relationship between children's ability to label a target shape and their performance on trials involving that target shape. In contrast, our analyses indicate that children performed similarly across trials regardless of target shape.

These findings help to mitigate concerns that shape knowledge may contribute to children's performance on the TrackIt task, given that knowledge of the different target shapes is likely to emerge at different time points and rates (i.e., if knowledge of the target shape names were a critical aspect of task success, we would expect young children in particular to perform relatively better on trials with high-frequency shapes relative to those with less familiar shapes).

At the same time, that two-year-old children performed at chance overall (on both the main task and the memory check) might indicate that these youngest participants have difficulty encoding any target shape, regardless of its relative frequency. Additional development and school experience might support older children in recognizing the properties of shapes, even if they are not familiar with the canonical names of these shapes (as both the Childes database and children's own performance suggest).

One limitation of the current studies is that our analysis did not account for object color, the other dimension by which target and distractor shapes differed. Children with limited shape knowledge might nonetheless be successful in encoding the target object by using color labels (see Sandhofer & Smith, 1999, for a review of the time course and developmental dependencies of color term learning). We did not test for this hypothesis because currently the TrackIt output records only object shape but not color.

Another limitation of the current set of studies is that some (but not all) of the children providing shape knowledge data in Experiment 2 also completed the TrackIt task in Experiment 1. An alternate design would have allowed us to more directly assess shape knowledge of TrackIt participants, rather than that of a representative peer group.

Conclusions

Across two experiments we obtained no evidence that shape knowledge contributed to children's performance accuracy on the TrackIt task. Accordingly, the results of the present study help to mitigate the concern that shape knowledge may fully or partially account for the age-related changes in performance on the TrackIt task reported in prior studies. Overall, the reported results help to support the previous interpretation of this task as an assessment of selective sustained attention in young children (Erickson et al., 2015; Fisher et al., 2013; Kim et al., 2017).

Abstract

This paper investigates whether a curiosity-based strategy could be beneficial to word learning. Children are active conversation partners and exert considerable influence over the topics that are discussed in conversation with their parents. As the choice of topics is likely to be intrinsically motivated, a formalization of curiosity is implemented in a word learning model. The model receives annotated Flickr30k Entities images as input, and is trained in two conditions. In the curious condition, the model chooses objects to talk about from the scene according to the curiosity mechanism, whereas in the random condition, the model receives randomly chosen objects as input. The goal of this study is to show how a curious, active choice of topics by a language learner improves word learning compared to random selection. Curiosity is found to make word learning faster, increase robustness, and lead to better accuracy.

Keywords: word learning; curiosity; interaction; connectionist model.

Introduction

Language learning research focuses more and more on child-parent interaction and the social aspects of early conversation. Children are active learners and have considerable agency as conversational partners. We will argue that curiosity is a plausible mechanism for the child to come up with new topics to talk about within this conversational context. While AI researchers have become inspired by the curiosity displayed by children, and have implemented intrinsically motivated exploration in computer models, this formalized curiosity has not been applied to computational models of language learning. At the same time, the implementations of curiosity in computer models are often not cognitively plausible or the degree of plausibility is unknown (as in reinforcement learning), or the input to the model lacks the complexity of the stimuli encountered by the word learner.

Curiosity can be seen as a viable mechanism in language learning if it provides an advantage to the word learning child. In order to see whether curiosity is beneficial to the word learning process, we propose a curiosity-based model that chooses which object in a scene to talk about next. The model chooses its object of interest from among a number of objects in an image, and triggers the adult to provide linguistic input related to that object. The curiosity mechanism suggested by Twomey and Westermann (2018), which maximizes the product of subjective novelty and plasticity, was implemented to select the objects. To reflect the complexity of visual scenes encountered by the child, the model takes Flickr30k images as input, which depict everyday scenes and objects and have been annotated with captions. The accuracy and loss of the model with a curiosity-based selection of topics were compared to those of a model that received the topics randomly.

Related Work

Interaction and Intentionality

Given the social nature of early conversation, language should not be seen as a product but as a dynamic system for communication (Clark, 2016). Language is used and learned in order to convey and receive information. This means that the child is a conversation partner first, and a language learner second. Furthermore, young children are active speakers and language learners. Bloom et al. (1996) observed that children aged 9 through 24 months are most likely to speak first in conversation with their mother, and the mother to speak after the child. Their evidence did not support the scaffolding model, in which the parent takes a prominent role in the conversation by providing a framework that controls the elements beyond the capacity of the learner and lets the learner concentrate on those elements they are capable of producing. Rather, children initiate conversations and, as shown in several studies (Chapman, Miller, MacKenzie & Bedrosian, 1981; Bloom et al., 1996), mothers are likely to adopt the topic proposed by the child, and continue to talk about it.

These studies show a pattern of turn-taking with a clear role division. Often, the child wants to discuss a certain topic and starts by talking about it. The parent makes sure they understand what the child is referring to by rephrasing what the child has said, which functions as feedback to the

language-learning child at the same time (Chouinard and Clark, 2003). The child then assesses whether the parent has understood the initial message, after which the conversation can continue. When children initiate conversations and their parents adopt the proposed topics, children can exert considerable influence on the topics that are discussed and consequently on the feedback they receive.

Because children initiate conversations, and continue discussing the topic when they feel they have been understood, their choice of topics is unlikely to be random. As the language learner decides on the topic themself, taking in the current surroundings and situation, the choice is likely to be intrinsically motivated. Our study investigates whether a curiosity-based selection of the topics to be discussed enhances word learning through comprehension of the symbol-referent pair.

Curiosity

Curiosity is a form of intrinsic motivation. Intrinsic motivation can be defined as doing "an activity for its inherent satisfaction rather than for some separable consequence. When intrinsically motivated, a person is moved to act for the fun or challenge entailed rather than because of external products, pressures, or rewards" (Ryan and Deci, 2000, p. 56). In the 1950s, psychological research assumed that human behavior is mostly extrinsically motivated, by physical drives such as those to alleviate hunger and minimize pain. A major shortcoming of this theory was that it did not account for exploratory and other curious behavior in humans and animals—behavior that does not seek immediate reward (Oudeyer & Kaplan, 2007).

When formalized to be programmed into a computer model or robot, intrinsic motivation and curiosity are often conflated (e.g. Pathak et al., 2017). Intrinsic motivation has mostly been applied in reinforcement learning, providing agents (robots and models) with an intrinsic desire to explore their environments and build better models and representations of them (Schmidhuber, 2010). Studies that implemented intrinsic motivation have shown that intrinsically motivated exploration increases the performance of a model when generalizing to other tasks (Pathak et al., 2017), and this is likely to be the case for humans as well (Twomey & Westermann, 2018).

Reinforcement learning implements a variety of formalizations of intrinsic motivation, such as maximizing the decrease of prediction errors, maximizing or minimizing predictability, or choosing the action that maximizes the agent's ability to perform a task. Some approaches use predefined rewards or external signals that provide feedback on motor functions, both of which are certainly not cognitively plausible. Of other approaches, it is simply not known how cognitively plausible they are (Oudeyer & Kaplan, 2007; Twomey & Westermann, 2018). In fact, not a lot is known for certain about the workings of curiosity in human cognition in general and children's cognitive development in particular.

What is clear is that children are natural explorers, displaying a novelty preference from an early age. Novel stimuli have most potential to yield new insights upon exploration, as little is known about them yet. As a stimulus is perceived, it becomes less interesting over time (habituation), and other stimuli become more interesting relative to the current stimulus as they remain novel when not examined (Mather, 2013).

Under various circumstances, however, children display familiarity preferences. While completely novel stimuli leave a lot to be explored, they can be uninteresting nonetheless as they differ greatly from the child's state of knowledge. Some have suggested that a moderate discrepancy between a stimulus and the child's representation of it could define the optimally interesting stimulus. What moderate means in this context, however, is not a trivial question. How familiarity and novelty preferences influence learning is little understood as of yet (Mather, 2013).

In a recent publication on curiosity-based categorization in infants, Twomey and Westermann (2018; henceforth T&W) simulate infant categorization using an autoencoder, a model that learns to reproduce the input after reducing it to a compact representation. They defined curiosity as maximizing

$$(i - o)o(1 - o) \qquad (1)$$

where i stands for the model input and o for the model output. $(i - o)$ reflects the difference between the input and the output, which is the error of the autoencoder in response to a particular stimulus. $o(1 - o)$ is the derivative of the sigmoid activation function. As such, this part of the formula reflects the potential update made to the model in response to this stimulus, when it is trained using gradient descent. The formula favors stimuli which the model is predicting least accurately (the difference between input and output is large), and stimuli where a small adjustment in representation has the greatest effect on the prediction in terms of accuracy (the sigmoid derivative is large). In T&W, the curiosity condition learned the most robust category, followed by the objective complexity condition.

T&W provide a cognitively plausible mechanism of curiosity, that produced results that fit their empirical data well. That the implementation of curiosity outperformed the other three mechanisms shows that a learner would benefit from applying this strategy. The inputs used in the study are very interpretable, but also rather simple, consisting of eight training instances and three test instances that differed on four features. The present model will use the same curiosity mechanism, and see how it performs when provided with more complex input, consisting of a sizable set of images to approximate the complexity of the language learner's surroundings.

The model of T&W went through the stimuli without replacement, so that the model encountered every stimulus once per epoch. A drawback of this setup is that it does not correspond to how children encounter stimuli in real life, as children have no control over the order in which stimuli are

presented to them. It is also unlikely for children to come across a string of examples of a certain category presented one after the other. Objects and living things are often seen in isolation from other category members, and amid objects of a wide variety of other categories. Our model was therefore presented scenes containing multiple objects it could choose from. The model would pick one object, skipping the other objects as it went on to the next scene. It was free to look at the same or any other object in the scene during the next epoch, meaning that some objects could be ignored altogether. This made the input sequences of our two experimental conditions more different, and perhaps less comparable than in T&W's case, but it also better approximated a word learning context, in which only certain aspects of a scene are in focus at any time.

Methodology

Model

Our language learner model is inspired by a model of referential expression resolution (Rohrbach et al., 2017), which incorporates an expression generation module as well as the main expression resolution component, which allows it to learn under self-supervision. We implement a similar complementary setup, consisting of a listener and a speaker module. The listener represents a child learning which words represent which objects in the visual modality, by receiving linguistic input from an oracle, which represents an adult conversation partner. The listener learns through supervision, comparing the true referent of a word to the referent it expected, and updating its language knowledge accordingly.

The incorporation of a speaker module in principle allows the model to be used in a conversational set-up, but in the current work, the emphasis is on comprehension. As we describe in more detail in the section on 'Curiosity', the model's curiosity about an object is calculated based on the ability of the listener to comprehend the label the speaker would give it. The oracle labels the object the learner model is most curious about. In analogy, a parent might name an object their child points out. Learning, however, is not simply mapping the label to the correct object: just like in the random condition, the model learns by predicting the referent of the given word and getting feedback on this prediction. The curiosity mechanism affects only the order the stimuli are presented in, but not the learning process itself. Figure 1 illustrates the architecture of the model. The listener learns to map a given word to its referent in the visual context. A visual scene consists of a number of objects. We extract a visual feature vector for each object using the VGG-16 object recognition model presented by Simonyan & Zisserman (2015), pretrained on ImageNet. We use the last fully connected 4096-dimensional layer, which contains high-level visual information. For each object in a given scene, the embedding of the word given by the oracle was concatenated to the object representation, which was input to the listener. The listener further consists of a 256-unit hidden layer followed by a sigmoid activation function, which is fully connected to a single output unit, also followed by sigmoid activation. Softmax applied to the concatenation of the output values for all the objects in a scene gives a distribution reflecting the probabilities of each object being the referent. The listener was trained under supervision using cross-entropy loss on the concatenated output values. The loss function is a quantification of how far off the model's prediction is from the actual target distribution. Hence, a lower loss value means a better performing model.

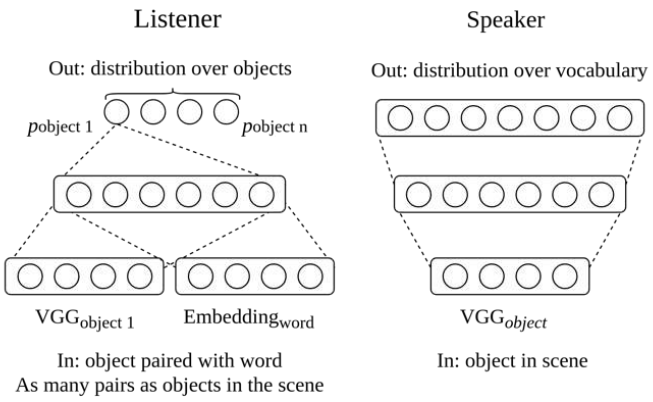

Figure 1: Simplified graphical representation of the model.

The speaker module learns to output a word, given an object. Input to the speaker is a VGG vector, which is fed to a 256 unit hidden layer followed by sigmoid activation, and fully connected to the vocabulary-sized output layer. The speaker was trained using cross-entropy in a self-supervised manner. Rather than training on a single object VGG vectors, it was fed the sum of the VGG vectors of all objects in the scene, weighted by the Softmaxed output vector of the listener (using it as attention). The self-supervision signal consists of the original input word to the listener. Therefore, the speaker can be thought of as learning in an unsupervised manner, although its performance is dependent on that of the listener, which is trained under supervision.

The model was trained using Adam optimization (Kingma & Ba, 2014) in batches of 40 images, for a maximum of 40 epochs. To decide on an initial learning rate, we ran both the 'curious' and the 'random' model, with learning rates ranging from .1 to .00001 for 20 epochs. We ran each condition-learning rate combination with 5 different random initializations. We found that the best scores on the validation data were sometimes obtained in epoch 20, which suggested the model might not have fully converged yet. We therefore decided to report on models trained for 40 epochs. A learning rate of .001 yielded the best results on validation data for both the listener and the speaker. The results reported reflect 20 different runs of both conditions, with learning rate set to .001. The model was implemented in PyTorch (Paszke et al., 2017). The code is available at https://github.com/DaanKeijser/Curious-Topics.

Data

The Flickr30k dataset (Young et al., 2014) was used as visual input to the model. The dataset consists of 31,783 images taken from Flickr, annotated with five captions per image (158,915 in total) via crowdsourcing. The images depict everyday activities and scenes. Plummer et al. (2015) expanded the dataset with Flickr30k Entities, by identifying which words in the captions refer to which entities in the images. They provided annotation for 244,035 such coreference chains, and located the entities they referred to in the images, resulting in 275,775 bounding boxes. It should be noted that this data has a high level of complexity, but the captions are not child-directed speech.

Figure 2 gives an example of the data our model was trained on. On the visual side, we simplified the learning problem by excluding any referring expressions that described multiple objects, such as 'plants' and 'pots' in Figure 2. Processing multi-word expressions requires a recurrent neural network and a cross-situational learning model, which is outside the scope of the current work. We therefore simplified the referring expressions to single words. The Flickr30k Entities "Sentences" files containing the annotated captions for each image were searched to find all descriptions for every object ID. From the expressions for every object ID, the most frequent word was chosen as the single word most likely to describe the object in the image. This required that at least two descriptions of the image mentioned the object by the same term, otherwise the object was excluded. The word selection was done after omission of very frequent, irrelevant words such as articles ('a', 'an', 'the'), third-person possessive determiners ('his', 'her', 'their'), the cardinal numbers one through ten, and primary and secondary colors (e.g. 'orange'), including 'silver' and 'gold'. If multiple objects in an image had been labeled with the same word, only one of them was selected (the first one in the loop, not randomly). Finally, images were removed that contained fewer than two objects after preprocessing.
