This yielded a total of 86,748 word-object pairs, resulting in a vocabulary of 4,237 unique words. It should be noted that objects paired to the same word could still display great visual variability. The least frequent words (e.g. 'beak' and 'paste') occurred only once, whereas the most frequent word occurred 7,891 times. The five most frequent words were *man* (7,891 times), *shirt* (4,536 times), *woman* (4,378 times), *boy* (1,477 times), and *girl* (1,428 times). The average frequency was 20.47 (*SD* = 172.33), and the median frequency was 2. After preprocessing, 24,670 images remained, of which 1,000 were set aside as validation data, and another 1,000 as test data.

Table 1: Number of objects and baselines per split.

Split	Objects	Listener baseline	Speaker baseline
Train	79,749	0.284	0.091
Test	3,493	0.286	0.089

Table 1 shows the total number of objects in the train and test splits of the data, as well as the baselines for the listener and speaker respectively. The listener baseline is one divided by the average number of objects per scene. The speaker baseline is the majority baseline of the most frequent word. The baselines represent the average accuracy obtainable by chance, which serves as the minimal performance expected of the model. High accuracy is only an indication of good performance if the model performs better than its baseline. Since many words occur only once or twice, there are 80 words in the test set that do not occur in the training set, with a token frequency of 80, and 776 words, with a token frequency of 3413 in the test set, that do occur in the training set. These numbers might suppress test accuracy.

Curiosity Mechanism

In order to measure the effect of active and curious learning, the model which performed curiosity-based object selection was compared to a model that received the next object to learn about randomly. In the first condition, curiosity values were calculated for each object using T&W's curiosity mechanism, and the object with the highest value was chosen to learn about. In the second condition, objects were randomly chosen from the scenes. The main purpose of the speaker part of the model was to produce a word guess as input to the listener so that the model could run without the input provided by the oracle. This way, the model could run (without weight updates) to compute curiosity values and

choose the most interesting object to talk about, before running (with weight updates) to learn about the form-meaning pair with feedback from the oracle.

T&W's curiosity mechanism (see equation (1)) was used to produce the curiosity values, where *i* was the object representation given as input to the speaker, and *o* was the object prediction produced by the listener. The curiosity values were computed element-wise, and the mean of the absolute values of the curiosity vector was taken as the curiosity value for an object in the scene. The object with the highest curiosity value was chosen as the next input for the speaker and target for the listener.

The random and curious conditions were compared on listener loss and accuracy, which indicate the models' ability to choose the appropriate referent of a word form. The loss and accuracy patterns produced over the 40 epochs were plotted to be interpreted as learning curves and compared between conditions.

Results

Figure 3 shows the value of the loss and accuracy of the listener, after each epoch of training. Curious listeners (the blue lines in all plots) show a consistent pattern: after one epoch of training, accuracy on the test set ranged from .49 to .61, far above the baseline of .286. The accuracy on the test set steeply increased in the first few epochs, and kept increasing more slowly, but steadily over later epochs, converging somewhere around epoch 20 with accuracy from .71 to .74. At epoch 40, accuracy ranged from .72 to .75. The exception to this pattern is one particular run, which shows a similar learning trajectory but started and ended with a much lower accuracy, of .32 and .58, respectively. The general pattern is reflected in the plots of the loss on the test data.

On the training data, accuracy also plateaued around epoch 20, with accuracy from .80 to .83 for 19 runs, and only small gains in accuracy until epoch 40, with scores from .83 to .84. Note that the training loss continued to decrease after epoch 20. This indicates the curious listeners started to overfit at that point, fitting to specific characteristics of the training set, that did not translate to accuracy or improvements on the test data. As we saw on the test data, one run shows a different pattern and reaches a maximum of .76 in accuracy on the training data.

The pattern for listeners in the random condition (the orange lines in all plots) is more erratic. After one epoch of training, all random listeners started around or just above the baseline accuracy of .286. Some listeners in this condition barely outperformed the baseline at epoch 40. Others outperformed the baseline, but plateaued after 10-20 epochs, eventually reaching maximum accuracy scores ranging from .39 to .48 on test data. For 6 runs, the accuracy after epoch 1 was around the baseline, but increased steeply until epoch 20, and continued to increase slowly after that. At

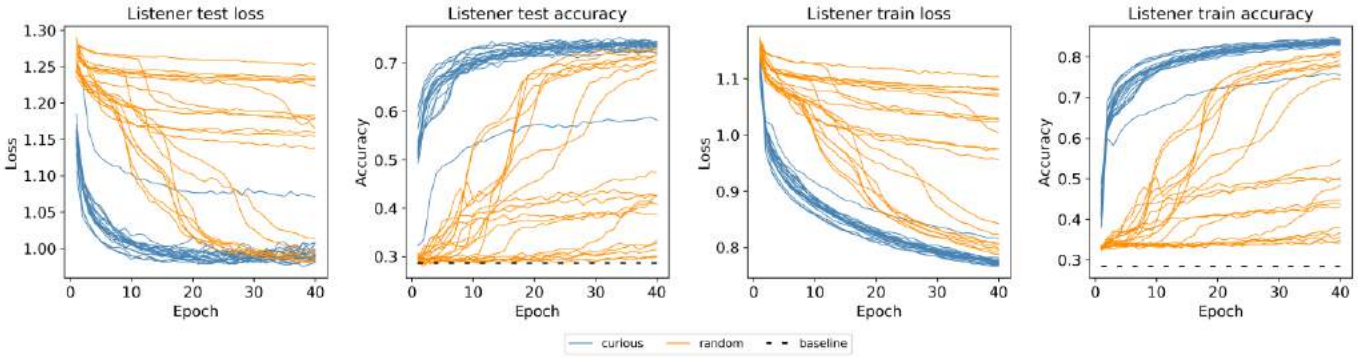

Figure 3. Test and train results of the listener.

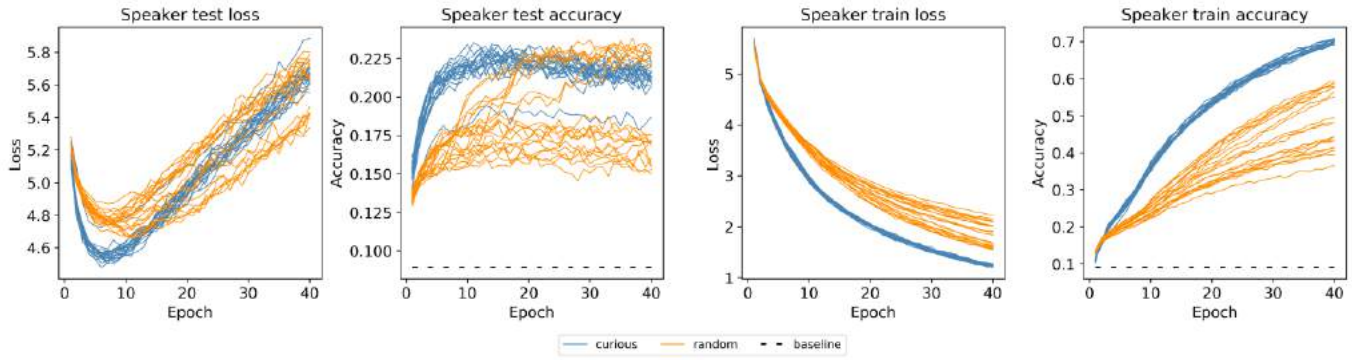

Figure 4. Test and train results of the speaker.

epoch 40, performance of 8 runs is slightly below that of most runs in the curious condition, with test accuracy ranging from .68 to .73, and train accuracy from .78 to .81. The same patterns are reflected in the loss plots.

Test accuracy of speakers trained in the curious condition peaked somewhere between epoch 10 and 25 around .23, with the exception of the one run in which the listener was also less successful, which peaked at epoch 12, with an accuracy of .19. The loss value was lowest around epoch 8. After this epoch, the training loss was still consistently going down, and training accuracy going up. After epoch 8-10, the curious speakers were overfitting rather than learning.

As with the listeners, initially, speakers in the random condition learned more slowly, as is reflected in the lower accuracy between epochs 1 and 20. In all random runs, the speaker outperformed the baseline. However, as was the case with the listeners in this condition, there are large differences between runs. Most runs plateaued relatively quickly, and peaked between .16 and .19, whereas in 8 of the 20 runs, accuracy continued to increase, eventually matching performance of the speakers in the curious condition, with accuracy peaking around .23. Although the training trajectories in the random condition are more discernable than for the curious condition, in all runs, performance on the training data continued to improve until epoch 40. As in the curious condition, all random speakers overfitted.

Discussion

Did curiosity increase the performance of the word learning model compared to the random choice of objects? Yes, the listener test loss decreased faster and the listener test accuracy increased faster in the curious condition than in the random condition. Whereas the curious model converged at a similar point on every run, the random model eventually equaled or approached the curious model on some runs, but learned nothing or was stuck in a local optimum on others.

A pattern that can be discerned is that curiosity, aggregated over the different initializations, performs better from the start and learns faster than random selection. In this experiment, the random initialization of the weights meant that the first objects selected in the curious condition were just as random as those in the random condition. This changed after a few weight updates when the curiosity formula took effect—the difference in performance becoming apparent after a single epoch. This behavior is different from what is typically proposed, as intrinsic motivation is expected to make learning slower initially, but make up for that with increased performance and better generalization in the long run (Oudeyer & Kaplan, 2007).

Another pattern that can be observed is that learning trajectories of curious learners were more similar to each other than those of random learners were. Curiosity seems to provide 'robustness', making learners less prone to being stuck in a local optimum.

The near instant performance advantage of curiosity may be explained by the inherent advantage it has over random selection when dealing with token frequency. Having a good word representation for the corresponding object brings an increase in overall accuracy equivalent to its token frequency. Whereas random selection is prone to select objects with a high token frequency, curious selection can focus on highly frequent word-object pairs first, and ignore them later once their representation is already accurate. Further research could establish whether the selection by the curiosity mechanism matches this strategy.

This would correspond to the notion that language is not a product, but a means for social interaction, where the child's initial interest is to get the message across and language learning follows (Clark, 2016). The intentionality theory of language learning describes how such intrinsically motivated behavior can drive language learning (Bloom, 2000). As of yet, there is no empirical data on what criteria or strategies children use to pick topics to talk about.

Whereas the model was evaluated on the listener performance (comprehension), the speaker's main purpose was to enable the curiosity mechanism, which was used to train the curious model. The high train accuracy of the curious speaker increased the accuracy of the curiosity mechanism, thereby improving the curious listener's comprehension. However, the speaker overfitted in both conditions, and did not generalize well to test data. The speaker test results therefore do not help to understand how improved comprehension leads to improved language production.

We have shown that modeling the language learner as an active solicitor of input, rather than a passive receiver, can lead to different learning outcomes. When objects in the context are selected as a topic according to curiosity, word learning is faster and more robust than when topics are selected at random. Future work may explore the distributional properties of the topics selected by curiosity over the course of the learning process.

The consistency of durative relations

Laura Kelly and Sangeet Khemlani

Abstract

Few experiments have examined how people reason about durative relations, e.g., "during". Such relations pose challenges to present theories of reasoning, but many researchers argue that people simulate a mental timeline when they think about sequences of events. A recent theory posits that to mentally simulate durative relations, reasoners do not represent all of the time points across which an event might endure. Instead, they construct discrete tokens that stand in place of the beginnings and endings of those events. The theory predicts that when reasoners need to build multiple simulations to solve a reasoning problem, they should be more prone to error. To test the theory, an experiment provided participants with sets of premises describing durative relations; they assessed whether the sets were consistent or inconsistent. The results of the experiment validated the theory's prediction. We conclude by situating the study in recent work on temporal thinking.

Keywords: events, temporal reasoning, durative relations, mental models, consistency

Introduction

A police officer stopped a driver on the suspicion of drunk driving near Vero Beach, FL. As the officer began to speak to the driver, he noticed an open bottle of Jim Beam on the passenger's seat. The driver explained to the officer that he had not, in fact, been drinking *while* driving – because he only drank when the car was stopped at traffic lights. He was arrested after failing a field sobriety test (Simmons, 2018).

In daily life, people use temporal relations such as "while" and "during" to convey information about events that endure across more than one point in time. Consider the function of the temporal preposition "during" in the following examples:

1a. The car broke down *during* the road trip.
b. Breckinridge graduated *during* the Progressive Era.

The statements each describe a punctate event, i.e., a single point in time (e.g., the breakdown, the graduation), that occurred in the context of a period that extends across multiple time points (e.g., the road trip, the Progressive Era). The sentential connective "while" can yield similar interpretations, as in the examples in (2):

2a. The man slept *while* the neighbors fought.
b. The neighbors fought *while* the man slept.

The examples show how syntax can change the way events are interpreted. For instance, (2a) seems to suggests that the neighbors fought for longer than the man slept, whereas (2b) seems to convey the opposite. Perhaps the two statements are compatible with one another, as in the situation in which the man started sleeping right as the fight began and woke up when the fight ended.

Researchers in artificial intelligence have developed many systems of temporal logic to cope with reasoning about durative events (e.g., Allen, 1983, 1991; Freksa, 1992). Temporal logics often stipulate relations between intervals of time. The logics were designed to describe durative events as they occur in the world – they were not developed to capture how humans think about time. Hence, many temporal logics posit relations that don't map onto prepositions or connectives in English. For instance, Allen's (1983) system includes the following types of relation that connect event A with event B:

```
AAAA
BBBBBBBB
```
A *starts* B.

```
    AAAA
BBBBBBBB
```
A *finishes* B.

```
AAAABBBB
```
A *meets* B.

The repetitions of the letters are used to depict how one event endures across multiple points in time. The descriptions of the relations in natural language can be quite complex, e.g., you might describe the *starts* relation as: "Event A and event B began simultaneously, but event A ended before event B did." Hence, while the relation is primitive in Allen's calculus, it depends on the composition of several different concepts in natural language: beginnings, endings, and the preposition "before." Despite the disparity between language and logic (see Knauff, 1999), researchers have built a wide variety of tools in artificial intelligence designed to explain what kinds of inferences can be drawn from the way relations between intervals interact (for reviews, see Fischer, Gabbay, & Vila, 2005; Goranko, Montanari, & Sciavicco, 2004).

In contrast to the computational analyses of temporal reasoning, few studies have examined how people reason about durative relations such as "while" and "during." Many studies have examined temporal relations such as "before" and "after" (Clark, 1971; Münte, Schiltz, & Kutas, 1998; Zhang et al., 2012), but durative temporal relations appear to be more complex – children comprehend and produce "while" after they understand the meanings of "before" and "after" (Keller-Cohen, 1981; Silva, 1991; Winskel, 2003). Previous work by Schaeken and colleagues investigated how adults reason about "while" (Schaeken, Johnson-Laird, & d'Ydewalle, 1996) using premises of the form *X happened while Y happened.* However, reasoners could draw inferences

from such relations without considering the durative nature of "while", i.e., the problems in Schaeken et al.'s (1996) studies implied that the two events both started and ended at the same time. Nevertheless, their work revealed two central patterns of temporal reasoning: first, reasoners appear to simulate a mental timeline of events when they reason about time (Bonato, Zorzi, & Umiltà, 2012; Casasanto & Boroditzky, 2008). Second, some temporal reasoning problems are easy, and some are difficult: people are more prone to error and they take longer to complete certain temporal reasoning problems (Baguley & Payne, 2000; Schaeken & Johnson-Laird, 2000; Vandierendonck & De Vooght, 1997).

Though no studies have examined how people reason about durations, many have focused on people's ability to estimate the durations of experienced or anticipated events (Zakay & Block, 1997). In typical tasks, people make estimations in minutes and hours or by using more qualitative boundaries. The research has shown that people overestimate short time periods and underestimate longer ones (Lejeune & Wearden, 2009), a robust pattern known as Vierordt's law. Gennari and Wang (2019) showed that these estimation biases are correlated with the relative amount of represented information per timepoint. People "compress" representations to avoid maintaining a representation of all timepoints over which an event transpires (Faber & Gennari, 2015, p. 157). The lesson for researchers interested in temporal reasoning is that some event representations can be compressed into a single timepoint, and reasoners can construe them as punctate events. Other event representations may resist such compression by requiring reasoners to maintain information about durations, i.e., information that spans two or more timepoints. Of course, even punctate events have some duration, but their duration is irrelevant to how people make inferences from them.

One recent account by Khemlani, Harrison, and Trafton (2015a) sought to explain how reasoners construct a mental timeline to represent durative relations such as "while" and "during" by specifying how time representations can be compressed. The account builds on previous theories of temporal reasoning that assume people build mental simulations that consist of discrete tokens to reason about time (Schaeken & Johnson-Laird, 2000; Schaeken et al., 1996). But Khemlani et al.'s account extends beyond previous research to make predictions about how people carry out different temporal reasoning tasks, such as reasoning about what is necessary, reasoning about what is possible, and assessing the consistency of a set of assertions (Khemlani, Lotstein, Trafton, & Johnson-Laird, 2015b).

In this paper, we spell out the central principles of Khemlani et al.'s (2015a) account of durative reasoning and use it to derive predictions about whether certain reasoning problems should be easy or difficult. We describe a preregistered experiment that tested these predictions. We conclude by describing limitations of the study and why durative inferences pose unique challenges for investigators.

Mental models of durative relations

Khemlani et al.'s (2015a) account of durative reasoning is based on the idea that humans build discrete mental simulations of possibilities – mental models – when they reason (Johnson-Laird, 2006; Johnson-Laird, Girotto, & Legrenzi, 2004). The model theory applies to relational reasoning across several different domains (Goodwin & Johnson-Laird, 2005), including reasoning about space (Ragni & Knauff, 2013; Jahn, Knauff, & Johnson-Laird, 2007), time (Schaeken et al., 1996; Schaeken & Johnson-Laird, 2000), consistency (Jahn, Johnson-Laird, & Knauff, 2004; Johnson-Laird, Girotto, & Legrenzi, 2004), and kinematics (Khemlani, Mackiewicz, Bucciarelli, & Johnson-Laird, 2013). The theory rests on three fundamental assumptions:

- **Models are iconic.** Mental models are discrete, iconic representations of possibilities. Iconicity constrains models so that their structure reflects the structure of what they represent (see Peirce, 1931-1958, Vol. 4). In the case of two or more events, models should be structured to reflect the events' chronology, i.e., the way in which those events unfolded. Since models are discrete, they cannot directly represent how long one event took relative to another. The restriction allows reasoners to efficiently compress temporal models to uniformly represent events that endure across vastly different timescales, such as seconds or decades.
- **Intuition vs. deliberation.** Reasoners rely on two primary processes of inference: an intuitive construction process and a deliberative revision process. The intuitive construction process rapidly builds and scans an initial, preferred mental model (Jahn et al., 2007). The process is subject to various heuristics and biases, and so reasoners who engage just the initial process are prone to make systematic errors (Khemlani & Johnson-Laird, 2017). A slower deliberative process can revise the initial models to search for alternative models and counterexamples to validate and correct any conclusions inferred by the intuitive process.
- **More models, more difficulty.** A final assumption of the theory is that each model that a reasoner builds demands cognitive resources to maintain. Hence, reasoners tend to rely on their preferred models most of the time. If a reasoning problem can be solved successfully from the preferred model, it should be easy: reasoners should be faster and their responses should be more accurate. If, however, a problem demands that reasoners engage in deliberation, they should be slower and less accurate.

We illustrate how the three principles apply to temporal reasoning by contrasting how the model theory treats punctate and durative events. Consider the premises in (3):

3. The meeting happened before the sale.
   The sale happened after the conference.
   The meeting happened before the conference.

The durations of the events in (3) are irrelevant, and so the premises can be represented as punctate events. The mental model representing the premises in (3) can be depicted in the following diagram:

meeting conference sale

The diagram shows an arrangement of events in which time moves from left to right. Only one such arrangement is possible for (3). The model is parsimonious; it can be used to infer many different relations that are not made explicit in the premises:

4a. The conference happened after the meeting.
b. The sale happened after the meeting.
c. The conference happened before the sale.

In contrast, the premises in (5) concern a durative relation:

5. The meeting happened during the sale.
The meeting happened before the conference.

The description is consistent with the following model:

$sale_{START}$ $sale_{END}$
meeting conference

The model represents the durative aspect of the sale as two separate tokens (following Khemlani et al., 2015a): one token marks the sale's beginning and the other marks its end. And the premises in (5) are consistent with at least one other model:

$sale_{START}$ $sale_{END}$
meeting conference

Hence, the premises in (3) are consistent with just one model, while the premises in (5) are consistent with multiple models.

In general, the model theory predicts that people should be less accurate when reasoning about descriptions consistent with multiple models than about those consistent with one model. No other theory of reasoning makes an analogous claim (Khemlani, 2018; Knauff, 1999, p. 286 et seq.). We next describe an experiment that tested and corroborated the prediction.

Experiment

To test whether participants make more errors when reasoning about problems that elicit multiple models, our experiment presented them with one- and multiple-model descriptions of events that consisted of premises that described temporal relations. Their task was to evaluate the consistency of the premises by assessing whether all of them can be true at the same time. Previous studies used similar problems, but they examined how participants deductively inferred relations between two specified events (Schaeken et al., 1996). In daily life, reasoners are seldom provided such constraints, and so our experiment used a task that does not provide participants with any restriction on which premises to consider. The approach also has the advantage of using the same question across all problems, and so it uses a uniform task to test participants' durative deductions.

To balance out participants' responses, half the problems were consistent and half were inconsistent. The theory predicts that people should be more accurate in assessing the consistency of one-model problems than multiple-model problems.

Method

Participants. 50 participants completed the experiment for monetary compensation ($2 and a 10% chance of a $10 bonus) through Amazon Mechanical Turk. All of the participants were native English speakers, and all but 6 had taken one or fewer courses in introductory logic. 5 participants were excluded from the analysis, either because of excessive and inappropriate keypresses, or else because the participant produced irrelevant debriefing responses. The analyses reported below are based on the remaining 45 participants (21 female, mean age = 35.0).

Preregistration and data-availability. The predicted effects were pre-registered through the Open Science Framework platform (https://osf.io/q45mw). The same link makes the data from the study available.

Task and design. Participants carried out 16 different problems. Each problem comprised 3 premises that describe how 3 different events relate to one another. They were asked to judge whether the 3 premises could all be true at the same time. Half the problems concerned descriptions that were designed to yield one-model after the first 2 premises and the other half yielded multiple models after the first 2 premises. And half the problems used a 3rd premise that was consistent with the previous premises, while the rest used a 3rd premise that was inconsistent with the previous premises.

The first premise of each problem was of the form: *X happened during Y*. Hence, the following is an example of a problem designed to yield one model:

6a. X happened during Y. Y_{START} X Y_{END}
b. Y happened before Z. Y_{START} X Y_{END} Z
c. X happened before Z. **Y_{START} X Y_{END} Z**

A compressed model of events is provided next to each premise to show how Khemlani et al.'s (2015a) system would update the represention after interpreting new information. The bolded text shows how the final model would look. The problem presents a consistent description of events, since all three premises can be true at the same time.

In contrast, the set of premises in (7):

7a. X happened during Y. Y_{START} X Y_{END}
b. Z happened before X. Z Y_{START} X Y_{END} (i)
Y_{START} Z X Y_{END} (ii)
c. Y happened during Z. NO MODEL POSSIBLE

corresponds to a multiple-model problem, because the 2nd premise is consistent with at least two different situations: one in which Z happened before Y started (i), and another in which Z happened before X and they both happened during Y (ii). But neither of those possibilities are consistent with the third premise, therefore (7) is an inconsistent multiple-model problem.

The sixteen different problems used in the study are provided in the Appendix. The experiment implemented a 2 (problem type: one- vs. multiple-model) x 2 (consistent vs. inconsistent) fully repeated-measures design.

Materials. The temporal terms in each problem were replaced by descriptions of everyday events, e.g., X was replaced with "the meeting" and Y was replaced with "the snowstorm". The materials were drawn from 16 sets of 3 events. Each set was designed to describe events that endure at comparable timescales, so that any event in the set could take place during any other event, e.g.,

The meeting happened during the snowstorm.
The snowstorm happened during the ceremony.
The meeting happened during the ceremony.
The snowstorm happened during the meeting.

and so on. Events that elicit strong punctative interpretations, such as "the sneeze," were not used in the study, as they would yield peculiar and unbelievable descriptions, e.g., "The meeting happened during the sneeze." Likewise, events were chosen so that they did not bear causal relations to one another.

Each of the 16 materials was rotated over the designs for each participant. Therefore, across the experiment as a whole, each of the 16 material sets was applied to each of the 16 problems approximately the same number of times. For any given participant, once the materials were assigned to the problems, the order in which the problems appeared was randomized. The counterbalancing scheme eliminated the possibilities that order effects and carry-over effects could account for participants' responses.

Procedure. Participants interacted with the experiment by registering responses through keyboard presses. For each problem, the participants were asked to consider an initial premise, and then pressed the spacebar to reveal each of the remaining premises on the screen. Previously revealed premises remained on the screen whenever the experiment displayed the next premise. The sequential display sought to encourage participants to read the sentences in the order displayed. Once a participant revealed all three premises, a prompt would appear that said: "Can all three of these sentences be true at the same time?" The 'f' and 'j' keys were used to indicate "yes" and "no" responses, respectively. Before taking part in the experiment proper, they completed an example problem and were shown a schematic of how their fingers should be placed on the keyboard. After completing all 16 problems, the participants were asked four open response debriefing questions, which probed their intuitive definitions of "before" and "during" as well as their reasoning strategies.

Results and discussion

Figure 1 plots the proportion of participants' correct assessments of consistency as a function of whether the premises yielded one model or multiple models, and as a function of whether the problem they carried out was consistent or inconsistent. Participants were more accurate for one-model problems than multiple-model problems (78% vs. 69%; Wilcoxon test, $z = 3.02$, $p = .003$, Cliff's $\delta = .43$). The result corroborated the model theory's central prediction that reasoners should find it easier to reason about one-model problems than multiple-model problems. The difference between participants' accuracies did not reliably differ depending on whether the model was consistent or inconsistent (72% vs. 75%; Wilcoxon test, $z = 1.12$, $p = .27$, Cliff's $\delta = .17$). However, the interaction between the problem type (one- vs. multiple-model) and the consistency of the premises was reliable (Wilcoxon test, $z = 4.03$, $p < .0001$, Cliff's $\delta = .42$). The interaction is evident in Figure 1, which shows that consistent problems had a higher accuracy rate when the premises yielded one-model rather than multiple-models. There was little difference by model quantity for inconsistent problems.

To test whether the type of problem is robust to participant and item random effects, we fit a generalized logistic mixed model (GLMM) regression to the data. The fixed effects were the problem type (one- or multiple-model), the consistency of the problem, and their interaction. The random effects components included intercepts and random slopes for all 3 fixed effects by participant. Intercepts also controlled for the items (paired syntax and material sets) and for the pattern of temporal relations in the three premises, i.e., "during/during/during", "during/before/during", etc. The

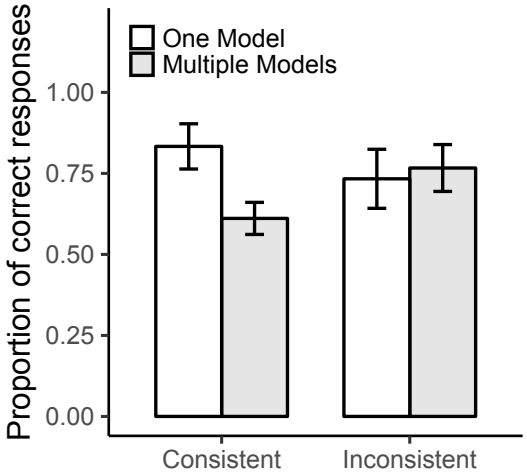

Figure 1. The proportion of correct responses in the experiment as a function of the type of problem (one- or multiple-model) and as a function of whether the premises was consistent or inconsistent. Error bars indicate 95% confidence intervals.

temporal relation pattern was included because a handful of participants reported making judgments based on the pattern alone, and so we treated it as a relevant random effect factor beyond the individual items. The analysis revealed a reliable difference between one- and multiple-model problems when both participants and items were controlled for, $\beta = 2.02$, $z = 3.41$, $p = .0006$, and a reliable interaction between consistency and the problem type ($\beta = 2.35$, $z = 3.21$, $p = .0013$). The GLMM therefore confirmed the nonparametric analyses. However, it further revealed a reliable effect of consistency: participants were more accurate on inconsistent problems than consistent problems ($\beta = 1.82$, $z = 4.34$, $p < .0001$); the model theory did not predict whether there would be an effect of consistency. The results of the regression analysis accordingly support the predictions of the model theory, though the analysis suggests that future studies should examine a broader set of problems to generalize beyond the four in each condition of the present experiment.

General discussion

How do people mentally represent and reason about durative temporal relations, i.e., relations such as "while" and "during"? Such relations describe events that persist across multiple points in time, and many logical frameworks exist that describe ideal temporal reasoning patterns (Fischer et al., 2005; Goranko et al., 2004). But those frameworks do not explain how people represent durations, and so they cannot characterize the mental processes or the strategies people use when reasoning about time. A recent treatment of temporal reasoning explains how people mentally represent durations when they reason. It is based on the idea that people construct mental models, i.e., iconic mental simulations, to draw conclusions from premises or observations (Johnson-Laird, 2006). Models implement a mental timeline, which people use to reason about events (Schaeken et al., 1996). To mentally simulate durative relations, reasoners do not represent all of the time points across which an event might endure. Instead, they construct discrete tokens that stand in place of the beginnings and endings of durative events (Khemlani et al., 2015a).

One way to diagnose the model theory is to investigate how people assess the consistency of durative premises. In principle, the theory should make predictions about people's assessments of consistency. It posits that if they can construct a coherent model of the premises, then those premises are consistent – they can all be true at the same time. If they fail to build a model of the premises, however, then they should consider the premises to be inconsistent (Johnson-Laird et al., 2004). The theory has explained how people reason about the consistency of spatial relations (Jahn et al., 2004), and, given the strong relationship between temporal and spatial metaphors (Casasanto & Boroditsky, 2008; Gentner, 2001), it should also explain how people reason about the consistency of durative relations.

We report an experiment that suggests it does. The experiment presented participants with a description of events as in (8):

8a. The burglar alarm happened during the fire.
b. The siren happened before the burglar alarm.
c. The fire happened during the siren.

The description is inconsistent, and participants capably judged such descriptions to be inconsistent. In contrast, they had difficulty with descriptions of the following form:

9a. The burglar alarm happened during the fire.
b. The siren happened before the burglar alarm.
c. The siren happened during the fire.

Many reasoners incorrectly evaluated the three assertions as inconsistent. What explains the disparity? The model theory suggests that people rapidly constructed a simulation of the first two statements to yield a model akin to the following:

$$\begin{array}{ccc} & \text{fire}_{\text{START}} & \text{fire}_{\text{END}} \\ \text{siren} & \text{burglar alarm} & \end{array}$$

As the theory posits, models cost cognitive resources to maintain, and reasoners are reticent to alter the initial models of the premises they construct. The premise (9c) does not hold in the initial model above, and so reasoners who base their judgments of consistency on it should consider (9) inconsistent. Only reasoners who construct an alternative model of the premises should get the correct answer, as in this model:

$$\begin{array}{ccc} \text{fire}_{\text{START}} & & \text{fire}_{\text{END}} \\ & \text{siren} \quad \text{burglar alarm} & \end{array}$$

In general, the model theory uniquely predicts that participants should find one-model problems easier to reason about than multiple-model problems, and the experiment corroborated the prediction.

One concern of the experiment is that the definition of "during" as an enclosure relation may have been overly restrictive. Consider example (7) above. If people take "during" to refer any two overlapping events instead of an enclosure relation, then the three premises could yield the following model:

$$\begin{array}{ccccc} Z_{\text{START}} & & Z_{\text{END}} & & \\ & Y_{\text{START}} & & X & Y_{\text{END}} \end{array}$$

Yet, a more permissive notion of "during" does not impact the central outcome of the experiment: if a problem is consistent under the restrictive construal of "during", then it is consistent under the permissive construal as well. Nevertheless, reasoners were least accurate on consistent multiple-model problems – a result that corroborates the theory on any construal of "during."

There are at least three limitations of the experiment we report. First, a small set of participants self-reported that they adopted reasoning strategies based on rapidly assessing the relations in the premises. It is not clear to what extent

participants' strategies attenuated or enhanced the difference in performance on one-model and multiple-model problems, but reasoners can spontaneously discover strategies when reasoning about punctate events (Schaeken & Johnson-Laird, 2000), and so future studies should investigate what kinds of strategies participants develop, and how those strategies promote or inhibit the construction of models. Second, the current design did not explore the nature of participants' errors. It could be that participants attempted to consider alternative models of the premises and failed; or it could be that participants chose not to consider alternative models in the first place. Future studies should explore why multiple-model problems yield systematic errors. Finally, only a limited number of problems could be designed for the study given that they described three relations among three events: hence, the study examined only the small number of configurations possible for three events. Future studies should explore an expanded set of problems. Indeed, the language used to describe durational events goes beyond the preposition "during". The connective "while" has a similar meaning, and both words are in the top 200 most frequent words in American English (Davies, 2008). Other words, e.g., "when", can sometimes be used to situate durative events, and the various ways people describe and discuss events, durative and punctate, can provide insight into how people represent and reason about time.

Temporal reasoning is an essential process that underlies how humans conceptualize time (Hoerl & McCormack, 2019; Kelly, Prabhakar, & Khemlani, 2019). Reasoners routinely make inferences about durations in order to carry out time-dependent tasks, such as picking a friend up at the airport. The model theory provides an explanation of the mental representations people build and processes people use when they think and reason about temporal sequences.

Thinking through the implications of neural reuse for the additive factors method

Abstract

One method for uncovering the subprocesses of mental processes is the "Additive Factors Method" (AFM). The AFM uses reaction time data from factorial experiments to infer the presence of separate processing stages. This paper investigates the conceptual status of the AFM. It argues that one of the AFM's underlying assumptions is problematic in light of recent developments in cognitive neuroscience. Discussion begins by laying out the basic logic of the AFM, followed by an analysis of the challenge presented by neural reuse. Following this, implications are analysed and avenues of response considered. Keywords: additive factors method; seriality assumption; anatomical modularity; neural reuse.

Keywords: additive factors method, neural reuse, stage models, seriality assumption

Introduction

A good place to start when trying to understand a complex process or system is to determine its constitutive parts or modules. For example, to figure out how people succeed in visual search during reading, the time between stimulus and response can be broken down into an encoding, feature extraction and identification stage (Resink, 2005; Tovey & Herdman, 2014). The decomposition of the time between the stimulus and response enables discovery of the underlying subprocesses. The stimulus–response time intervals reflect the series of processing stages underlying complex behaviours.

One method for uncovering the subprocesses of mental processes is the "Additive Factors Method" (henceforth AFM) (Townsend & Nozawa 1995; 2001, 2011, 2013; Coltheart, 2011). The AFM uses reaction time data from factorial experiments to infer the presence of separate modules or processing stages. A mental process can be broken down into subprocesses when those subprocesses are 'separately modifiable' – that is, when each of the proposed modules can be modified without effect to the other, and vice versa. For example, to show that two stages A and B are separately modifiable it must be shown that two factors, F and G, affect only either A or B, but not both. In other words, F can affect A and G can affect B, but not the reverse. The result of an AFM analysis is what are called 'stage models'.

This paper investigates the conceptual status of the AFM. It argues that one of the AFM's main assumptions is problematic in light of recent developments in cognitive neuroscience. In particular, the argument is that theories of neural reuse present a challenge to the conceptual link between AFM's 'seriality assumption' and the single processor cases it relies on. Discussion begins by laying out the basic logic of AFM, followed by an analysis of the challenge presented by neural reuse theories. Implications are then analysed and avenues of response considered.

The Additive Factors Method

Factorial experiments are studies in which the effects of two or more variables are investigated by manipulating the presence of each factor across various conditions. In its simplest version (the complete factorial experiment), two factors are studied by comparing the difference each factor has on some measure of performance, such as reaction time. For example, to evaluate the effect of familiarity on pattern recognition, orientation (the rotation of a pattern) can be compared to familiarity (whether subjects are better or worse at recognising the pattern) (Tovey & Herdman, 2014). If orientation has an effect on familiarity, then conditions in which stimuli are presented with different orientations, e.g. 0^0 vs. 90^0, will result in delays in the time required to recognize a pattern.

Factorial experiments form the raw data of the AFM. Factorial data indicates whether two or more factors have either an additive or interaction effect on mean reaction time. Leaving interaction effects to one side for the moment, an additive effect involves two or more factors selectively influencing individual stages of a process. So, for example, if stage A normally takes 10ms and stage B normally takes 15ms and F influences the length of A by 5ms and G influences the length of B by 7ms, then the total duration of time to complete the process that includes stages A and B will be the result of the presence of F and G. The total duration of a process is simply the added the sum of each stage as influenced by each factor.

Factorial experiments supply modifiability information by revealing the selective influence of some factor(s) (Miller et al., 1995). When two or more factors affect the total duration of a process (measured using reaction time), the process can be separated into different modules or processing stages. When patterns of factor effects are observed, a set of hypothesized stages and factor relations that underlie the pattern are proposed. The effects inferred from the factorial experiments are what support inferences about the processing stages, justifying the decomposition of a process or stimulus-response interval into distinct subprocesses.

The Seriality Assumption

One key assumption of the AFM is what Sternberg (2001, 2013) calls the 'seriality' assumption. The seriality assumption says that the AFM can only be applied to processes that are sequentially arranged. For a process to be sequentially arranged, one of two situations must hold, either:

(i) the process must be data-dependent or (ii) a single processor must be responsible for carrying out the process.

In the first set of cases, seriality depends on information being passed along from a previous stage of the process. To use a simple example, heading home from grocery shopping (stage 2) requires first having collected and bagged the groceries at the store (stage 1). In the second set of cases, seriality depends on a process being the result of a single processor. So, for example, if one bakes with two hands multiple steps can be accomplished in parallel, e.g., cracking and whisking eggs; while if one bakes with only one hand, then the process is limited to being complete one task at a time, e.g., cracking each egg individually and then whisking them all together.

How a single process relates to a given processor or set of processors can also vary considerably from case to case. For example, for even a three stage process, there are several types of relations that might hold: (i) a separate processor might carry out each process, (ii) the same processor might carry out every process, or (iii) there be might some combination of the two, where one processor carries out two processes and another processor carries out one process. Figure 1 provides an illustration.

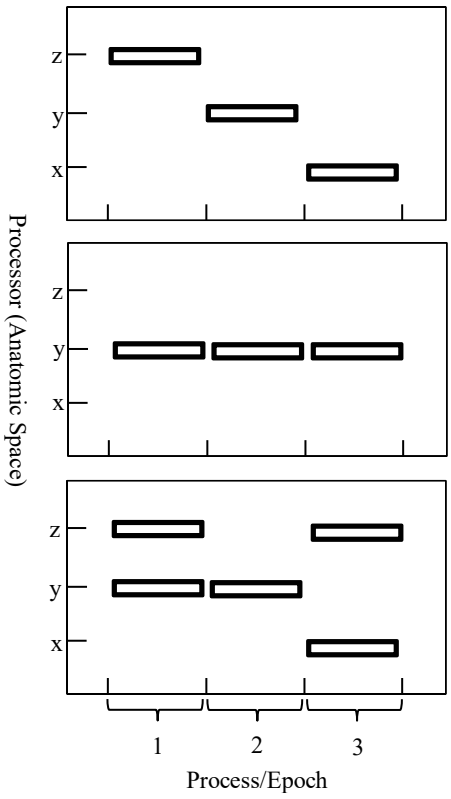

Figure 1. Possible relations between processors and processes for a three stage process.

What is interesting is that the seriality assumption maintains that in at least a subset of cases specialised structures are responsible for carrying out mental processes. That it is possible to find one-to-one mappings between process modules or stages and processing devices. Sternberg (2001), for instance, notes: "Perhaps more surprising is the finding of operations that are partially or wholly sequential when there is no data-dependence…The basis for the sequential structure in such cases may be that the system that carries out the set of operations, possibly the same single processor, is inherently limited in capacity" (original italics, p.735). Not only can processes be sequentially arrange when they involve data dependence but they can also be sequentially arranged when the realising processor has a limited capacity.

However, notice that this is a claim about neural organisation. The single processor view says that neural organisation will take a 'modular' form in certain cases. That in at least some cases mental processes are implemented or realised by dedicated pieces of neural hardware. The claim is that what makes it possible for a given process to be serially arranged is the physical constraints of the realising processor. The view is one of a neural organisation wherein a particular sequential process is carried out by a chainlike structure of connected processing units. To support this claim, for example, Sternberg (2001) appeals to cases of highly specialised anatomical structures, such as the visual cortex of Macaque monkeys. Call this 'anatomical modularity'.

Of course, anatomical modularity is usually considered a 'functional' theory, whereas processing stages are periods of time. Sternberg (2001), for instance, notes: "A stage theory says nothing about the pieces of physical anatomical machinery that carry out the operations in the two stages…information 'transmitted from one stage to the next' does not necessarily go from one place to another; the phrase is unfortunate because it suggests otherwise (p.732). Processor devices that carry out process stages might have functional properties, but the processing stages themselves, at least as informed by the AFM, are neutral with respect to such questions (Kersten, 2016). Nonetheless, there are reasons to see the two views as sides of the same coin. This is because while the processing stages themselves may not have functional properties, they are realised by processors that do, i.e. neurological structures. The point here is simply that the seriality assumption makes specific a claim about the relation between such subprocesses and processors. It does not make a claim about what features those subprocesses have.

It will be worth dwelling on this point as it crucial for the argument to follow. For one might wonder whether 'anatomical modularity' is not better understood as a claim about 'functional' organisation or architecture. If so, then the AFM would be involved in a form of functional decomposition, as it would be set to uncover functional architecture rather than neural organisation.

Crucially, this is not the case. Stage models are set to uncover the subprocesses of mental processes, such as those involved in visual search, understood as epochs or periods of

time. Despite some shared inferential machinery, such as factorial experiments, the target and output of the AFM is importantly different from those methods aimed at providing functional decomposition (see Carruthers, 2006).

A brief case study will help flesh out the point further. Consider Tovey and Herdman's (2014) investigation of visual search during reading. Using the effects of familiarity on change perception via a 2 × 5 × 2 factorial design, Tovey and Herdman examined the effects of orientation (upright vs. inverted, set size (4, 7, 10, 13, 16) and change size (Small vs. Large) across four different experiments. In line with Rensink (2005), they suggested that change perception was divided into three process modules: a pre-processing stage, a feature extraction stage, and an identification stage. They proposed that an interaction between change size and orientation and change size and stimulus quality indicated that change size exerted an effect not only on the feature extraction stage but also on the identification stage of change perception. Figure 2 provides an illustration of the model.

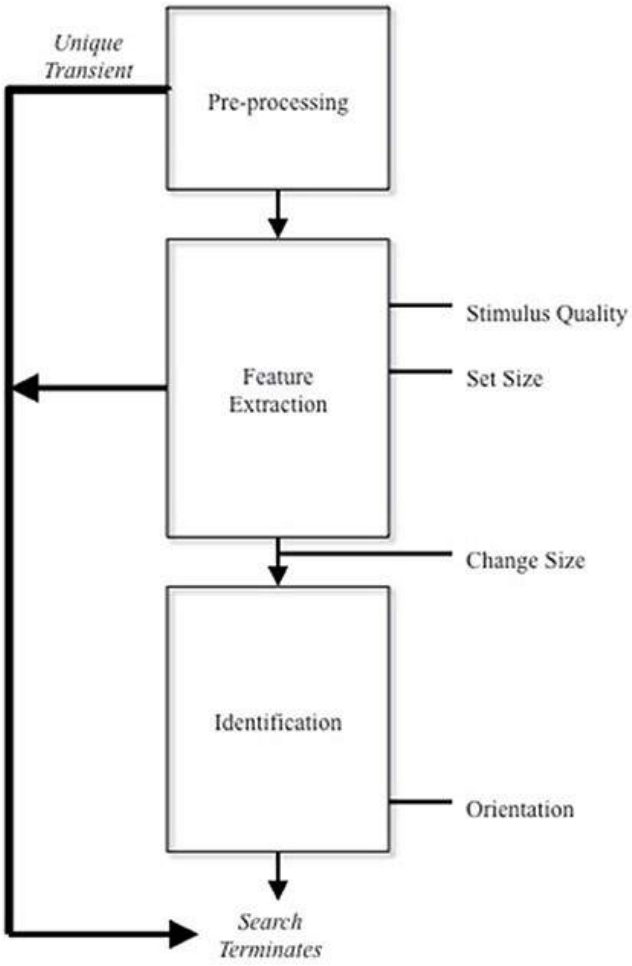

Figure 1. Tovey and Herdman's stage model. Visual search is divided into three stages: a pre-processing stage, a feature extraction stage, and an identification stage.

To explain the effects of change size, Tovey and Herdman proposed a 'gating' mechanism. The gating mechanism redirects information to different stages of the process via detecting changes in size, either by passing the information on to the feature-extraction stage for further processing (assuming the changes are large) or by retaining and verifying the information at the identification stage (assuming the changes are small). The problem is that introduction of a gating mechanism complicates interpretation of Tovey and Herdman's model as a stage model. This is because it introduces functional properties into the model.

Notice that Tovey and Herdman place change size outside of the processing stages, after feature extraction but before identification. This changes the structure of the diagram from a flowchart to a circuit diagram. The arrows no longer represent a succession in time of a series of processes but instead denote the flow of information. The gating mechanism is conceived of as the change size, representing the redirection of information from one stage to another, not only how change size influences time duration.

However, if processing stages are events in time, they need to be strung together end to end, as in a flowchart. If the model represented the effect of change size, it would have to effect the period of time as represented by the box, not the passage or succession of time as represented by the arrows. When represented as a circuit diagram – that is, as describing how processing devices are connected – stage models misleading suggest that the process stages are also processing devices; an interpretation, which, as mentioned, fails to acknowledge the variety of possible relationships that might obtain between process stages and processing devices. Sternberg (2001) frames the point nicely: "It is remarkably easy to slip into a mode of thinking in which stages are processors rather than processes, actors rather than actions; confusion about what a stage might be finds its way into much writing on the subject, even by experts" (p.828). So while Tovey and Herdman's results may be correct, their inclusion of a functional property complicates interpretation of the model (Kersten, 2016).

The ambiguity introduced by the gating mechanism is suggestive of the nature of stage models. For if the AFM is to uncover the subprocesses (understood as epochs of time) of mental processes, then it cannot do so by revealing the functional properties of cognitive systems. If it did, this would blur the distinction between the AFM and other experimental methods.

To illustrate, consider the method of double-dissociation. If two factors F and G are damage to different parts of the brain, and one can show using some measure, such as an EEG, that factor F influences performance on some task A but not task B, while G influences B but not A, then one can infer that the F and G perform different functions. The separate modifiability of tasks A and B by factors F and G on tasks A and B indicate that F and G are have different functions.

Contrast this with the AFM. Whereas double-dissociation uses a direct measure for separate modifiability (the differential activity of different brain regions), the AFM only indirectly tests for separate modifiability via mean-reaction times. It is interested in how a given process can be separated or 'cut' via finding the selective influence of different factors. What this means is that the focus in stage models is on temporal rather than functional properties. Thus, one thing that cannot be meant by the seriality assumption is that what constrains processing stages is functional modularity.

The general point is that anatomical modularity forms more than just a peripheral assumption within the AFM. Indeed, it is what helps, in part, justify inferring the presence of serial processes. If two processes are not data-dependent and yet perform the same function, then it is safe to assume that they are realised by the same processor. That anatomical modularity should underlie part of the seriality assumption is not an insignificant result. The problem is that anatomical modularity is increasingly being called into question.

Neural Reuse and the AFM

Many of the cognitive functions once thought to have dedicated, isolated neural localisations (e.g., Broca's area) are increasingly shown to engage a diverse range of neural units. In a recent meta-review, for example, Anderson and Pessoa (2011) found that 78 different anatomical regions were active in 95 tasks across 9 cognitive domains. Accounts of 'neural reuse' aim to describe how different brain regions often exploit, recycle, or redeploy neural circuitry for various cognitive ends (Hurley 2005; Dehaene & Cohen, 2007; Dehaene, 2009; Anderson 2007, 2011, 2014).

A large swath of evidence now favours neural reuse as a thesis of neural organisation. To spare a long digression, consider a small sampling of some characteristic studies. Glenberg and Kaschak (2002), for instance, show that when asked to make sense judgments about different sentences participants take longer on sentences that run counter to the required action than those that do not. Richardson et al. (2003) show that certain sets of verbs, such as 'hope' and 'respect', activate meaning-specific spatial schemas. Pulvermuller (2005) demonstrates that listening to action words, such as 'lick' or 'pick', activate regions of the primary motor cortex, areas often associated with the actions themselves. Casasanto and Boroditsky (2008) show that people are often unable to ignore irrelevant spatial information when making judgments about duration, but not the converse. That mental representations of time are intimately tied up with perceptions of space. Finally, Casasanto and Dijkstra (2010) demonstrate that there is a bidirectional influence between motor control and autobiographical memory.

Neural reuse theories raise a number of interesting questions about cognition, such as whether a new 'cognitive ontology' needs to be developed (Anderson, 2014). However, for present purposes, the point to note is that neural reuse also raises questions for the second set of cases appealed to by the seriality assumption: namely, that some processes are sequentially arranged in virtue of being realised by single processors. The issue is that if neural reuse is true, then it is unlikely that there will be any single process that has a unique anatomical structure or processor supporting it. Finding a one-to-one mappings between processor and process will prove particularly troublesome if neural regions support multiple operations.

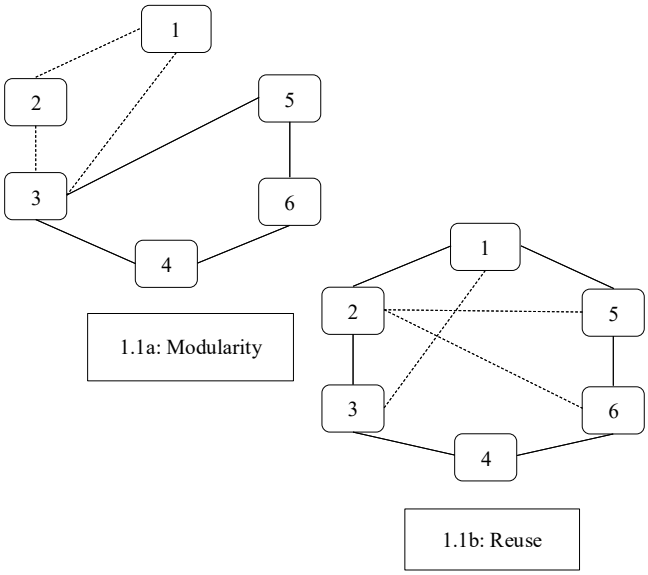

Figure 3.Two possibilities of neural organisation for two cognitive operations.

There seem to be two options. 1.1a represents a modular design, where each cognitive operation has specific dedicated neural circuitry. This is what is required by the second half of the seriality assumption. 1.1b, on the other hand, represents a neural reuse design, where each cognitive process is shared among a number of neural circuits. The AFM requires that 1.1a hold for at least a subset of cases. However, if, as noted, neural reuse is true, then whatever else might be right about the AFM, the single processor cases might not exist. Neural reuse seems to challenge the link between the seriality assumption and one of its inferential bases.

It is important to be clear about this point. For it might be still maintained that the AFM uncovers something about functional organisation. That it would not matter if the same neural hardware were involved in multiple operations because once those operations were fixed the AFM would be set to uncover functional organisation.

But again, once it is appreciated that the target and output of the AFM is not functional models but models of temporal stages it follows that the underlying assumption about processors has to be about neural organisation. For although it is right to point out that neural architecture can stand in complex relations to functional architecture, such as distributed neural regions supporting a functionally modular architecture, such considerations cannot do much work here.

This is because they threaten to undermine the AFM's conceptual standing. If AFM did reveal insights into functional architecture, then its distinctiveness would be undercut, for it would no longer reveal insights into the organisation of cognitive subprocesses understood as temporal sequences.

Another tack would be try to accept the incompatibility of anatomical modularity and neural reuse but nonetheless reject neural reuse on the basis of the wider importance of the AFM. One might argue, in other words, something along the following lines: (1) AFM is essential to psychology; (2) AFM is incompatible with neural reuse; therefore, (3) neural reuse is false.

But there are at least two problems with this type of argument. One is that it assumes that cognitive psychology can operate independently of cognitive neuroscience. That the conceptual autonomy of psychology ensures the survival of the AFM. However, the increasing integration of neurological data into cognitive theorising and modelling makes it unlikely that cognitive psychology will continue to function independently of the findings of cognitive neuroscience in this way (Forstmann et al. 2011; de Hollander et al., 2016). The other is that the argument problematically assumes that the choice facing the proponent of AFM is either/or: that either neural reuse has to be rejected or the AFM does. But no such dichotomy is required. As is argued later, it is possible to endorse a version of the AFM that drops anatomical modularity but which still nonetheless operates in other sets of cases.

Three Options for the AFM

It seems fair to say, then, that neural reuse casts some doubt on the inferential bases of one of the key assumption of the AFM. Given this, three options seem available to the proponent of the AFM. One is to drop the seriality assumption altogether. One might maintain that the AFM can continue on without the seriality assumption. This option seems undesirable insofar as the seriality assumption is part and parcel of the AFM logic. Separate modifiability only makes sense when the processes being investigated are sequentially arranged. Dropping seriality would be tantamount to dropping the method altogether; and scuttling the method altogether seems undesirable given the good deal of fruitful research that has been carried out using the AFM (e.g., Resink, 2005; Tovey & Herdman, 2014).

A second option would be to reform the seriality assumption in light of neural reuse. One might claim, for instance, that serial processes can be the product of distributed neural processors. The problem with this option is that it undermines the inferential link between processor and processing stages. Anatomical modularity forms a key assumption within the AFM. Without it, the AFM would lose its ability to infer a serial ordering. Return, for example, to the baking case, it is only because there is one single processor that the stages are arranged serially. The addition of a second hand opens up the task to being achieved in multiple stages, i.e. in parallel. If multiple processors are admitted, then inferences to processing stages are underdetermined.

But, one might object, it could be that a bunch of miniature 'hands' accomplish the baking task. In other words, that a distributed network of miniature processors performs the task serially, whose actual decomposition is discoverable (at least in part) by the AFM. The problem with this rejoinder is that again misses the key point of stage models, and to lesser extent the baking example. For while it is true that adding more processors speeds up the process, it also makes it impossible to interpret the process as serially ordered. For example, switching to using two hands during the baking (i.e. allowing multiple processors) opens the process up to being completed in parallel. There is nothing that forces the process into being completed in successive stages. Thus, in assuming that a process is realised by distributed set of processors one undermines the ability to interpret that process as serial in the first place. The grounds for inferring seriality rests on the process being carried out by a single processor.

Finally, one might jettison the seriality assumption's commitment to the single processor view, i.e. anatomical modularity. This might preserve what is right about the AFM (i.e. inferring seriality on the basis of data-dependence), while dropping the theoretically suspect part (i.e. reliance on single processor cases). The idea would be to restrict the set of cases under which seriality could be legitimately inferred. That is, whereas previously cases of single processors and data-dependence cases could be used, now only data-dependent cases would be allowed to infer seriality.

For example, a study such as Tovey and Herdman's would not be affected according to the third proposal, because visual search during reading is a data-dependent process. The serially ordering is dependent on each of the previous stages being completed before the next one begins; one cannot, for instance, detect the presence of certain letters before those letters have been registered by the visual system. Tovey and Herdman's study does not rely on the single process cases to work, so it can still be used to infer separate modifiability. However, cases where seriality is inferred because of the supposed presence of a single processor, such as Scarbourgh and Landauer's (1981) study on word repetition effects, would have to be dropped according to this proposal. So, although the removal of anatomical modularity might involve the loss of some of the AFM's methodological punch, as not an insubstantial number of cases involve the assumption (Sternberg, 2001, p.831-2), the method itself would still be preserved in an attenuated form.

Given the spread options, the third proposal seems the most preferable going forward. The first and third options suggest either too high a methodological price or an endorsement of a conceptual tension. Only option three seems to allow the AFM to continue on, though in slightly modified form. On the third proposal, serial stage models can be inferred, but only on the basis of data-dependent cases. The single processor cases underlying the seriality assumption need to

be bracketed, at least until such a time that neural reuse can be thoroughly vetted. This might be a welcomed result for some (Stanford & Gurney, 2011; Sternberg, 2013), but maybe not so much for others (Coltheart, 2011).

So, to summarize, though not a devastating blow, neural reuse does represent a serious challenge to some aspects of the AFM. Insofar as neural reuse presents a challenge to anatomical modularity, and anatomical modularity falls out of the seriality assumption, some of the AFM's conceptual foundations need to be reworked. The methodological implications still need to be worked out, but the conceptual moral seems relatively clear: the seriality assumption can no longer rely on single processor cases. Hopefully, then, in having identified the problem and charted some potential responses, the AFM can be put on surer theoretical footing going forward.

Polysemy and Verb Mutability: Differing Processes of Semantic Adjustment for Verbs and Nouns

Daniel King (dking@u.northwestern.edu)
Department of Psychology
Northwestern University

Dedre Gentner (gentner@u.northwestern.edu)
Department of Psychology
Northwestern University

Abstract

Previous research has found that verbs are more likely to adapt their meaning to the semantic context provided by a noun than the reverse (verb mutability). One possible explanation for this effect is that verbs are more polysemous than nouns, allowing for more sense-selection. We investigated this possibility by testing polysemy as a predictor of semantic adjustment. Our results replicated the verb mutability effect. However, we found no evidence that polysemy predicts meaning adjustment in verbs. Instead, polysemy was found to predict meaning adjustment in nouns, while semantic strain was found to predict meaning adjustment in verbs (but not nouns). This suggests that processes of meaning adjustment may be different for nouns vs verbs.

Keywords: polysemy, mutability, computational linguistics, word2vec, semantics

Introduction

A remarkable aspect of language is that it is both stable enough to reliably convey meaning and flexible enough to accommodate unusual or semantically-strained utterances. For example, the sentence "The hostess galloped to the door" is a bit odd, but we can readily understand it as meaning "The hostess moved rapidly and somewhat gracelessly." While overt metaphorical language has been studied extensively, there is much less work on how people resolve semantically-strained utterances of this type, which may be far more prevalent than traditional "X-is-a-Y" metaphors.

Gentner and France (1988) found that, in paraphrases of simple intransitive sentences of the form *The noun verbed*, participants tended to adjust verb meaning to a greater extent than noun meaning – a phenomenon termed the *verb mutability effect*. *Mutability* can be defined as the degree to which a word's semantic interpretation differs across contexts. The verb mutability effect was found to be strongest when the stimulus sentence was semantically strained – that is, when the noun was incompatible with the paired verb's expected argument, resulting in a nonliteral sentence. For example, one participant paraphrased *The lizard worshipped* as *The reptile stared unblinkingly at the sun*, largely preserving the meaning of the noun *lizard* while shifting the meaning of the verb *worshipped* dramatically.

Little research has examined the processes that drive mutability – that is, how semantic structures are altered during these types of adjustments. In an initial investigation, Gentner and France (1988, Experiment 3b) proposed that verbs are adjusted in a graduated manner, by altering the domain-specific aspects of meaning just as far as is necessary to render a meaningful interpretation – a process they called *minimal subtraction*. We refer to accounts like these as *online adjustment* accounts, as they involve the adjustment of meaning *in situ,* constrained by the context provided by the noun.

Another possibility, however, is that mutability is simply a matter of selecting an appropriate alternate meaning from a word's extant senses. There is evidence suggesting that verbs are more polysemous than nouns across all frequency levels (Gentner, 1981). Thus, higher verb mutability may simply be due to there being more available senses to choose from. We refer to this account as the *sense-selection* view.[1]

Indeed, Gentner and France did not control for polysemy in their original study. We evaluated the polysemy of their stimuli by counting the number of synsets (i.e., senses or meanings) for each word in WordNet 2.1 (Miller, 1995).[2] Our analysis found that the verbs from their study were significantly more polysemous than the nouns, $M_V = 4.13$, $SD_V = 2.17$, $M_N = 2.25$, $SD_N = 1.39$, $t(14) = 2.06$, $p = .03$ – leaving open the possibility that the greater verb mutability they observed was due to the relatively higher polysemy of the stimulus verbs.

Thus, a more precise characterization of the processes underlying these types of semantic adjustments is needed – specifically, the extent to which sense-selection and/or online adjustment drive mutability needs to be better understood.

To investigate this question, we tested polysemy as a predictor of mutability. If polysemy is found to predict mutability, it would provide evidence for the sense-selection account of meaning adjustment. If no such relationship is found, this would instead favor the online adjustment view.

[1] Our descriptions of sense-selection and online adjustment are similar (but not identical) to sense-selection and sense-creation as discussed by Gerrig (1989).

[2] We chose WordNet 2.1 over newer versions due to concerns of a proliferation of synsets in later iterations.

In addition, we seek to understand whether the processes employed vary by word class.

This study follows the paradigm established by Gentner and France. Participants were asked to paraphrase intransitive sentences of varying levels of semantic strain. These sentences were generated by combining 6 nouns and 6 verbs for a total of 36 stimulus sentences (see Figure 1).

For verbs, two expected a human argument (*complain, suffer*), two expected a dynamic artifact object artifact (i.e., a man-made object that functions in some way) as an argument (*pause, fail*), and two expected a static inanimate object as an argument (*dry, burn*). For nouns, two were human (*professor, queen*), two were a dynamic artifact object (*motor, bell*), and two were static inanimate objects (*tree, box*). Combinations in which the noun was incompatible with the verb's expected argument resulted in semantically-strained sentences (e.g., *The box suffered*), while those that were compatible resulted in unstrained sentences (e.g., *The professor complained*).

Half the nouns and verbs used were highly polysemous (at least 10 senses) and half were low in polysemy (1-2 senses; see Figure 1). This resulted in both "balanced" combinations, where the noun/verb polysemy matched—both high (N+/V+) or both low (N-/V-)—and "unbalanced" combinations, where the noun/verb polysemy differed greatly (N+/V- or N-/V+). Thus, across the 36 stimulus sentences, every possible combination of high- and low- polysemy nouns and verbs was realized.

Assessing Meaning Adjustment

A thorny issue in this research is how to quantify meaning adjustment. Gentner and France, using human raters, approached this from three different angles. Across these techniques, they obtained converging evidence for the verb mutability effect; however, each method had drawbacks.

In their *divide and rate* method, raters were asked to divide each paraphrase into *the part that came from the noun* (in the stimulus sentence) and *the part that came from the verb*. They then rated the similarity of each part to the original word. This was problematic for several reasons. It was time-consuming and labor-intensive, and judges often had difficulty deciding how to properly divide the sentence, resulting in a high amount of data loss. Worse, in some cases, some words in the paraphrase were clearly affected by both the original verb and noun, making division impossible. For example, consider the following paraphrase of *The motor complained*: *The badly-functioning engine let out a strange noise from its exhaust*. Here, *badly-functioning* modifies the noun in a context-specific manner (i.e., a motor can function badly but a rock cannot), but it also seems to owe its presence in the paraphrase to the original verb *complained*. The same case can be made for the phrase *from its exhaust.*

Therefore, a way to assess semantic change without dividing paraphrases into noun- and verb-originating components is necessary. Gentner and France employed two such methods: a *double paraphrase* and *retrace* task.[3] While both these methods mirrored the results of the divide-and-rate approach in finding verb mutability, they were similarly labor intensive.

In an attempt to address these issues, we used word2vec (Mikolov et al., 2013) to assess meaning adjustment. This allowed us to quantify semantic change by comparing each paraphrase as a whole to the initial noun and initial verb, without having to divide the paraphrases into components. This provided a hands-off approach that the reduced the time and labor costs of using human judges, as well as data-loss due to low inter-rater agreement. In addition, we hoped to obtain a finer-grained quantification of adjustment than was possible with Gentner and France's methods.

Against these advantages, however, we must ask whether vector-space word embedding models (WEMs) like word2vec can adequately capture human similarity judgments. We next describe these models and discuss issues in using them to assess similarity.

Vector Space Word Embedding Models

WEMs take as their foundation the notion that words are similar or related to the extent that they appear in similar contexts. WEMs are trained on a large corpus and derive a vector representation for each word (typically 100 to 300 dimensions) based on co-occurrence patterns in the corpus. Thus, each word's meaning is represented as a point in an *n*-dimensional vector space. The relatedness between any two words is calculated by taking the cosine of the angle between their two associated vectors, resulting in a score between -1 and 1. Scores closer to 1 indicate high levels of relatedness, and scores closer to 0 indicate low levels of relatedness.

While promising in some areas, the evidence regarding WEMs' ability to approximate human similarity judgments is mixed. Latent Semantic Analysis (LSA; Landauer & Dumais, 1997) has been shown in a number of studies to match human judgments of similarity fairly well in certain contexts (Günther et al., 2016; Landauer & Dumais, 1997; Landauer et al., 1998). In addition, previous work has used it as a measure of semantic change over time (Sagi et al., 2011). Other studies, however, suggest that it fails to approximate human intuition, both in literal similarity judgments (cf., Simmons & Estes, 2006), and in relational similarity tasks (Chen et al., 2017) . That the vectors used in WEMs lack explicit relational structure calls into question whether these problems are fully surmountable.

Perhaps the deepest problem lies in the fact that WEMs do not provide a pure measure of similarity, as associations can

[3] In the double paraphrase task, a new group of participants paraphrased the original paraphrases, and any reoccurrences of the original nouns and verbs were scored. There were higher rates of reoccurrence for nouns, indicating greater meaning preservation in the paraphrase. In the retrace task, a new group of participants were given a set of paraphrases, as well as a list of the original eight nouns or verbs used, and asked to guess which noun or verb they thought had occurred in the stimulus sentence. They showed higher accuracy for nouns, indicating greater meaning preservation.

Figure 1: Stimulus nouns and verbs. Shaded cells indicate combinations that result in strained sentences. Pluses and minuses indicate high or low polysemy, respectively. For example, - / + indicates a low-polysemy noun and high-polysemy verb combination, while + / - indicates a high-polysemy noun and low-polysemy verb combination.

			Human		Dynamic Artifact		Static Inanimate	
			complain	suffer	pause	fail	dry	burn
		# *senses*	2	11	2	13	2	15
Human	professor	1	- / -	- / +	- / -	- / +	- / -	- / +
	queen	10	+ / -	+ / +	+ / -	+ / +	+ / -	+ / +
Dynamic Artifact	motor	2	- / -	- / +	- / -	- / +	- / -	- / +
	bell	10	+ / -	+ / +	+ / -	+ / +	+ / -	+ / +
Static Inanimate	tree	2	- / -	- / +	- / -	- / +	- / -	- / +
	box	10	+ / -	+ / +	+ / -	+ / +	+ / -	+ / +

also influence their scores. For example, the words *cow* and *milk* cooccur frequently, resulting in a high cosine similarity score, despite the obvious fact that a cow is not at all similar to milk.

Thus, we consider the present research to be in part an exploration of WEMs' efficacy in this domain. Future work will involve comparing our word2vec results with human judgments. For now, we will provisionally assume that they can be used as an *approximate* assessment of similarity. We chose word2vec based on evidence that it outperforms other WEMs in approximating human similarity judgments in humans (Pereira, et al., 2016).[4,5]

Method

Participants

112 undergraduates completed the study in person at the lab. One participant was excluded for not being a native speaker of English, one was excluded for providing nonsensical answers to all questions, and two were excluded for failing the catch-trial criteria of repeating a noun and/or verb on both catch trials, for a net of 108 participants.

Materials

6 nouns and 6 verbs were used to generate a total of 36 intransitive sentences. Half of the nouns and half of the verbs used were highly polysemous, and half were low-polysemy. Polysemy was evaluated by counting synsets in WordNet 2.1, excluding any that referred to actual people, places, or events.

The shaded cells in Figure 1 indicate the combinations in which the noun does not satisfy the verb's expected argument, resulting in a semantically-strained sentence (e.g., *The bell suffered*). The unshaded cells indicate those combinations where the noun is compatible with the verb's selectional restrictions, resulting in an unstrained sentence that is literally interpretable (e.g., *The professor complained*).

Procedure

Participants were university students who completed the study on a computer. They saw sentences one at a time and were told to paraphrase each sentence without repeating any of the original content words. They were asked to aim for a plausible interpretation of what the speaker meant, rather than a mechanical, word-by-word translation—e.g., to paraphrase *The slimy senator* as something like *The corrupt politician* rather than *The gooey politician*.

So that each participant saw each noun and verb exactly once, the 36 total stimuli sentences were divided into 6 different assignment factors of 6 sentences. Each assignment factor contained two strained and four unstrained sentences. Sentences were presented in randomized order. In addition, two catch trials were included. The catch trials were simple unstrained sentences designed to test for attention and following directions; the criteria for excluding a subject was repeating a content word in both of the catch trial paraphrases or any obviously nonsensical answers in either.

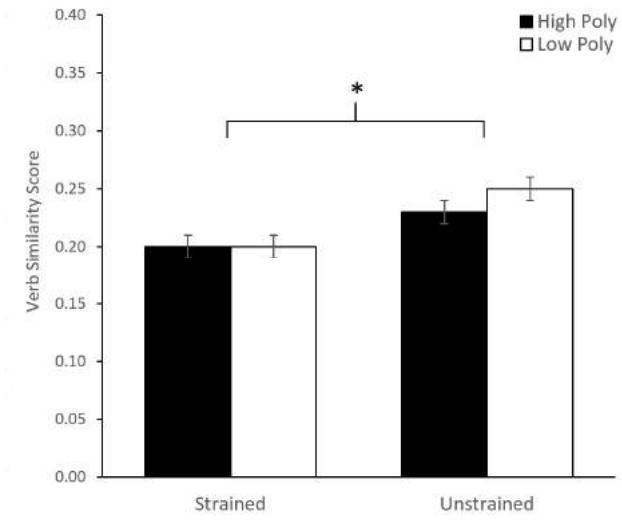
Assessing Semantic Adjustment

For each paraphrase, word2vec was used to obtain two similarity scores, representing the amount of semantic adjustment the initial noun or verb underwent, respectively. The following procedure was used. First, separate normalized vectors were derived for each initial noun and verb. Next, a

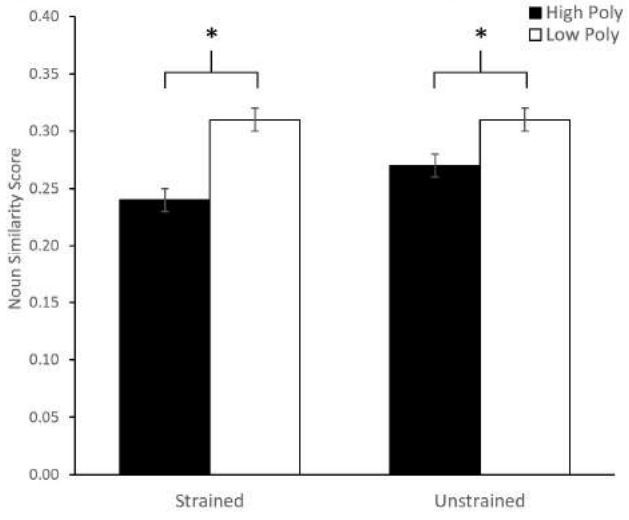
[4] We used pretrained vectors available from Google, which were trained using the CBOW method on part of the Google News corpus (about 100 billion words), available at https://code.google.com/archive/p/word2vec/.

[5] We have also begun analyzing our results following the method outlined by Sagi (in press) for using LSA and other WEMs.

Figure 2. Noun and verb similarity scores. Note that lower scores indicate greater semantic adjustment.



A. Verb similarity scores



B. Noun similarity scores

vector for each paraphrase was generated by averaging its normalized component word vectors.[6] Then the similarity of each paraphrase to the initial noun and to the initial verb was computed by taking the cosine of the angle between the vector representing the initial noun/verb and the entire paraphrase vector.

Any words not found in the corpus were skipped (along with any stop words like *the, a*, etc.). If none of the words in the paraphrase were present in the word2vec dictionary, a null vector was generated. Any paraphrases generating null vectors were discarded (this only occurred twice).

Coding

Certain types of responses were excluded from analysis. First, blatantly noncompliant responses (e.g., paraphrasing *The box dried* as just *fruit*) were excluded. Second, responses that did not constitute a meaningful interpretation of the stimulus noun and verb were excluded as well. This included responses that described the context suggested by the stimulus sentence (e.g., paraphrasing *The tree shivered* as *It is cold outside*), as well as any mechanical, word-by-word paraphrases of strained sentences (e.g., paraphrasing *The box complained* as *The object was frustrated*). For unstrained sentences (which are literally interpretable), a word-by-word paraphrase *is* a meaningful paraphrase (e.g., paraphrasing *The professor paused* as *The teacher stopped*) and therefore were not discarded in these cases.

Two human coders were used. Each coder was presented with the original sentence and its paraphrase and was asked to code each paraphrase as described above, resulting in the exclusion of 137 paraphrases. Cohen's κ was run to determine interrater reliability. There was moderate agreement between the two judges, $\kappa = 0.60$, (95% CI, 0.52 to 0.68), $p < .0001$.

Analysis and Results

The 108 participants generated a total of 648 paraphrases. 137 paraphrases were discarded after coding, leaving a net of 511 paraphrases. All analyses were conducted in R (R Development Core Team, 2008) using the *lmer* package (Bates, Mächler, et al., 2015). Fixed-effect hypothesis tests were conducted using a Satterthwaite approximation for degrees of freedom (Luke, 2017).

First, in order to test Gentner and France's initial finding – that verbs are more mutable than nouns overall – a difference score for each paraphrase was calculated by subtracting verb score from noun score. Next, a linear mixed-effect model was fit, with the difference score as the dependent measure, the intercept (mean) as the fixed effect, and random intercepts for subject and item. The mean of the difference scores was found to differ significantly from 0, $t = 2.99$, $p = .01$, indicating that, on average, verbs (M = 0.23, SD = 0.11) changed their meaning significantly more overall than nouns did (M = 0.28, SD = 0.13; lower similarity scores correspond to greater amounts of semantic adjustment).

Next, to test for effects of semantic strain and polysemy, two additional linear mixed models were fit: one for nouns and one for verbs. In both models, similarity score was the dependent measure, and polysemy (high vs. low), strain (strained vs. unstrained), and the interaction term were included as fixed effects. Both models were initially fit with random slopes and intercepts for subjects and random

[6] These sentence vectors can be viewed as representing the "average meaning" of all the words they contain (Landauer, et al., 1998).

intercepts for items. The random effects structure was then simplified as far as necessary as described in Bates, Kliegl, et al. (2015).

For verbs, the effect of semantic strain was significant, β = -0.18, SE = .08, F = 4.90, p = .03, with verb meaning being adjusted to a greater extent in the strained condition (M = 0.20, SD = 0.09) than in the unstrained condition (M = 0.24, SD = 0.11). There was no significant effect of polysemy, F = 0.98, p = .33, and the interaction was not significant, F = 0.62, p = .43). These results are shown in Figure 2a.

For nouns, there was no significant effect of semantic strain, F = 0.11, p = .74. A significant main effect of polysemy was found, β = -0.19, SE = .06, F = 8.95, p = .01, with high-polysemy nouns (M = 0.25, SD = 0.15) being adjusted to a greater extent than low-polysemy nouns (M = 0.30, SD = 0.11). The interaction was not significant, F = 0.60, p = .44. These results are shown in Figure 2b.

Discussion

There were three objectives in the present research: (1) to replicate Gentner and France's finding that verbs are more mutable than nouns under conditions of semantic strain, using new materials and a new method of assessment; (2) to better understand the processes that drive semantic adjustment; and, (3) to investigate possible noun-verb differences in these processes.

The results regarding objective (1) were as predicted: on average, across conditions, participants adjusted verb meaning significantly more than noun meaning. In addition, verbs (but not nouns) were adjusted to a greater extent in strained contexts than in unstrained contexts (see Figure 2a). Both these results replicate Gentner and France's findings and provide additional evidence for the verb mutability effect: during sentence interpretation, the verb's default meaning is more likely to be adjusted to fit the context provided by the noun, rather than the reverse – especially under semantic strain.

More surprising were the results regarding objectives (2) and (3). Polysemy significantly predicted meaning adjustment in nouns, but not verbs; and semantic strain predicted adjustment in verbs, but not nouns.

This leads to the intriguing conclusion that the processes driving semantic adjustment vary by word class. That polysemy predicted noun adjustment favors the sense-selection view. That it did *not* predict verb adjustment is evidence that their increased mutability is not a matter of having more senses to choose from; rather, online adjustment is taking place. Indeed, a qualitative examination of the paraphrases supports this explanation. For example, nouns were frequently paraphrased as close synonyms (e.g., *tree* as *plant* or *oak*; *box* as *container*), while verbs were frequently adjusted to express meanings that were outside the word's existing set of senses (e.g., paraphrasing *The box complained* as *The container couldn't hold all of its contents*).

What explains the noun polysemy effect?

That semantic strain predicted meaning adjustment in verbs but not nouns is consistent with our prediction that verbs are the locus of change in resolving strained utterances. What is more surprising is the effect of polysemy in driving meaning adjustment for nouns. Why did participants consistently adjust high-polysemy nouns to a greater extent than low-polysemy ones—even in unstrained contexts, where no significant adjustment was necessary? We propose three possible explanations.

1. Higher polysemy allows for more creativity. The first possibility is that higher polysemy granted participants more freedom of interpretation, allowing them to choose a more distant meaning than was available with low-polysemy nouns. We believe this to be unlikely. Examining the paraphrases suggested that, regardless of polysemy (or strain), participants usually attempted to choose a meaning as close to the original noun as possible (unlike with verbs, whose meaning was often changed dramatically). For example, it's not clear that, in substituting *container* for *box* (a high-polysemy noun), one has attempted to adjust meaning further than when one substitutes *oak* for *tree* (a low-polysemy noun). The similarity scores for each pair, however, are 0.12 and 0.80 respectively – a relatively large difference.

2. The results reflect a problem with word2vec. A second possibility is that the observed effects of polysemy are simply an artifact of word2vec and don't reflect actual human intuitions. In all WEMs, the meaning of a word derives from the contexts it appears in. A more polysemous word is likely to appear in a wider variety of contexts than a less polysemous word, rendering it less similar, on average, to any one of those meanings (cf., Beekhuizen et al., 2018).

3. High-polysemy words are less similar to their synonyms than low-polysemy words are. A third possibility is that the relationship between higher polysemy and lower similarity scores reflects a psychologically real pattern: namely, that the more polysemous a word is, the less similar it is, on average, to any one of its synonyms. In this account, polysemy significantly predicted adjustment in nouns because, for a high-polysemy word, any synonym one replaces it with will, on average, be less similar to the original word than when the same is done for a low-polysemy word, despite an equal intention to preserve meaning. That is, the subjective similarity between synonyms of a given word is lower for high-polysemy words than for low-polysemy words. If so, the difference in word2vec scores between *box-container* and *tree-oak* reflects a real psychological difference.

To decide between these latter two possibilities, we conducted a preliminary study with human raters. The results suggest that our WEM results do match human intuitions. We asked raters (N=18) to rate the similarity of eight nouns and verbs (drawn from Gentner & France, 1988) to their closest

synonyms, as determined by a thesaurus (Lewis, 1978). Each base word was paired with three synonyms as well as one antonym as an attention check. Participants rated the similarity between each base word/synonym pair on a scale of 1 to 10, resulting in 865 target ratings. A linear mixed-effects model analysis was conducted, with human similarity rating as the dependent measure, polysemy of the base word as the fixed effect, and random intercepts and slopes for subject and random intercepts for item. A significant negative correlation between polysemy and similarity rating was found, β = -0.20, SE = 0.09, F = 5.63, p = .02.

Thus, we found evidence in favor of our third explanation: on average, the more polysemous a word was, the less similar it was considered to be to its synonyms. In this way, the human findings paralleled our results with word2vec. If this pattern generalizes across other materials, it will be important to understand the reasons for this converging result in humans and in WEMs.

Do Noun and Verb Change Mean the Same Thing?

There are several outstanding issues to acknowledge before concluding. First, an important question is whether semantic distance means the same thing for nouns as it does for verbs. In other words, are the two scales commensurable? WEMs like word2vec are blind to syntactic category and thus employ the same method of generating and comparing vectors for both nouns and verbs (and all word classes). But whether humans judge similarity between nouns on the same dimensions that they do for verbs is unclear.

Similarly, whether polysemy means the same thing for nouns and verbs is also uncertain. It is possible that verb meanings are extended differently than noun meanings, resulting in qualitatively different patterns of relatedness among senses. At present, little work has examined this issue.

Lastly, one might question whether there is a circularity in assessing mutability using word2vec. As with polysemy, if verbs are more mutable than nouns overall, they likely appear in a wider variety of contexts than nouns. Thus, the vectors for any two verbs may, on average, be further apart than is the case for any two noun vectors.

These objections are important and demand further investigation. At the same time, there are striking qualitative differences in the manner of adjustment for nouns versus verbs. As noted earlier, nouns are often paraphrased as close synonyms, whereas verbs are often extended in quite novel ways. This suggests that the verb mutability phenomenon is not simply a difference in similarity scales, but reflects a qualitative difference in processing.

Conclusion

There are three main findings. First, we replicated Gentner and France's (1988) results: verbs changed their meaning more than nouns overall, and did so to a greater extent in a strained context. Second, we found evidence that both sense selection and online adjustment processes drive mutability. Third, we found that these processes differ between nouns and verbs. Semantic adaptation to context appears to be driven by sense-selection for nouns, but by online adjustment for verbs.

We also presented initial evidence that the relationship between polysemy and meaning adjustment may reflect a property of polysemous words; namely, that higher-polysemy words are, on average, perceived as less similar to their synonyms than low-polysemy words are.

Our results invite a number of future research directions. First, the number of items used in this study is small. We are currently testing new word sets. Future work will also involve more systematic testing of specific verb classes to examine how well the results observed here generalize. Second, we plan to compare the WEM results with human judgments of similarity. Our ultimate goal is to provide a clearer characterization of the processes underlying semantic adjustment in nouns and verbs.

Abstract

The purpose of the present study was to investigate the effects of addressee of verbalization, self or other, on insight problem solving. Thirty-five participants were assigned to one of the three conditions: toward-self verbalization, toward-other verbalization, or irrelevant verbalization (control). A 3-minute verbalization phase was inserted after 5 minutes of solving the T-puzzle. The participants were asked to write down their thoughts during the first 5 minutes as a record in the toward-self verbalization condition, and as an instruction for other participants in the toward-other verbalization condition. The participants in the control condition were required to write down their concerns. After that, they were asked to engage in the puzzle again for 10 minutes. The results showed a detrimental verbalization effect while allowed a wide range of effects for the self vs other distinction going in either direction. We are using this study as a basis for a pre-registered report.

Keywords: insight problem solving; verbalization; self vs other; metacognitive monitoring

Introduction

Collaboration is ubiquitous in our daily life. Previous studies have shown that collaboration facilitates problem solving (Miyake, 1986; Okada & Simon, 1997; Shirouzu, Miyake, & Masukawa, 2002). Specifically, collaboration is effective in solving problems when novel ideas or perspectives are needed. Insight problems are a typical example of this sort of problem. Since most studies have addressed whether or not collaboration can facilitate problem solving, little is known about why collaboration has facilitative effects on problem solving. By identifying the factors causing the facilitative effects of collaboration on problem solving, we may be able to collaborate with others more effectively.

Diversity of background knowledge is assumed to be one of the most important factors causing the facilitative effects of collaboration on problem solving (Surowiecki, 2005). This hypothesis posits that people can make use of more diverse knowledge when working together. If the diversity of background knowledge was the only factor, then the facilitative effects of collaboration on problem solving would not be obtained when members have the same knowledge bases. Collaboration, however, facilitates problem solving even when there is little diversity in background knowledge. Bahrami et al. (2010) showed that two people working together to detect a subtle visual signal can do better than the best one working alone. Crucially, Kiyokawa (2002) showed that two people working together can solve a problem better than working alone even when one of the members was prohibited to express his/her ideas to solve the problem. Okada and Simon (1997) found that participants were able to reach the solution in a scientific discovery task when working together than when working alone but there was not a significant difference in diversity of hypotheses they entertained. It may be useful to consider factors other than diversity of background knowledge as contributing to the facilitative effects of collaboration on problem solving.

Metacognitive Monitoring in Insight Problem Solving

Facilitation of metacognitive monitoring during collaboration is another potential factor which may be responsible for the facilitative effects of collaboration on problem solving, especially insight problem solving. In other words, collaboration may facilitate insight problem solving because people can monitor their cognitive processes better when working together than when working alone. Previous studies have shown that metacognitive monitoring plays a critical role in problem solving. That is, the more appropriately one can monitor one's cognitive processes, the better one can solve the problem. However, previous studies have also shown that metacognitive monitoring does not always work in problem solving, and in particular not for insight problem solving, when working alone (Metcalfe, 1986; Metcalfe & Wiebe, 1987). This phenomenon is interpreted as implying that the processes underling insight problem solving when working alone is implicit and non-reportable. Indeed, this dysfunction of metacognitive monitoring is assumed to be one of the factors responsible for the difficulty of insight problem solving. Since people cannot know correctly where they are in the problem space when working alone, they cannot choose their moves so as to head in the right direction, and as a result, cannot readily reach the correct solution.

When working together, on the other hand, people have to communicate what they are thinking to their partners. Therefore, they have to change their thinking modes from implicit and non-reportable to explicit and reportable ones during collaboration. These changes in thinking modes when working together may enhance metacognitive monitoring and, as a result, facilitate insight problem solving. Based on this hypothesis, the tendency to think about one's cognitive processes explicitly or verbally specifically in order to

communicate them to a partner may be a key contribution to the facilitative effect of collaboration. Therefore, not only an actual collaborative setting but also a hypothesized one will be enough for people to change their thinking modes and facilitate their metacognitive monitoring and performance in insight problem solving. To reconcile the claim that verbalizing to others is helpful with the previous claim that people have poor metacognition of insight processes, we draw a distinction between verbalizing to oneself as a target and verbalizing to others, which we now consider.

Metacognitive Monitoring and Verbal Overshadowing Effect

There is evidence relevant to our hypothesis in a line of research on the verbal overshadowing effect. These studies have shown that verbalization directed toward oneself disrupts insight problem solving and verbalization directed toward others does not. Schooler, Ohlsson, and Brooks (1993) showed that verbalizing thoughts after each trial when attempting to solve insight problems can disrupt performance [1]. This disruptive effect of verbalization on insight problem solving is called verbal overshadowing effect. The verbal overshadowing effect may originate from a dysfunction of metacognitive monitoring in insight problem solving. The hypothesized process is as follows. People cannot verbalize what they are actually thinking about because they cannot know where they are in the problem space. Therefore, they tend to verbalize what is easy to do so irrespective of their actual cognitive processes. As a consequence, they cannot make use of information other than what they verbalize and so find it hard to reach the correct solution (see also Kiyokawa and Nakazawa, 2006).

Kiyokawa and Nagayama (2008), on the other hand, have found that verbalizing thoughts toward others does not disrupt but rather facilitates insight problem solving. They examined the effects of failure-focused verbalization on insight problem solving using the same task as that used in Kiyokawa and Nakazawa (2006). Participants were randomly assigned to either of the failure-focused verbalization or the irrelevant verbalization (control) conditions. The participants in the failure-focused verbalization condition were asked to write down the ways they thought inappropriate for solving the problem as advice toward other participants. The participants in the control condition were asked to describe in detail what they were studying and interested in. The results revealed that failure-focused verbalization facilitated insight problem solving. The study is consistent with, but was not designed to support the claim, that there is something beneficial about directing one's verbalization to someone else rather than oneself, in acquiring a metacognitive grasp on where one might be in a problem space. Bahrami et al (2012) argue that a key function of meta-cognition is social collaboration; if this is so, engaging socially, or trying to, may facilitate what seems a private process, metacognition. This is the claim we wish to test. The mechanism by which meta-cognition, an apparently private process, is maximally engaged may thus paradoxically rely on social cues.

Purpose of Present Study

The purpose of the present study is to clarify the effects of addressee of verbalization, self or other, on insight problem solving in terms of metacognitive monitoring by examining the verbal overshadowing effects. Our hypothesis is that verbalizing one's thought just as a record disrupts insight problem solving because metacognitive monitoring does not work well, whereas verbalizing one's thought for communicating with other facilitates insight problem solving because it helps metacognitive monitoring.

We will address this question by comparing each solution rate of the puzzle in the two experimental conditions and the control condition. The first experimental condition was the toward-self verbalization condition. In this condition, participants were asked to verbalize reflectively what they were thinking during struggling with the puzzle as a record for themselves. The second experimental condition was the toward-other verbalization condition, in which participants were asked to verbalize their thinking during the previous solving phase as advice for other participants. In the control condition, participants were asked to verbalize not their thinking about their problem solving but their recent concerns irrelevant to solving the puzzle. Thus, the theory that metacognition may not work in a solo setting but does best when engaged in a social context was tested by the following prediction: 1) less participants should solve the puzzle in the toward-self verbalization condition than in the toward-other condition. If in contrast there is just a general overshadowing effect, then there should be little difference shown in the previous contrast but 2) less participants should solve the puzzle in the verbalization conditions than in the control condition. We here investigate these predictions in an exploratory study, that is one that was not pre-registered, in order to have a firm basis for a pre-registered study. We will thus estimate the sort of effect sizes we find that are relevant to the predictions.

[1] Schooler et al. (1993; Exp. 3) found verbalizing reduced percentage of problems solved in 6 minutes by 25% for insight problems and about 5% for non-insight problems, a difference of 20%. Gilhooly, Fioratou & Henretty (2010) tightened up the design and compared percentage of insight with non-insight problems solved in 4 minutes. Crucially, for them verbalizing versus silence did not significantly interact with problem type, $F = 1.63$. Does this fail to replicate Schooler et al? We need a Bayes factor to determine whether the data supported H0 over a reasonable H1. The raw interaction effect would be expected to be 20% (i.e. Schooler et al.'s effect) x 4/6 (correcting for time difference) = 13%. In fact, Gilhooly et al. found a sample overshadowing effect of 4% for insight problems (57 – 53%) and 0% for non-insight (48 vs 48%), i.e. a raw interaction effect of 4% (with $SE = 4\%/\sqrt{1.63} = 3.1\%$). Modelling H1 as a half-normal with $SD = 7\%$, gives a Bayes factor $B_{H(0,7)} = 0.92$, i.e. Gilhooly et al.'s interaction does not count against Schooler et al.

Method

Participants

Thirty-five participants were recruited from the participant pool of the School of Psychology at the University of Sussex. All were required to have UK or EU passports. They received 2 course credits or 3 pounds for taking part in the study. The participants granted their informed consent before participation and the Ethical Committees both of the University of Sussex and Nagoya University approved the study.

Design

We used a between-participants design. The independent variables had three levels: toward-self verbalization, toward-other verbalization, and irrelevant verbalization. The key dependent variable was the proportion of participants who solved the T-puzzle.

Procedures

The participants were randomly assigned to one of the following three conditions: toward-self verbalization, toward-other verbalization, or irrelevant verbalization (control). The experiment took place in a small room with the experimenter present and only one participant at a time. After providing their informed consent to the study, the participants engaged in a practice task for 3 minutes. Before the main task, as a practice task, they were asked to make a rectangle shape (see Figure 1 (b)) using the four pieces presented (see Figure 1 (a)) for three minutes in order to get accustomed to manipulating the pieces they would use in the main task After that, they were asked to solve the main shape puzzle, called the T-puzzle on a display using a mouse for a total of 15 minutes. In the puzzle, they were asked to form a T shape (see Figure 1 (c)) using the same four pieces as the practice task. They were asked to let the experimenter know when they think that they had reached the correct solution. Then the experimenter checked if they have reached the correct solution and if so, the solution phase was terminated at that time. If not, they continued the task.

A 3-minute verbalization phase was inserted after 5 minutes of solving the puzzle. In this phase, the participants were asked to enter their thoughts using a keyboard following the particular instructions in each condition. The first two sentences in the instructions both in the toward-self and other verbalization conditions were the same as those used in Schooler et al. (1993). Those in the toward-self verbalization condition were instructed to write down what they were thinking about in the first 5-minute solution phase, as a record to themselves. The instruction was as follows. "Please write down, in as much detail as possible, everything you can remember about how you have been trying to solve the problem. Give information about your approach, strategies, any solutions you tried, and so on. Write as a record to yourself, like a diary of how you tried to solve the problem in the last five minutes. Remember you are addressing yourself in making these notes; it should feel exactly like talking to yourself. Try to write about 100 words. You can check how many words you have written by looking here. You can take 3 minutes for this writing."

Those in the toward-other verbalization condition were asked to write down their thoughts in the first 5-minute solving phase as advice to other participants. The instruction was as follows. "Please write down, in as much detail as possible, everything you can remember about how you have been trying to solve the problem. Give information about your approach, strategies, any solutions you tried, and so on. Write instructions for other participants on how to solve the problem, based on what you found out in the last five minutes. Remember you are talking to someone else when making these notes; it should feel exactly like a conversation with someone else. Try to write about 100 words. You can check how many words you have written by looking here. You can take 3 minutes for this writing."

Those in the control condition are asked to write down their recent interests as an irrelevant topic to the puzzle. The instruction is as follows. "Please write down, in as much detail as possible, everything you can remember about what you have been interested in. Give information about your interests, hobbies, any things you want to do, and so on. Write about your interests that have nothing to do with the problem you have been trying to solve in the last five minutes. We

(a) Used pieces (b) Solution of the practice (c) Solution of the T-puzzle

Figure 1: Tasks.

want you to take a break from the problem. Remember to write about something other than the puzzle. Try to write about 100 words. You can check how many words you have written by looking here. You can take 3 minutes for this writing."

After the verbalization phase, the participants were required to solve the puzzle again for 10 minutes. They were given a hint to solve the puzzle. Specifically, they were asked to put the pentagon piece not vertically or horizontally but diagonally. This hint was shown to be effective in reaching the correct solution by Suzuki and Hiraki (1998).

After the main task, the participants were asked to fill in a question sheet. The following questions were included in the sheet: (1) "Have you ever tried to solve this puzzle before?" (2) "If you answer "yes" in the first question, when it was it?" (3) "Did you know the correct solution to the puzzle before the experiment?" (4) "To whom did you address your verbal description in the middle of doing the puzzle?" "(5) What was your description about?" (6) "What's your nationality?"

Results

Based on the answers to the questions (1) and (3), we made sure that none of the participants had experienced the T puzzle before the experiment or knew the correct solution. Based on the answers to the question (6), we also made sure that the nationalities of all the participants were UK or EU. A participant in the toward-other condition engaged in the practice task longer than 3 minutes and therefore the data of the participant was excluded from the analyses.

Manipulation Check

We checked whether the participants followed the instructions on the verbalization by the following two ways. First, we examined their recognized addressees based on the question (4) in the post-task questionnaire. Second, we examined what the participants wrote down in the verbalization session. We will report the 95% credibility intervals based on a uniform prior, which are numerically the same as 95% confidence intervals.

Recognized Addressees Table 1 shows frequency of each option the participants selected as their addressees in the post-task questionnaire in each condition. If the participants followed the instruction properly, the participants in the toward-self verbalization condition should have chosen "Self" and those in the toward-other verbalization condition "Other People". Indeed, the selection rate of "Self" was considerably higher in the toward-self verbalization condition than the toward-other verbalization condition with odds ratio, OR = 50.00, 95% CI, [3.88, 643.90].

Table 1: Number of each option selection in each condition.

	Toward-self	Toward-other
Self	10	2
Other people	1	10
Total	11	12

Table 2: Number of participants who used or did not use "You" as a subject or imperative form at least once in their descriptions in each condition.

	Toward-self	Toward-other
Used	1	9
Did not use	10	3
Total	11	12

What the Participants Verbalized We examined the quantity and quality of the participants' verbalization in order to check whether they followed the instructions. First, we compared the number of words among these 3 conditions. Hopefully there would be only minor differences in the sheer quantity of their verbalization, as number of words, among these conditions (Toward-self verbalization: M = 92.8, SD = 12.8; Toward-other verbalization: M = 80.6, SD = 16.3; Control: M = 82.5, SD = 19.5, 95%CI, Toward-self verbalization vs Toward-other verbalization: [-18.43, 42.90], Toward-other verbalization vs Control: [-35.68, 39.42], Toward-self verbalization vs Control: [-23.56, 44.29]).

Second, we examined the subjects and predicates the participants used in their verbalization. Specifically, we counted the number of participants who used "you" as a subject or imperative form at least in their description. If the participants followed the instructions, more participants in the toward-other verbalization condition should use "you" or imperative form than in the toward-self verbalization condition. Indeed, as Table 2 shows, more participants used "You" as a subject or imperative form in their description in the toward-other verbalization condition than the toward-self verbalization condition with odds ratio, OR = 30.00, 95% CI, [2.63, 342.75].

Task Performance

The performance in each condition is shown in Table 3. First, we compared the solution rates between the toward-self and other verbalization conditions in order to test the effects of the addressee of verbalization on insight problem solving. Plausible odds ratios spanned interesting effect sizes around the null value of 1 (OR = 1.90, 95% CI [0.33, 11.01]).

Next, we combined the data in the toward-self verbalization and in the toward-other verbalization conditions into the verbalization condition and compared the solution rates between the verbalization and control (non-verbalization) condition. The result showed that the solution rate could be higher in the control condition than the verbalization condition by a small to a considerable amount (OR = 5.00, 95% CI, [1.03, 24.29]).

In sum, while the evidence allowed a wide range of effects for the self vs other distinction going in either direction, the

Table 3: Performance in each condition.

	Toward-self	Toward-other	Control
Solved	3	5	8
Unsolved	8	7	3
Total	11	12	11

evidence favoured a detrimental verbalization effect rather than an overall positive effect of verbalization. In particular, the crucial theoretical distinction between verbalizing to self vs other had a 95% probability of lying in the interval 1/3 to an effect as high as OR = 11, that is higher than the estimated effect of verbalizing versus non-verbalizing, for which OR = 5 in our sample.

Based on these rough estimates, we can now determine the sort of effect sizes we would expect in a follow up study, for which this report constitutes its pre-registration. Specifically, using the identical procedure as for this exploratory study, for analyzing results we will use an odds ratio of 5 as a roughly predicted effect size for our pre-registered experiment for all effects. The function of this exploratory study was to check the procedure worked smoothly and determine plausible possible effect sizes (Considering the past literature using the same task, Kiyokawa & Nakazawa, 2006, an odds ratio of 3.11 was found for a verbal over-shadowing effect, which is in the same ballpark). We will use this estimate for Bayes factors to make existential claims of whether or not an effect exists. To get evidence for whether an effect does or does not exist, a rough idea of the scale of effect to be detected is needed. Following Dienes and Mclatchie (2018), we will model H1 by setting the *SD* of a half-normal to 5. We will collect participants until the contrast given as prediction 1) at the end of the introduction has a Bayes factor either greater than 3 or less than 1/3.

Discussion

In the present study, we investigated the effects of addressee of verbalization, self or other, on insight problem solving in terms of metacognitive monitoring by examining the verbal overshadowing effects. Our hypothesis was that verbalizing one's thought just as a record disrupts insight problem solving because metacognitive monitoring does not work well, whereas verbalizing one's thought for communicating with other facilitates insight problem solving because it helps metacognitive monitoring. The results showed that the manipulation worked well in terms of participants obeying instructions. Further, the results were consistent with a small to large verbal overshadowing effect on insight problem solving. Crucially, the results allowed a wide range of effects for the self vs other distinction going in either direction. In the following section, we will discuss the necessity of re-examining the verbal overshadowing effect on insight problem by Bayes factors and another possible self vs other difference in metacognitive monitoring.

Verbal Overshadowing Effect Should Be Examined Using a Bayes Factor

There has been a debate between the special-process view and business-as-usual view of insight problem solving. The former posits that insight problem solving processes are implicit, unlike non-insight problem solving. The latter, on the other hand, assumes that the same processes used in non-insight problem solving are involved in insight problem solving. Since the prediction for the verbal overshadowing effect based on the special-process view is different from that based on the business-as-usual view, previous studies have addressed whether or not the verbal overshadowing effect is obtained in order to determine which view is valid (Ball et al., 2015; Fleck & Weisberg, 2004; Gilhooly et al., 2010; Schooler et al., 1993). Specifically, based on the special-process view, verbalization should disrupt only insight problem solving. Based on the business-as-usual view, on the other hand, verbalization should disrupt neither insight nor non-insight problem solving. The evidence from the present study supports the special-process view.

There is a methodological problem on how to determine whether or not the verbal overshadowing effect is obtained. Previous studies concluded that the verbal overshadowing effect was not obtained when there was a non-significant effect of verbalization on problem solving. But non-significance includes both the case where the data were insensitive and where there is evidence for no verbal overshadowing. In contrast, Bayes factors distinguish evidence for no effect relative to a model of the sizes of effect expected, from no evidence at all. In our follow up experiment, we will use Bayes factors.

Self vs Other Differences in Metacognitive Monitoring May Be Emerged Only by Attribution

The present study was motivated by the self vs other difference in metacognitive monitoring when asked to communicate one's thinking processes to others. If the function of metacognition is intrinsically social (Bahrami et al, 2012), the module or mechanism may be best engaged when social cues trigger it. But there may be other factors related to facilitation of metacognitive monitoring in insight problem solving during collaboration. Specifically, the facilitation of metacognitive monitoring may be obtained only by regarding the processes to be monitored as generated by others. (For example, the thinking of others may be regarded with more skepticism than one's own thinking.) Several studies have supported this hypothesis.

Schunn and Klahr (1993) compared performance on an insight-like rule discovery task between self- or other-generated hypothesis conditions. The participants in the self-generated hypothesis condition were asked to generate their own initial hypotheses. The participants in the other-generated condition were given the most frequently generated hypothesis. The results showed that the hypothesis

was investigated more thoroughly in the other-generated condition than in the self-generated condition and that the participants in the other-generated condition terminated with incorrect solutions less than those in the self-generated condition. Kiyokawa, Ueda, and Okada (2004) compared the performance of an insight-like rule discovery task between the self- or other-generated hypothesis conditions. The results showed that the participants in the other-generated hypothesis condition outperformed those in the self-generated hypothesis condition and that the plausibility dropped down after the participants in the other-generated hypothesis condition faced some counterevidence while that increased in the self-generated hypothesis condition.

Kiyokawa, Izawa, and Ueda (2007) investigated effects of swapping between doing and observing a partner or oneself on insight problem solving using the T-puzzle. The results showed that swapping between doing and observing a partner solving the puzzle facilitated insight problem solving, whereas swapping between doing and seeing one's past actions (i.e. within an individual) disrupted problem solving. Kotera et al. (2011) compared the performance of the T puzzle when they observed moves regarded as generated by oneself or by others. The results revealed that observation disrupted insight problem solving if one attributed the observed moves to oneself, but not if one attributed them to another person.

However, all these results may also be explained by our original hypothesis, in the introduction, that it is simply engaging in a social way that maximizes the efficacy of meta-cognition. Our replication of the current study (of which this paper constitutes its pre-registration) until we get evidence for or against the self versus other contrast being effective will help settle the matter: If other is more effective than self, then it may simply be a matter of engaging social cues.

Acknowledgments

This paper, together with https://osf.io/tzf8g/ constitutes the pre-registration for a follow-up experiment we will start in February. We would like to thank Prof. Kazuhiro Ueda at the University of Tokyo for allowing us to use the program. This work was supported by JSPS KAKENHI Grant Number JP17K04350.

A Bayesian model of memory in a multi-context environment

Dave F. Kleinschmidt (dave.kleinschmidt@rutgers.edu)

Abstract

In a noisy but structured world, memory can be improved by enhancing limited stimulus-specific memory with statistical information about the context. To do this, people have to learn the statistical structure of their current environment. We present a Sequential Monte Carlo (particle filter) model of how people track the statistical properties of the environment across multiple contexts. This model approximates non-parametric Bayesian clustering of percepts over time, capturing how people impute structure in their perceptual experience in order to more efficiently encode that experience in memory. Each trial is treated as a draw from a context-specific distribution, where the number of contexts is unknown (and potentially infinite). The model maintains a finite set of hypotheses about how the percepts encountered thus far are assigned to contexts, updating these in parallel as each new percept comes in. We apply this model to a recall task where subjects had to recall the position of dots (Robbins, Hemmer, & Tang, 2014). Unbeknownst to subjects, each dot appeared in one of a few pre-defined regions on the screen. Our model captures subjects' ability to learn the inventory of contexts, the statistics of dot positions within each context, and the statistics of transitions between contexts—as reflected in both recall and prediction.

Keywords: Bayesian modeling; memory; learning; belief updating

Introduction

Every cognitive function—perceptual inference, learning, memory, decision making, etc.—takes place in *context*, and understanding these cognitive functions requires understanding the role that the context plays. When cognitive functions are considered in isolation, context can appear to be a source of errors, distraction, or added uncertainty. For example, Roediger and McDermott (1995) induced "false recall" by having subjects study lists of near associates of a word but not the critical word itself. However, when considered ecologically, larger-scale regularities in the environment mean that context can function as a source of additional *information*, reducing the amount of information that must be stored about particular instances. Evidence abounds that people draw on the *context* an item occurred in as an additional source of information (e.g., DuBrow, Rouhani, Niv, & Norman, 2017; Huttenlocher, Hedges, & Duncan, 1991; Orhan & Jacobs, 2013; Schulz, Franklin, & Gershman, 2018; Qian & Aslin, 2014). In this view, so-called "false recall" is really a reflection of the mis-match between the *experimenter's* defined context and the *subject's* inferred context.

However, this raises the question of what *is* a context, and how do people know? For instance, Huttenlocher et al. (1991) found that immediate spatial recall of a location in a circular area is biased towards the average radius of all locations in the experiment. They proposed that memory for an individual item's location is encoded at two levels: the item itself, and the *category* it was assigned to. However, their proposed model does not address what constitutes a category or how subjects decide, and instead simply defines the category based on the long-run statistics of locations encountered in their experiment. However, Robbins et al. (2014) discovered that in a similar task with multiple (implicit) contexts, subjects recall draws on *context*-level statistics, rather than the long-run (experiment-level) statistics.

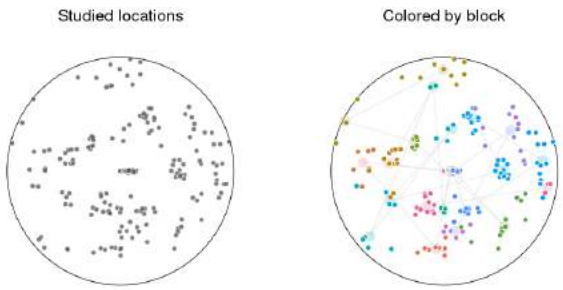

Figure 1: All locations that subject 4 studied (left), color-coded by their block (right), large dots show the average location for each block, and the gray lines show the sequence of blocks

Here, we propose a Bayesian model of learning and memory in multi-context environments, and apply this model to the data from Robbins et al. (2014) human spatial memory experiment. The model treats the problem of identifying latent contexts as a sequential non-parametric clustering problem, where agents must update their beliefs about which context they are in and the properties of that context *online*, with one data point at a time. This model thus captures psychological constraints on the discovery of latent contexts which is not captured by previous Bayesian models.

Data

The data we model is described in detail in Robbins et al. (2014), but we provide a brief summary of the procedure here. In this experiment, 8 participants were asked to record the location of a dot presented in a circle (see Figure 1) and reconstruct that location from memory. Participants were given a cover story in order to keep the task engaging; they were told that the circle was a garden and the dots were moles. In order to save their garden, they had to "catch" the moles by clicking on the locations where they saw them.

After an initial presentation of 20 dots at the center of the circle, dots were presented in blocks (3, 6, 9, or 12 presen-

tations in a cluster), sampled from a multinomial normal distribution with a mean of a given radius and one of three variances (0.01, 0.04, and 0.06 in a unit circle). There was no explicit signal to the subject when one block ended and the next began. The mean angles and radii were informed by Huttenlocher et al. (1991). There were 24 angle measures including the axes, and the measures consisted of the same relative angles in each quadrant. Four different distances measuring out from the center of the circle to the circumference were chosen

Each dot was viewed for one second followed by a combined visual mask and distractor task designed to remove the dot from participants' visual field and introduce uncertainty in the memory process. This mask consisted of a grid of black and white squares; after this mask was removed, an "X" appeared on the screen and participants were asked to report the color of the square (black or white)previously in that location. Data from the distractor task was recorded but not analyzed. After the completion of the distractor task, participants were asked to **recall** the location of the dot from memory by clicking a spot in the circle. After every three trials, participants were asked to make a **prediction** about a future dot location. Prediction trials alternated between prediction for the next trial and prediction for five trials from now. Each block (defined as a cluster of trials at one mean) was followed by a prediction for the expected dot location 10 trials from the current trial. This resulted in a total of 280 trials: 80 prediction trials and 200 recall trials.

Modeling

Our model has three components. First, we model how people infer the assignment of stimuli to contexts as nonparametric Bayesian clustering, approximated sequentially with a particle filter. Second, we model encoding and recall of locations as Bayesian cue combination with a prior from the context (much like Huttenlocher et al., 1991). Third, we model subjects' predictions about future locations via the posterior predictive distribution of the context model.

Context model

We modeled learners inferences about the underlying context on each trial as a sequential Bayesian non-parametric clustering problem. The goal of the learner in this model is to infer the cluster assignment z_i of observation x_i, given the previous observations $x_{1:i-1}$ and their labels $z_{1:i-1}$:

$$p(z_i = j|x_{1:i}, z_{1:i-1}) \propto p(x_i|z_i = j, z_{1:i-1}, x_{1:i-1})p(z_i = j|z_{1:i-1})$$

The sequential prior $p(z_i = j|z_{1:i-1})$ is a "Hibachi Grill Process" (Fox, Sudderth, Jordan, & Willsky, 2011, 2A; Qian & Aslin, 2014), which is like the standard Chinese Restaurant Process (CRP) with an added (constant) probability assigned to the previous state. This corresponds to the following generative model: with probability $0 < \rho < 1$ the previous state is picked, $j = z_{i-1}$, and with probability $1 - \rho$ a component is chosen from a Chinese Restaurant Process with concentration α, which assigns probability to each state proportional to the number of observations assigned to it already,[1] and creates a new state with probability proportional to $\alpha > 0$. We refer to the ρ parameter as the "stickiness" because it controls how likely, a priori, the model is to stick to the same state.

The likelihood $p(x_i|z_i = j, z_{1:i-1}, x_{1:i-1}) = p(x_i|x_{\{k;z_k=j\}})$ is computed by marginalizing over the mean and covariance of a multivariate normal distribution given the data points previously assigned to that cluster and a conjugate Normal-Inverse Wishart prior (Gelman, Carlin, Stern, & Rubin, 2003). This has the advantage that it only requires tracking the sufficient statistics of the previous observations from the cluster (sample mean and covariance), and not the individual observations.

Inference: Sequential Monte Carlo

Instead of a standard batch inference technique, we use an online, Sequential Monte Carlo/particle filter technique. This method approximates the posterior beliefs after $i-1$ observations $p(z_{1:i-1}|x_{1:i-1})$ as a weighted population of K particles, each of which is one possible value of the $i-1$ labels, denoted $z^{(k)}_{1:i-1}$. This population of particles represents an *importance sample* from the posterior. When a new observation x_i comes in, the population moves to target the updated posterior $p(z_{1:i}|x_{1:i})$. There are many algorithms to do this, and the effectiveness of a particular algorithm will depend on the problem. We use the algorithm of Chen and Liu (2000), as described in, Fearnhead (2004): for each particle k, a state assignment is sampled for x_i according to $p(z_i|x_{1:i}, z^{(k)}_{1:i-1})$, and the weight $w^{(k)}_i$ is updated by the ratio of

$$\frac{\sum_j p((z^{(k)}_{1:i-1}, j)|x_{1:i})}{p(z^{(k)}_{1:i-1}|x_{1:i-1})}$$

to ensure that each particle's weight reflects its ability to *predict* the point x_i, rather than just *explain* it. When too much of the total weight for the population (constrained to sum to 1) is captured by a small number of particles (measured by the ratio of the variance of the weights to their mean being greater than 0.5), a new population is resampled (with replacement) and the weights are set to be uniform.

This is for two reasons. First, because we wish to query the model's beliefs about the current context at every point throughout the experiment, an online approximation is much more computationally efficient. A batch algorithm like Gibbs sampling or Hamiltonian Monte Carlo requires one full sweep through the data for each sample, which must be done independently for each data point, so drawing K samples for each of N data points is $O(KN^2)$. A particle filter propagates uncertainty with a fixed population of K particles, updating each particle in parallel as each data point comes in, meaning the complexity is only $O(KN)$. This means it is possible to effectively model longer experiments.

[1] One important difference from a standard CRP is that only non-sticky transitions count for the purposes of sampling new states from the CRP.

Second, an online learning algorithm better approximates *psychological* constraints on learning, and in particular unlike batch MCMC algorithms does not assume that learners can go back and revisit each observation and their decisions about it.[2] This class of models thus provides a possible bridge between computational and algorithmic level approaches to modeling learning and memory (Kleinschmidt, 2018; Sanborn, Griffiths, & Navarro, 2010).

Encoding and recall

The noisy memory trace is modeled as a normal distribution centered at the studied location x with an isometric covariance matrix Σ_x, whose diagonal elements are all equal to σ_x^2, which is a free parameter of the model. This noisy memory trace is combined with a *context prior*, which is approximated by the population of particles. Specifically, each particle k represents one possible assignment of the observations $x_{1:i}$ to clusters $z_{1:i}^{(k)}$. We can thus model each particle's context as the expected mean and covariance matrix for all the points that particle k has assigned to the same cluster as the studied point $z_i^{(k)}$:

$$\mu_c^{(k)}, \Sigma_c^{(k)} = E(\mu, \Sigma)_{p(\mu,\Sigma|x_{1:i}, z_{1:i}^{(k)})}$$

Then the best guess of the studied location under particle k's model of the context is the combination of a normal likelihood (from the noisy trace of the studied item) and a normal prior (from the context), which works out to be the inverse variance-weighted average of the two means:

$$\hat{x}^{(k)} = ({\Sigma_c^{(k)}}^{-1} + \Sigma_x^{-1})^{-1}({\Sigma_c^{(k)}}^{-1}\mu_c^{(k)} + \Sigma_x^{-1}x)$$

Prediction

To model subjects predictions about future locations, we sample 100 locations from the posterior predictive distribution of the population of particles. To sample one predicted location at a n trials in the future, we sample a particle from the population according to their weights, draw a sample of n future states from that particle's Hibachi Grill Process, and then sample one point from the posterior predictive distribution of the resulting cluster. In the case that the predicted cluster is a new cluster, we sample from the prior predictive.

Procedure

To evaluate this model, we simulated the data from Robbins et al. (2014) with a range of parameter values. The concentration parameter α was set to $0.01, 0.1, 1$, or 10, and the stickiness parameter ρ was set to $0.1, 0.5$, or 0.9. The memory noise standard deviation parameter σ_x varied along $0.01, 0.1, 1$, (for a circle with a radius of 1), although only results from $\sigma_x = 0.1$ are presented here. The prior for the cluster parameters was based on the distribution of true block means/covariances. In principle, this could be inferred as well but we leave that enhancement for future work. We ran 10 repetitions with each of the 36 combinations of parameters, all of which used 100 particles for each subject's data.

The particle filter algorithm was implemented in Julia 1.1 (Bezanson, Edelman, Karpinski, & Shah, 2017). The code, simulation results, and Weave.jl (Pastell, 2017) source for this paper is available from osf.io/dqz73/

[2] These approaches also do not *preclude* revising previous decisions, they just do not *require* it.

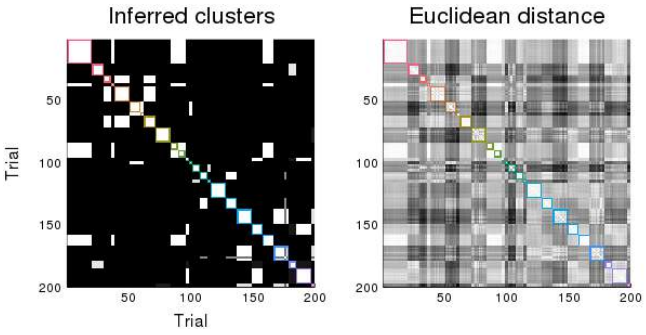

Figure 2: Cluster assignment similarity matrix for clusters inferred by one population of particles from subject 4's studied locations (left), with the true (experimenter-defined) blocks outlined in colors (see Figure 1). The similarity matrix based on the Euclidean distance between each location is shown for comparison (right) and to show that the model groups some similar locations into the same cluster even though they are from different blocks.

Results

Clustering

First, how well does this algorithm do at recovering the underlying cluster structure? This is not a straightforward question to answer: each particle in the population represents a potentially different assignment of observations to clusters, and the cluster indices used in one particle might not align with those in another particle. To get around this we look at the assignment similarity matrix, which is an $N \times N$ matrix, where element (i, j) is the probability that trials i and j are assigned to the same cluster. This probability is calculated by averaging across all particles in the population according to their weight.

Figure 2 shows the assignment similarity matrix for one subject, based on a 100-particle filter with $\alpha = 0.01, \rho = 0.9$ (left) with the true, experimenter-defined block structure is outlined in the colors from Figure 1, and the pairwise Euclidean distance between the locations for comparison (right). This example shows a number of important features of the model's inferences about the underlying changes in context. First, relative to the experimenter-defined blocks, the model occasionally undersegments, grouping adjacent blocks together into a single context. Second, the model also sometimes infers that it has *returned* to a previous context, instead of creating a new context when it infers that the block has

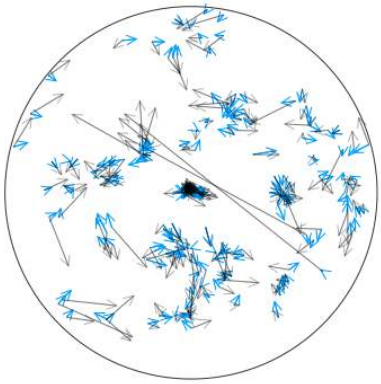

Figure 3: Subject 4's recalled locations (gray arrows, pointing from studied to recalled location) compared with model simulation (blue arrows; $\alpha = 0.01, \rho = 0.9, \sigma_x = 0.1$)

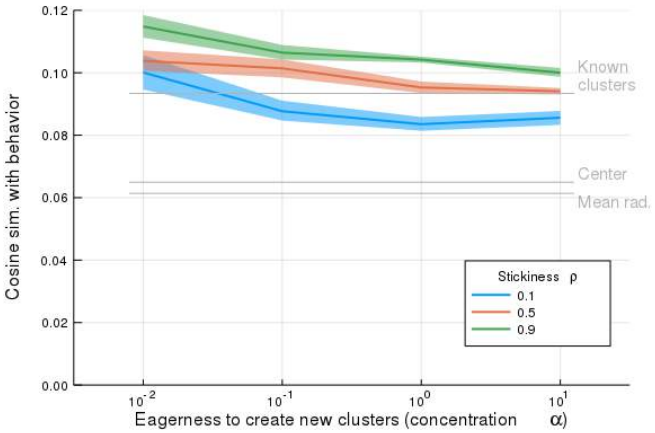

Figure 4: Mean cosine-similarity of model predicted and actual recall deviations across parameter values (ribbons show 95% bootstrapped CIs over model runs). Gray lines show baselines: always deviate toward center, average radius, and center of true clusters

changed. This can be seen from the off-(block)-diagonal entries in the assignment similarity matrix (Figure 2, left). As the Euclidean similarity matrix (Figure 2, right) shows, this tends to happen when the points in two blocks are close together. Third, because of the online nature of the model, it maintains relatively less uncertainty about the clustering of early trials. Note though that Figure 2 shows the beliefs of the model at the *end* of the experiment, which reflect the totality of the locations it has encountered.

Recall

Next, we assess how well the inferred contexts can predict recall. Figure 3 shows one subject's actual deviations from studied to recalled locations (gray arrows) versus the model's predicted deviations (blue arrows). To quantify goodness of fit, we use the cosine similarity of the model's and subject's recall deviation (i.e., blue and black arrows in Figure 3), which ranges from 1 (deviations perfectly aligned) to -1 (deviations in opposite directions), with 0 corresponding to orthogonal deviations. We chose this metric because it is less sensitive to large outlier responses than mean-squared error, and because approximations of the likelihood of a subject's response given the model is highly sensitive to free parameters and difficult to reliably estimate. Moreover, the baseline models we compare against also do not have straightforward likelihood models, but they *do* make straightforward predictions about the directions of recall deviations.

Figure 4 shows the cosine similarity with of all subjects' responses with the multi-context Bayesian model. The ribbons show the 95% bootstrapped confidence intervals over model runs, which indicate that the approximate inference strategy leads to reasonably consistent inferences for a given set of parameters. At all parameter settings, the model performs better than chance, predicting subjects' recall deviation directions at a cosine similarity of around 0.1 (relative to a chance level of 0). The model performs best for high ρ stickiness and low α concentration.

We also compare the model's performance against three baselines. First, we compare it against a "known clusters" model, which uses the true (experimenter defined) clusters with the same Bayesian cue combination model of encoding and recall. Second, we compare it to two baselines based on previous literature on similar memory tasks (Huttenlocher et al., 1991): one that always biases recall towards the center (the average location of all trials), and one that biases recall towards the mean radius.

First, at the whole range of parameters explored, the multi-context model performs better than the center- or mean-radius-biased baselines. Second, except for low stickiness $\rho = 0.1$, our model provides a better fit to human behavior than the "known clusters" baseline, which differs from our model only in that the true cluster labels are provided for each data point, rather than being inferred. This suggests that, at least according to the cosine similarity metric, our context-inference model better captures how people combine information about the current context during recall than the "ground truth" clusters.

However, an important caveat is that there is substantial variability across *subjects*. The cosine similarity for $\alpha = 0.01, \rho = 0.9$ has a 95% boostrapped CI across subjects of $[0.05, 0.17]$, which while significantly better than chance is not significantly better than the baseline models, even when taking into account the substantial variability in the cosine similarity for the baseline models themselves. With only 8 subjects in this dataset it is unclear how well the model's performance will generalize to other datasets, and future work with better-powered designs is required.

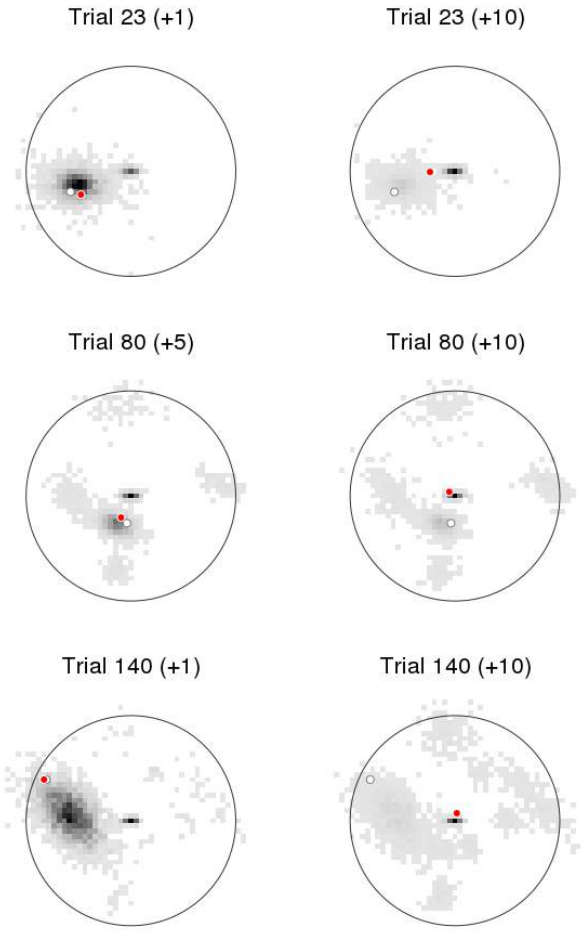

Figure 5: Subject 7's (red points) and model's (gray regions) predictions about upcoming locations at various points throughout the experiment and various prediction horizons. The white points show the last recalled location.

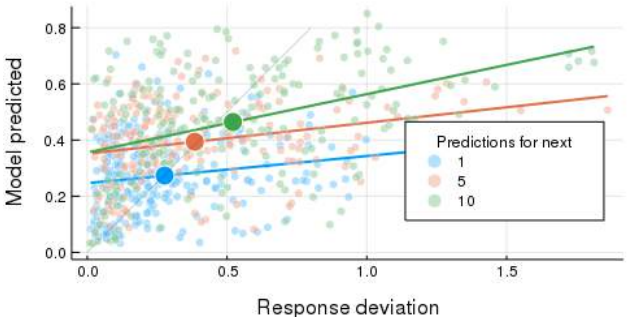

Figure 6: Model predicted ($\alpha = 0.01, \rho = 0.9$) and actual deviations from last studied point for prediction task. Small points show deviations of predictions for each trial, and large points show average deviations for each lag (1, 5, or 10 trials).

Prediction

Subjects also, every three recall trials, predicted the location where points would appear in 1, 5, or 10 trials in the future. This is a more explicit probe of what subjects know about the cluster structure than the recall task. Figure 5 shows six examples of how the model's prediction about upcoming locations capture subjects' behavior. For +1 trial predictions, the model's distribution of predicted locations primarily reflects its beliefs about the *current* cluster (as reflected by the higher density of predictions near the white studied point), because of the "sticky" Hibachi Grill Process prior on states. At +10 trials, the model is much more likely to predict the center cluster, which recurs frequently throughout the experiment (see also Figure 2). Likewise, subjects also have picked up on this pattern and are more likely to predict locations close to the center on +10 prediction trials.

Our model also captures how the average distance from the last studied point increases as subjects are asked to predict the location of points +1, +5, and +10 trials into the future (Figure 6, large points). Moreover, the model also captures variation *within* these delay levels: after removing the effect of delay level by centering, the model's and subjects' prediction deviations are correlated at $\rho = 0.31$ (95% bootstrapped CI: $[0.25, 0.38]$, and significant at $p = 0.014$ in a mixed model with random intercepts and slopes by subject).

Discussion

We have demonstrated that human recall and prediction in a multi-context spatial memory task can be modeled by a Bayesian model that infers the latent contexts via nonparametric clustering. This model updates its beliefs *online*, one observation at a time, with Sequential Monte Carlo. Exploring a range of parameters for the state transition prior, we found that subjects recall behavior is best captured with high "stickiness" (prior probability of remaining in the same cluster) and low concentration (prior probability of creating a new cluster). Together, this suggests that people expect—

until they receive evidence to the contrary—that contexts will continue for a number of trials, and that old contexts will return in the future.

While we treated these parameters as free when fitting our model, this was merely a simplifying assumption that we made to make the model easier to implement. It is possible—and conceptually fairly straightforward in a Bayesian model like this—that they could be *inferred* from the same data that the model uses to infer the contexts themselves. It is thus possible that our interpretation of what these parameter values mean for people's expectations about the latent cluster structure actually reflect what people have *learned* from their experience in this particular experiment, where contexts *do* tend to go on for a number of trials and recur multiple times (at least for the central cluster). Future work is required to tease these possibilities apart.

The possibility that people might be inferring the hyperparameters that govern how contexts change raises the question of what kind of changes people expect in the structure of contexts across environments. That is, are people's models of contexts nested hierarchically, in a way that allows for variation not only in the specific features of each context (e.g., the location of dots in space) but also the properties of how contexts *change* within a larger context/environment (e.g., the stickiness of contexts)? This calls for future experiments that manipulate the generative model for the contexts themselves, within subjects and over time.

More work is also needed to assess whether people actually are remembering and revisiting old contexts, as our model assumes. It is possible that people are really just detecting *changes* in context, and creating a fresh representation of a context every time they detect such a change. One way to address this is by simulating such a change-point model, which is the limiting case of our model when the concentration parameter α goes to infinity. Another way is to collect more empirical data with changes in context explicitly designed to elicit anticipation for returning to old contexts.

Finally, the strategy of our model—inferring discrete changes in context and remembering contexts—presupposes a particular underlying structure for how contexts actually tend to change in the world. A number of different strategies could be optimal, given different environments, and it is an ecological question as to which strategies are likely to be useful in the kinds of environments people tend to find themselves in. For instance, environments where latent variables don't change suddenly but rather drift slowly and continuously call for a very different family of strategies. So while our model describes behavior well in *this* particular experimental environment, that does not necessarily mean that it would also describe behavior well in an environment that does not follow the structural assumptions that the model makes.

Conclusion

In a structured world, local context—either simultaneous or temporally extended—can provide a great deal of information about how to interpret or remember stimuli. We have proposed a Bayesian model that infers latent context variables from unlabeled data, and uses that context to encode and retrieve information from memory. This model processes data *online*, one observation at a time, and captures people's behavior in a multi-context spatial memory task.

Abstract

Recently, cognitive science researchers have revealed that human cognition involves the body and is a kind of self-organization phenomenon emerging from dynamic interaction across body-brain-environment. Some of the data obtained from such cognitive, behavioral, or physiological activities are often complicated in terms of non-stationarity and nonlinearity. Researchers have proposed several analytical tools and frameworks. *Recurrence analysis* is one of the nonlinear data analyses developed in nonlinear dynamics. It has been applied to various research fields, including cognitive science, for language (categorical) data or motion (continuous) data. However, most previous studies have applied recurrence methods individually to categorical or continuous data. We aimed to integrate these methods to investigate the relationship between speech (categorical) and motion (continuous) directly. To do so, we added temporal information (a time stamp) to categorical data and applied the joint recurrence analysis methods to visualize and quantify speech-motion coordination during a rap performance. Our pilot study suggested the possibility of visualizing and quantifying it.

Keywords: Visualization; Quantification; Recurrence Analysis; Speech-Motion Coordination; Rap

Introduction

Cognition as a Self-Organizing Phenomenon

Recent studies have revealed, theoretically and empirically, that we cannot separate cognition from the body and its environment, which are interdependent (e.g., Anderson, Richardson, & Chemero, 2012; Riley, Shockley, & Van Orden, 2012). This notion is called *embodiment*. From the viewpoint of embodiment, cognitive processes related to language and communication interact with bodily motion and behavior (e.g., Richardson, Dale, & Shockley, 2008; Shockley, Richardson, & Dale, 2009). We can consider cognition to be a complex phenomenon that emerges from the body-brain-environment interaction (e.g., Dale, Fusaroli, Duran, & Richardson, 2013; Richardson, Dale, & Marsh, 2014).

Research has shown that the body is not only connected to cognitive processes, but also to linguistic processes. Since McNeill (1992) found the significant relationship between gestures and speech, both in production and comprehension, the number of studies on co-speech gestures has increased. Previous research has shown that co-speech gestures facilitate the speaker's speech process. For example, when participants were asked to not move their hands while speaking, the proportion of unfilled pauses (Graham & Heywood, 1975) or fillers (Rauscher, Krauss, & Chen, 1996) increased. These findings suggest that speech is closely linked to meaningful hand movements.

To deal with such a complex phenomenon, the *dynamical systems approach* (DSA) has been widely applied to human movement science, developmental psychology, and cognitive science. Compared to the traditional approach, assuming internal computation in the brain, DSA focuses more on interactions between the body (including the brain), environment, and task. The DSA has provided both a theoretical framework and analytical tools based on the nonlinear dynamics theory (e.g., Van Orden & Riley, 2005).

Visualization and Quantification

Recurrence Plot (RP): A RP is a two-dimensional graph visualizing recurring patterns of dynamical systems, in which the matrix elements correspond to those times at which a state of a dynamical system recurs in the phase space (Marwan, Carmen Romano, Thiel, & Kurths, 2007). It is an advanced technique of nonlinear data analysis and was originally developed in the fields of descriptive statistics and chaos theory (Eckmann, Kamphorst, & Ruelle, 1987).

Recurrence Quantification Analysis (RQA): RQA is a method of nonlinear data analysis that quantifies the number and duration of recurrences of a dynamical system (Marwan et al., 2007). It was originally developed to uncover subtle time correlations and repetitions of patterns, and is relatively free of assumptions about data size and distribution (Zbilut & Webber, 1992). RQA can provide researchers with some useful measures to quantify self-organizing dynamical system behavior.

RP and RQA have been applied to both continuous data, for example, a numeric value obtained by sensor devices, and categorical data, for example, a letter or word sequence in

literature pieces (Coco & Dale, 2014). However, most previous studies have applied these recurrence methods (categorical or continuous) separately. We aimed to integrate the two within the same recurrence analytical framework in order to visualize and quantify speech-action coordination/coupling.

For this purpose, we developed the *categorical recurrence analysis* and applied the *joint recurrence analysis* methods (see "Data Analysis" section under "Method"). If we can integrate these different types data within the same analytical framework, we are of the view that recurrence analysis can be extended widely to visualize and quantify various complex phenomena in cognitive science. As a first attempt to explore such a possibility, the current pilot study focused on a speech-motion coordination/coupling during a rap performance. Because rap or hip-hop music has a relatively obvious rhythm structure, and because mind-body coordination/coupling is important in rapping behavior, we assumed that this relationship would be relatively easy to extract using recurrence methods.

Method

Participants

A professional rapper (male, 30 years old, right-handed) participated in our experiment. He has more than 15 years of rapping experience and was the champion of a national freestyle rap battle. He has also released his tunes as a professional musician. The participant signed an informed consent form, agreeing to participate in this study.

Apparatus

We used a 3D motion capture system (OptiTrack Flex13, Natural Point, Inc.) to measure the participant's body movements (sampling frequency was 120 Hz) (Figure 1). Twelve reflective markers were attached to the participant's body (head, both shoulders, both elbows, both wrists, hip, both knees, and both toes). We used Motive (Natural Point) to process the time series data, MATLAB (R2017b, MathWorks) and RStudio (1.1.423) to analyze the data. We also used a video camera (HDR-PJ720, Sony) (frame rate of 50 FPS) and a headset microphone (Hafone). To analyze the audio data, we used Audiacity (2.2.2) after down-sampling at 25 FPS.

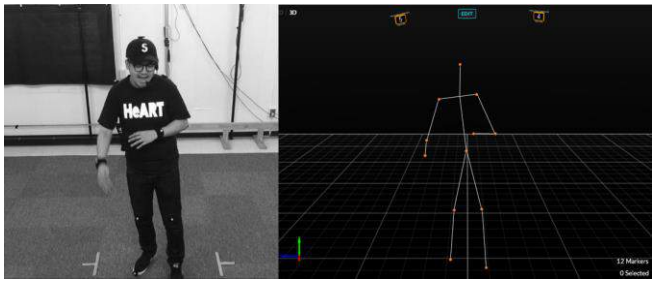

Figure 1: An experimental situation and the motion capture system.

Procedure

We required a professional rapper to perform parts of his rap song, which included an Introduction, Verse, and Hook (totaling one minute). Before recording, we attached twelve reflective markers and a microphone to his body, and we asked him to stand in front of the camera. We then instructed him to perform naturally, as if he were presenting a live performance. After sound checking, we started the recording. In this presentation, we report the results of our analysis of part of the tune (from the first Verse and Hook).

Data Analysis

To visualize and quantify the rhythmic structure and coordinated behavior between the rap (speech) and body movement (motion), we applied *recurrence analyses* (for tutorials, refer to Wallot, 2017; Webber & Zbilut, 2005). We briefly describe these recurrence methods, and we introduce the *joint recurrence method* (Marwan et al., 2007) to integrate them as described in the following paragraph.

In the case of continuous data, time series data are embedded, their trajectory is reconstructed in a higher dimensional phase space, and the distances between all possible combinations of each vector are calculated and distributed within a distance matrix (Webber & Zbilut, 2005). All elements in the distance matrix with distances at or below the threshold (i.e., radius) are said to be *recurrent* (recurrence point) and are included in the recurrence matrix, while all other elements are excluded from it. Such calculations and definitions are used to construct a *recurrence plot* (RP), a method of visualization that shows the dynamic properties and temporal patterns of the system as a two-dimensional representation (Eckmann et al., 1987). A *recurrence quantification analysis* (RQA) allows researchers to quantify and assess the properties of a dynamical system, based on RP or the phase space trajectory (more detail in Webber & Zbilut, 2005). This study reported four RQA measures, namely, the *recurrence rate* (***RR***), *percent determinism* (***DET***), *maxline* (***maxL***) and *mean line* (***L***). ***RR*** is the density (percentage) of recurrence points in a RP; ***DET*** is the percentage of recurrence points forming diagonal lines in the recurrence plot given a minimal length threshold; ***maxL*** is the length of the longest diagonal line; ***L*** is the average of the diagonal line's length (Coco & Dale, 2014). The units of these lines are indicated in time (e.g., seconds). If the length of these lines is long, it means that the system repeats the same state persistently for a long time. These measures have been interpreted as indexes related to stability or complexity of human motor/posture systems (e.g., Pellecchia, Shockley, & Turvey, 2005; Riley, Balasubramaniam, & Turvey, 1999).

In this study, we used only the hip and right wrist movements data in a vertical direction as continuous data (a collective marker of whole-body movement at the macro scale and a specific marker of rap-related rhythmic movement at the micro scale, respectively). After each time series was smoothed, it was then down-sampled at 25 Hz to integrate it with the categorical data.

In the case of categorical data, researchers generally need not to embed the data in a phase space, but to define the level or unit of analysis (e.g., a word or letter). Each unit is converted into numeric categorical sequence (e.g., 1, 2, 3, …). Researchers can create a recurrence point when the two series (original and self-copied sequential series) share the same state (i.e., the same word/letter) in time. Thus, the same RQA measures can be calculated and they provide meaningful indexes that can be considered *dynamic natural language processing*; for example, ***DET*** and ***RR*** are associated with *compressibility ration* and *co-occurrence* respectively (Dale, Duran, & Coco, 2018).

We obtained sequential data by analyzing the lyrics and converting each voice unit into a Japanese vowel (*a/i/u/e/o*), a syllabic nasal (*n*), or an assimilated sound (*x*). We chose a vowel as a main unit of analysis, because rap lyrics tend to rhyme (match rhyming words at vowel level) more often in hip-hop music, generally. We then categorized vowels into numbers as follows: *a*(1), *i*(2), *u*(3), *e*(4), *o*(5), *n*(6) and *x*(7). To analyze the audio data, we imported the audio file into a software, played the voice at each frame (25 FPS), and judged how the voice sounded. If there was no voice, we categorized the frame into *no-voice* (0); If there was a voice, we categorized it according to each vowel, a syllabic nasal, or an assimilated sound as described above (1, 2, 3, 4, 5, 6, 7). After categorization, we obtained two categorical data: first, sequential data of seven categories without any time information, and, second, time series data that included temporal information (i.e., a time stamp at 25 Hz) using eight categories from 0 to 7, as shown above.

Most previous studies have applied these recurrence methods (categorical or continuous) separately, but we integrated them within the same recurrence analytical framework in order to visualize and quantify speech-action coordination/coupling. For this purpose, we developed categorical recurrence analysis by adding temporal information (i.e., a time stamp) and applied the joint recurrence method.

The *joint recurrence analysis* was used to analyze two physically different time series (Marwan et al., 2007). A joint recurrence point can be considered as joint probability in which both systems have simultaneous recurrence points (more detail in Marwan et al., 2007). A *joint recurrence plot* (JRP) is a graph that shows all those times at which a recurrence in one dynamical system occurs simultaneously with a recurrence in a second dynamical system. In other words, the JRP is the Hadamard product of the recurrence plot of two systems (Marwan et al., 2007). JRPs capture the commonalities between two systems (i.e., signals or time series) as coinciding instances of recurrence between the individual RPs of those systems (Wallot, Roepstorff, & Mønster, 2016). First, each RP is constructed for each system, then their JRP can be computed by joining the plots together, so that common instances of recurrences are kept, but different instances between the two RPs are discarded (Wallot et al., 2016). JRQA measures such as ***RR*** and ***maxL*** as explained above (in **Data Analysis**) can be calculated from the JRP in the same way as auto/cross RQA. Originally, the joint method was proposed for two continuous time series, which can recur simultaneously in their individually reconstructed phase spaces, to compare two physically different systems at different units or dimensions. We extended this to compare continuous (motion) data with categorical data (rap).

We performed recurrence analyses using the MATLAB toolbox "CRP TOOLBOX," version 5.22 (Marwan & Kurths, 2002), and the R package "crqa," version 1.0.9 (Coco & Dale, 2014). We determined the optimal values for input parameters with reference to the standard guidelines for the RQA method (Webber & Zbilut, 2005) using *average mutual information* for determining the delay and *false nearest neighbor method* for determining the dimension (e.g., Marwan et al., 2007). As a result, for continuous data, we chose parameters of 10 for time delay, 3 for embedding dimensions, and 0.75 for the radius with *z-score* normalization, while for categorical data, we input 1 for time delay and embedding dimensions, and .001 for the radius.

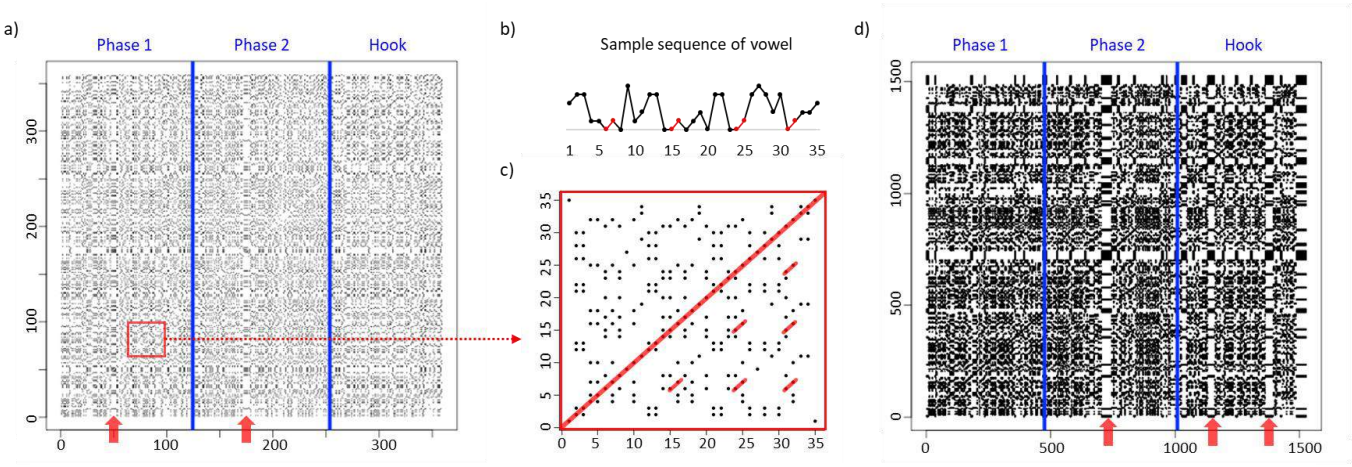

Figure 2: Categorical recurrence plot (CaRP) of rap.
a) Standard CaRP, b) Sample sequence of vowel, c) Part of CaRP, d) Proposed CaRP

Results and Discussion

Categorical Recurrence Plot: Rap Data

Figure 2a shows the categorical RP (CaRP) of the lyrics of the current rap song generated by the standard procedure (with neither temporal information nor a time stamp). Here, we report the partial result of analysis of the tune, the first Verse and the Hook. We indicated three phases consisting of the first part of the Verse (Phase 1), the latter part of the Verse (Phase 2), and the Hook by adding two blue lines (see Figure 2a). Using vowels as a unit of analysis, the lyric consisted of 359 units (Phase 1: 124, Phase 2: 129, Hook: 106). The CaRP does not have random dots, but a structured pattern across the phases. The white bands observed in Phase 1 and Phase 2 (red arrows in Figure 2a) visually represent successive vowels, then a constant value (i.e., "*a*" repeated four or five times).

Figure 2b presents a sample sequence of vowel units, while Figure 2c shows its CaRP, extracted from Figure 2a (red square). Red circle markers in Figure 2b indicate repetition (i.e., rhyming) of the same vowel units (i.e., *a*-*i*) four times in part of the lyric. The same part appears in Figure 2c as red lines parallel to the diagonal line in the center of CaRP. These parallel diagonal line structures can be interpreted as a rhyming structure, which appeared temporally. These results suggest that CaRP can provide a visualization of rhyming structure in musical lyrics.

Figure 2d presents the proposed CaRP with temporal information (i.e., a time stamp at 25 FPS). It has 1527 points (25 Hz, approximately 60 seconds) including vowels and a no-voice zero value. Accordingly, it is possible that the same value (e.g., "*a*") can appear successively; for example, "*a*" can repeat 25 times if the voice stays for one second. By adding such temporal information as a time stamp, we integrated categorical data with continuous data within the same framework (joint recurrence analysis), as discussed below. This new method seems to provide a more obvious structured pattern than the standard method, comparing Figure 2d and Figure 2a. For example, the transition point where the phase changed, or which was a *break* and *pause* in the tune, can be observed as a white band that indicates a no-voice state (red arrows in Figure 1d). These characteristics seem to express the original music (rap performance) and its temporal structure more clearly.

Our results show that CaRPs can extract a repetitive structure or recurrence pattern of the lyric and rap performance. Our proposed method can visualize the RPs in a more informative way by including temporal information. In the future, quantification and analytical indexes of rhyming structure should be explored.

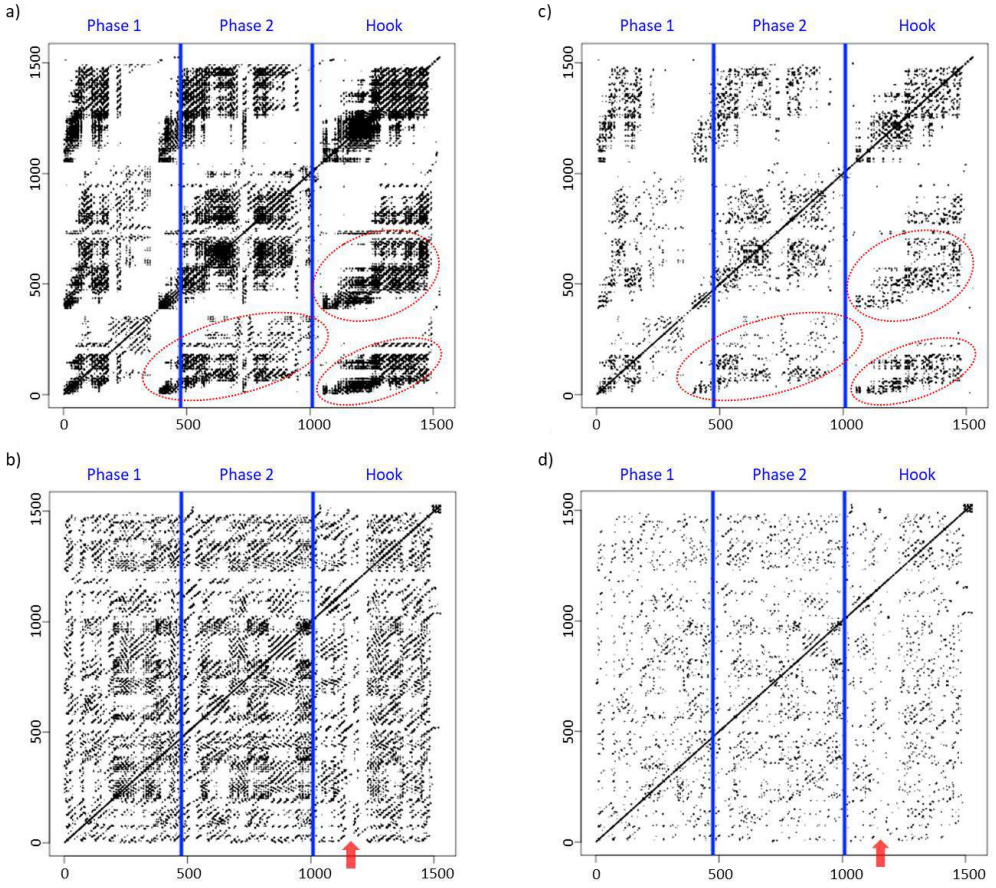

Figure 3: Continuous recurrence plot (CoRP) of rap and Joint recurrence plot (JRP).
a) CoRP of hip, b) CoRP of hand, c) JRP of rap-hip, d) JRP of rap-hand

Continuous Recurrence Plot: Motion Data

Figure 3a represents the continuous RP (CoRP) of hip motion in the vertical direction. Blue lines separate the phases again. We assumed that the vertical hip motion could represent whole-body rhythm. The CoRP shows a recurrence pattern at the macro level, but not random dots. Interestingly, a white band can be observed at the center of the CoRP like the proposed CaRP (the first red arrow in Figure 2d). We could observe the change in bodily rhythm at this break point in the actual video data. In each phase, recurrence points are shown as a whole-body beat rhythm repeatedly. Furthermore, a similar recurrence structure can be found in the red areas (i.e., Phase 1-Phase 2, Phase 1-Hook, and Phase 2-Hook). These results suggest that the participant beat out a rhythm with whole-body movement and that similar/common rhythm patterns can be found across the phases.

Figure 3b shows the CoRP of hand (i.e., right wrist) motion in the vertical direction. Blue lines separate the phases again. We chose the right wrist marker motion for analysis, because the participant was right-handed and showed specific hand movements, such as beating or gesturing, during the rap performance. Compared with hip motion, hand motion seemed to be more closely related to rap performance and to have a high frequency. As a result, its RP (Figure 3b) shows a more detailed recurrence pattern at the micro level than that in Figure 3a. The white band in Hook phase (red arrow) corresponded to no-voice part, and the right hand stopped at this moment.

Joint Recurrence Plot

Figure 3c and Figure 3d depict the joint RP (JRP) of rap-hip coordination and rap-hand (i.e., right wrist) coordination. Blue lines separate the phases again. Compared to the CoRP of hip motion (Figure 3a), the JRP of rap-hip coordination seems to hold a common recurrence pattern at the macro level (red circles in Figure 3c). This suggests that the whole-body rhythm was coupled with rap rhythm. Similarly, the JRP of rap-hand coordination (Figure 3d) seems to hold a common recurrence pattern with the RP of hand motion at the micro level (Figure 3b). This can also be considered rap-hand coupling. These results indicate that JRPs can visualize speech-motion coordination/coupling during rap performance.

Recurrence Quantification Analysis

Table 1 shows the RQA measures quantified from each RP.

Categorical RQA: The proposed method provided higher values in ***DET*** and ***maxL*** than the standard method. This came as a result of adding temporal information at 25 Hz, because it can realize successive value.

Continuous RQA: The total hip RQA measures were higher than hand RQA measures. These results suggest that the participant maintained a stable whole-body rhythm, although he moved his dominant hand rhythmically, but in a complicated manner, synchronizing with the rap lyric and beat during rap performance. To address this possibility, the relationship between hand movement (e.g., gesture) and rap lyrics can be researched in more detail in future studies.

Joint RQA: While ***RR*** and ***DET*** were higher in rap-hip coordination than in rap-hand coordination, interestingly, ***maxL*** was higher in rap-hand coordination than in rap-hip coordination. This suggests that hand movement is likely to couple with rap performance more sustainably and is involved in the content of the lyrics. We found that the right hand of the participant seemed to express the lyric contents, match with the rap tempo (e.g., beating rhythm) and correlate with rapping.

Table 1: Recurrence quantification analysis measures.

	Rap standard	**Rap** proposed	**Hip** vertical	**Wrist** vertical	**Joint** rap-hip	**Joint** rap-hand
RR	19.68	17.22	7.91	3.77	1.68	0.79
DET	36.20	91.85	94.23	76.89	76.84	61.35
maxL	18	60	435	229	16	35
L	2.28	3.74	4.35	2.88	2.82	2.66

General Discussion

In this report, we introduced temporal information (i.e., a time stamp) to the standard categorical recurrence analysis. We showed the possibility of revealing the lyrical structure and the temporal structure (i.e., rhythm) of rapping (singing) or beat (music) itself more clearly. Furthermore, we applied the joint recurrence method to integrate categorical data (rap) with continuous data (bodily motion). By employing such integration, we showed the applicability of the joint recurrence method to the investigation of the speech-motion coordination/coupling and suggested the possibility of visualizing and quantifying it.

Our current pilot study focused on hip-hop music, a music genre that has a relatively obvious rhythm and a repetitive/recurring structure (i.e., rhyme) in its lyrics, which helped us to investigate speech-motion relationship. We guessed that this relationship would be relatively easy to extract using the joint RP and RQA. Some similarities between rap dynamics and motion dynamics were found because common auditory information (i.e., a musical track) might affect these dynamics.

Future Direction

Given that we analyzed only one sample in this study, it needs to be confirmed whether our findings are robust by collecting and analyzing further data. If we could collect other rappers' data, it would be possible to compare original data to virtual pair data of rap-motion coordination/coupling generated from other rappers' performance data. This analysis would show that the current result was not produced by an artifact or possible random matching in terms of surrogate data method (e.g., Shockley, Baker, Richardson, & Fowler, 2007). It would heighten the applicability of the joint method that integrates categorical data (rap) with continuous data (motion). Although the present study focused on an intrapersonal coordination

between speech and motion, interpersonal coordination across participants can also be examined within the same framework as investigated by previous studies that have applied the recurrence analysis to various joint action tasks (e.g., Fusaroli, Konvalinka, & Wallot, 2014; Shockley & Riley, 2015). The proposed method should be applied to not only ready-made songs but also improvisational freestyle performance, including various music genres. Improvisational performance is more like everyday social interaction, in the sense that it also has complex aspects emerging from real-time interaction (Walton et al., 2018). The complex dynamical systems methods (e.g., recurrence analysis) are also expected to reveal the creative process in detail using more advanced techniques (e.g., the windowed sliding method; Coco & Dale, 2014; Kodama, Tanaka, Shimizu, Hori, & Matsui, 2018). We also aim to apply the framework not only to experimental situations but also to more ecological situations, such as the practical field of artistic performance, and daily natural conversations involving speech-motion coordination in the future (D'Ausilio, Novembre, Fadiga, & Keller, 2015; Sekine & Kita, 2015; Shimizu & Okada, 2018).

Acknowledgments

We would like to thank Prof. Rick Dale for providing us with meaningful advice and the useful R code to conduct the joint recurrence analyses. We are also grateful to two Japanese professional rappers, Darthreider and TKdakurobuchi, for collaborating with us and participating in our experiment.

Abstract

We present a novel method for constructing neurally implemented spatial representations that we show to be useful for building models of spatial cognition. This method represents continuous (i.e., real-valued) spaces using neurons, and identifies a set of operations for manipulating these representations. Specifically, we use "fractional binding" to construct "spatial semantic pointers" (SSPs) that we use to generate and manipulate representations of spatial maps encoding the positions of objects. We show how these representations can be transformed to answer queries about the location and identities of objects, move the relative or global position of items, and answer queries about regions of space, among other things. We demonstrate that the neural implementation in spiking networks of SSPs have similar accuracy and capacity as the mathematical ideal.

Keywords: Semantic Pointer Architecture; spatial semantic pointer; spatial representation; fractional binding; continuous spaces; spiking neural networks

Introduction

There is evidence for a wide variety of types of mental representation. Some mental representations are well-described using *discrete* structures (e.g., graphs, trees, lists, and so on). Others are well-described using *continuous* structures (e.g., images, maps, surfaces, and so on). Here we propose a kind of mental representation of continuous structures that is amenable to neural implementation.

Recently, there have been several proposals for how neural networks can represent discrete structures. One family of approaches, called Vector Symbolic Architectures (VSAs), defines algebras over high-dimensional vector spaces, and uses those algebras to encode such structures. VSAs have been used to characterize a variety of cognitive behaviours, including analogical reasoning (Plate, 1994), language processing (Jones & Mewhort, 2007), and concept encoding (Crawford et al., 2015). Most VSAs are defined over continuous vector spaces, including Multiply Add Permute (MAP; Gayler, 2004), Holographic Reduced Representations (HRR; Plate, 1995), and Vector-derived Transformation Binding (VTB; Gosmann, 2018). When VSAs are used to model cognitive behaviours, they essentially define methods for characterizing continuous vectors as both slots and fillers and define a method of binding fillers to slots.

In this work, we will use the Semantic Pointer Architecture (SPA; Eliasmith, 2013), which proposes a means of neurally implementing VSAs for explaining cognitive behaviour in biologically plausible spiking networks. This architecture uses aspects of VSAs for cognitive representation, but the SPA also addresses visual processing, motor control, memory, decision making, and cognitive control in ways that do not use VSAs. However, all of these elements of the SPA use representations called semantic pointers (SPs), which result from compressing and decompressing information in cortex. As a result, we can think of VSA algebras as proposing a family of compression operators that are well-suited for certain cognitive tasks.

However, as with most uses of VSAs, in past work the SPA addresses cognitive tasks with a focus on representations of discrete structures (i.e., discrete slots in a represented structure). Here we propose a method for encoding cognitive structures over continuous spaces. We call this kind of representation "spatial semantic pointers" (SSPs). In this paper we propose and examine in some detail a specific kind of SSP implemented using a particular "fractional binding" operator to encode real-valued quantities – although a variety of other operators can be analogously defined.

In the remainder of the paper we provide a mathematical definition of SSPs, and show how SSPs can provide a natural means of generating and manipulating representations that are useful for spatial cognition. We identify desiderata for spatial representation that are useful for cognitive explanations. We then implement this representation both mathematically and neurally, and perform simulation experiments to demonstrate that it has a variety of useful properties, including: being able to query a memory for its spatial or non-spatial contents, representing multiple objects and locations simultaneously, spatially transforming memory contents without decoding them, and representing regions of space of various shapes and sizes. The choice of VSA and binding operator used in this work allows the representation and various transformations to be implemented efficiently by a spiking neural network.

A spatial representation

Our proposed representation generalizes the notion of vector binding to continuous spaces. By analogy to fractional powers defining the multiplication of reals, we define fractional bindings for vectors in a vector space. To explain, let us first consider binding a vector to itself a discrete number of times. That is, let $k \in \mathbb{N}$ be a natural number, $B \in \mathbb{R}^d$ be a fixed d-dimensional vector (i.e., semantic pointer), and $\circledast$ be a binding operator. We can repeatedly bind B with itself $k-1$

times[1] as follows:

$$B^k = \underbrace{B \circledast B \circledast \ldots \circledast B}_{B \text{ appears } k \text{ times}}. \quad (1)$$

This representation has been used in several cognitive models, for instance, to encode the position (k) in a list in serial working memory (Choo & Eliasmith, 2010). We propose to generalize this to continuous quantities (as opposed to discrete lists, for example) by permitting k to be real. Allowing a real k means that the resulting vector B^k encodes a continuous quantity. Most VSA operators can be interpreted in this manner (including MAP (Gayler, 2004), VTB (Gosmann, 2018), and HRR (Plate, 1995)), but not all (e.g., spatter codes (Kanerva, 1994)).

In the specific case of the SPA, we take the binding operator to be circular convolution (as proposed by Plate) and the fixed d-dimensional vectors to be semantic pointers chosen from the unit sphere. We then define our fractional binding operation by expressing equation 1 in the complex domain:

$$B^k = \mathcal{F}^{-1}\left\{\mathcal{F}\{B\}^k\right\}, \quad k \in \mathbb{R}, \quad (2)$$

where $\mathcal{F}\{\cdot\}$ is the Fourier transform, and $\mathcal{F}\{B\}^k$ is an element-wise exponentiation of a complex vector—analogous to exponentiation using fractional powers (e.g., $b^{2.5}$)—permitting k to be real.[2] In the present paper, we use unitary vectors for B due to the fact that their length does not change with multiple bindings, and their inverse is equal to their approximate inverse (see below).

This definition comes with many useful algebraic properties analogous to the relationship between multiplication and exponentiation (e.g., $b^{2.5}b^{1.5} = b^4$), in particular:

$$B^{k_1} \circledast B^{k_2} = B^{k_1+k_2}, \quad k_1, k_2 \in \mathbb{R}. \quad (3)$$

In essence, fractional binding is to circular convolution as exponentiation is to multiplication. We exploit equation 3 to perform semantically meaningful operations (e.g., shifting space) in our experiments.

Next, we extend this representation to multiple dimensions, which is the focus of our experiments below. In general, we can represent points in $\mathbb{R}^n$ by repeating equation 2, n times, using a different semantic pointer for each represented dimension (i.e., for each axis), and then binding all of the resulting vectors together. For $n = 2$, we think of the representation as encoding a continuous 2-D spatial representation (e.g., the location of objects on a map). In this case, the SSP that represents the point (x, y) is defined as the vector resulting from the function:

$$S(x, y) = X^x \circledast Y^y, \quad (4)$$

where X and Y are fixed semantic pointers, x and y are reals, and we are using fractional binding as defined by equation 2.

Similarly, the SSP that represents a continuous region (e.g., a solid rectangle), specified by some infinite set of 2-D points R, is defined as:

$$S(R) = \int_{(x,y)\in R} X^x \circledast Y^y \, dx\, dy. \quad (5)$$

There are efficient ways to compute equations 4 and 5 with spiking neurons using the Neural Engineering Framework (NEF; Eliasmith & Anderson, 2003). We use a publicly-available implementation in several of our results below.

To represent a single object occupying some location or region, we bind its semantic pointer representation, OBJ, with the SSP from equation 4 or 5, respectively:

$$M = OBJ \circledast S. \quad (6)$$

In general, to represent a set of m labelled objects together in the same memory, we can use superposition:

$$M = \sum_{i=1}^{m} OBJ_i \circledast S_i, \quad (7)$$

with a distinct semantic pointer OBJ_i tagging each object.

Given a representation like that in equation 7, we can query it in a number of ways. For example, to determine what object is at location (x, y) we can compute:

$$M \circledast (X^x \circledast Y^y)^{-1} = M \circledast X^{-x} \circledast Y^{-y}. \quad (8)$$

By the properties of binding and superposition, the resulting vector will have highest cosine similarity (i.e., dot product) with the object at (x, y).[3] Note that the inverse used in equation 8 is approximate, but choosing X and Y to be unitary vectors guarantees it is equal to the true inverse.

We can construct a heatmap of representations defined by equation 7, to visualize a decoding of the objects back into the original continuous space. For instance, for $m = 2$ (i.e., two represented objects), taking the dot product of $M \circledast OBJ_i^{-1}$ (M is from equation 7) with vectors representing positions spaced by Δx and Δy to tile the 2-D space, provides the visualization of Figure 1.

In summary, fractional binding provides a scheme for encoding a set of n-dimensional points into a d-dimensional SSP. This comes with an algebra for operating on these SSPs in meaningful ways (e.g., querying, shifting, and so on). When combined with the methods of the SPA, we can spatially manipulate collections of objects in a spiking neural implementation, as detailed in our experiments below.

Desiderata for spatial representation

To test if the proposed metric representation is useful, we consider its ability to be used in a variety of ways for representing, querying, and updating representations of objects in a spatial map. Here we describe the tests we perform, and in the next section we present the results of these tests.

[1] When $k = 0$ we get the identity vector corresponding to $\circledast$.

[2] For natural k, equations 1 and 2 are mathematically equivalent.

[3] This assumes d is sufficiently large, relative to m, as is typical for VSAs.

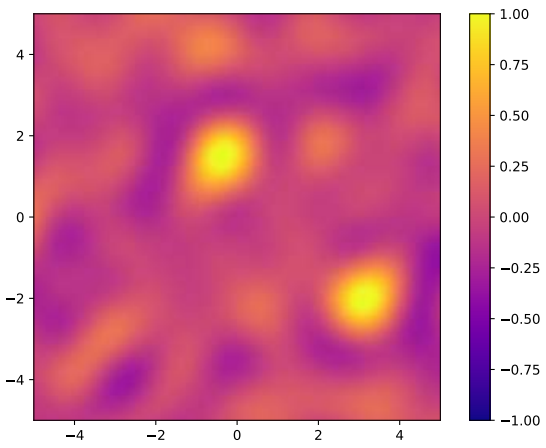

Figure 1: A heatmap visualizing the representation of two objects at different locations, as specified by equation 7. This graph is the sum of the decoding for each object.

The proposed desiderata for manipulating 2-D spatial representations are identified and briefly described in Table 1. In this table, M refers to the representation generated as described in the previous section.

Example queries

To illustrate the application of representing objects at continuous spatial locations using SSPs we demonstrate a variety of example queries in Figure 2. A set of animals (items) at random spatial locations are encoded into an SSP using equation 7 as shown in Figure 2a. This is accomplished by binding the SP representing each object with the SSP corresponding to its location, summing these values together, and then normalizing the result.

Various queries can be made with this representation. Figure 2c (top) shows the results of asking for the locations of different objects, decoded as a heatmap. If the object exists at more than one location, the resulting SSP will be highly similar to all of these locations (image on the left). If the object does not exist at any location, the resulting SSP will not be similar to any location on the heatmap (image on the right). Figure 2c (bottom) shows the reverse is possible too: given a location, find out which objects are at that location. If there are no objects at the queried location, the result will be noise and will not be similar to any object in the vocabulary (as shown in the far right).

Location queries can also be extended to regions of space, as shown in Figure 2b. If the region encompasses multiple objects, all objects should be returned, as depicted by the bar charts at the bottom. The region semantic pointers themselves are a single vector that is formed by integrating over the spatial semantic pointers within the region and normalizing the result, as described by equation 5. This process creates a vector that has a high dot product similarity with all vectors within a particular area while having a low dot product with vectors outside the region. Two example represented regions are illustrated in the heatmaps at the top of the figure. It is important to note that due to the normalization, the dot product with the region vector and a single point within the region will decrease as the area of the region increases. The consequence of this fact is that the optimal threshold for detection is a function of the area.

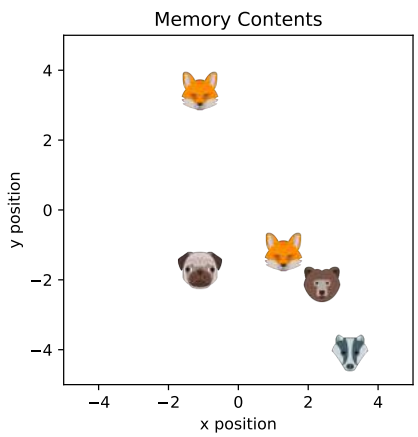
Desiderata	Description
Capacity	Determine how many objects can be encoded into M and a target object successfully decoded.
Query single object	Find the location of an object given the object and M.
Query missing object	Indicate if an object is not present when queried.
Query location	Determine what object is at a given location.
Query duplicate object	Determine the positions of multiple versions of the same object.
Neural implementation	Implement the operations in spiking neurons.
Region representation	Represent an entire region in the 2-D space.
Query Region	Determine which objects are in a spatial region.
Shift single object in group	Change the position of a single object without decoding M.
Shift whole group	Change the position of all objects in M similarly.
Readout (x,y) location from SSP	Map from the SSP representation to the 2-D space.

Table 1: Desiderata for metric representations of space.

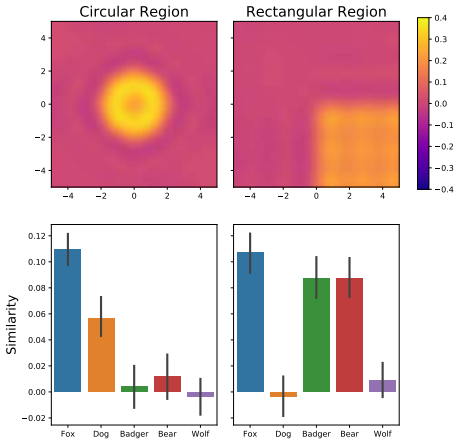
Experimental methods

To quantify how well this spatial representation performs in general for each of the desideratum a consistent measure must be used. In this paper we chose to use the accuracy of the output. When the output is a semantic pointer for an object, it is considered correct if its vector is more similar to the vector for the correct object than any other vector from a vocabulary of objects. Vocabularies are randomly generated semantic pointers of between 4 and 48 items, as described below. Similarity is determined by taking the dot product between vectors, with a larger value corresponding to a better match. When the output is a semantic pointer for a location, it is considered correct when the represented location is within 0.5 units of the true location. This threshold is chosen because it is approximately the radius of the region of similarity that a spatial semantic pointer has around itself.

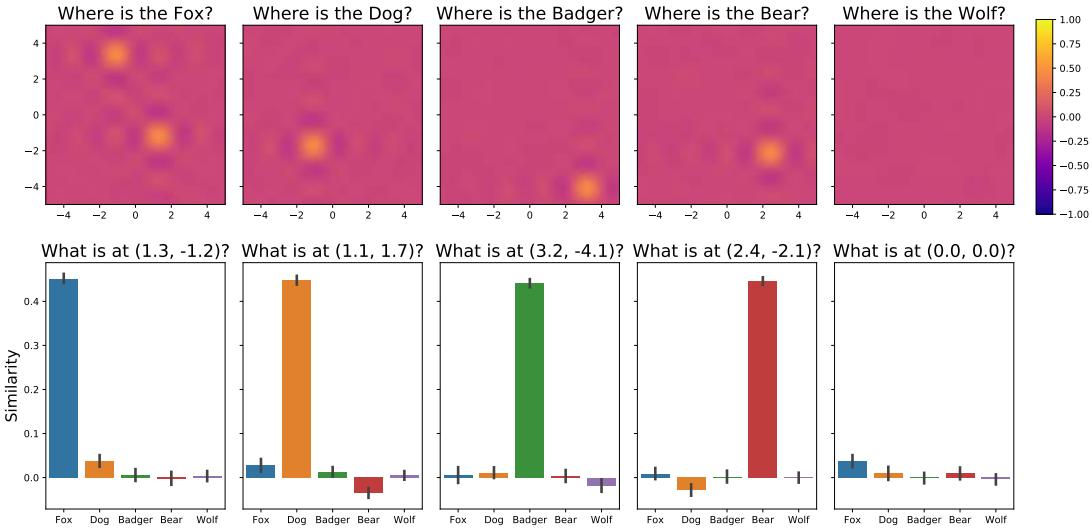
The capacity calculation requires identifying a threshold



(a) Memory contents



(b) Region queries



(c) Location and item queries

Figure 2: Example queries of items, locations, and regions. a) An example memory encoded into an SSP. b) Region queries applied to the memory in (a). c) Object (top) and location (bottom) queries applied to the memory in (a).

above which an item is identified as present in the representation. For this purpose we pick a threshold that is 3 sigma above the mean, ensuring a 99.7% chance of accepting only correct items.

For our capacity tests, we experiment with a dimensionality of 128, 256, and 512, and observe the overall effect on performance. In all other tests we fix the number of dimensions to 512, which we have found achieves good performance across a wide variety of tasks in both spiking and non-spiking regimes.

For each desideratum, accuracy reported is the mean across 6,000 trials with memory sizes varying uniformly between 2 and 24 items. For each trial the vocabulary of objects is chosen to be twice the number of objects encoded into memory (i.e., 4 to 48).

Each object is assigned a random unitary vector. All semantic pointers used in each task are normalized after every operation. All 2-D coordinates used in the experiments are chosen uniformly at random within the domain of -5 to 5 for both x and y. The size of the domain in relation to the dimensionality of the semantic pointers determines the ideal level of performance (not shown).

Query single object Equation 9 is used to produce an SSP representing the location of the desired object. Accuracy is computed by decoding this high-dimensional vector, S, into the 2-D coordinate it represents and comparing to the true location.

$$S = M \circledast OBJ^{-1}. \tag{9}$$

Query missing object Given a memory containing objects, query an object that does not exist (using equation 9). The correct behaviour is a result that is highly dissimilar to all

locations within the domain of interest. This is determined by the dot product of S and every SSP being less than 0.1.

Query duplicate object Given a memory containing many objects with some duplicates, query an object that appears twice. The correct behaviour is to return a spatial semantic pointer that represents both locations of this object.

Query location Use equation 8 with the location for one of the objects in memory. The correct behaviour is to return a semantic pointer for the object at that location.

Query region On each trial a circular region is created with a radius between 1 and 3 units and centered at a random location. An SSP is constructed for this region using equation 5. The inverse of this SSP is convolved with the memory to obtain a semantic pointer representing all objects in the region. Accuracy is computed by adding the number of objects correctly detected in the region to the number of objects correctly not detected from outside the region and then dividing by the total number of objects in the memory.

Shift single object in group Moving a single object within a group can be accomplished by adding the object of interest convolved with a vector that is the difference between the start and end positions, as shown in equation 10. Accuracy is reported for all objects as well as just the object that was moved.

$$\Delta M = OBJ \circledast \Delta S. \tag{10}$$

Shift whole group The memory is convolved with an SSP that corresponds to a random displacement, which leverages the property of equation 3. An object query is then performed for each object in the memory and the result is considered correct if it moved by the displacement amount. A heatmap visualizing the result of the two shifting operations is shown in Figure 3 for a group of three identical objects.

Readout (x,y) location from SSP For the non-neural case location is extracted from the maximum point in the heatmap. In spiking neurons a heteroassociative memory is optimized to map from a 512-dimensional SSP to a 2-D location.

Construct SSP from (x,y) location This can be computed directly from equation 4. For the experiment using spiking neurons each axis is first computed separately and then convolved together.

All experiments were repeated using networks of leaky integrate-and-fire (LIF) neurons and the NEF to implement the necessary transformations. In all trials 50 neurons were used per dimension to represent the memory and to compute circular convolutions.

Results

The results of the experiments for each of the desideratum are shown in Table 2.[4] As can be seen from the table, the SSP representation is able to address the desiderata quite well, both in purely mathematical and neural implementations. The worst performance is evident in the shifting of a single object in a group. Specifically, the accuracy of the representation for the objects that were not shifted decreases, while the accuracy for the shifted object increases. This is due to normalization effects making the moved object be re-encoded with a larger relative magnitude than the rest of the items. Using a scaling factor proportional to the number of items in the memory mitigates this effect (improves accuracy from 75.7% to 97.8%), but in general the number of items within a memory is not always known without first retrieving items from memory, and equation 10 is agnostic to the other contents of the memory.

To better characterize the capacity of a single memory using this representation we performed queries on memories with progressively larger numbers of items encoded (see Figure 4). The shape of the curve is very similar for both location and object queries since the decrease in the dot product is mostly a result of the normalization of the memory to a unit vector. The standard deviation for the dot product of two

Table 2: Experiments for the desiderata for metric representations of space. Accuracy is calculated using SSP representations containing 2 to 24 items. When the output is a location, it is considered correct when the result is within 0.5 units of the true location.

[4] All source code required to reproduce these experiments and generate the figures is available at https://github.com/ctn-waterloo/cogsci2019-ssp.

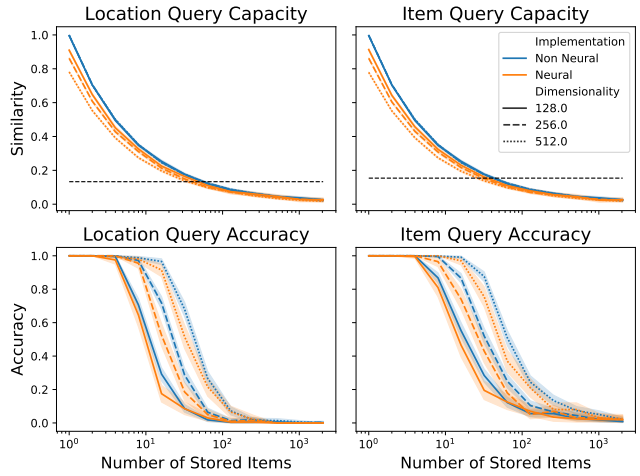

Figure 4: Memory capacity and accuracy as a function of the number of items in the SSP for ideal and neural implementations while varying the dimensionality. Top panels show the item and location capacity. Bottom panels show the item and location accuracy.

random vectors in a unit hypersphere is $\sqrt{1/D}$ where D is the dimensionality of the space. The mean is zero, so for 512 dimensions this results in a 3-sigma threshold similarity of 0.133. SSPs that represent coordinates within a finite domain will span a smaller subspace of the hypersphere, so their threshold will be a little higher. Specifically, we estimated the threshold by generating 10,000 random SSPs from a 10×10 2-D domain and computing the dot product between every pair. The mean is approximately zero, and three standard deviations is 0.154. Consequently 99.7% of queries will be above this value for items actually in the memory. The accuracy plots show the importance of dimensionality on accuracy of decoding memories.

Discussion

We have proposed a novel neural representation, SSPs, for encoding structured continuous spaces using fractional binding. We have demonstrated that these representations satisfy desiderata for representations that are useful for spatial cognition. By implementing these methods at the level of spiking neurons, this work enables future exploration of tradeoffs between neural constraints and performance for tasks of increasing complexity. In addition, a spiking neural implementation serves as a prerequisite for constructing dynamical models of spatial cognition that operate sparsely over time and in an event-driven manner.

SSPs have many potential applications for modelling cognitive phenomena that involve spatial reasoning over time, such as path planning and navigation. Objects that a cognitive agent encounters while traversing a space can be stored in memory in such a way that their relative distances and directions from each other are preserved.

The extension of Vector Symbolic Architectures to continuous representation presented in this work is not limited to representing physical space. Any continuous dimension over which concepts may vary (e.g., mass, colour, value, and so on) can utilize this representation.

While we have explored some of the capacity and accuracy limitations of this representation, it is important to note that the effective capacity can likely be increased by hierarchically chunking items into groups when encoding them into the memory by using a similar technique as the method demonstrated in Crawford et al. (2015).

Areas of future work include exploring the theoretical foundations of this method to improve our understanding of its strengths and limitations. As well, there remain many questions regarding how well a cognitive model using these representations can scale and how well the behaviour and neural recordings from such a model match that of animals.

The trajectory of counterfactual simulation in development

Abstract

Previous work has argued that young children do not answer counterfactual questions (e.g. "what would have happened?") by constructing simulations of alternative possibilities in the way adults do. Here, we propose that children can engage in simulation when answering these questions, but consider different counterfactual possibilities than adults. While most previous research has relied on narrative stimuli, we use causal perception events, which are understood even in infancy. In Experiment 1, we replicate earlier findings that children struggle with counterfactual reasoning, but show that they are capable of conducting the required simulations in a prediction task. In Experiment 2, we use a novel multiple-choice method that allows us to study not only *when* children get it right, but also *how* they get it wrong. We find evidence that 4-year-olds engage in simulation, but preserve only some features of what actually happened and not others.

Keywords: causality; counterfactual reasoning; perception; child development; multinomial process trees

Introduction

When considering whether some event C caused another event E, we do not merely consider events as they actually unfolded. Rather, we think about what *could* or *would* have happened had C been altered in some way (Byrne, 2016; Lewis, 1973). This capability for counterfactual reasoning is an essential, and perhaps even automatic, feature of causal cognition (Gerstenberg, Peterson, Goodman, Lagnado, & Tennenbaum, 2017), with a variety of consequences. For example, the relevance of different counterfactual possibilities affects causal judgments (Phillips, Luguri, & Knobe, 2015; Icard, Kominsky, & Knobe, 2017; Phillips & Kominsky, 2017), counterfactual reasoning undergirds emotions, like regret and relief (Beck & Riggs, 2014), and is an implicit component of Bayesian causal learning (Pearl, 2000).

One of the essential properties of counterfactual reasoning is *simulation*. When people engage in counterfactual reasoning, they construct a mental model of the events as they actually happened, and then imagine how the events would have unfolded if something about the situation had been different. This mental simulation is guided by a causal model of the situation which dictates the consequences of counterfactual interventions (e.g., Sloman & Lagnado, 2005).

The developmental origins of counterfactual reasoning in the human mind remain a challenging mystery to cognitive science. Piaget held that counterfactual reasoning emerged in the developmental stage of "formal operations", starting at about 12 years of age (Inhelder & Piaget, 1958). Later work found that children as young as 3 could answer certain counterfactual questions correctly. For example, presented with a story about a girl named Carol who walked across a floor with dirty shoes, 3-5-year-olds who were asked "what would have happened if Carol had taken her shoes off?" correctly answered the floor would be clean (Harris, German, & Mills, 1996).

However, later work suggested that children may arrive at such answers without engaging in counterfactual simulation, and simply rely on conditional reasoning instead. In general, dirty shoes make floors dirty, while clean shoes leave floors clean (Rafetseder, Schwitalla, & Perner, 2013). However, basic conditional reasoning and counterfactual reasoning come apart in situations in which the outcome is causally *overdetermined*. When an outcome was overdetermined, this means that there were multiple individually sufficient causes such that the outcome would still have come about even if one (or more) of the causes hadn't occurred. For example, if both Carol and Max walk across the kitchen floor with dirty shoes, and children and adults are asked what would have happened if Carol had taken her shoes off, adults say the floor would still have been dirty (because of Max), whereas 5-year-olds overwhelmingly say the floor would have been clean. Remarkably, 10-year-olds responded at chance, and adult-like performance emerged only around 14 years of age (Rafetseder et al. 2013).

Recent work has, again, been more optimistic about children's counterfactual reasoning abilities. When narratives are replaced by simple "blicket detector" causal systems in which only some blocks (called "blickets") can make a machine go, children show above-chance success for overdetermined outcomes around age 6 (Gopnik & Sobel, 2000), or even at age 4-5 (Nyhout & Ganea, 2019).

However, we believe that what it means to succeed in counterfactual reasoning needs to be examined more closely. In the research to date, researchers have generally concluded that the reason why children answer these questions incorrectly, is because they *do not simulate* counterfactual alternatives, but instead arrive at their answers by some other reasoning strategy (Rafeteseder et al., 2013; Nyhout & Ganea, 2019). This is remarkable given that other work has found that children are quite adept at simulation when making *predictions* about events that have not yet occurred (Atance & O'Neill, 2005). Given that children can engage in simulation in some cases, and that adults naturally do so when answering causal questions (Gerstenberg et al., 2017), the assumption that young children fail to reason counterfactually because they do not engage in counterfactual simulation *at all* is worth re-examining.

There is another possible reason for why children respond differently than adults: Rather than failing to simulate, they instead simulate different counterfactual alternatives than

adults do. This proposal aligns with a recent proposal that young children may consider a broader hypothesis space than adults do when engaging in causal reasoning (Gopnik et al., 2017). Similar to how children may be more flexible in what hypotheses they consider in causal reasoning, it is possible that they also consider different possibilities than adults do, when simulating counterfactuals. Here, we are interested to see whether there is systematicity in the way in which children consider counterfactual possibilities. When children get the answer to a counterfactual questions wrong, are they just randomly guessing, or may they systematically consider different possibilities than adults do? Characterizing such potential systematicity could give unique insight into the development of counterfactual reasoning, and a deeper understanding of what features of an event children consider *mutable* (Byrne, 2016).

In order to examine which specific counterfactual possibilities children consider, we depart from the narrative studies that have been used in most prior work. Narrative stimuli add a great deal of memory load and room for influence from idiosyncratic knowledge. The ideal stimuli would be a causal event that children understand nearly effortlessly, that they can see in full while answering a counterfactual question, and which offers the opportunity to ask not just whether they are simulating counterfactual alternatives, but which specific alternatives they consider.

Simple physical interactions that fall under the category of "causal perception" perfectly fit these criteria. Events in which one object appears to collide with another and cause it to move are perceived as causal by 6 *months* of age (Leslie & Keeble, 1987; Saxe & Carey 2006; Kominsky et al., 2017), and recent work has used these events to demonstrate counterfactual simulation in causal judgment with adults (Gerstenberg et al., 2017).

In the current work, we present two experiments investigating the development of counterfactual simulation, using causal perception events. In Experiments 1a and 1b, we replicate previous findings that children struggle with counterfactual reasoning in overdetermined cases, but in the domain of causal perception events. However, we also find that children are highly accurate when making *predictions* about these events, showing that they are able, in principle, to conduct the necessary simulations to answer the questions correctly.

In Experiment 2, we present children with concrete counterfactual alternatives to causal perception events in a multiple-choice answer format similar to that employed by Rafetseder and Perner (2018). This response format allows us to examine not only *whether* children engage in counterfactual simulation, but *which specific counterfactual possibilities* they consider.

Experiment 1a

The goal of this experiment was to validate the domain of causal perception in the study of children's counterfactual judgments, by having children make counterfactual judgments about simple causal perception events.

Methods

Participants We planned to run 40 children in each age group (20 in each of two conditions), and continued collecting data until we had reached that target, replacing any participants that were excluded (see below). 40 5-6-year-olds (15 female), 40 7-8-year-olds (15 female), and 40 9-10-year-olds (18 female) participated in Experiment 1a, recruited from local schools and children's museums. In addition, 10 5-6-year-olds (5 female), 3 7-8-year-olds (2 female) and 1 (male) 9-10-year- old participated but were excluded from analyses based on predetermined exclusion criteria (see below).

Stimuli and procedure We constructed simple animations modeled on those used by Gerstenberg et al. (2015) (see Fig. 1, videos of the animations can be found here: http://osf.io/qwphr/). In these animations, there are two balls, A and E, a red area that was described as a "goal", and black walls on either side of the goal. The stimuli were animated .gif files placed into a Qualtrics survey (Qualtrics, 2005). The survey was presented on an iPad.

All participants first saw two training items in counterbalanced order. In one training item, ball A hit ball E, which then bounced off the wall above the goal. In the other training item, ball A hit ball E, which then went into the goal. Following each training trial, participants were asked two questions: "Before ball A hit ball E, was ball E moving or sitting still?", and "Did ball E go into the goal?" Participants could verbally respond and the experimenter would record their answer, or older children could select the option on the iPad directly. If participants answered either question incorrectly on one of the training trials, they were shown that training animation a second time and asked again.

Participants then saw one of two test trials, between-subjects. In the "difference-making" condition, the animation was almost identical to the training item in which ball E bounced off the wall above the goal, except that there was a "brick wall" (see Fig. 1) that ball E bounced off of, and ball E went into the goal. In the "overdetermined" condition, the animation was almost identical to the training item in which the ball went into the goal, except that the ball bounced off the brick wall before going into the goal, thus leaving the outcome unchanged.

Following the test trial, participants were asked the same two questions as in the training trials. If children answered either question incorrectly, they were not corrected but their data were excluded. Then, children were asked the critical test question: "What if the brick wall had not been there? Would ball E have gone into the goal?"

Results and discussion

Results can be found in Fig. 2. A simple inspection of this figure gives a clear sense of the results, which were similar across all age groups: Near-perfect performance on cases in which the brick wall made a difference (where the correct answer is that ball E would not have gone into the goal), but only roughly 50% accuracy for overdetermined events (where the correct answer is that ball E would still have gone

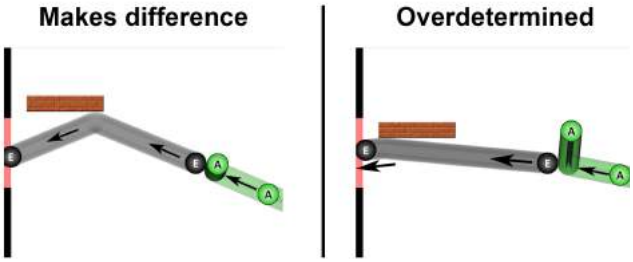

Figure 1. Example stimuli from Experiment 1a. In the difference-making event (left), the brick wall altered ball E's trajectory such that it went into the goal. In the overdetermined condition (right), ball E also deflects of the wall, but would have gone into the goal regardless.

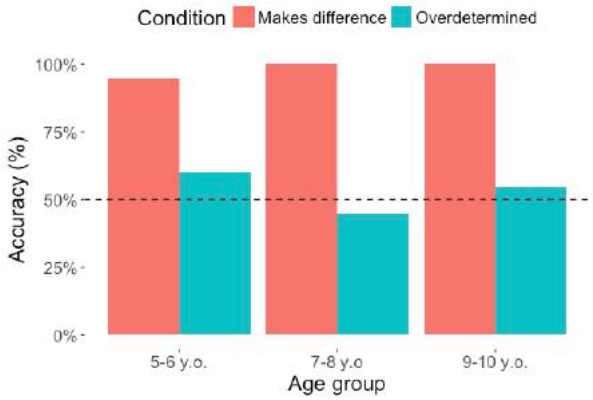

Figure 2. Proportion of accurate responses to the counterfactual question in Experiment 1a.

into the goal). A logistic regression with age group and condition as factors revealed a main effect of condition, ß = 2.54, p = .02, but no effect of age group and no interactions, p > .9. As children demonstrated nearly uniform perfect performance in the difference-making condition (one incorrect answer in total), no further analyses were conducted for this condition. For the overdetermined condition, a logistic regression with age group also showed no effect of age (p > .3) and no significant intercept (p = .37), indicating that accuracy did not differ from chance (i.e., .5).

These results are very similar to many earlier results investigating children's counterfactual reasoning (e.g., Rafetseder et al., 2013): Children can answer counterfactual questions when the correct answer changes the outcome, but struggle in overdetermined cases. One reason for this could be that children are unable to successfully simulate the required counterfactual possibility in these causal perception events. Experiment 1b tested this hypothesis by asking children to make predictive simulations about these very events, without the brick wall.

Experiment 1b

In this experiment, we wanted to see whether children are capable of correctly predicting what will happen after the animation is paused. It is possible that children failed to answer the counterfactual question correctly in the overdetermined situation because they have trouble simulating what would have happened in this case.

Methods

Participants This study was stopped early due to the fact that all children responded correctly. Our final sample sizes were therefore 21 5-6-year-olds (10 female) and 26 7-8-year-olds (14 female) recruited from the same populations as Experiment 1a. In addition, 4 5-6-year-olds (2 female) and 1 (male) 7-8-year-old were excluded based on predetermined exclusion criteria (see below).

Stimuli and procedure The stimuli were similar to Experiment 1a with the following differences: Participants first saw four training trials in random order: Two in which ball E went into the goal and two in which it missed the goal. First, children saw an animation where ball A struck ball E, and ball E moved approximately halfway from its starting position to the left edge of the display (where the wall and goal are located). At this point the animation froze and a large "pause" icon appeared (that didn't obstruct either of the balls). Children were then asked, "If ball E keeps going, will it go into the goal?" Children could respond "yes" or "no". For the training trials, children then saw the rest of the animation. If children made incorrect predictions on at least two of these items, they were excluded from analyses on the basis that they did not understand the task.

Following training, children saw two test trials, a "difference-making" trial and an "overdetermined" trial in counterbalanced order. The test trials were identical to those used in Experiment 1a, with two exceptions: First, the brick wall was not visible (i.e., identical to Experiment 1a's training trials). Second, the animation paused on the frame in which the ball would have collided with the brick wall in Experiment 1a (participants had no way of knowing this). Participants were then asked the same question as in the training items, but were not shown the end of the animation. Note that the predictions that children are asked to make in Experiment 1b are identical to the counterfactual simulation that is required to answer what would have happened without the brick wall in Experiment 1a.

Results and discussion

Every single child who passed the training provided correct answers to both test questions (21/21 5-6-year-olds and 26/26 7-8-year-olds). We report no statistical tests because the uniformity of these responses renders such tests uninformative.

Experiment 2

Experiment 1b showed that, in line with prior work, children are capable of engaging in the kind of physical simulation that is required to answer counterfactual questions correctly, but did not do so consistently for the overdetermined item in Experiment 1a. This result suggests that children's counterfactual reasoning about causal perception stimuli is similar to their reasoning in other domains. However, we

cannot tell based on these findings why children sometimes get it wrong. One explanation is like that proposed by Rafetseder et al. (2013): Children did not engage in simulation at all when asked to consider the counterfactual question. While this is still possible, given that they are obviously capable of engaging in simulation, we must ask *why*.

One possibility is that children cannot simulate while holding the event as it actually occurred in mind (Beck & Riggs, 2014). For example, a correct answer in Experiment 1a requires mentally rewinding the animation and then simulating what would have happened without the brick. The corresponding prediction in Experiment 1b is simpler because the brick is not present in the scene, the clip is paused, and it only requires children to simulate the future without the need to go back in time.

An alternative is that the wording of the question influenced children's performance. Notably, we found a pattern that aligns more closely with Rafetseder et al. (2013) than more recent work (Nyhout & Ganea, 2019; Rafetseder & Perner, 2018). One key difference between our study and that of Nyhout and Ganea (2019) is that the question in Nyhout and Ganea was "would [outcome] *still* [have happened]?" (emphasis added). While a systematic investigation is necessary, children may sometimes be answering on the basis of pragmatic cues: Why ask "would the outcome have been different" if the outcome was unchanged?

A second, not mutually exclusive alternative is that children *did* engage in simulation, but considered different counterfactual possibilities than adults did. We explore this possibility in Experiment 2 using a multiple-choice task modeled on Rafetseder and Perner (2018). We hypothesized that children may arrive at the wrong answer because they hold some of the features of the actual event constant, but allow other features to vary in ways that adults and older children do not. Based on pilot data, we predicted that children will specifically maintain the point of origin of a ball's movement from the event they saw, much as we would expect adults to, but allow the initial trajectory of the ball to vary, which we would not expect adults to do.

Methods

Participants We pre-registered (https://osf.io/qn3b9) a planned sample size of 24 participants in each of three age groups: 4-year-olds, 5-year-olds, and 6-year-olds. We therefore recruited 24 4-year-olds (15 female), 24 5-year-olds (7 female) and 24 6-year-olds (8 female). In addition, 6 4-year-olds (2 female) and 2 (female) 5-year-olds participated but were excluded due to failing to complete the study (4) or parental interference (3; see below). Participants were recruited from TheChildLab.com (Sheskin & Keil, 2018).

Stimuli and apparatus Children saw a total of ten trials in which featured animated events, and then still images representing what actually occurred in the animation, as well as four counterfactual possibilities (see Fig. 3; Full stimuli are available online at https://osf.io/5jw6y/).

Animated events were constructed using Flash, converted to a movie format, embedded in a PowerPoint presentation, and presented over a videoconferencing system. The animations were slightly modified from Experiment 1. This time, there was only one ball, resembling a soccer ball, and the brick wall was replaced with a triangular wedge with a wood texture. The background was made green with a white line to mimic a soccer field. The goal was turned into a grey rectangle, and there were no walls on either side of it.

We created a total of eight test animations and two training animations. In all test animations, the ball entered the stage from the right side and moved in a perfectly horizontal trajectory. In six of the test animations, the ball deflected off of the wedge, which did (4 animations) or did not (2) change whether it went into the goal. In two other test animations, the ball did not interact with the wedge, and simply moved across the field in a straight line.

Along with each test animation, we made a still image that showed the entire trajectory the ball had taken (center, Fig. 3), which was visible while the child was answering the counterfactual question, thus eliminating memory load. In addition, we constructed still images representing four counterfactual possibilities for each animation (Fig. 3). In these counterfactual possibilities, the wedge was removed, and the complete trajectory of the ball was shown as in the still image of the actual event. These four possibilities were constructed in systematic ways for the six items in which the ball interacted with the wedge.

- "**Correct**" (red): In this image, the ball is shown moving horizontally across the entire field, starting from the same point of origin that it had in the actual animation. In other words, it preserved both the origin and the initial trajectory of the ball.
- "**Match origin**" (yellow): The ball started from the same point of origin, but had a diagonal trajectory, ultimately ending up in the exact same place as the ball ended up in the actual event, in which it deflected off the wedge. This option preserved the origin but not the trajectory of the actual event.
- "**Match trajectory**" (purple): The ball originated from a y-coordinate that was level with where the ball *ended* in the actual animation, and the ball moved across the whole field in a perfectly horizontal trajectory. This option preserved the initial trajectory but not the origin of the actual event.
- "**Match neither**" (blue): The ball started from the same place as it did in the "match trajectory" image, but had a diagonal trajectory ending in the same place as the "correct" image, thus matching neither the point of origin nor the initial trajectory of the actual event.

For the events in which the ball and wedge did not interact, the four images still contained two options that preserved the origin and two that preserved the trajectory, but because the

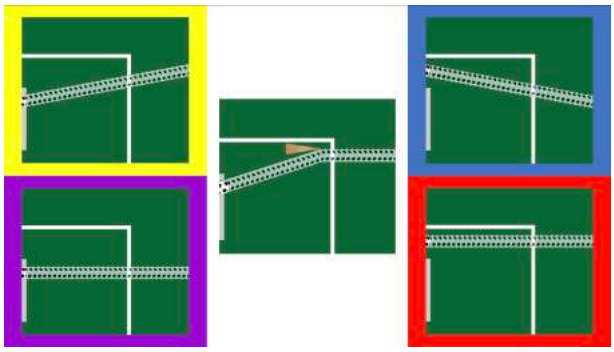

Figure 3. Example item from Exp. 2, as a child would see it. The center image is a rendering of the video the child just watched. On this trial, red is "correct", yellow is "match origin", purple is "match trajectory", and blue is "match neither".

ball did not deflect off the wedge in the actual event, the "match origin" and "match trajectory" images in fact showed the ball ending up in a location that was not present in the original event, while the "correct" and "match neither" images did. The model we used to analyze children's responses (described below) therefore does not apply to these images.

In addition, there were two training animations, one in which the ball bounced off the wedge and one in which it did not interact with the wedge. In both training animations, the ball entered on a diagonal trajectory. No still image of the event was presented in the center of the response screen, and in the still images for training items, the wedge was still present, as the training task was matching the *actual* event rather than considering a counterfactual one.

Procedure The script can be found in the presenter notes of the PowerPoint presentations at http://osf.io/5jw6y/

After parents gave informed consent, children were first shown the two training animations, and after each one asked to find the image that matched what they saw from the four possibilities. This was primarily to familiarize children with the multiple-choice response method. For test trials, children were asked "If there were no block on the field, how would the ball have moved?"

The experimenter was blind to what the child was seeing at all times, and only recorded the color that they said. Children's responses were then transcribed by another coder who was blind to condition, and later matched to images based on the condition the child had been assigned to (see data files in repository). There were two exclusion criteria: If the child failed to finish the study for any reason, or if the parent interfered in a way that guided the child toward a specific answer on any item, in the opinion of the experimenter or coder. As both were blind to what the child was seeing, these judgments could not be influenced by knowing what option the child was selecting.

Analysis plan We focused on the six test items in which the ball collides with the wedge. For those items, we used a multinomial processing tree (MPT) model (Riefer & Batchelder, 1988) to model the proportions with which the

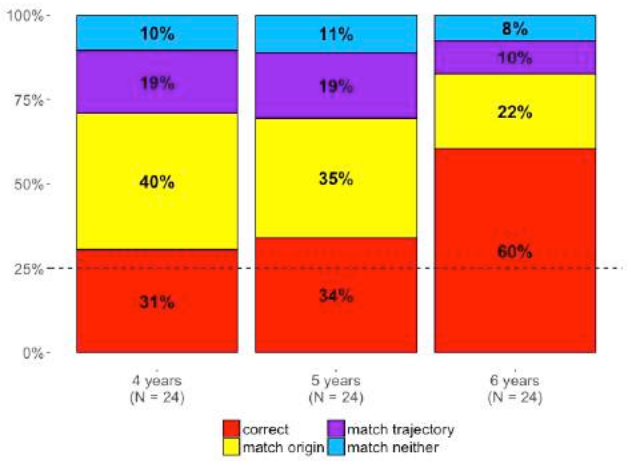

Figure 4. Results of Exp. 2. Proportion of responses is on the y-axis, and chance responding is indicated at 25%.

different age group chose the four possible response options, $P(C)$ (= "Correct"), $P(O)$ (= "match origin"), $P(T)$ (= "match trajectory"), and $P(N)$ (= "match neither"). Our model has three free parameters, $\boldsymbol{s}$, $\boldsymbol{m_o}$, and $\boldsymbol{m_t}$, which each represent the (conditional) probability of reaching a specific discrete cognitive processing stage (e.g., $\boldsymbol{s}$ = probability of engaging in simulation). In addition, our model allowed for the possibility of unbiased guessing.

The first parameter (s) represents the probability whether the children engage in simulation or not. If they do not (with probability $1–s$), we assume children simply make an unbiased guess for one of the four response categories (i.e., the conditional probability of choosing any one response category is .25). We assume that this will be unbiased as the multiple-choice question lacks the pragmatic demands of the questions used in previous studies. In case children engage in simulation (with probability s), we assume two further (unordered) processing steps: how likely they are to maintain the origin from the actual world in their simulation (parameter m_o), and how likely they are to maintain the trajectory (parameter m_t)? In order to examine this, we ignore the cases in which the ball does not interact with the block. For the remaining six cases, we can enumerate how the four different response categories follow from the assumed processes. For example, if children maintain both the origin and the trajectory (with probability $m_o \times m_t$), they will provide the correct response. If, however, children only maintain the origin, but not the trajectory (with probability $m_o \times (1 - m_t)$), they will choose the "match origin" response option, $P(O)$. Analogous arguments can be made for $P(T)$ and $P(N)$. Thus, the following model equations are assumed to hold:

$$P(C) = s \times m_o \times m_t + (1 - s) \times 0.25$$
$$P(O) = s \times m_o \times (1 - m_t) + (1 - s) \times 0.25$$
$$P(T) = s \times (1 - m_o) \times m_t + (1 - s) \times 0.25$$
$$P(N) = s \times (1 - m_o) \times (1 - m_t) + (1 - s) \times 0.25$$

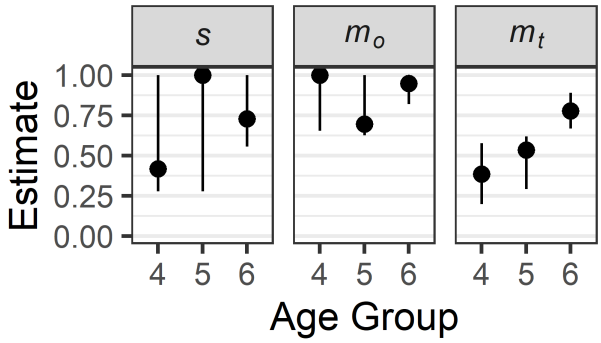

Figure 5. MPT model parameter estimates for s, m_o, and m_t in each age group. Error bars are bootstrapped 95% CIs.

To obtain estimates of the model parameters s, m_o, and m_t, we fitted the model to the aggregated data using maximum-likelihood estimation. This provides us with a model-based estimate of how likely each age group is engaging in simulation, and the likelihood, in each age group, of maintaining the origin and the trajectory of the actual world. Note that, although the model is saturated (i.e., three free parameters for three independent data points provided by the multinomial distribution with four categories), it cannot account for any possible data pattern. That is, our model imposes testable constraints on the data. For example, it predicts that, after accounting for the proportion of unbiased guessing, the conditional ratio of $P(C)/P(O)$ must be equal to the conditional ratio $P(T)/P(N)$. Therefore, finding that the model adequately accounts for the data (i.e., it fits the data), provides some evidence for the underlying assumptions and validity of the interpretations associated with the parameters.

Results and discussion

Fig. 4 shows how often children chose each of the four options for the six test items where the ball collided with the wedge. For the two cases in which the ball and wedge did not interact, the correct answer was the modal response in every age group (4-year-olds: 50%; 5-year-olds: 71%; 6-year-olds: 88%).

A visual inspection of the figure suggests a clear pattern when it comes to choosing the correct answer: Above-chance performance emerges around age 6. However, it also appears that, of the three possible incorrect responses, all age groups preferred "match origin" over "match trajectory" and "match neither", which suggests that the younger children are not just guessing randomly. Rather, they are simulating possibilities that maintain the origin but not the trajectory of the ball in the actual event.

To verify this impression, we fit our MPT model to children's responses. As our model was saturated, we used a double bootstrap procedure (van de Schoot, Hoijtink, & Dekovic, 2010) to evaluate model fit. This approach revealed a p-value of .04 ($G^2 = 3.48$) for the 4-year olds and .05 ($G^2 = 2.66$) for the 5-year-olds, suggesting that the main patterns in the data were well accounted for, but there was some misfit. Specifically, the model cannot predict both $P(C) < P(O)$ and $P(T) > P(N)$ at the same time, as was observed in the data. One possible reason for this misfit is individual differences in the simulation behavior of the 4- and 5-year-olds, such that some individual children consistently responded in a particular way and others did not. For 6-year-olds, the fit was perfect ($G^2 = 0$). Given the small magnitude of misfit, the model is interpretable, and we can evaluate the likelihood that children engaged in simulation, and how.

The parameter estimates for each parameter in each age group, with 95% confidence intervals estimated by parametric bootstrapping, can be seen in Fig. 5. In short, we find little evidence for developmental change in m_o or s, but a clear developmental increase in the estimate of m_t. Put in plain terms, this analysis suggests that 4- and 5-year-olds were not significantly different from 6-year-olds or each other in their likelihood of engaging in simulation, nor in how likely they were to choose an option that maintained the ball's point of origin from the actual event. However, 6-year-olds were significantly more likely than younger children to maintain the ball's initial *trajectory* from the counterfactual event. In addition, for 6-year-olds we have considerably smaller CIs for s, indicating we that we have higher certainty that they engage in simulation most of the time.

In short, children ages 4-5 do seem to engage in counterfactual simulation, and systematically hold constant some, but not all, features of the actual world in those counterfactual simulations, while allowing other features of the world (which older children hold constant) to vary.

General Discussion

In two experiments, we provide evidence that young children engage in counterfactual simulation, but do so in a different way than older children and adults. Experiment 1 validated the stimuli by replicating previous findings about children's ability to answer counterfactual questions and conduct predictive simulations, but in the domain of causal perception. Experiment 2 asked children to choose among four counterfactual trajectories rather than answering a simple yes/no question, and found that when 4-5-year-old children engage in simulation, they consider counterfactual possibilities in which the origin of an object's motion is preserved while its initial trajectory is allowed to vary, while 6-year-olds are more likely to preserve both features in their counterfactual simulations.

We consider these findings in the context of a general theory of children's reasoning put forward by Gopnik et al. (2017): When reasoning about different possibilities, children's hypothesis space may be quite different from adults, but the basic process of simulation could be very similar. In particular, this theory suggests that children have a broader and "flatter" hypothesis space (i.e., priors across all hypotheses are similar), in which they conduct a "higher-temperature" (i.e., broader) search. This theory can be readily applied to children's struggles with counterfactual reasoning: When considering counterfactual possibilities, children may be sampling from a broader set of possibilities, none of which

are favored over the others, and the way they pick possibilities out of this space is more random.

However, unlike Gopnik et al. (2017), we find that children are only showing evidence of this broader search space for certain specific features of these events. In other words, while our results align with the general proposal that children conduct simulations over a "flatter" hypothesis space, the space is only flatter over certain "dimensions" (i.e., components) of the events being considered. In this case, children are unlikely to consider possibilities that change where the ball enters from, but between 4 and 6 they narrow the search space for the initial trajectory of the object to be more like adults'.

This is a critical advance for understanding children's reasoning. We must not only test whether they are searching a broader space of possibilities in general, but also identify the separate features of that hypothesis space and determine which aspects of the event-structure are treated in an adult-like way (in this case the point of origin of the object's motion). Doing so will not only help us better understand children's reasoning processes, but allow us to predict specific challenges they face, or errors they will make.

One limitation is that we selected the range of possibilities for children to consider, and so there may be a possibility that we did not include which they would prefer over and above the ones they selected here. While verbal pragmatics are no longer a viable explanation, there are other possible explanations for children's responses that would not rely on simulation, such as path similarity, or some kind of contextual inference about the scenario, such as whether there is an agent launching the ball into motion.

This work provides an exciting new approach to the study of counterfactual reasoning in development. We should consider that "failure" in these tasks may result not from a failure to simulate *per se* but rather from different assumptions about what to hold constant and what to change when simulating counterfactuals.

Abstract

Transmission of information by means of language is a potentially lossy process. Especially adjunct information, such as the graded degree of evidence, is a piece of information that seems prima facie likely to be distorted by reproduction noise. To investigate this issue, we present the results of a two-step iterated narration study: first, we collected a corpus of 250 crime story reproductions that were produced in parallel reproduction chains of 5 generations in depth, for 5 different seed stories; a second separate large-scale experiment then targeted readers' interpretation of these reproductions. Crucially, strength of evidence for the guilt of each story's suspect(s) was manipulated in the initial seed stories. Across generations, readers' guilt perceptions decreased when the evidence was originally strong, but remained stable when evidence was originally weak. Analysis of linguistic measures revealed that dissimilarity between a seed story and its reproduction, story length, and amount of hedging language affected the readers' own guilt perception and the readers' attribution of guilt perception to the author differently. The results provide evidence that evidential information indeed influences guilt perception in complex ways.

Keywords: experimental pragmatics; iterated narration; transmission chains; uncertain evidence

Introduction

One of the central goals of language use is the exchange of information. New information is obtained by reading the newspaper, listening to a friend, etc., and often immediately communicated as stories to other people it may be relevant to. Yet this process of iterated reproduction is not innocuous: the original story may be distorted or altered by various sources of noise, including cognitive biases, memory reconstruction processes, or other limits on information processing capacity (Bartlett, 1932; Tversky & Marsh, 2000; Mesoudi & Whiten, 2004; Griffiths & Kalish, 2007; Hills, 2018). The game of Telephone is essentially a caricature of this process: the first person whispers a sentence to their neighbor, who in turn passes it on to the next person, and so on. The last person in the transmission chain announces the sentence they ended up with, which often differs remarkably from the initial seed story. This simple game nicely exemplifies the information loss and distortion that is associated with repeated exposure and reproduction of information.

Bartlett (1932) first introduced the methodology of transmission chains, i.e., chains of story reproductions, as a scientific method. In a series of transmission chain studies, using stories such as Native American tales or sport reports for reproduction, he observed a significant information loss in the stories over generations of reproductions. He also reported that the content of the reproduced stories increasingly aligned with the reproducing author's prior beliefs. Bartlett used these observations as a foundation for his theory of memory retrieval involving reconstruction processes.

In recent years, the transmission chain method has undergone a revival in cognitive and social psychology. Mesoudi and Whiten (2004) showed that with each iteration descriptions of everyday events, such as visits to a restaurant, became more abstract, in line with hierarchically organized script knowledge. Other research showed that reproductions can be influenced by cultural, racial and gender stereotypes (e.g., Kashima, 2000). The iterated transmission method has therefore also been used as a tool to investigate cognitive biases in general (e.g., Kalish, Griffiths, & Lewandowsky, 2007). In evolutionary linguistics, the transmission chain method has been used to study experimentally how iterated learning of a language exerts a selective pressure on language itself, so that learning biases create an indirect pressure on languages to be efficiently learnable (e.g., Scott-Phillips & Kirby, 2010; Kirby, Griffith, & Smith, 2014).

The transmission chain method thus presents an exciting opportunity for asking questions at the interface of linguistics and psychology. In particular, while previous studies have focused particularly on properties of the reproductions themselves, we here present an extension in which we investigate an external readership's interpretative perspective on the reproduced texts. We achieve this by a second experiment that uses as materials the output from the previous iterated transmission experiment. The stories used as seeds are five crime or ethical violation stories based on true events (animal smuggling, arson, sexual assault, beehive destruction, and email scams). Each seed started out with both a weak and a strong evidence version (see Table 1). This manipulation has successfully been used by (Van Prooijen, 2006) to uncover in-

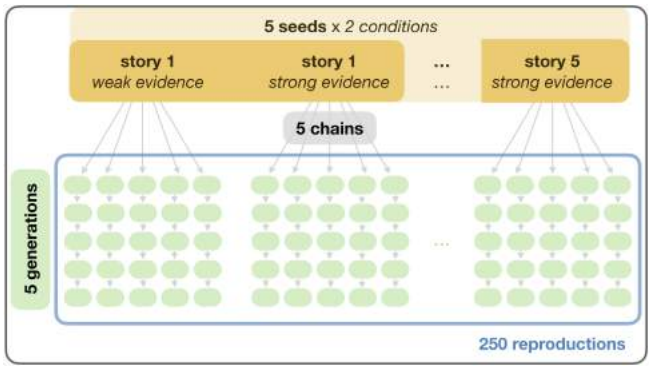

Figure 1: Overview of corpus of stories collected in Exp. 1.

and out-group effects in guilt judgments of suspects. Similarly to that study, the different conditions were implemented by adding a last sentence to each story that either suggested strong or weak evidence for the suspect's guilt. To evaluate the interpretations of the stories that readers arrive at, we collected answers to eight questions regarding the readers' perception of the stories' suspect(s), the readers guilt perception attributed to the author of the story, as well as, somewhat less importantly, indexes of more general author and reader related features, such as trustworthiness and subjective engagement.

Experiment 1: corpus collection

Methods

74 undergraduate students participated in this online study for course credit[1]. We constructed five stories (*seeds*) that marked the beginning of each reproduction chain. Stories were written in the style of short news articles and followed a similar structure. They reported a crime or moral rule violation that occurred, the authorities' determination of and search for the perpetrator(s), and the possible punishment the suspect(s) would face if found guilty. Furthermore, each of these five seed stories occurred in one of two conditions: a *weak evidence* and a *strong evidence* condition. Evidence strength was manipulated in the final sentence of the story (see example seed in Table 1).

Each participant read and reproduced five stories. For each story, they were either assigned to read and reproduce the seed story or continue an already started reproduction chain where they read and reproduced a reproduction from previous participants. The assignment was random. On each trial, participants first read a story. They were told to click the 'Continue' button when they were confident that they had internalized the story. Once they clicked the button, the story disappeared and they were asked to reproduce it freely in a text field. Order of stories was randomized.

[1]The current study was one several they could choose from.

Results

Participants produced 370 stories. For each seed, we defined a complete chain as one that has 5 reproductions/generations. For subsequent analysis, we randomly selected 50 complete chains, evenly distributed across stories and conditions. This yielded a corpus of 250 reproductions (5 seeds in 2 conditions with 5 complete chains each, see Figure 1). This was the maximal set of complete chains that was present in every condition for each seed. This corpus is a rich source of linguistic information which merits detailed investigation. Yet, with an eye to clear operationalizability, we focus here on a few general features, which we will subsequently use as predictors in the analyses of Exp. 2 below.

Proportion of hedges. As a proxy for vagueness, we extracted the number of hedges per story relative to its length. The seed stories were designed to contain various hedges, such as "nearly", "about", "up to" or "allegedly". As shown in Figure 2, the proportion of hedges decreased in each generation ($\beta = -0.01,\ SE = 0.00,\ t = -4.16,\ p < 0.0001$) , suggesting that participants portrayed the stories with more certain language over generations. There was no significant effect of evidence condition on proportion of hedges ($\beta = -0.00, SE = 0.00, t = -0.79, p < 0.44$) .

Story length. As shown in Figure 2, the number of words in a story decreased across generations ($\beta = -17.12,\ SE = 1.02,\ t = -16.79,\ p < 0.0001$), replicating a well-known phenomenon in reproduction studies (Bartlett, 1932). While the original seeds (generation 0) consisted on average of 159 words, that number dropped to 25 by generation 5. Examples of reproductions of the seed in Table 1 (strong condition) from generation 1 and 5 are shown in (1) and (2) below. There was no significant effect of evidence condition on story length.

(1) In late December 2017, a couple in Iowa went to check on their beehives. They found a tragic scene: their hives had been overturned and their equipment and facilities had been ransacked. A few weeks later, the police arrested a 12-y.o. and 13-y.o. for the crime. They are charged with multiple offenses, with fines up to $100,000 and up to 10 years in prison, yet will be tried as minors. The trial hasn't happened yet, but they seem guilty.

(2) A 12 and 13 year old were arrested for destroying a beehive, and face up to 10 years of jail time.

Similarity of seeds and reproductions. To assess the similarity between seed stories and their reproductions quantitatively, we computed the Jaccard distance between each reproduction and its generation 0 seed. Jaccard distance ranges between 0 and 1 (where 1 indicates greatest distance) and captures the amount of overlap between two stories in the following way:

$$D_J(X,Y) = 1 - \frac{|X \cap Y|}{|X \cup Y|}$$

where X is the set of words in the reproduction and Y the set of words in the respective original seed story. In this

Table 1: Example of a seed story used in Exp. 1.

In late December 2017, a couple in Iowa was checking on their 50 beehives when they discovered a tragic scene. The hives had been overturned and hacked apart, and the equipment had been thrown out of the shed and smashed. This destruction caused the death of about half a million bees and approximately $60,000 in property damage. Nearly three weeks later, police arrested two boys (12 and 13 years old) who, allegedly, were responsible for the damage. The charges against them include criminal mischief, burglary, and offenses to an agricultural animal facility. Since they are still minors, they will be charged in juvenile court where they face up to 10 years in prison and fines of up to $10,000 if convicted.	
(*strong evidence condition*) Police officials explained that the investigation is still in progress, but the evidence so far overwhelmingly speaks to the guilt of the suspects.	(*weak evidence condition*) Police officials explained that the investigation is still in progress, and the evidence so far doesn't warrant rushed conclusions about the guilt of the suspects.

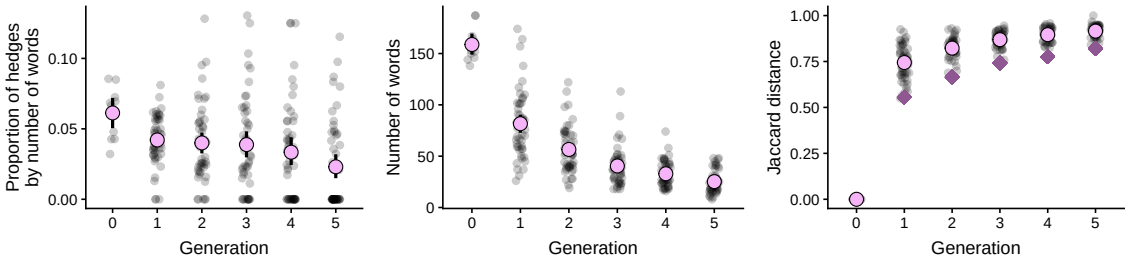

Figure 2: Mean of the three linguistic metrics (proportion of hedges (by number of words), number of words and Jaccard distance) over generations of reproductions. Error bars indicate bootstrapped 95% CIs. Pink dots indicate generation mean, gray dots are individual stories. The purple squares indicate the lowest possible distance given the mean length of the stories.

case, we took words as the basic unit over which distance was computed. Figure 2 shows that D_J increased across generations ($\beta = 0.08$, $SE = 0.01$, $t = 13.18$, $p < 0.0001$) . This is not surprising given that as the number of unique words decreases, D_J between seed and any of its reproductions necessarily increases. However, we will see later that length and D_J have different effects on story interpretation. There was no significant effect of evidence condition on Jaccard distance ($\beta = 0.00$, $SE = 0.02$, $t = -0.12$, $p < 0.91$).

In sum, in a corpus of 250 reproductions of 5 seed stories, the length of the stories, the similarity to the seed story, and the proportion of hedges decreases over generations, regardless of the initial evidence strength condition.

Experiment 2: story ratings

In order to assess the extent to which, as a function of the originally provided evidence, the generation of reproduction affects readers' interpretation of various features of the stories we collected judgments from a second group of independent participants. We were particularly interested in features related to the uncertainty of presented evidence and the associated judgments of suspect guilt. We also collected judgments concerning the readers' general attitude towards the author and the story.

Methods

5392 participants were recruited over Amazon Mechanical Turk. Each participant read one story from the 250 story corpus reported in the previous section, and answered twelve questions about the story (including four attention checks). They indicated their response by moving a slider on a continuous scale (slider endpoints were coded as 0 - 100). Each question was shown in isolation in a randomized order. Participants spent on average two to three minutes on this experiment and were paid $0.60 ($12-$18 per hour). The story was visible throughout the experiment.

The list of questions asked is provided in (3) to (10). Questions (3)–(7) assessed the extent to which the reader believes the suspect(s) is/are guilty of the alleged crime. Questions (8)–(10) assessed the reader's trust in the author, the extent to which they considered the story to be objectively written, and the extent to which they felt emotionally connected to the story. Overall, participants were asked eight questions of interest and four attention check questions designed to filter out participants who were just clicking through the experiment.

(3) **Strength of evidence:** How strong is the evidence for the suspect's / suspects' guilt?

(4) **Suspect guilt:** How likely is it that the suspect is / the suspects in the crime are guilty?

(5) **Suspect conviction:** How likely is a conviction of the suspect(s) in the crime?

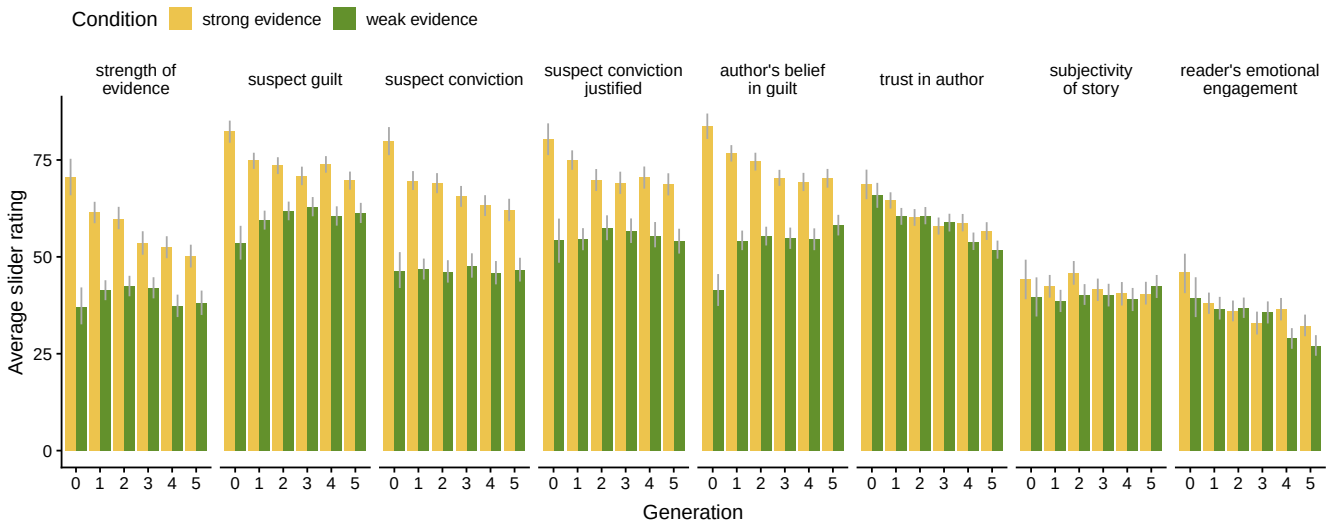

Figure 3: Mean ratings in strong (yellow) and weak (green) evidence condition for each dimension (facets).

(6) **Suspect conviction justified:** How justified would a conviction of the suspect(s) in the crime be?

(7) **Author's belief in guilt:** How much does the author believe that the suspect is guilty?

(8) **Trust in author:** How much do you trust the author?

(9) **Subjectivity of story:** How objectively / subjectively written is the story?

(10) **Reader's emotional engagement:** How affected do you feel by the story?

Results

Exclusions. We excluded 107 submissions because the participants could not be uniquely identified due to a data submission error. Furthermore, 12 participants were excluded because they completed the study multiple times (177 submission exclusions) and another 535 participants because they failed at least two of the attention check questions. This left us with 4573 participants (84.8% of the original set). After exclusions, each reproduction received on average 17 ratings, ranging from 9 to 22 and two outliers with 27 and 38 ratings. The original seed stories received between 25 and 31 ratings.

Analysis procedure. Of main interest was whether participants give judgments of suspect guilt in line with the originally provided evidence, whether those judgments change over generations, and whether those judgments pattern with related measures of evidence for guilt, probability of conviction, justification of conviction, and attributed suspect guilt (i.e., an estimate of the author's belief in the suspect's guilt). We refer to these measures as *guilt related measures* (questions 3–7). Additionally, we analyzed trust in the author, story subjectivity, and emotional engagement as measures of secondary interest (questions 8–10). Mean slider ratings corresponding to the analyses are shown in Figure 3. Judgments were analyzed using linear mixed effects models. For each question, slider rating was predicted from fixed effects of generation, condition (reference level: strong), and their interaction. The models also included random by-story intercepts. An overview of the results is shown in Table 2. Each row presents the model results for one of the questions and the columns show the model outcomes for fixed effects.

Generation and evidence strength effects on guilt related measures. We observed main effects of condition on all guilt related measures (see first 5 panels of Figure 3) , such that ratings in the strong condition were higher than ratings in the weak condition, suggesting that participants in Exp. 1 were sensitive to the evidence strength manipulation (reproducing stories in such a way that evidence strength information was maintained); and also suggesting that participants in Exp. 2 were sensitive to the reproduced evidence strength information in their judgments. We also observed significant or marginally significant interactions between condition and generation for all but one of the guilt related measures, such that ratings decreased across generations in the strong condition but remained stable in the weak condition.

Generation and evidence strength effects on secondary measures. The secondary measures look very different from the guilt related measures. In particular, there were no significant effects of evidence strength condition on any of the measures with the following exception: stories were rated as less subjective in the weak evidence condition in earlier generations, though subjectivity ratings did not vary as a function of generation and remained on the 'objective' side of the scale throughout. In contrast, both trust in the author and readers' emotional engagement with the story decreased across generations. This is presumably the result of the stories becoming shorter over generations (see Exp. 1) and readers therefore having less material to be emotionally affected by, and less

Table 2: Model output for each fixed effect (condition, generation, and their interaction) for each rated question (rows).

	condition			generation			condition*generation		
	β	SE	p	β	SE	p	β	SE	p

material to build trust in the author on in later generation stories.

Preliminary discussion. It seems prima facie plausible that trust in the author, the subjective quality of the story, or the reader's emotional engagement with the story are important factors in readers' assessment of the described suspects' guilt. But the presented data suggest otherwise. The guilt related measures are only weakly correlated with the secondary measures (maximum correlation: $r = 0.30$, minimum correlation: $r = 0.01$, mean correlation: $r = 0.12$). The evidence strength effect was expected, given the strong manipulation in the final sentence of the seed story. However, what it is that changes over generations that affects the guilt related measures in the strong and weak evidence conditions differently merits further investigation. The change across generations is presumably driven by the content of the stories. We next report a second set of analyses in which we assess the extent to which the linguistic features reported in Exp. 1 predict ratings in Exp. 2, focusing on the readers' assessment of suspect guilt and of attributed suspect guilt.

Effects of linguistic features on suspect guilt and author belief in suspect guilt. In this part of the analysis, we focus on the measures of *suspect guilt* and *author's belief in guilt* (attributed suspect guilt). These measures are interesting to examine in more detail because a) suspect guilt is the main issue raised in the 5 seed stories, so it is relevant to understand the linguistic conditions that lead to changes in perceived guilt; and b) while there is no obvious reason why readers' ultimate beliefs and the beliefs they ascribe to the author *should* differ after reading these stories, Degen et al. (2019) showed that listeners maintain uncertainty about the state of the world even when they ascribe a strong belief to speakers. In the following, we therefore analyze for both measures the effect of the proportion of hedges in a story, story length, and dissimilarity between a story and its seed.

Results are shown in Figure 4. In order to analyze the effects of proportion of hedges, story length, and Jaccard distance on the two guilt measures of interest, we asked whether the linguistic features explained variance above and beyond generation. To assess this, we first residualized each feature against generation, due to the substantial correlations between the features and generation observed in Exp. 1. The final mixed effects linear regression models predicted slider rating for each of the two measures and each of the three linguistic features of interest from main effects of evidence strength condition, residualized linguistic feature, generation, the interaction between evidence strength condition (reference level: strong) and generation, and the interaction between evidence strength condition and residualized linguistic feature.[2]

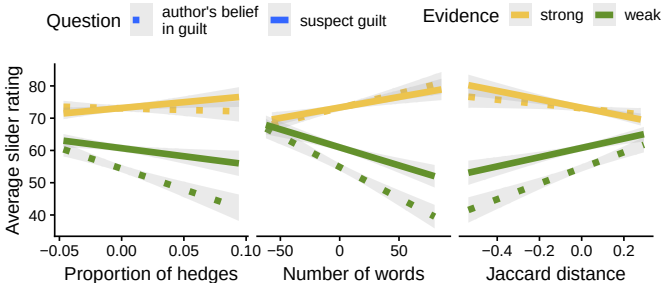

Figure 4: Linearly smoothed mean slider ratings as a function of generation-residualized proportion of hedges (left), number of words (middle), and Jaccard distance (right). Suspect guilt ratings shown in solid lines, author belief in suspect guilt ratings shown in dashed lines. Gray ribbons indicate 95% confidence intervals.

We observed significant interactions between evidence strength condition and generation-residualized linguistic feature for two of the three linguistic features on the suspect guilt measure (hedge proportion: $\beta = -79.57$, $SE = 54.05$, $t = -1.47$, $p < 0.15$, story length: $\beta = -0.18$, $SE = .06$, $t = -2.93$, $p < .01$, Jaccard distance: $\beta = 29.52$, $SE = 10.82$, $t = 2.73$, $p < .01$) and for all three linguistic features on

[2]Nested model comparison revealed that the inclusion of the residualized linguistic feature fixed effect was justified for all linguistic features on both measures, with the exception of hedge proportion when used to predict suspect guilt.

the attributed suspect guilt measure (hedge proportion: $\beta = -115.82$, $SE = 58.46$, $t = -1.98$, $p < .05$, story length: $\beta = -0.30$, $SE = .07$, $t = -4.38$, $p < .0001$, Jaccard distance: $\beta = 33.43$, $SE = 11.80$, $t = 2.83$, $p < .01$) .

To further understand these interactions, we conducted a simple effects analysis. The analysis revealed that there was no evidence of an effect of the linguistic metrics in the strong evidence condition for either of the two guilt related measures. However, in the weak evidence condition, as can be seen in Figure 4, increased number of words in a story was associated with a decrease in both suspect guilt and attributed suspect guilt. An increased proportion of hedges was also associated with a decrease in attributed suspect guilt ratings. Conversely, increased Jaccard distance was associated with an increase in both guilt related measures. Inspecting the beta coefficients suggests that these effects were always stronger for attributed suspect guilt than for suspect guilt.

These results suggests that when evidence for suspects' guilt was initially strong, that evidence was carried through the stories despite changes in hedge proportion, story length and increased dissimilarity between the retelling and respective seed story, and therefore did not change ratings of suspect guilt and attributed suspect guilt. In contrast, when evidence was weak, participants were more likely to believe that suspects were guilty, even while recognizing that the author was less likely to believe so. This discrepancy increased with increased proportion of hedges, increased number of words, and increased similarity to the original story[3].

General discussion

In this work we investigated the effects of lossy transmission on readers' interpretation of crime stories under varying initial evidential conditions in an iterated narration paradigm. First we constructed a corpus of 5 original seed stories in 2 conditions of evidential strength for a suspect's guilt, and 250 reproductions thereof. This corpus replicates previously found effects of a decrease in story length over generations of reproductions (Bartlett, 1932). Furthermore, the stories become less similar to the original seed story and the proportional number of hedges decreases.

We here introduced a, to our knowledge, new experimental extension of the transmission chain paradigm, where we subjected the text reproductions from the first study to a second empirical study focusing on the interpretative effect of the reproductions on an independent set of readers. In this way, we obtained ratings for each story on 5 guilt related measures and 3 secondary measures regarding trust in the author, story subjectivity, and the reader's emotional engagement. Our results suggest that, for one, the subtle manipulation of varying evidential strength in the original seed stories did have a lasting effect on reproductions and subsequent judgments of guilt, lasting several generations. For another, manipulation of evidence did not seem to have an effect on the readers' perception of the trustworthiness of the author, the subjectivity of the story or the general engagement readers had with the story. This is partially surprising because it seems naïvely plausible that providing weaker evidence could lead to less trustworthiness and more subjectivity. However, if reproductions are convincing and weak evidence is presented appropriately, there is no need to assume that the author is not trustworthy or the text more subjective.

We also observed effects of generation on especially the guilt related measures, which we found to be attributable to the ways in which the reproduced stories changed across generations. We found that, contrary to pessimistic expectations, it did not appear to be the case that repeated reproductions of stories with nuanced degrees of evidential information would have dropped these nuances, e.g., to arrive at a black-and-white picture, which would have been reflected in floor and ceiling slider ratings on the guilt related measures. Instead of increasing ratings for strength of evidence in the weak evidence conditions, we rather see a decline of perceived evidential strength over generations in the strong evidence condition. Reproducers seemed to have been rather careful in their formulations, despite the observed decrease in the proportion of hedges.

Most interesting is the relationship between readers' belief in the suspects' guilt and the belief they attributed to the author of the story in this regard. When the presented evidence was strong, these judgments aligned. However, when the evidence was weak, they diverged. Crucially, participants believed that the suspect was more likely to be guilty compared to the belief they attributed to the author. It is worth noting that the stories did not contain any information about the author and none of the reproductions contained first person narrations. Therefore, readers did not receive direct evidence to support the idea that the author's beliefs should differ from the presented view. The more dissimilar the reproductions were from the original story, the more participants' beliefs aligned with the beliefs they attributed to the author. They converged onto the highest guilt ratings in the weak condition. The difference between believed and attributed suspect guilt was greatest for large proportions of hedges in the story – this difference disappeared for small proportion of hedges. This suggests that, surprisingly, rather than hedges affecting readers' beliefs about suspect guilt directly, they instead lead only to readers attributing a weaker belief in suspect guilt to the author. In essence, readers are less willing to commit to beliefs that were communicated via hedging language.

We see the main achievements of this work in the contribution of an interestingly structured text corpus, with rich empirically obtained information on readers' assessments of the individual texts. This dataset will enable more detailed linguistic analyses in future work,[4] which will look more closely

[3]These three linguistic features are highly correlated and future research needs to investigate to what extent each of them contributes to these differences in guilt ratings.

[4]The corpus will become publicly available by January 2020 as part of a Github repository at https://github.com/elisakreiss/iteratednarration.

at the more specific contribution of different types of hedges and other types of constructions that signal information about graded evidence.

Abstract

Animal behavior is not driven simply by its current observations, but is strongly influenced by internal states. Estimating the structure of these internal states is crucial for understanding the neural basis of behavior. In principle, internal states can be estimated by inverting behavior models, as in inverse model-based Reinforcement Learning. However, this requires careful parameterization and risks model-mismatch to the animal. Here we take a data-driven approach to infer latent states directly from observations of behavior, using a partially observable switching semi-Markov process. This process has two elements critical for capturing animal behavior: it captures non-exponential distribution of times between observations, and transitions between latent states depend on the animal's actions, features that require more complex non-markovian models to represent. To demonstrate the utility of our approach, we apply it to the observations of a simulated optimal agent performing a foraging task, and find that latent dynamics extracted by the model has correspondences with the belief dynamics of the agent. Finally, we apply our model to identify latent states in the behaviors of monkey performing a foraging task, and find clusters of latent states that identify periods of time consistent with expectant waiting. This data-driven behavioral model will be valuable for inferring latent cognitive states, and thereby for measuring neural representations of those states.

Keywords: Belief dynamics; Foraging; Partially observable switching semi-Markov process; Animal behavior

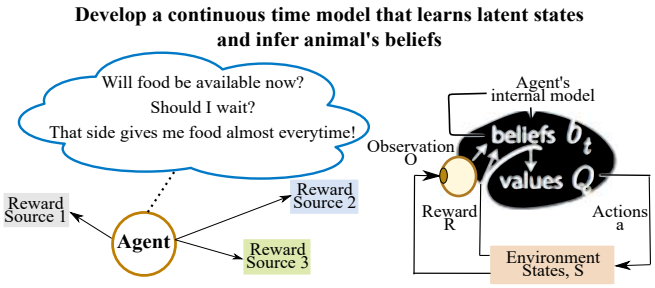

Figure 1: *Overview*: In complex natural tasks such as foraging, an animal faces a continuous stream of choices. Some of the choices pertain to hidden variables in the world, such as food availability at a given location and time. These variables determine time- and context-dependent rates for observation events and rewards. To perform well at these tasks, animals must learn these hidden rates and act upon what they have learned. Our goal is to develop a data-driven, continuous-time model for inferring an animal's latent states and their dynamics.

Introduction

An animal's survival depends on effective planning for future costs and rewards. One of the most fundamental purposes of the brain is to create and execute such plans. However, these plans cannot be directly observed from behavior. To understand how the brain generates complex behaviors and learn how an animal builds a representation of the surrounding environment, it is valuable to construct hypotheses about the brain's internal states that narrow the search space for neural implementations of planning. These hypotheses often come from models of the task implemented as artificial agents, whose internal state representations provided a latent space. However, differences between the model task and agent and the real task and animal create the potential for severe model-mismatch, injecting unknown biases into scientific conclusions. Here we use a latent-variable model to impute latent behavioral states based on observed behavior directly, using a data-driven latent-variable analysis that is designed to match the dependency structure of agent-based models without enforcing parametric structure.

To understand the mechanisms underlying behaviors, it is crucial to study hard tasks that involve inferring latent variables, since only then will an animal need to create a mental model of the world; otherwise the animal could perform well simply by responding to its immediate sensory input. Naturalistic foraging is one such task where an agent has to make decisions from many difficult choices in an uncertain environment. When foraging, an animal must take actions to procure rewards, and these actions have costs. How the animal schedules its actions determines the balance between total costs and rewards, Charnov & Orians (2006). The animal's goal in foraging is to use its energy resources for short term and long term sustenance. Decisions must be made continuously, and therefore time is a key ingredient in foraging: An animal benefits from tracking *when* reward is likely accessible at different locations. A natural way to represent such temporal quantities is in terms of dynamic event rates. For this reason, our work highlights the continuous-time aspects of decision problems.

Fig 1 illustrates our motivation for the foraging problem. An agent develops an internal model and takes an action, which may result in a reward. As a result, the agent updates its internal model in an attempt to learn the environmental dynamics. We explore the plausibility that an animal's internal states in

continuous time manifest as measurable consequences on its behavior, using a switching hidden semi-Markov model, and demonstrate the model's applicability in inferring latent states on a foraging task.

In the remainder of the document, we provide background, discuss the presented model and procedure followed by the experiments, results and discussion.

Background

Behavior identification using computational models has a rich history, and clear value–the ability to learn rich representations of behavioral constituents provides important insights into underlying neural processes which can also be incorporated into the development of artificial agents (Anderson & Perona (2014)). Early behaviorists explored behavioral sequences in an attempt to learn determining causal factors underlying behavior, aiming to explain effects like when an agent switches to an alternate choice. These approaches are still common in animal ecology, where hidden Markov time series models (HMMs) have been used to analyse animal's internal states Nathan et al. (2008); Langrock et al. (2012). Macdonald & Raubenheimer (1995) proposed using HMMs to capture causal structure in putative motivational states. However, they also observed that there are no one-to-one correspondences between the learned states and behavior, and Zucchini et al. (2008) found that behavior also influences internal states through feedback, challenging the dependency structure assumed by HMMs. To capture non-stationarity in behavior, Li & Bolker (2017) use temporally varying transition probabilities to model animal movement. However, behavior identification has struggled to produce more than a description of the behavior, with unknown relationships between the elicited latent states and the animal's representations. These failures are less surprising when it's realized the behavior expressible by HMMs is incompatible with key characteristics of observed behavior.

In these works and others, an important question left unanswered is what kind of latent belief states could be inferred that not only represent belief dynamics but also the choices that an animal or an agent makes. We attempt to uncover latent state beliefs in a continuous time model and apply it to a complex ecological process, foraging, which has multiple underlying sub-processes including satisfaction of needs, searching for alternatives, motivation, decision making, and control. We show that by generalizing allowing action-dependent transitions and more complex temporal dynamics, we can capture the expressivity of artificial agents designed for these domains, and highly interprable representations from animal behavior.

Model

Ecological behavior in animals is often well characterized by quick transitions between discrete behavioral modes. These transitions are difficult to predict from external events, and instead reflect a shift of the animal's internal state based on integrating events over a longer time scale. A process with quick transitions separated by long inter-event intervals can be approximated by a discrete-time hidden Markov process involving transition probabilities, but many of the probabilities (those for which the state is unchanged) will be close to one, while the remaining probabilities will be very small and decrease with the discrete time scale. Instead, we expect there will be advantages in treating these latent dynamics in *continuous time*, based on rates or time intervals between transitions and events.

A natural model to account for these point-like transitions in continuous time is the semi-Markov Jump Process, Rao & Teh (2013). This process is a simple but powerful class of continuous-time dynamics featuring discrete states that transition according to a generator rate matrix, producing rich and flexible timing that is potentially better matched to animal behavior. In contrast, times of transitions between states in a Markov process are exponentially distributed, which describe animal behavior poorly.

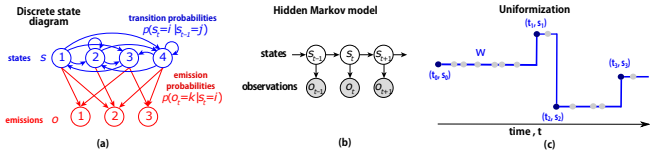

Figure 2: A discrete-state Hidden Markov Model. *a*: Discrete state diagram shows latent states (blue circles) and their transitions (blue lines), as well as the possible emissions from each state (red circles) with their emission probability (red lines). *b*: Directed probabilistic graphical model showing dependence of state variable s_{t+1} and observation o_t on the previous state s_t. *c*: We present a continuous-time extension for latent states and discrete time observations using uniformization, Rao & Teh (2013)

However, agents who control their environment affect transition rates through their actions, which means a single generator rate matrix is not sufficient to model behavior. An important example are Belief MDPs, which is a representation of a Partially Observable Markov Decision Process (POMDP, Kaelbling et al. (1998)). POMDPs are a model for inference and control when sensory measurements provide only partial observations of the state of the world. Belief MDPs have distinct transition matrices that update beliefs differently for each action. Action-dependent transitions imply that a standard semi-Markov model with a single transition generator is not expressive enough to match action-dependent belief dynamics.

To allow for action-dependent belief dynamics, we propose a switching semi-Markov (SMJP) model that matches an agent's belief dynamics by switching its generator depending on the action a: $A_{s'|s,a}$. Let $s \in \mathcal{S}$ be a discrete latent state, and $A_{s'|s}$ be an $N \times N$ generator rate matrix that can be interpreted as an instantaneous transition matrix $A\,dt = P(s'(t+dt)|s(t))$. This generator defines a point process that jumps from state s to s' at time t according to the time-dependent matrix $P_t = \exp(At)$. The process can be implemented by sequen-

tially sampling a time $t_i(s_i)$ from the total rate leaving state s_i, followed by sampling a new destination state s' according to the matrix $P_{t_i(s_i)}(s'|s_i)$ evaluated at this sample time (Gillespie's algorithm Gillespie (1977)). An analogous process occurs for the generation of observable events o, through the emission generator matrix $B_{o|s}$. The resulting process is similar to a simple Markov process, except that the time between transitions is stochastic and depends on the starting state (but not the end state), illustrated in Fig 3; the animal's behaviors and decision making are continuous, albeit partially observable only at discrete recording times.

The Markov Jump Process extends discrete time Markov processes in continuous time. Rao & Teh (2013) introduced Markov chain sampling methods that simplify structures by introducing auxiliary variables. We adapt jump structures to provide a continuous-time representation for the free foraging task and the trajectory is introduced using a generator matrix. Let $A \in \mathbb{R}^{N\times N}$ be the generator matrix, which is skew symmetric and negative diagonal entries. We can represent $P_t \in \mathbb{R}^{N\times N}$ as continuous-time transition matrix given by $P_t = \exp(At)$, $B_t \in \mathbb{R}^{N\times N}$ as discrete time transition matrix that is induced by *uniformization*, and $L_t \in \mathbb{R}^{N\times|O|}$ as observation matrix $P(O|s)$.

Uniformization instantiates the Markov Jump Process as a sequence of discrete time transition matrices (Fig 2), by introducing a latent sequence of random times that are adapted to the process generator but occur at a rate $\Omega \geq \max_s A_s$. For each interval, a random discretization vector of sampled times is $W = [w_1, w_2, ..., w_n]$, and we impute sampled times for a trajectory. Using this notation, we sample both random times as a Poisson process with intensity Ω and states using the generator matrix. The hidden Markov model characterizes a sample path of a piecewise constant stochastic process over these sampled and event times as (s_0, S, T) where T is now an ordered union of event times and randomly sampled discretized times. The chain can jump from a state to the same state or any other state, while the emissions are observed only at certain specified times. Since we sample intervals with these virtual jump times, the constructed process represents the same chain.

To learn the discrete time transition matrix B and emission matrix L, we consider an ensemble of sample sequence of observed emissions as generated from an HMM, and update the matrices using an EM algorithm to best account for the available observations. However, if we sample discrete times once, the estimates would be biased, so we resample latent trajectories repeatedly and randomly based on uniformization. The learned B matrix is then used to update the generator matrix using the relation $A_{\text{new}} = (B_{\text{new}} - I)\Omega_{old}$ while preserving its structure, and the random times are resampled to adapt to the modified A_{new}. The resulting algorithm exploits uniformization to enable learning the generator via an EM-algorithm, which is orders of magnitude more efficient than Gibbs sampling.

Belief MDPs are a convenient representation for POMDPs that treats current beliefs (posterior probabilities) over partially observable world states as fully observable. Agents following a Belief MDP exhibit transitions between beliefs $b_{t+1} = f(b_t, a_t, o_t)$, take actions according to a policy $\pi(a_t|b_t)$, and expect observations according to their beliefs via $p(o_t|b_t)$ (Fig 3). The proposed SMJP model matches the agent's action-dependent belief dynamics by switching its generator conditional on the action a: $A_{s'|s,a}$. To infer the agent's model from experimental observations, we develop an EM algorithm to infer it's parameters. When applied to our switching model, the forward α, backward β and update ξ equations of hidden Markov model, Rabiner (1989), can be written as:

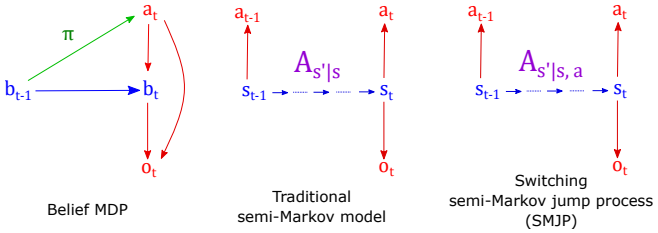

Figure 3: Comparison of graphical models of behavior. *Left*: In Belief MDP, belief transitions depend on actions selected by a policy. *Center*: Transitions in Semi-Markov Jump Process are independent of actions. *Right*: The Switching SMJP allows transition rates to depend on actions.

$$\alpha^{k'}_{t+1}(j) = \left[\sum_{i=1}^{N} \alpha^{k}_{t}(i) B^{k}_{ij}\right] L_j(o_{t+1}); \quad (1)$$
$$1 \leq t \leq T-1; 1 \leq j \leq N; 1 \leq k, k' \leq K$$

$$\beta^{k}_{t}(i) = \sum_{j=1}^{N} B^{k}_{ij} L_j(o_{t+1}) \beta^{k'}_{t+1}(j); \quad (2)$$
$$t = T-1, T-2, ..., 1; 1 \leq i \leq N; 1 \leq k, k' \leq K$$

where k, k' are the action switching indices at time t and t+1 respectively. We adjust the model parameters to maximize the probability of the observation sequence given the model and train using EM. Updates are made using the ξ variable, which is the probability of being in state i at time t and state j at time $t+1$, and is given as

$$\xi^{k}_{t}(i,j) = \frac{\alpha^{k}_{t}(i) B^{k}_{ij} L_j(o_{t+1}) \beta^{k'}_{t+1}(j)}{\sum_{i=1}^{N}\sum_{j=1}^{N} \alpha^{k}_{t}(i) B^{k}_{ij} L_j(o_{t+1}) \beta^{k'}_{t+1}(j)}; \quad (3)$$
$$1 \leq t \leq T-1; 1 \leq i, j \leq N; 1 \leq k, k' \leq K;$$

The usual semi-Markov model is a special case of the switching semi-Markov model where the generator remains the same without action dependent switching. Our model is a switching model that changes rate, transition and emission matrices in accordance with the action taken by the agent. We learn the model using an EM approach , updating model parameters given transition times sampled by the uniformization

process, and resampling the transitions given the new model parameters.

Procedure

We provide a brief description of the procedure, illustrated in Fig 4, that consists of pre-processing, initialization, training and validation steps. The overhead video, lever press and reward time sequences were used to set up observations and actions sequence required for training and validation. We processed the video recording using blob tracking to estimate position and velocity. Estimated positions and velocities were then clustered using k-means to assess different locations. By matching the time sequence of lever presses with the time sequence of locations, we augmented the observation space with locations. Therefore, the augmented observations for the model were lever press, reward delivery, and location. The actions were pressing either of the levers, stay at a location or move. The lever pressing actions were directly available from recording and we identified stay and move actions from the video location tracking. We defined similar observation and action spaces for simulations. To facilitate cross validation, we used a fixed 5-fold split to form training and validation sequences.

The proposed SMJP model has two main procedural components. The trajectorySampling function samples time intervals between consecutive observations using uniformization. It gives us imputed time sequences with missing observations within time intervals, allowing the model to transition between its hidden states at missing observations and use observations only at the end of the time interval. The switchHMM function implements EM approach using action switching and imputed sequences. We instantiated the transition, emission and rate matrices by training the model on observation and action sequences without imputed trajectories. Upon learning the emission and transition matrices for a sampled sequence, we use scaling factor, see model description, and make gradient like updates to the rate matrix while preserving its structure in the function GeneratorUpdate. The procedure of trajectory sampling and training on re-sampled sequence is repeated until the log-likelihood on held out data stops changing within a small tolerance. Therefore, we learn transition, emission probabilities and a rate matrix that capture the underlying continuous time process.

Experiment

We perform three experiments. We use the simulated toy data both to estimate a required training size and to ensure that the switching model is able to learn latent states, establish correspondence between partially observable Markov decision process belief states with SMJP latent states using theoretical optimal agent model and, then, apply our method to a real agent in a free foraging task. The number of states were selected by estimating the value at which the log-likelihood on the validation set stops improving.

Simulated toy data

To create a toy test data generated by the assumed model, we set up two transition matrices and one emission matrix with 5 states, 2 emissions and observation dependent actions. The expected size of the output sequence is set to 5000. Initial action is selected randomly and based on the action index, a transition matrix is selected. Thus, the selected transition matrix and emission matrix combination is used to estimate state transition and generate an emission. The observations, times and actions are added to the output sequence and the observation dependent action value is updated to get new observations. The simulated toy data sequence is used as a basic check if the SMJP model can learn and explain the observations. We fit SMJP model to the simulated data and observe that the log-likelihood starts stabilizing as it reaches the true number of states. It means that the model is able to explain the test data with an equivalent number of latent states (Fig 5). Therefore, we pursue a similar procedure to estimate the required number of latent states for both the optimal agent and the real agent.

Optimal agent

To test our SMJP model we fit it on an optimal agent performing a foraging task. We model the beliefs of an ideal observer in this task using a POMDP. There is a one-to-one correspondence between a POMDP over partially observable world states z and a fully observed Belief MDP in which the 'state' is the 'belief' b or posterior distribution $b_t = p(z_t|o_{1:t})$ over the world state z.We solve this optimal actor problem using a Belief MDP on a discretized belief space. The agent keeps track of its belief state about the world following transition dynamics $p(b'|b,a)$, where b' is the new belief state, b is the current state, and a is an action. The agent's sensory information depends on the world state according to the probability $p(o|b,a)$. Upon taking action a, the agent receives immediate reward $R(b,b',a)$. The goal of the agent is to maximize the

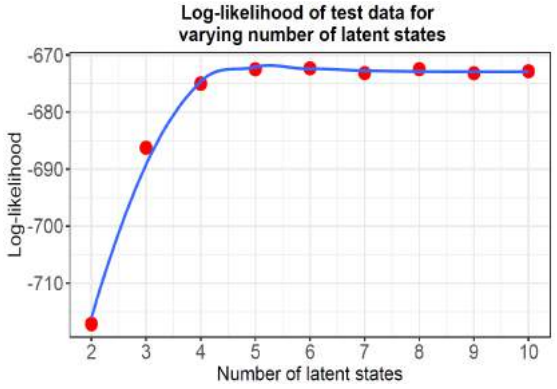

Figure 5: The model is able to explain simulated test data and the log-likelihood on held out data starts flattening out at the true number of states.

long-term expected reward $\mathbb{E}[\sum_{t=0}^{t=\infty} \gamma^t R(b_t, b'_t, a_t)]$. Our model agent achieves this goal using a policy that solves for its policy Bellman (1957), by value iteration on the discretized belief states.

The beliefs serve as latent states which control the agent's behaviors, and give its actions a non-exponential interval distribution, which is recapitulated by the fitted SMJP. We find that the likelihood of the observed data is maximal for a number of states that is smaller than the true size of the underlying POMDP belief space, indicating that the semi-Markov process is able to compress the agent's dynamics into a smaller effective number of latent states. To validate the semi-Markov model in our foraging task, we discover the latent states of the artificial agent for whom we know the ground truth. We model this agent as a near-optimal actor that maximizes reward given partial observations of the true process. This agent maintains beliefs about the availability of food at different locations. Our agent is suboptimal because we do not store the beliefs with arbitrary precision, but rather discretize the beliefs to a finite resolution, and allow some diffusion between those belief states.

Application to the free-foraging task

We apply the SMJP model to infer latent states of agents performing a simple foraging task. We applied the model to both theoretical agents with near-optimal behavior, and real agents (macaques) whose behavior we measured experimentally. In this task, two boxes contained rewards that became available after random exponentially-distributed time intervals. If an agent presses a lever on one box when the food is available, that reward is released and that box timer is reset. The benefit of the reward is offset by two action costs: pressing the lever, and switching boxes. The state of the box is not observable, so the agent must choose its action based on an internal belief about the box, with the presumed goal of maximizing total reward minus costs. This internal belief constitutes a latent state that we infer using the semi-Markov process, both from the artificial agent and behaving monkeys.

We applied the SMJP model to infer latent states of macaques performing a simple two-box foraging task. The animal freely moved between two feeding boxes with levers that released food after an exponentially-distributed random time interval (mean of 10 or 30 sec) had passed. The model observations were lever pressing, reward delivery, and location within the box (Fig 7a). Actions were: stay, move, or press either lever. The monkey's movements were tracked using overhead video, and quantized by k-means into different locations. The number of latent states is estimated by the log-likelihood maximization (Fig 7b). The resultant process constructs the monkey's latent states to explain the non-exponentially-distributed intervals between lever presses (Fig 7).

Results and Discussion

Optimal agent

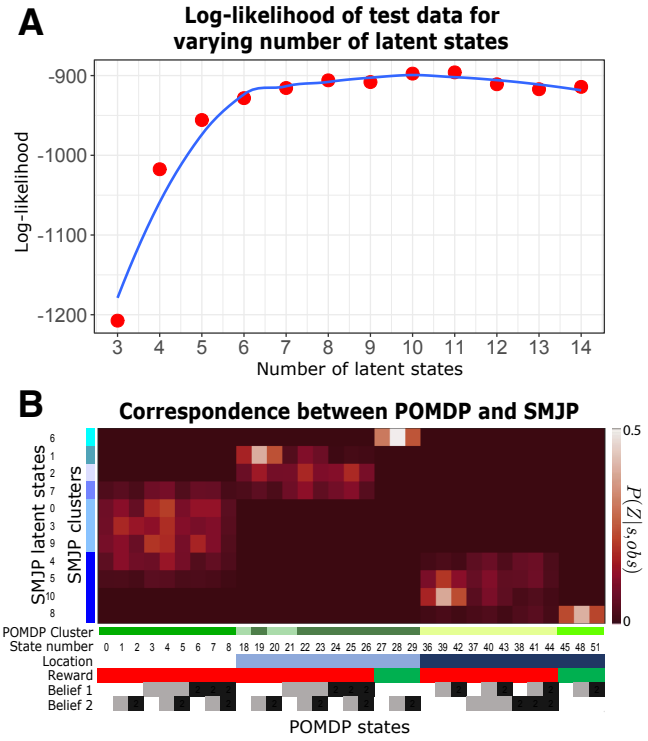

Figure 6: *Latent states inferred by SMJP for an optimal agent implementing a POMDP*. (**a**) Log-likelihood on held out data provides an estimate of the required number of latent states. (**b**) Co-clustering of states in a POMDP and our SMJP, based on the conditional probability of observing each POMDP state Z from each SMJP state, $P(Z|s,obs)$. The POMDP states Z are depicted below the horizontal axis. Clustered structure in the plot reveals that the SMJP states have information about the agent's belief dynamics.

We trained the SMJP on an observation sequence generated by the optimal agent, and optimized the number of SMJP latent states by maximizing the log-likelihood of held-out data (Fig 6a). While the Belief MDP agent's relevant states Z (including

location, reward, and beliefs b) should be implicitly embedded in the SMJP latent states s, these two state representations are not immediately comparable.

To establish a correspondence, we compute the joint distribution over s and Z at any one time point using the shared time series of observations: $p(s,Z|obs) = \frac{1}{T}\sum_t p(s_t|o_{1:T})p(Z_t|o_{1:T})$. This joint distribution shows which SMJP and POMDP states tend to occur at the same time. It therefore provides a dictionary for translating the interpretable POMDP Z states into our learned and unlabeled SMJP s states.

To increase interpretability, we cluster $p(Z|s,o)$ using information theoretic co-clustering, Dhillon et al. (2003), which provides a principled coarse-graining of the states with improved semantic interpretability. We determine the required numbers of SMJP and POMDP co-clusters by finding minimum information loss in information theoretic co-clustering. Fig 6b shows that latent SMJP states are associated with different belief states. Co-clustering also reveals that the SMJP latent states have dynamics that match the belief dynamics (not shown). These results demonstrate that the switching SMJP model can capture latent belief states and dynamics for behavioral data.

Real agent

We trained the SMJP on an observation sequence generated by the real agent (Fig 7a), and optimized the number of SMJP latent states by maximizing the log-likelihood of held-out data (Fig 7b). The SMJP model constructs latent states and dynamics using the real agent's observations to predict choices and timing, including the non-exponentially-distributed intervals between lever presses. Fig 7c shows states extracted for the action 'stay'. Beliefs precede an action and the extracted states reflect beliefs for the next action. For example, being in states $5,8$ are rewarding to the monkey. States that can be interpreted as 'expectant waiting for reward' are highlighted (Fig 7c): these states form a self-exciting delay network that is activated from other rewarded belief states. Moreover, the lower entropy of latent states associated with lever 1 revealed guarding behavior we identified from video. Overall, the model network encodes a set of complex but interpretable dynamics of the animal's beliefs and reward expectations which emphasize the complex computations underlying the decision making process.

Each transition matrix acts like an action operator and the real agent performs operations in sequences. So, we examine joint operators $T_{ji} = T_i T_j$, where T_i and T_j are operators for actions i and j respectively. We use an off-the-shelf package using, Brandes et al. (2008) to extract subgraphs and then persistent subspaces from all the six joint operators corresponding to different action pairs. Fig 7d shows subgraphs for two joint operators of interest (involving actions: lever press and stay). The latent states (within subspaces p and q) appearing in the same subgraphs of the joint operators illustrate the real agent's persistent reward belief states. The states outside the subspaces p and q correspond to other beliefs, for example, switching. These results demonstrate that the presented model is able to extract subtleties, albeit complex, in the belief states and their dynamics. The extracted latent states and dynamics will be useful regressors for finding neural correlates of the computations underlying the monkey's behavioral dynamics.

Conclusion

We presented a continuous-time switching semi-Markov model that learns the latent states dynamics in conformance with the belief structure of a partially observable Markov decision process. The revealed latent states are capable of inferring complex animal behavior and its belief dynamics in naturalistic tasks like foraging. Several aspects of the inferred behaviors and belief dynamics were examined to reveal that indeed, the internal latent structural representation match the agent's belief structure. The data-driven switching semi-Markov model provides useful estimates of the structure of the internal latent states for hard tasks. The latent states from this behavioral model could potentially be used to understand correspondences between neural activity and the latent belief dynamics that govern how an animal selects actions.

AI and Cognitive Testing: A New Conceptual Framework and Roadmap

Anonymous CogSci submission

Abstract

Understanding how a person thinks, i.e., measuring a single individual's cognitive characteristics, is challenging because cognition is not directly observable. Practically speaking, standardized cognitive tests (tests of IQ, memory, attention, etc.), with results interpreted by expert clinicians, represent the state of the art in measuring a person's cognition. Three areas of AI show particular promise for improving the effectiveness of this kind of cognitive testing: 1) behavioral sensing, to more robustly quantify individual test-taker behaviors, 2) data mining, to identify and extract meaningful patterns from behavioral datasets; and 3) cognitive modeling, to help map observed behaviors onto hypothesized cognitive strategies. We bring these three areas of AI research together in a unified conceptual framework and provide a sampling of recent work in each area. Continued research at the nexus of AI and cognitive testing has potentially far-reaching implications for society in virtually every context in which measuring cognition is important, including research across many disciplines of cognitive science as well as applications in clinical, educational, and workforce settings.

Keywords: artificial intelligence; behavioral sensing; cognitive modeling; computational psychiatry; neuropsychology.

Introduction

The meat of the matter is often *how* a patient solves a problem or approaches a task rather than what the score is.
(Lezak et al., 2012, *Neuropsychological Assessment*, p. 160)

Different people think in different ways. This seemingly obvious statement masks many deep scientific mysteries about the human mind and also has enormous implications for individual and societal well-being.

How a person thinks is central to everything that they do: it affects how they learn, work, communicate, set goals, make decisions, etc. Thus, the scientific study of individual cognitive variations is critical not just for (1) advancing our basic understanding of human cognition and development across the lifespan, including research on genes, brain, and behavior, but also for (2) improving evidence-based practices in education and special education, workforce training, clinical diagnosis and treatment, rehabilitation, and more.

However, measuring cognition is uniquely challenging, as cognitive entities and processes are not observable in the same way that genetic, physiological, behavioral, and even neural characteristics can be measured using physical sensing technologies. **We have no way (at least at present) of *directly* measuring a person's mental representations.**

Even with advances in neuroimaging technologies that can capture subtle characteristics of neural activity, measuring such activity is only a rough proxy for actual cognitive activity; the question remains of how to "allow the brain measurements to make contact with putative cognitive processes" (Forstmann & Wagenmakers, 2015, p.144).

Currently, the gold standard for individual cognitive evaluations are those carried out by expert clinicians, usually psychologists or neuropsychologists.[1] These evaluations might be done to diagnose learning or developmental disabilities in children, detect signs of cognitive decline in elderly patients, or identify cognitive deficits after stroke or other brain injury (Lezak et al., 2012). Such evaluations combine two types of information about an individual: (1) information about how that individual is functioning *outside* the clinic, through self-report measures, interviews or questionnaires given to parents or caregivers, etc.; and (2) information about how that individual is functioning *inside* the clinic, usually through the administration of standardized cognitive tests, e.g., tests of memory, IQ, visuospatial reasoning, language, etc.

It is the second item in this list—cognitive testing—that is the focus of this paper. Distinct research paradigms within artificial intelligence (AI) have the potential to advance cognitive testing in (at least) three key ways:

1. *Behavioral sensing*: to more robustly quantify individual test-taker behaviors.
2. *Data mining*: to identify and extract meaningful patterns from behavioral datasets.
3. *Cognitive modeling*: to help map observed behaviors onto hypothesized cognitive strategies.

Before getting into the details of these three areas, however, it is important to first understand how conventional cognitive testing works. **This paper presents a new conceptual framework that explains the strengths and limitations of current methods for cognitive testing and highlights specific ways in which AI can help.** We also provide a sampling of recent AI research in each area.

[1] Cognitive evaluations also often occur in education and workforce settings, though these are typically less detailed but more domain-specific than clinical evaluations. In many human research studies across all areas of science, cognitive evaluations are used for participant inclusion/exclusion, group matching, and/or covariate analyses. While this paper focuses primarily on the clinical setting, our observations pertain to these other settings as well.

How Cognitive Testing Works

The rationale behind cognitive tests is straightforward. A given test poses problems for a test-taker to solve. Problems are specifically designed to tap certain cognitive representations and processes, which we refer to as *cognitive strategies*. Test designs are often validated (i.e. to "prove" that a test indeed is tapping into the right cognitive strategies) through converging evidence from many different sources, including data from neuroimaging studies, patients with known cognitive or neurological issues, and/or other cognitive tests. A person's test score thus provides an indirect measure of these hypothesized cognitive strategies.

However, a well known issue with most cognitive tests is **ambiguity**: while test scores do indicate *how well* a person solves test problems, i.e., that person's level of ability, they do not indicate *how* a person solves test problems, i.e., their actual cognitive strategy. In other words, two people can get the same test score using very different cognitive strategies. Moreover, this ambiguity can occur with low or high scores:

> "'There are many reasons for failing and there are many ways you can go about it. And if you don't know in fact which way the patient was going about it, failure doesn't tell you very much' (Darby & Walsh, 2005). There can also be more than one way to pass a test." (Lezak et al., 2012, p. 160)

Because of this ambiguity, expert clinicians often combine scores with other observed behaviors, such as errors, eye gaze, emotions, general demeanor, etc., in order to better interpret a person's test performance. This supports the rationale for why only "trained" clinicians should administer cognitive tests, and also why clinicians develop such deep expertise with their particular population and goal (e.g. screening children for learning disabilities versus working with elderly patients to detect memory issues).

In reality, as mentioned in the introduction, clinicians likely never rely on results from a single cognitive test to make judgments about a person's cognition. They combine results from many tests with additional information about a person's performance outside the clinic (e.g. school performance, medical history, etc.). For the purposes of this paper, however, we focus on thinking about just a single cognitive test and what it can tell us.

Proposed framework

In this section, we propose a new formalism for describing what is happening during a conventional cognitive test. For added clarity, we also use the Raven's Progressive Matrices (RPM) intelligence test as a running example. The RPM is a well studied standardized test that poses problems similar to geometric analogies: a matrix of visual figures is presented with one missing, and the missing figure must be chosen from among a set of candidate answer figures (i.e., multiple choice). The RPM is one of the best single-format measures of intelligence among all cognitive tests (Snow, Kyllonen, & Marshalek, 1984) and thus is very widely used.

Definition 1. Let the set X_{human} represent all possible cognitive strategies that a person can use to attempt to perform a given cognitive test, successful or not.

Definition 2. Let the set Y represent all possible scores that can be earned on a given cognitive test.

Definition 3. Let the function F represent a mapping from a person's use of a particular cognitive strategy onto the resulting test score:

$$F(x_i \in X_{human}) = y_i \in Y$$

We do not concern ourselves with how X_{human} might be represented. The set is infinite, even if we exclude obviously irrelevant strategies.[2] An individual person probably can access at least a few strategies from X_{human}, and certainly they can also be taught to use particular strategies.

Though not, perhaps, designed this way on purpose, the RPM is amenable to multiple distinct strategies. For example, there is evidence that many neurotypical individuals often use verbal, inner-speech-like strategies, whereas many individuals on the autism spectrum use visually mediated, mental-imagery-like strategies (Soulières et al., 2009). In fact, some argue that the reason the RPM is such a good intelligence test may be because it is actually testing metacognitive flexibility, in terms of strategy selection/adaptation (Kirby & Lawson, 1983)...a point that we return to later on in this paper.

For simplicity, let us assume that a person uses a single strategy $x_i \in X_{human}$ to solve a given cognitive test. Using this strategy x_i, they receive a score y_i. In other words, the act of taking the test is what "computes" the function F.

In the case of the RPM, the test is scored as number of correct answers, and so possible scores (for the standard version of the test) range from 0 to 60. So, suppose someone uses a verbally mediated strategy, and they get a score of 50/60.

Using these definitions, ambiguity exists because F is a many-to-one function. There are many possible strategies in X_{human} that may lead to a score of 50. As a result, the inverse function $F^{-1}(y_i) = x_i \in X_{human}$ is ill-defined.

To help with this problem, we expand our definitions to include additional test-taker behaviors, beyond just test score:

Definition 4. Let the vector B_{human} represent a sequence of observable behaviors generated by a person taking a cognitive test, including test score y as well as response times, types of errors made, patterns of eye gaze, etc.

Definition 5. Let the function G represent a mapping from a person's use of a particular cognitive strategy onto the sequence of resulting behaviors:

$$G(x_i \in X_{human}) \rightarrow B_{human}$$

For example, for a person taking the RPM, one might include in B_{human} the time taken to complete each problem, the

[2] Making a peanut butter and jelly sandwich is one possible strategy for solving RPM problems. It is, however, an exceedingly poor strategy, and so let's exclude it from X_{human}.

answer choice that is selected, the pattern of eye gaze between different visual elements, etc.

Now, while the function G is still a many-to-one function (i.e., multiple strategies might still map onto the same sequence of behaviors), it is "less" many-to-one than our earlier function F that mapped strategies onto scores. Each behavioral observation that is made places an additional constraint on the subset of strategies in X_{human} that could have produced the full sequence of behaviors. Therefore, given a sequence of observable behaviors B_{human}, the inverse function $G^{-1}(B_{human}) = x_i \in X_{human}$ provides a better estimate of a person's cognitive strategy than does the inverse function F^{-1} that relies on test score alone.

For example, research on geometric analogies has shown that different patterns of eye gaze seem to be indicative of different high-level problem-solving strategies (Bethell-Fox, Lohman, & Snow, 1984). Some people look at the "problem" part and come up with their own answer before looking at the answer choices, while others look at the answer choices early and use more of a trial-and-error approach, mentally plugging in each answer choice to see which one looks best.

One problem remains: where does the sequence of behaviors B_{human} come from? For traditional cognitive tests, usually administered in a pencil-and-paper or objects-on-a-table format, there is no perfect record of B_{human}. Clinicians observing a person taking a test use their own, expertly trained powers of perception, memory, and note-taking to process B_{human} in real time in order to extract meaningful patterns:

Definition 6. Let the function P represent a mapping from a sequence of low-level behaviors B_{human} to a selected set of patterns (i.e., a subset and/or transformed view of individual observations in B_{human}).

We use P_{expert} to denote the function that a clinician applies to extract meaningful patterns from the raw behavioral sequence B_{human}. **Thus, when a clinician observes a person's test performance to infer information about that person's cognition, they are implicitly computing the function:**

$$G^{-1}_{expert}(P_{expert}(B_{human})) = x_i \in X_{human} \quad (1)$$

Where do the functions G^{-1}_{expert} and P_{expert} come from? In general, they are learned over years or decades of administering cognitive tests to certain segments of the population. For example, a clinician with expertise in learning disabilities likely uses G^{-1} and P functions that are tuned to patterns of behavior most relevant for diagnosing these conditions in children. Another clinician who works mostly with brain injury patients would likely use different G^{-1} and P functions, even when administering similar tests.

The problem with implicit functions, and current, non-AI-based solutions

The main problem with these learned G^{-1}_{expert} and P_{expert} functions is that they are implicit in a clinician's expertise. Not only are they implicit, but they are also very difficult to make explicit, even if a clinician tries to do so. This difficulty in turn complicates efforts to measure the validity or reliability of these functions, both for individual clinicians and for the field of cognitive assessment as a whole.

The Boston Process Approach to neuropsychology was essentially an attempt to "write down" these functions using a combination of expert judgment and carefully designed research studies, so that the resulting functions could be more rigorously evaluated for validity and reliability, and also so these functions could be explicitly taught as part of professional neuropsychology training. However, while the ideas of the Boston Process Approach have been influential, the complexity of its methods and the challenges of real-time data collection during testing sessions limited its widespread adoption (Milberg, Hebben, Kaplan, Grant, & Adams, 2009).

The advent of computer-based testing has provided new methods for recording sequences of test-taker behaviors, such as detailed reaction times, errors, etc. Some , like the California Verbal Learning Test (Delis, Freeland, Kramer, & Kaplan, 1988), have been designed specifically to enable the use of these additional behaviors to infer more and better information about a person's cognitive strategy than would be obtainable from their score alone.

These and similar efforts from the neuropsychology research community have been analyzed more recently under the heading of the Quantified Process Approach (Poreh, 2012), which emphasizes the critical need to understand cognitive strategies, i.e. "process," using quantifiable measures, in addition to the subjective and often qualitative judgments of individual clinicians (what we describe here as the implicit G^{-1}_{expert} and P_{expert} functions). The Quantified Process Approach outlines three categories of potential solutions: 1) using additional tests to essentially triangulate a person's strategy using multiple points of measurement; 2) using additional measures of behavior from a single test to develop new indices of interest; and 3) decompose scores into subscores that might reflect different underlying factors. Of these three categories, the latter two would fall into our proposed framework as efforts to come up with explicit G^{-1} and P functions, depending on whether the behaviors B_{human} considered are taken from behavioral dimensions above and beyond scores (category 2) or from behavioral dimensions within scores that pinpoint more detailed subscores (category 3).

However, these various pockets of research have yet to transform the daily practice of cognitive testing. Problems remain in how to quantify G^{-1} and P functions in a scalable way that can be applied across many different cognitive tests and many populations, while also ensuring that methods are readily usable by practicing clinicians.

AI to the Rescue[3]

Using this framework, we now describe ways in which AI can help solve some of these problems through 1) behavioral sensing, 2) data mining, and 3) cognitive modeling.

[3]Possibly.... https://xkcd.com/1831/

Behavioral sensing

The first, and perhaps most obvious, role for AI in cognitive testing is in recording behavioral observations, i.e., in obtaining the sequence of behaviors B_{human} from a test session.

Part of behavioral sensing involves advances in hardware, such as the development of more advanced (and more affordable) eye trackers. Computer-based testing platforms can easily log many kinds of behaviors, including mouse movements, key presses, etc. Tablet-based tests are being used to capture more detailed manual behaviors such as velocity of pen strokes (Davis, Libon, Au, Pitman, & Penney, 2014).

While behavioral sensing in computer-based environments is currently more common, one of the most exciting new areas for behavioral sensing involves sensing in real, 3D environments, which often calls for a combination of advances in hardware and in signal processing algorithms. Eye tracking technology is now getting to the point where head-mounted eye trackers are relatively lightweight and affordable (Kassner, Patera, & Bulling, 2014), and computer vision algorithms can be used to help analyze the video stream coming from such eye trackers. These advances enable scalable eye-tracking in 3D environments, which, in previous years, would have been virtually unthinkable in the context of cognitive testing from usability or scalability perspectives. Physiological sensors are also now often incorporated into cognitive assessments, e.g., using skin conductance sensors to obtain measurements of heart rate, etc. as a proxy for measuring cognitive stress or other affective variables during a testing session (Fletcher et al., 2010).

In addition, even data recorded from regular sensors (cameras, microphones, etc.) can now be analyzed automatically using AI algorithms coming from computer vision, natural language processing, etc. The term *behavioral imaging* has been coined to describe this new subfield of AI directed at producing robust and reliable measurements of human behavior in 3D assessment settings (Rehg et al., 2014).

Behavioral sensing can thus be understood in terms of its two components: sensors to record raw signals coming from a testing session(e.g., pixels from a video camera), plus algorithms to process those raw signals into measurements of behavior (e.g., computer vision algorithm to detect, from a raw video stream, when a person moves an object on a table).

Behavioral sensing can help in measuring many types of behaviors. Some behaviors are already easily measured by humans, but automated approaches may increase the scalability or accuracy of such measurements (e.g., counting how many errors a person makes while solving a table-top block copying task). Other behaviors might be currently detectable by human clinicians but only in qualitative ways. For example, many social assessments for the diagnosis of autism use "quality of eye contact" as a measurement of interest, which is often recorded as a subjective overall impression by a human clinician, but could be broken down into quantified components by an algorithm (Ye et al., 2015). Still other behaviors might not be detectable by human clinicians at all; for example, being able to capture the exact velocities and pressures manually applied by a person performing a tablet-based drawing test (Davis et al., 2014).

Data mining

The next role for AI is in quantifying the function P that takes in a sequence of behaviors B_{human} and extracts meaningful patterns. Meaningful patterns can be created in many different ways, including by identifying subsets of behaviors that are particularly relevant, or by producing transformations of low-level behaviors into higher-level constructs.

For example, there has been work that first uses a tablet-based version of the clock drawing test to record low-level manual drawing behaviors, and then applies machine learning classification algorithms to these data to help diagnose Alzheimer's, Parkinson's, and other cognitive conditions (Souillard-Mandar et al., 2016).

In another effort, eye tracking data from a visual recognition test (the Visual Paired Comparison test) have been used to train classifiers to detect early signs of mild cognitive impairment, which is often a precursor to Alzheimer's (Lagun, Manzanares, Zola, Buffalo, & Agichtein, 2011). A clever extension of this work aims to see if mouse movement data from a non-eye-tracking variant of the task can support comparable classification performance, which would greatly increase the scalability of the test by removing the need for an eye tracker (Agichtein et al., 2017).

In general, the broad umbrella of data mining approaches for cognitive testing can include the use of: 1) new algorithms applied to existing behavioral datasets; 2) conventional statistical analyses applied to new behavioral datasets; and 3) new algorithms applied to new datasets. All of these approaches represent important routes for improving our understanding of the low-level behaviors that come out of cognitive tests, i.e., to identify which behaviors or combinations of behaviors are most important for a given clinical goal.

Cognitive modeling

The third important role that AI can play in cognitive testing is through cognitive modeling. What does a computational cognitive model actually accomplish? To answer this question, we begin by supposing that we have created a particular type of AI system—a computational cognitive architecture—that can employ different problem-solving strategies to solve problems from a given cognitive test.

Critically, such an AI system is not just a mathematical model of relationships between hypothesized cognitive entities involved in solving the test. It is a computational model of the hypothesized entities themselves; it provides a mechanism-level view of what might be going on. The key difference between a mathematical model and a computational model is that a computational model bears an analogical relationship with what it is trying to model; there is some structural correspondence between the model and what it represents (Hunt, Ropella, Park, & Engelberg, 2008).

Definitions 7 through 12 (below) refer to concepts related to this kind of computational model, which are also analogous (but not identical) to the concepts given in Definitions 1 through 6 (above) for human test-takers.

Definition 7. Let X_{AI} represent the set of problem-solving strategies that an AI system can use to solve a given cognitive test, including successful and unsuccessful strategies.

Definition 8. Let y_{AI} represent the score the AI system receives on a given cognitive test.

Definition 9. Let the function F_* represent a mapping from an AI system's use of a particular strategy onto the resulting test score, i.e., $F_*(x_i \in X_{AI}) \rightarrow y_{AI}$.

Definition 10. Let B_{AI} represent the sequence of *simulated* observable behaviors b_i generated by an AI system taking a cognitive test. These behaviors can include test scores y_{AI} as well as response times, types of errors made, patterns of eye gaze, etc.

Definition 11. Let the function G_* represent a mapping from an AI system's use of a particular strategy onto the resulting test score plus simulated behaviors, i.e., $G_*(x_i \in X_{AI}) \rightarrow B_{AI}$.

Definition 12. Let the function P_* represent a mapping from a sequence of low-level behaviors B_{AI} to higher-level features.

To take our previous example of the Raven's Progressive Matrices test, many computational cognitive models of this kind have been developed over the years (Carpenter, Just, & Shell, 1990; Lovett, Tomai, Forbus, & Usher, 2009; Kunda, McGreggor, & Goel, 2013; Strannegård, Cirillo, & Ström, 2013). There has also been much work in the cognitive architectures community (e.g. using SOAR, ACT-R, etc.) to develop richly detailed models of many different tasks.

Given such a computational cognitive model, we can run experiments that have the model use a variety of different strategies to solve a given cognitive test. We can measure data from these experiments to obtain test scores and behaviors, just as we do for human test takers. **The key difference here is that cognitive strategies in a cognitive model are directly observable!** We have the "ground truth" for our model in a way that is (at least currently) impossible to obtain for human test takers.

At minimum, we can study the function F_* to understand more about potential ambiguities on a particular cognitive test, which would itself a valuable contribution to the field of cognitive testing.

Also, such a cognitive model provides a systematic way to obtain quantified functions for mapping from the space of observed behaviors back onto cognitive strategies, i.e., the function G^{-1}. This is still not easy (though it is much easier when we have the ground truth for X!). There are probably many possible approaches for obtaining the G^{-1} function. One might be to run a large set of computational experiments to get two linked datasets X_{AI} and B_{AI}, and then use machine learning and data mining algorithms to find relevant patterns and predictors within these.

One important area for research using computational cognitive models is to more effectively capture individual differences. Much of the research on cognitive architectures, for example, focuses on modeling generalized human performance or broad group differences. As the quantity and quality of behavioral measurements increase, through behavioral sensing and data mining, cognitive models should also be able to take advantage of these datasets to create more precise explanations of individual variations.

Another extremely interesting open question is: where do the strategies in X_{AI} come from? For now, X_{AI} is defined by the AI system's designers, informed by research on human cognition. An important AI frontier is to develop AI systems that *learn* strategies through instruction, observation, and experience, as people do (Laird et al., 2017). This research would not only expand the capabilities of our cognitive models, but results would also help us better understand human cognitive strategies at the metacognitive level. As mentioned earlier, for example, work on the Raven's Progressive Matrices test suggests that a person's methods for strategy selection are just as important for test performance as are the strategies themselves (Kirby & Lawson, 1983).

A Call to Action

Similar observations have been compiled under the heading of computational psychiatry (Montague, Dolan, Friston, & Dayan, 2012; Huys, Maia, & Frank, 2016), though the specific formalism given here is (to our knowledge) new.

What our analysis suggests is that interdisciplinary collaboration is critical for advancing the science of cognitive testing, not just between clinicians and AI researchers in general, but between clinicians and AI researchers coming from the distinct subfields of behavioral sensing, data mining, and cognitive modeling.

In addition, one extremely promising horizon is to think about the development of new cognitive tests that are enabled by the types of technological advances described above. For example, now that we can measure and understand very rich sets of behavior, and also map these onto detailed hypotheses about cognitive strategies, can we begin to measure complex forms of cognition in more naturalistic tasks? So much of current test design has been shaped by the limitations in the scalability of these elements in previous decades. Previously, cognitive test designers had to construct very constrained tasks, that would only measure one or two cognitive constructs at a time, and that would produce easily measurable scores. Now, for example, could we give people a realistic search task in a complex, 3D environment to test their attention and/or memory? There is a great opportunity here to begin coming up with much more creative and naturalistic ways to tap into a person's realistic cognitive processes.

Abstract

The interrelatedness of lexical items, typically defined in terms of semantic or phonological overlap, has been shown to influence language learning. Given that language also contains sequential structure, we investigate here whether temporal overlap among words, formalized in graph theoretical terms as displaying the property of *community structure*, might also have consequences for learning. We create a graph organized into clusters of densely interconnected nodes with relatively sparse external connections. After assigning a novel pseudoword to each node in the graph, we generate a continuous sequence of visually-presented items by walking along its edges. Word-by-word reading times suggest that learners are indeed sensitive to temporal overlap. Compellingly, we also demonstrate that prior exposure to sequences organized into temporal communities influences performance on a subsequent word recognition task.

Keywords: network science; statistical learning; language acquisition

Introduction

A foundational question in cognitive science asks how the human brain converts a vast amount of sensory input into usable knowledge. Fortunately for our brains, sensory input, though noisy, tends to be richly patterned. A means of characterizing broad-scale patterns, network science enables the mathematical description of systems as varied as social relationships (Scott, 2017) and neural connectivity (Bassett & Sporns, 2017). Of particular relevance to the present series of experiments, applications of network science to the domain of natural language have dramatically increased our understanding of the organization of phonological (Vitevitch, 2008; Arbesman, Strogatz, & Vitevitch, 2018), syntactic (Ferrer i Cancho, Solé, & Köhler, 2004; Liu, 2008), and semantic systems (Collins & Loftus, 1975; Borge-Holthoefer & Arenas, 2010).

A growing body of evidence suggests that humans use network-level properties when acquiring and accessing linguistic knowledge (for a review, see Karuza, Thompson-Schill, & Bassett, 2016). For example, an index of the extent to which phonological neighbors of a word are themselves neighbors, clustering coefficient has been shown to predict acquisition of novel object labels designed to vary with respect to this property (Goldstein & Vitevitch, 2014). Learners also show sensitivity to lexical islands, or small groups of phonologically related words isolated from a network's "giant component," or the largest group of interrelated words. Siew & Vitevitch (2016) observed that words drawn from lexical islands are recognized and recalled more easily than those from a giant component. For semantic networks, in which nodes representing concepts are linked according to some similarity metric, evidence suggests that densely connected words are most likely to be acquired early in development (Steyvers & Tenenbaum, 2005). In sum, the structural properties of complex language networks may carry important implications for learning.

Outside the language domain, a number of studies have also begun to probe human sensitivity to network topology, generally focusing on community structure in temporally-defined graphs. In these studies, nodes correspond to fractals, glyphs, or button press combinations, and edges mark the transition between two images in a continuous sequence (Schapiro, Rogers, Cordova, Turk-Browne, & Botvinick, 2013; Karuza, Kahn, Thompson-Schill, & Bassett, 2017; Tompson, Kahn, Falk, Vettel, & Bassett, 2018; Kahn, Karuza, Vettel, & Bassett, 2018). Response times are typically recorded as participants view an uninterrupted stimulus stream created by "walking" along the edges of a graph comprised of sparsely connected clusters of densely interconnected nodes (i.e., that display the property of community structure; Figure 1). Results point to a signature response pattern associated with the transition between communities: a pronounced increase in learners' processing times when measured against within-community transitions (Karuza et al., 2017).

Expanding on prior work, which has focused exclusively on non-linguistic visual stimuli, we investigate here whether learners display a comparable sensitivity to community structure when it dictates the order of visually-presented pseudoword sequences. One defining characteristic of linguistic signal is that it unfolds in time. In light of this, we examine whether the temporal overlap between words, not only their phonological and semantic interrelatedness, might steer the learning process. In adapting this paradigm to the language domain, our work makes two additional contributions: first we expand on the size of tested network structures, creating graphs of 40 nodes instead of the 10-15 used in related prior work (Schapiro et al., 2013; Karuza et al., 2017; Tompson et al., 2018; Kahn et al., 2018). Second, we refine an offline measure that allows us to investigate the influence of community structure not only in moment-to-moment processing of novel stimulus streams, but also in accessing previously acquired knowledge in future contexts.

Study 1: Community Structure and Substring Familiarity

We first examine whether learners exhibit cross-community reaction time (RT) increases as they process continuous sequences of unfamiliar linguistic stimuli. We also ask whether sensitivity to community structure will manifest in the expression of knowledge in offline familiarity judgements involving short sequences (substrings) extracted from the original exposure stream. Analyses test the hypothesis that learners prefer substrings drawn from within communities relative to those that span communities.

Materials and Methods

Participants 33 neurologically normal participants (5 male, 28 female; 18-21 years old) participated in this study. They were recruited from the undergraduate psychology research pool at Pennsylvania State University and were granted course credit for their participation. All participants provided informed consent. Three participants were excluded for performance below a pre-determined threshold on an orthogonal cover task (<70% correct; Karuza et al., 2017).

Stimuli

Network properties. Exposure streams were generated via a random walk on a graph featuring five communities of eight nodes each (Figure 1). Each community was connected to two other communities through boundary nodes sharing a single edge with an adjacent community. With the exception of boundary nodes within the same community, which were unlinked, each other node was connected to every other node in their community. Thus, all nodes had equivalent degree, or number of incident edges. Because edges were undirected and unweighted, (1) they could be traversed in any direction and (2) transitions between any two nodes were equally probable. Nodes within the graph corresponded to a unique, pronounceable pseudoword, and edges represented the direct succession of two pseudowords within the stimulus stream.

Pseudoword properties. Pseudowords were selected from the ARC non-word database (Rastle, Harrington, & Coltheart, 2002). Forty orthotactically plausible, single-syllable words were chosen, 20 four-letter words and 20 five-letter words. All words had 5-30 orthographic neighbors and 5-30 phonological neighbors. While metrics such as Coltheart's N

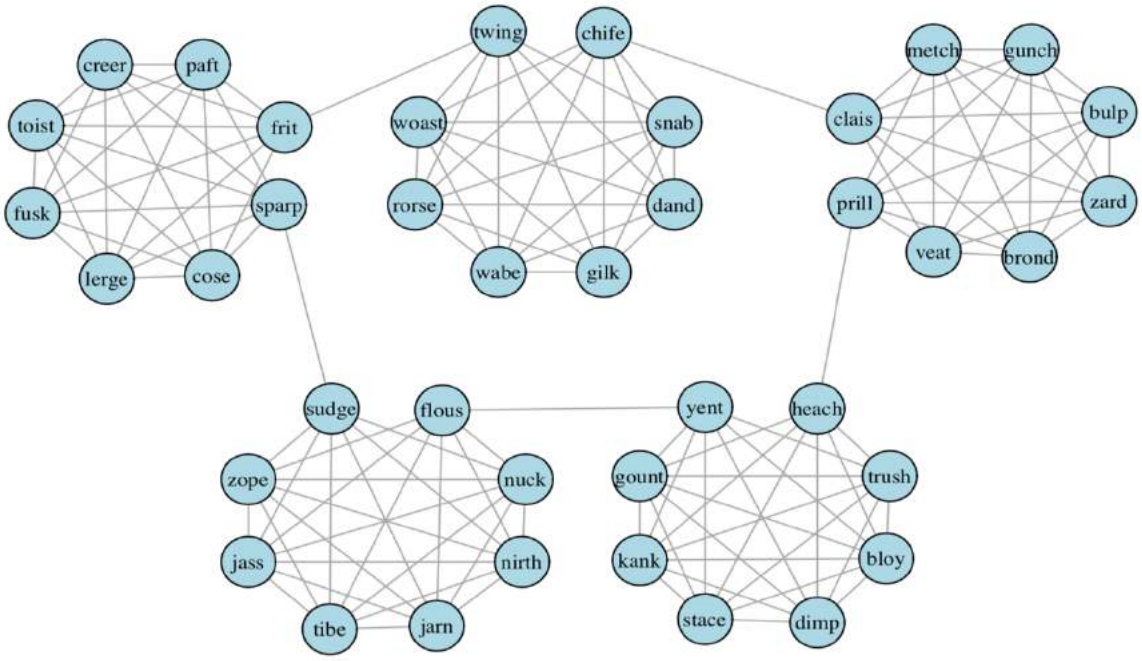

Figure 1. The network architecture used to generate stimulus streams in Studies 1 and 2. Each node represents a pseudoword, and edges represent the co-occurrence of two pseudowords in a continuous sequence

have been shown to have certain limitations (Yarkoni, Balota, & Yap, 2008), and indeed some pseudowords shared surface-level similarities, we stress that any *systematic* phonological or orthographic overlap was minimized by our word-to-node randomization procedure. For the purposes of the cover task (described below), we created a scrambled, unpronounceable version of each pseudoword (e.g., *clais* and *gilk* became *aislc* and *igkl*).

Test items. Eighteen short test sequences (length 5-7 pseudowords) were spliced out of the continuous exposure stream. Half of these substrings consisted exclusively of nodes from within one community, while the other half included traversal of a community boundary. Matched pairs of intra- and inter- community substrings were created by equating length (number of items in the string), number of node repetitions (if any), chunk strength (within one standard deviation of the mean; Meulemans & Van Der Linden, 1997), and general position in the exposure stream (first third, second third, etc.).

Procedure The experiment was composed of four phases: familiarization, exposure, test and debriefing. Participants were randomly assigned to one of four conditions consisting of a unique random walk (i.e., ordering of nodes) in the exposure phase and a unique series of test items. Independent of condition, node-to-pseudoword correspondence was randomized (i.e., "node 1" might correspond to *clais* in one participant and *gilk* in another).

Familiarization phase. Participants were told that they would see a list of made up and scrambled words presented in alphabetical order. They then viewed the list of pseudowords and the scrambled words in a series of 1.5-second trials. They were instructed to press [1] if the word on the screen followed the rules of English (these were the pseudowords) and [2] if the word did not follow the rules of English (these were the scrambled versions). To facilitate their understanding of the task, participants first saw two examples: the pseudoword was *corb*, and the scrambled word was *brco*.

Exposure phase. Following the familiarization phase, participants viewed a 1000-trial continuous sequence of individually presented pseudowords. To obtain RT measures across the entirety of the exposure phase, we instructed participants to complete an orthogonal cover task. At each trial, they were asked to press [1] if the pseudoword appeared in its "regular form" and [2] if the pseudoword appeared scrambled (12% of trials). Each pseudoword was presented for 1.5s with no interstimulus interval. Total duration of the exposure phase was 25 minutes.

Test phase. At the conclusion of the exposure phase, participants were presented with 18 pairs of substrings presented simultaneously on the screen, one above the other (position was randomly determined). They selected which of the two short sequences looked more familiar to them based on what they saw during the previous phase of the experiment. We adopted a familiarity-based approach to judging pairs to promote relatively implicit access of knowledge during the test phase. Unlike the exposure phase, the test phase was self-paced (i.e., both sequences stayed on screen until participants made their selection), with an interstimulus interval of 1.5 seconds.

Analysis and Results

Scrambled Word Detection Participants generally succeeded in distinguishing between pseudowords and their scrambled versions (95.8% accurate, SD = 2.4, excluding the three participants who scored below threshold).

Data Exclusions In the exposure phase, data were prepared for analysis by first eliminating any implausible RTs (i.e., less than 100 ms), then by removing RTs that were greater than three standard deviations away from the mean (4.5% of total data). We also removed all scrambled word trials (12% of total data) and any incorrect responses (4.2% of total data). As we were particularly interested in the RT cost associated with crossing between communities, data were then subset to include only nodes corresponding to entry into a new community (transition nodes), as well as boundary nodes immediately prior to that transition (pre-transition nodes).

Exposure Phase In a linear mixed effects model (library *lme4* 1.1-19 in R 3.5.1), RTs were regressed onto the main effects and interaction of Node Type (pre- vs. transition) and Trial (1-1000). All transitions were included in analysis. The model included the fullest random effects structure that allowed the model to converge: a random intercept for participant and a by-participant random slope for Node Type, Trial, and their interaction.

We observed a significant main effect of Node Type (β = 10.080, t = 2.310, p = 0.022), indicating a processing cost for transition nodes compared to pre-transition nodes. The main effect of Trial (β = -22.798, t = -3.191, p = 0.003) was also significant, an expected finding given that participants were likely to become faster overall at executing button presses. No interaction between Node Type and Trial was observed (β = -6.911, t = -1.477, p = 0.150).

Test Phase Accuracy scores from the posttest did not differ significantly from chance (t(29) = 1.161, p = 0.255). When a post-hoc analysis (mixed logit model) was run to determine whether accuracy was affected by the length of sequences (5 vs 6 word sequences: β = 0.103, z = 0.959, p = 0.341; 5,6 vs 7 word sequences: β = 0.054, z = 0.860, p = 0.390), position on the screen (top or bottom) (β = -0.107, z = -1.208, p = 0.227), or trial number (β = 0.027, z = 0.305, p = 0.761), we continued to observe no significant effects.

Study 2: Community Structure and Word-Level Recognition

Study 1 offers evidence of a cross-community RT increase as learners viewed sequences of written pseudowords. Online measures, collected during the exposure phase, serve to

demonstrate learners' expectation that words within a community should co-occur in time. When that expectation was violated by entry into a new community, RTs reflected a processing penalty. Despite these promising results, we found no evidence that participants applied this knowledge offline as they made substring-level familiarity judgements. Successful language acquisition requires not only the accumulation of statistical regularities, but also accessing that accumulated knowledge in varied contexts. Therefore, the focus of Study 2 was on a post-exposure measure that would speak to the role of community structure in the latter process.

Materials and Methods

Participants 37 neurologically normal participants (9 male, 28 female; ages 18-21) participated in this study. They were recruited from the undergraduate psychology research pool at Pennsylvania State University and were granted course credit for their participation. All participants provided informed consent. Four participants were excluded for cover task performance below the pre-determined threshold used in Study 1.

Stimuli Pseudowords and the graph used to generate the exposure streams were identical to those used in Study 1. However, we increased the length of random walk by 40% in order to ensure participants were receiving sufficient exposure before completing a post-test. For the test phase, we developed a new approach to evaluating the influence of network architecture on retrieval of knowledge following initial learning.

Test items. Our method represents an extension of a classic paradigm developed by Meyer & Schvaneveldt (1971). In that pioneering study, participants completed a lexical decision task on various pairs of words and pseudowords. Compellingly, RTs for pairs of semantically related words were significantly faster than RTs for pairs of semantically unrelated words. Instead of asking whether *semantic* similarity influences retrieval processes, we ask instead whether community structure, or *temporal* similarity, influences retrieval. Here, we test the hypothesis that participants will be faster to make old/new judgements on pairs of words drawn from the same community relative to those drawn from distant communities.

We created 75 new pseudowords which were not seen in the exposure phase ("new words"). We then selected 15 non-boundary pseudowords ("old words") from the exposure phase (3 from each community). These old words were combined exhaustively to form 95 pairs in which items varied by community distance. Next, each old word was paired once with three new words (45 pairs). Finally, the 30 remaining old words were then paired with each other (15 pairs). In total, 165 pairs were created.

For the purposes of analyses, distance between items in a pair was construed as follows: a community distance of 0 meant the pair came from the same community (e.g. *creer* and *toist* in Figure 1). A community distance of 1 meant that the nodes were drawn from adjacent communities (e.g. *creer* and *twing*). A community distance of 2 meant that the nodes were two communities apart (e.g. *creer* and *metch*). There could be no measurement of community distance between old and new words, as the new words were not present in the exposure stream.

Procedure With the exception of the test phase, described below, procedures for Study 2 mirrored that of Study 1. Due to the increased number of trials presented during the exposure phase, its duration was 35 minutes.

Test phase. Participants were simultaneously presented with both items in a pair, one word above the other. Participants pressed [f] for "familiar" if both items had been seen in the exposure phase and [n] for "not familiar" if one or both of the items were new. All new words were only presented once to minimize confusion during the test phase. Trials were self-paced and separated by a 1.5 second blank screen. The order of the pairs and the position (top or bottom) of all pseudowords was randomized across participants.

Analysis and Results

Scrambled Word Detection Participants generally succeeded in distinguishing between pseudowords and their scrambled versions (93.5% accurate on average, SD = 5.6, excluding the four participants below threshold).

Data Exclusions For the exposure phase, data trimming techniques were identical to those described in Study 1 (17.0% of total data removed). Similarly, we subset trials to include only transition and pre-transition nodes.

For the test phase, we removed data corresponding to incorrect trials and any RTs greater than 3 standard deviations from the mean (total data loss = 11.3%).

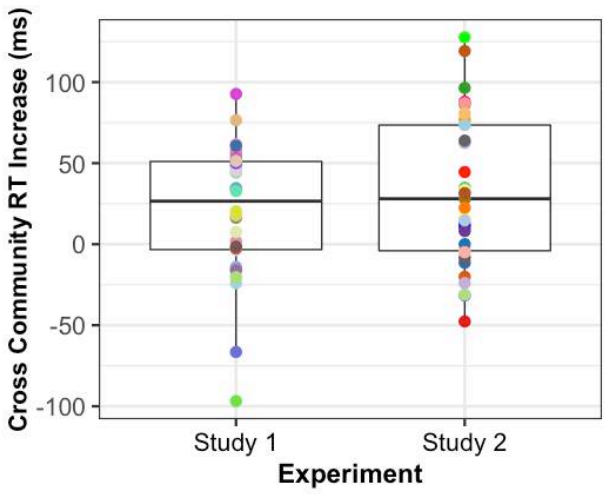

Figure 2. Cross community RT increase for Studies 1 and 2. Values included in the boxplot were calculated by subtracting, for each participant, mean RTs for pre-transition nodes from mean RTs for transition nodes.

Exposure Phase Similar to the previous study, RTs were regressed onto the main effects and interaction of Node Type (pre- vs. transition) and Trial (1-1400). The model included the fullest random effects structure that allowed the model to converge: a random intercept for participant and a by-participant random slope for Node Type, Trial, and their interaction.

Again, we observed a significant main effect of Node Type (β = 15.582, t = 3.782, p = 0.0002), indicating a processing cost for transition nodes compared to pre-transition nodes. The main effect of Trial (β = -18.251, t = -2.609, p = 0.014) was also significant. As in Study 1, no significant interaction between Node Type and Trial was observed (β = -0.924, t = -0.226, p = 0.821). Cross-community RT increases from both Study 1 and Study 2 are presented in Figure 2.

Repetition priming. Prior work examining the influence of community structure on RT patterns has addressed the potential for perceptual priming effects (e.g., Karuza et al., 2017; Kahn et al., 2018). It is well known that humans are faster to process a stimulus that they have seen recently. Though we propose that priming can in fact be considered a form of learning (see e.g., Chang, Dell, Bock & Griffin, 2000), we make contact with prior work by adding to both exposure phase models (Studies 1 and 2) the following measures of repetition priming: Lag10 and Recency. Lag10 indexes the number of times a particular node has been seen in the last 10 trials. Recency indexes the number of trials that have elapsed since a given node was last seen in the exposure stream. When adding these new predictors to our models, the main effect of Node Type was no longer significant (Study 1: β = 2.345, t = 0.441, p = 0.660; Study 2: β = 5.906, t = 1.104, p = 0.273).

Test Phase As in Meyer & Schvaneveldt (1971), our dependent measure of interest was RT for the old/new judgements. Given our lengthy exposure phase, and the fact we never repeated any of the "new words" during the test phase, participants attending to the test phase should have been able to easily and accurately make judgements about the novelty of items in the word pairs. Accuracy scores, though high (88.0% correct overall, SD = 9.9), were not our measure of interest. Rather, we were interested in whether RTs would vary as a function of the distance between nodes in a pair, with the fastest RTs for nodes within the same community. Thus, we imposed a cut-off of 75% accuracy on the test phase to exclude participants who were not complying with this relatively simple task, resulting in the exclusion of three additional participants. We note that without the exclusion of these participants, the significant results reported below do not hold.

Response times from the old/new judgments were regressed onto main effects of Community Distance (reverse-Helmert coded to reflect an increase in processing cost as distance increased) and Trial (1-165; intended to capture general task adaptation). Results are summarized in Table 1. Participants were fastest to respond to pseudoword pairs drawn from the same community relative to pseudowords drawn from the two adjacent communities. Unsurprisingly, participants were faster when responding to pseudowords pairs when they had seen both pseudowords before, compared to pairs in which when one or both of those pseudowords was new (Figure 3).

Table 1: Coefficients, t-values, and p-values for each predictor in a model examining the effect of Community Distance and Trial on participants' RTs for old/ new judgments (Study 2).

Predictor	Results
Community Distance (1 vs. 0)	β = 0.018, t = 2.062, p = 0.041 *
Community Distance (2 vs. 0,1)	β = 0.005, t = 1.040, p = 0.302
Community Distance (new vs. 0,1,2)	β = 0.024, t = 4.480, p = 0.0001 ***
Trial	β = -0.018, t = -1.626, p = 0.115

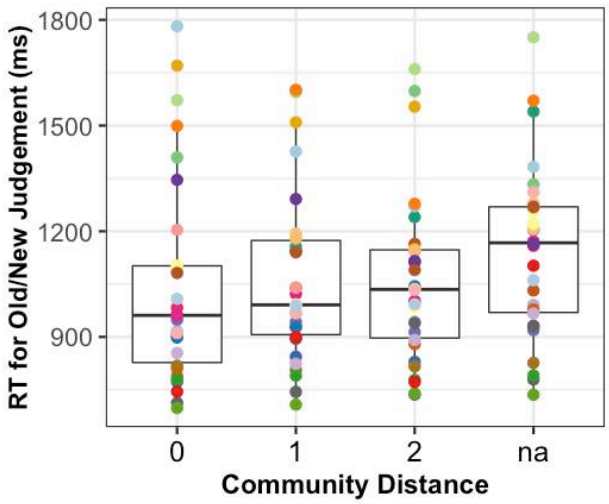

Figure 3. Boxplot of RTs for old/ new judgments on word pairs (Study 2). Values included in the boxplot were calculated by averaging, for each color-coded participant, mean RTs for nodes within a community (community distance = 0), from adjacent communities (= 1) and from non-adjacent communities (= 2). "NA" signifies that at least one word in the pair had not been seen by participants during exposure.

Discussion

We present data from two related studies demonstrating that learners are attuned to the network architecture underpinning continuous streams of linguistic stimuli. Specifically, we show that participants exhibited an increase in processing times when transitioning from one community of words to the next, suggesting that their expectations about upcoming input were influenced by the presence of element clusters in the sequence. As previous investigations into learners' sensitivity to network architectures have taken place

exclusively in the visuomotor domain (Schapiro et al., 2013; Karuza et al., 2017; Kahn et al., 2018; Tompson et al., 2018), one notable contribution of the present work is that it speaks to the potential domain-generality of this learning mechanism.

Complex network analysis of natural language has consistently revealed that, among other properties, community structure may be essential to the organization of the mental lexicon. To varying degrees, real-world networks in which edges represent phonological overlap, semantic relatedness, and temporal co-occurrence, display this property (De Deyne, Verheyen, & Storms, 2016). The present experiments break new ground in that they demonstrate that community structure is not only an emergent property of language, but also a form of high-level regularity that can guide sequence-level learning. Perhaps of greatest interest, we show through a post-exposure measure in Study 2 that temporal overlap can be translated into an accessible representation, as evidenced by the influence of community distance as participants completed a subsequent word recognition task.

At first blush, it is potentially surprising that we observe no significant interaction between Node Type and Trial. In other words, the magnitude of the cross-community RT increase did not change significantly over the course of exposure. However, these results align with previous findings suggesting that sensitivity to community structure may emerge very early in exposure (e.g., Karuza et al., 2017; Karuza, Kahn, & Bassett, 2019). To be clear, we do find a key point of divergence between the present findings and the existing literature on community structure in visuomotor sequences. Specifically, the effect of traversing an inter-community edge was substantially weakened by the inclusion of nuisance regressors intended to account for repetition priming. While there are several possible explanations for this pattern of results, we narrow in on two of them. First, we studied stimulus streams generated from a significantly larger graph than those used in related experiments (i.e., a total of 40 nodes relative to 15). Participants therefore observed far fewer unique edge traversals throughout the course of the experiment. Perceptual priming may have an inflated effect when learners are exposed to more varied stimulus streams in which nodes are repeated only a handful of times. Second, the choice to include pronounceable pseudowords with relatively few real-word orthographic and phonological neighbors meant that these features of our stimuli may have also exerted an undue influence on processing times (Vitevitch, Chan, & Roodenrys, 2012). This source of noise, coupled with some phonological overlap between the pseudowords themselves (e.g., *wabe* and *woast*), may have also contributed to null results obtained for the substring comparison post-test of Study 1. We reiterate that the randomization of word-to-node mapping should have minimized these effects. Nevertheless, evaluation of the full impact of phonological and orthographic neighborhood, defined in terms of the extent of overlap with existing English words as well as among stimulus items themselves, will be an important area of future study. It is possible, for example, that cross-community RT effects shift in magnitude in cases where pseudoword stimuli have an extremely high number of real-word neighbors.

Taken together, this set of results opens up a number of intriguing future directions not limited to investigations into learners' sensitivity to multiple layers of structure (e.g., through the construction of multiplex networks that simultaneously take into account phonological and temporal overlap; Stella, Beckage & Brede, 2017). In a broader context, formalization of the relationship between linguistic network structure and learning could add substantially to discussions regarding how language networks change with development (Ke & Yao, 2008) or why they display certain characteristic properties in special populations (Beckage, Smith & Hills, 2011). On a final note, decreased sensitivity to statistical associations has been linked to disorders ranging from Broca's aphasia (Goschke, Friederici, Kotz, & van Kampen, 2001) to dyslexia (Schmalz, Altoe, & Mulatti, 2017) and developmental language disorder (Lammertink, Boersma, Wijnen, & Rispens, 2017). Extending these lines of inquiry to reveal potential impairments in the extraction of network-level patterns could have powerful consequences, not only in terms of informing rehabilitative practices but also in deepening our understanding of language acquisition more generally.

Abstract

The internal representations of three dimensional objects within visual memory are only partially understood. Previous research suggests that 3D object perception is viewpoint dependent, and that the visual system stores viewpoint perspectives in a biased manner. The aim of this project was to obtain detailed estimates of the distributions of 3D object views in shared human memory. We devised a novel experimental paradigm based on transmission chains to investigate memory biases for the 3D orientation of objects. We found that memory tends to be biased towards orthogonal diagrammatic perspectives aligned with the ends of the standard basis for a set of common 3D objects, and that these biases are strongest for side views as well as top or bottom views for a small set of bilaterally symmetric objects. Finally, we found that views sampled from the modes were easier to categorize in a recognition task.

Keywords: Memory; 3D object perception; Serial reproduction; Iterated learning; Vision.

Introduction

Humans do not possess photographic memories of the things they see. Instead, visual memory is known to be biased towards systematic and simplified representations. The perception of 3D objects is known to be viewpoint dependent, but detailed estimates of the distributions of 3D object views in shared human memory remain unknown. For a given object, towards what views does visual memory tend to be biased? Are the number of views the same across different objects? How many views are there? Evidence from prior work points to systematic viewpoint-specific biases in 3D object perception such as so-called "canonical" views of common everyday objects (Palmer & Rosch, 1981). Canonical views are associated with improvements in categorization accuracy and recognition (as measured using response-time latencies). While the human visual system is largely robust to perspective transformations, this work provided early evidence for viewpoint dependence in human object perception, a finding that was corroborated in subsequent work (Bülthoff et al., 1995). However, none of this work fully characterized the object-specific distributions of views that bias visual memory, and provided mostly indirect evidence for them. We therefore attempt to provide a detailed picture of the structure of memory biases for the orientation of 3D objects.

We aimed to uncover the distributions of 3D object views in shared human memory. Doing so is of particular interest to disambiguate theoretical explanations for viewpoint dependence in 3D object perception, and to determine if biases in remembered views of objects correspond to canonical views. Two theoretical explanations have been suggested in order to explain canonical views: the "frequency hypothesis" and the "maximal information hypothesis" (Mezuman & Weiss, 2012). The "frequency hypothesis" states that privileged views correspond to the views that are most commonly taken when viewing or interacting with everyday objects, while the "maximal information hypothesis" states that these views change the least under small local perspective transformations. The "frequency hypothesis" is most consistent with the notion of a statistical "prior" in Bayesian accounts of perception and memory. However, it remains an open question as to whether memory representations for 3D objects resemble canonical views, and if these representations are shaped by statistical priors.

To answer this question, we used transmission chains adapted to a 3D orientation memory experiment. Under experimentally verifiable conditions, transmission chains are known to approximate samples from shared priors (Xu & Griffiths, 2010), and can be used to characterize shared biases in reconstructive memory. In this paper, we start by outlining past computational approaches and empirical findings regarding 3D object representations, as well as theoretical properties of transmission chains. Next, we present our novel findings revealing hitherto unknown distributions of 3D memory biases for a range of everyday objects. We find that these distributions are characterized by systematic patterns of biases towards diagrammatic orthogonal views that appear to be aligned with the faces of the objects (strong side views,

front and back views, top and bottom views). These views do not appear to match known canonical views, which are typically semi-profile views, although they are consistent with past findings that revealed similar biases in visual inspection of novel objects in adults (Perrett et al., 1992), as well as infants (Pereira et al., 2010). We also find that these views were associated with improved categorization accuracy relative to views sampled from areas far from the modes in these distributions.

Background

Transmission chains and experimental methods Transmission chains are analogous to the so-called "telephone game." In the most famous and early example, Bartlett had a series of people reproduce a drawing of an owl hieroglyph, and as the the reproductions of the image progressed through the chain, what began as an imperfect but recognizable facsimile of the hieroglyph morphed into an image of a cat (Bartlett, 1932), revealing that the participants shared a common bias to distort the unusual image into an image for which they had a strong collective prior.

Transmission chains have since been adopted to study phenomena in many fields, including evolutionary biology, cognitive science, anthropology, vision science, and music cognition (Kirby et al., 2008; Jacoby & McDermott, 2017; Lew & Vul, 2015). A recent analysis of reconstruction from memory examined how information should change as it is transmitted through a chain of rational agents (Xu & Griffiths, 2010). Under the rational analysis, reconstruction from memory is defined as the problem of inferring the most accurate state of the world despite a noisy or imperfect sensory input (such as an imperfect memory trace of a scene or an object in the world). Using the framework of Bayesian statistics, this problem can be captured as follows: Previous experience is characterized by a prior distribution over possible world states (a hypothesis space of all conceivable world states, such as all possible 3D orientations of an object). The posterior is computed by integrating that prior with the likelihood, which in this case simply describes the probability of observing a world state (such as an object in a particular orientation), given a hypothesis about the true state of the world. In this work, (Xu & Griffiths, 2010) found that a transmission chain populated by rational Bayesian agents defines a Markov chain with the following transition probabilities:

$$p(x_{n+1} \mid x_n) = \int p(x_{n+1} \mid \mu) p(\mu \mid x_n) d\mu,$$

where x is a noisy stimulus (such as noisy recollection of the orientation of a previously viewed object) and μ is the true state of the world that generated that stimulus. This Markov chain captures the probability of a new stimulus x_{n+1} being created as a reconstruction of a previously seen stimulus x_n in each iteration in the transmission chain, and has a stationary distribution which defines the probability of observing a stimulus x when μ is sampled from the prior:

$$p(x) = \int p(x \mid \mu) p(\mu) d\mu.$$

This process approximates a Gibbs sampler for the joint distribution on x and μ defined by multiplying $p(x \mid \mu)$ and $p(\mu)$. In other words, assuming that participants share common inductive biases, the transmission chain will converge to a sample from their shared prior.

Computational theories of 3D representations To date, a significant body of work has explored the nature of human representations of 3D objects and a great deal of experimental work has been done to elucidate the characteristics of human perceptual representations of 3D objects and scenes. (Palmer & Rosch, 1981) provided early evidence for the existence of privileged "canonical" views that facilitate 3D object recognition, in keeping with principles of categorization (Rosch, 1999) that introduced the notion of "prototype exemplars." Later work introduced the recognition-by-components (RBC) theory of image understanding (Biederman, 1987). This work proposed that representations of objects in memory are accessed when components ("geons") derived from perceptual mechanisms (Lowe, 2012; Rock, 1983) are combined, and that these components form a perceptual basis for a "componential representation of real world objects in memory." A third computational theory argues that objects are represented as lists of viewpoint-invariant properties (A piano has keys, pedals, legs) (Bülthoff et al., 1995; B. Tversky & Hemenway, 1984; A. Tversky, 1977), or by points in abstract multidimensional feature spaces (Carr et al., 2001; **?**; Su et al., 2015).

Theories based on list-based feature descriptors or viewpoint-invariant parts have been difficult to reconcile with experimental data showing systematic view-specific variations in human response-time latencies and recognition accuracy (Bülthoff et al., 1995; Tarr et al., 1998). These results have tended to favor theories that postulate viewpoint-specific and largely 2D representations (Vetter et al., 1995; Bülthoff et al., 1995) as forming the basis for human object representations. However, to our knowledge, little work has been done to devise an experimental method for revealing the distributions of viewpoint-specific biases in memory representations.

Canonical perspectives were discovered for objects that were bilaterally symmetric due to experimental constraints, and although (Palmer & Rosch, 1981) confirmed the presence of privileged views for each, it is possible that other canonical views, such as the mirror images of bilaterally symmetric objects exist. In fact, work using online images returned by search engines estimated the modes of the distribution of 3D perspectives for a variety of objects, and found that canonical views for bilaterally symmetric objects are typically bi-modal (Mezuman & Weiss, 2012). In this paper we adapted transmission chains to a memory paradigm in which we probed collective biases in reconstructive memory for the 3D orientation of a handful of everyday objects in order to uncover any and all biases in 3D reconstructive memory.

Methods

Participants

All participants were recruited online using Amazon Mechanical Turk and gave informed consent. according to a protocol was approved by The Committee for the Protection of Human Subjects (CPHS) at the University of California, Berkeley. Each experiment required approximately 100 participants.

Stimuli

The stimuli used in these experiments were 3D objects that could be viewed from any angle by rotating a camera oriented towards the origin of the object, and at a fixed distance (travelling on the surface of a sphere around the object) and with the camera tilted (in a direction tangent to the sphere). We started with a detailed mesh model of a typical teapot, and shoe. In addition, we used grayscale versions of the teapot and shoe, as well as a grayscale 3D model of a car, alarm clock, armchair, coffee maker, camera, and grand piano, see Figure 1A. We selected objects matching the objects in (Palmer & Rosch, 1981) as closely as possible.

Procedure

For each object, we ran a serial reproduction experiment with 250 chains and 20 iterations (see Figure 1B). Participants viewed timed displays of the 3D object. The chains were initialized as camera views over the surface of a unit sphere with the object in the center. The camera frame orientation was always oriented towards the center of the object, but was tilted at random angles orthogonal to the sphere (the "up" vector, see Figure 1D). The position of the camera and the view were sampled uniformly from the Haar measure on $SO(3)$ (Perez-Sala et al., 2013). Following the timed display, and 1000 ms retention phase when the screen went blank, a probe screen containing the object at a new random orientation was shown.

Participants were instructed to orient the object (which is equivalent to rotating the camera view) so that it matched the original orientation of the object that was shown during the initial timed display. Participants were not given time constraints during the probe, and could change their responses as many times as they needed. The object on the screen could be rotated by means of the mouse, as well as a set of buttons (see Figure 1C). Participants were given 10 practice trials during which the initial display was shown for 4000 ms in order to familiarize them with the nature of the task, and the user interface. Only after they completed the practice trials was the presentation time reduced to 1000 ms. In addition, they were given trial-by-trial feedback based on their performance (either a green message saying "Well done! Your response was sufficiently accurate", or a red message stating: "Your response was insufficiently accurate"), see Figure 1C.

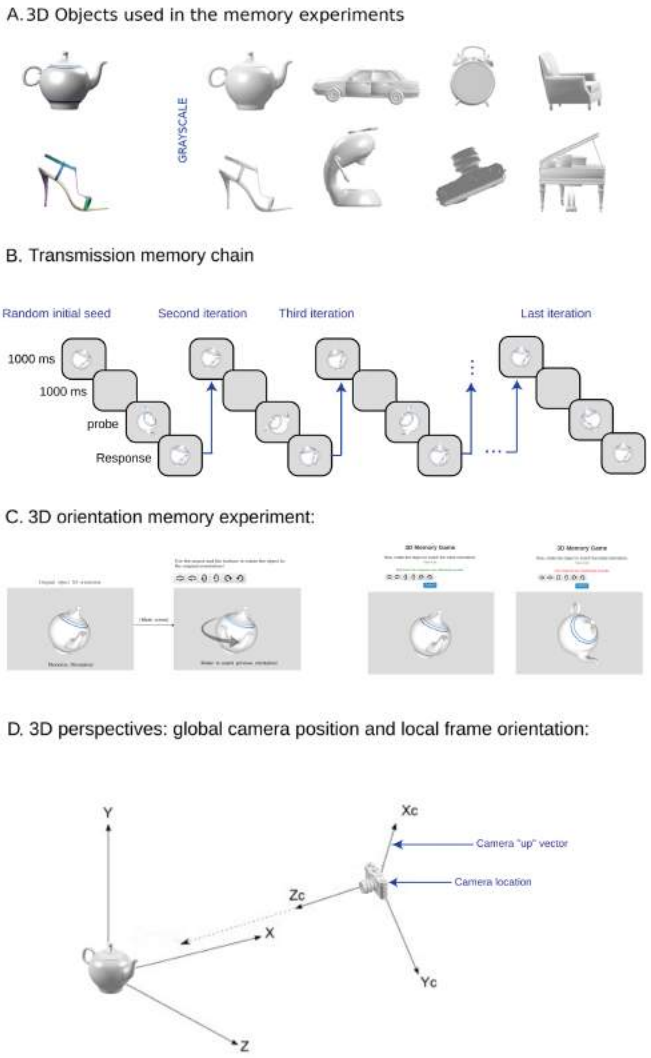

Figure 1: 3D objects, experiment structure, task and geometry. A. Textured and grayscale 3D objects used in the transmission chain experiments. B. Transmission chain structure: A 3D view of an object (teapot) is initialized somewhere at random over a unit sphere. This view is presented as a stimulus to a subject who then reconstructs this view from memory. The subject's response is then presented as the stimulus to a second subject, who must reproduce this second view, and so on. C. The experiment instructions and trial structure. Participants could rotate the object with the mouse and a set of buttons displayed over the image. They were instructed to reproduce the view they saw as accurately as possible, and were given feedback on their performance. D. Geometry of 3D object views adopted in the experiment. Views (cameras) were always positioned on the surface of a sphere centered at the object, and was always pointed towards the center of the sphere (towards the object). The local frame of the camera could vary according to the "up" vector, which controls the tilt of the camera

Results

By the final iteration of the transmission chain process, a clear pattern emerges: 3D views are biased towards a small set of orthogonal "diagramatic" views that are aligned with the top,

bottom, and side views of the objects. In some cases, the views in the modes correspond to the front and back (for the clock in particular), see Figure 2 for the results obtained with the textured teapot and shoe. While all the starting views of the chains are camera views sampled uniformally over the sphere surrounding the objects, the distributions quickly change and become clustered around four distinct modes as the chains progress. Figure 2A shows the initial distribution, the distribution at the 5th, 10th, 15th and 20th iteration of the transmission chains for the teapot and shoe.

Figure 2B shows the distributions of all points across all iterations for the shoe and teapot. In addition, the four modes with respect to the camera directions are plotted in four colors for both distributions. Next to each of these distributions, we show the corresponding histograms of the angles of the "up" vectors at the modes, where the direction most aligned with the data is centered to 90 degrees for the first two modes of the teapot and shoe. Surprisingly, while the "up" vectors in modes I, II (side views) of the Teapot are centered mainly in one direction, those in modes III and IV (the top and bottom views) show a bimodal distribution (top and bottom views are remembered with the handle and spout oriented vertically, while the side views show them to be oriented horizontally, orthogonal to the vertical orientations in the top and bottom views). We don't find this pattern in the case of the shoe, where the distributions of "up" vector angles were unimodal for all modes (I, II, III, and IV). This suggests that memory representations contain interaction patterns where some objects are memorized with a specific location *and* orientation, while memory for views of other objects are not necessarily associated with particular angular orientations. The columns on the far right of Figure 2B show spherical kernel density estimates (KDEs) of the final iteration data oriented according to the top four modes. Thumbnail insets to the right of the KDE modes show the corresponding object views. For both objects, the top two views are side views, while the remaining two modes correspond to the top and bottom views.

In order to verify if our chains showed convergence, we measured the mean copying error of the camera views for the textured teapot and shoe objects (See Figure 2C). The copying error was computed separately for each iteration by averaging the difference between the remembered camera view responses and stimulus views. We found that the copying error tends to reduce over the course of the experiment. Indeed, whereas the copying error for the first iterations was significantly smaller compared with the last iteration ($t(364)=6.6$, $p<0.001$ and $t(386)=5.6$, $p<0.001$ for the teapot and shoe, respectively), the difference between the copying error in the last iteration was not significantly different from the preceding four iterations ($p > 0.1$). For all cases this holds true even with Bonferroni corrections for multiple comparisons). This suggests that convergence occurs by the last five iterations of the chains.

In order to control for effects of colors and texture on 3D memory biases, as well as to control these factors for the

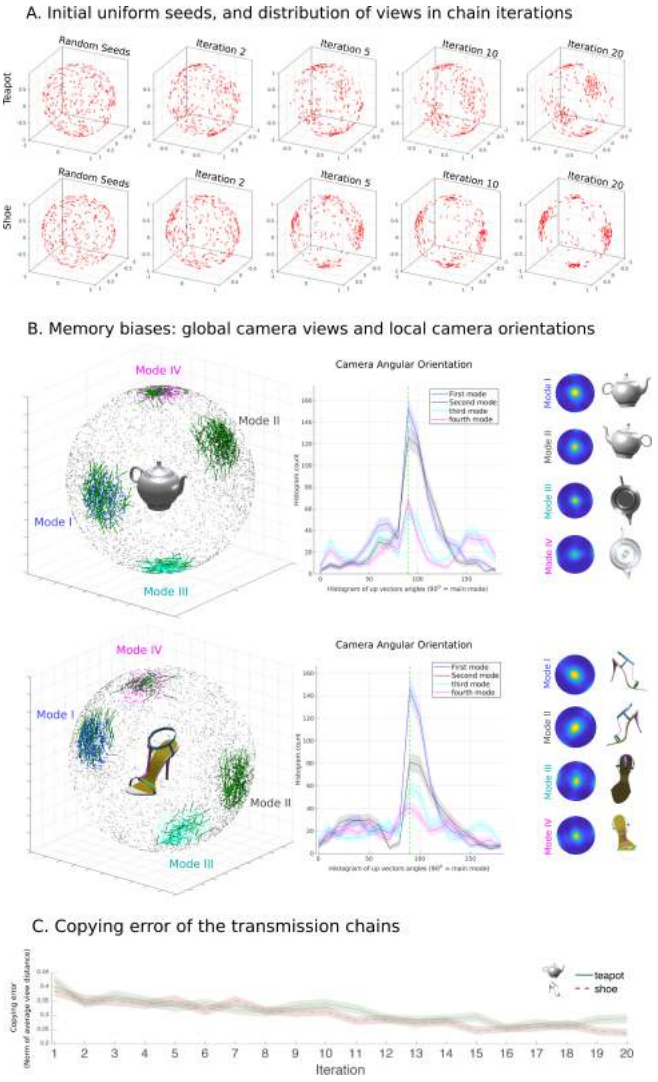

Figure 2: Transmission chain results for a teapot and shoe. A. Scatter plots showing camera views and "up" vectors for four chain iterations, and the initial uniform random seed locations. First row shows results for the teapot (initial seed, 5th, 10th, 15th, and 20th iteration distributions), and second row shows results for the shoe. B. Modes in the 20th and final distributions of views for the teapot and shoe. Four modes are clearly discernible: the side views of the objects, and the top and bottom views. Spherical subplots show a superposition of camera views across all iterations, highlighted are the four modes obtained by the 20th and final iteration of the chains. These correspond to the side views as well as the top and bottom views. The central subplots show histograms of the "up" vector angles, which show the frequency of local camera orientations at each of the modes. They reveal that perspectives in the first two modes (side views in both cases) are biased towards views where the camera is oriented towards a 90 degree angle, which yields views of the objects that are upright. These views are visualized in the far right columns, for each object, along with views of the modes in spherical Kernel Density Estimates (KDEs) of the 20th iteration data. C. Copying error across the chain iterations.

recognition experiments that follow, we ran a set of grayscale objects. Figure 3A the data for the novel objects. The results for the teapot and shoe were largely consistent with the results obtained with the textured versions of these objects, although only three clear modes were observed for the grayscale shoe (side views, and top view). Similarly, the modes for the car reveal four orthogonal views: left and right sides, as well as top, and bottom views. For the remaining objects, either three or two modes were present. Only two primary modes revealing frontal views, and back views were observed for the clock. Finally, the results for the remaining objects reveal primarily three orthogonal views. In sum, we find that 3D object memory representations are not equivalent to canonical views, and are characterized by multi-modal biases that may reflect the symmetry of the objects, a finding that corroborates findings revealing the presence of bi-modal views in distributions of online images (Mezuman & Weiss, 2012), although those were not views aligned with the faces of the objects, nor were they necessarily orthogonal. The memory representations we uncovered replicate past findings showing systematic biases towards the same views in a variety of visual inspection tasks in both infants and adults, suggesting that memory biases may be influenced by encoding precision and angular discrimination.

Figure 3 shows the results of a categorization experiment in which we compared the categorization accuracy for the set of eight grayscale objects when they were presented from views sampled in the modes of our memory KDEs, or from views far from the modes (sampling 4 nearest neighbors around the points that were farthest from the modes on the sphere, in the initial seed distributions of the chains). Figure 3B shows example views, and the experimental task: subjects were presented with a view for 100 ms, and then asked to categorize the object. The eight object labels were shown, as well as two additional labels ("house", "horse"). Figure 3B shows recognition d' results as a function of view type. We found that views of the shoe, clock, car, teapot, and coffee machine were recognized more accurately when they were sampled from the modes in our KDEs ($p < 0.001$ in all cases, following a Bonferroni correction for multiple comparisons). Overall, views sampled from the modes were associated with improved classification accuracy ($p < 0.0001$).

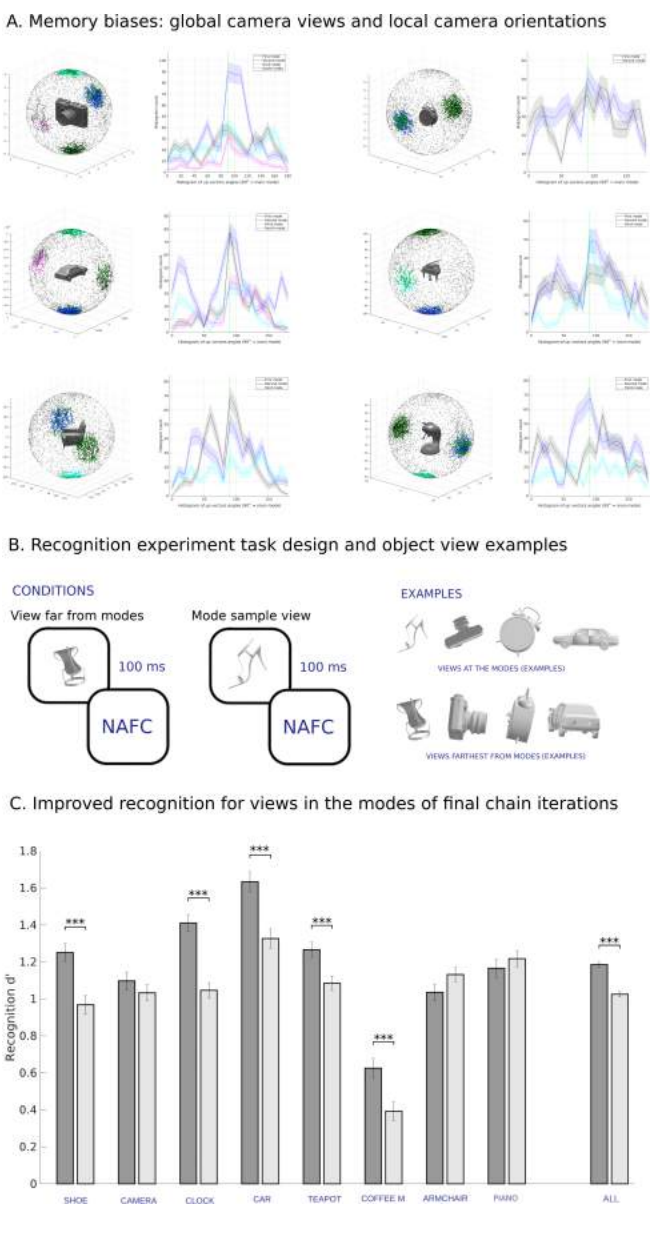

Figure 3: Recognition experiments. A. Memory biases for global camera views and local camera orientations for grayscale objects. B. Recognition experiment task design and view examples. For each object, participants were presented with a view sampled either from one of the perspective modes obtained from the final chain iteration, or from a point farthest from one of the final modes sampled from the uniform seed distribution, for 100 ms. They were then asked to select the correct object name from a list of possibilities. C. Recognition d' results for each of the objects, and for all the objects. Results show that in most cases, participants were more likely to select the correct object label when the view shown was sampled from one of the modal views sampled form the final chain iteration. Error bars correspond to 1000 bootstrapped samples of the data, with replacement. We used the Bonferroni correction for multiple comparisons.

Discussion

We found the use of transmission chains to be particularly sensitive to characterizing shared 3D memory biases. The biases we observed for a small set of bilaterally symmetric everyday objects are highly systematic and not identical to known canonical views. They are strongly diagrammatic views of the sides, top and bottom, or front and back faces of the objects. In this respect, they resemble the bimodal characteristics of the distributions of online images estimated by (Mezuman & Weiss, 2012), although the diagrammatic aspects of these views are more reminiscent of well-known biases in visual inspection of 3D objects Perrett et al. (1992);

Pereira et al. (2010). However, we did observe differences between objects, with some object representations containing four distinct modes, and others containing fewer (the clock). In addition to finding clear biases in camera locations, we also observed that camera views tended to be consistently oriented upright for the side views, but not for top or bottom views. Finally, we determined that categorization accuracy was higher for views that were sampled from the modes of the distributions we estimated, when compared to views sampled from regions that were farthest from the modes. This suggests that 2D memory representations of 3D objects are informative for recognition.

Finally, using this tool to uncover memory priors for objects that are not bilaterally symmetric, and with different geometries could help determine what factors are responsible for shaping biases in 3D memory representations. Our current findings do not appear to be altogether consistent with statistical priors (the "frequency hypothesis"), since diagrammatic views (especially of the bottom of objects like cars, teapots, and pianos) are not views of these objects that are typically experienced. However, they may be due to variable angular discrimination accuracy, which may be increased for sides that are aligned with the first principal component axes of the objects, and decreased for the shorter sides. Our approach provides a powerful tool for estimating detailed distributions of biases in 3D memory, and can provide an empirical basis for spurring novel theoretical insights on the nature of these representations.

Abstract

Words influence cognition well before infants know their specific meanings. For example, three-month-olds are more likely to form visually-based categories when exemplars are paired with spoken words than with sine-wave tones. We tested whether structure in infants environment can foster this effect. Caregivers often use exaggerated showing gestures when labeling objects, presenting words in synchrony with object motion, and creating amodal temporal structure in auditory and visual modalities. Because attention to amodal structure attenuates encoding information specific to just one modality, we hypothesized that it can lead auditory signals to impact visually-based categorization. Indeed, when 3-month-olds are familiarized to videos in which tones occur in synchrony with object motion, tones subsequently facilitate categorization, just like words. Moreover, familiarizing infants to word-object synchrony enhances their subsequent categorization in the presence of words. These results suggest that structure in infants environment may contribute to the special effects that words have on categorization.

Abstract

We investigate whether children preferentially select informative actions and make accurate inferences from the outcome of their own interventions in a causal learning task. Four- to six-year-olds were presented with a novel system composed of two gears that could operate according to two possible causal structures (single or multiple cause). Given the choice between interventions (i.e., removing one of the gears to observe the remaining gear in isolation), children demonstrated a clear preference for the action that revealed the true causal structure, and made subsequent causal judgments that were consistent with the outcome observed. Experiment 2 addressed the possibility that performance was driven by children's tendency to select an intervention that would produce a desirable effect (i.e., spinning gears), rather than to disambiguate the causal structure. The results replicate our initial findings in a context in which the informative action was less likely to produce a positive outcome than the uninformative one. We discuss these results in terms of their significance for understanding both the development of scientific reasoning and the role of self-directed actions in early learning.

Keywords: cognitive development; causal learning; exploration; scientific reasoning; decision-making; experimentation

Introduction

The concept of the learner as an intuitive scientist—forming and evaluating hypotheses about the world—has provided an illuminating and productive model for understanding the mechanisms underlying cognitive development. In particular, 'Theory Theorists' have long advanced the analogy between the processes underlying knowledge acquisition and formal scientific theory change, in which children formulate, test, and rationally revise their intuitive theories in light of new evidence (Gopnik & Wellman, 2012). Indeed, much of what we know about self-directed learning in early childhood (and beyond) appears to resemble the basic inductive processes of science. From infancy, learners are sensitive to statistical information in the data they observe (e.g., Saffran, Aslin, & Newport, 1996; Xu & Garcia, 2008), and use these patterns to infer the abstract causal theories that allow for explanation, prediction, and action in the world (e.g., Carey, 1985; Keil, 1989; Wellman & Gelman, 1992).

However, the scientific process is not limited to passive observation and interpretation of statistical data. Instead, learning as an intuitive scientist also requires that children design, select, and execute informative interventions to evaluate the accuracy of their currently held beliefs and acquire new knowledge. The need for experimentation is especially apparent in the domain of causal learning, where observation alone is often insufficient. Instead, observations must typically be paired with appropriate and informative investigations in order to disambiguate between potential causes or causal structures (Pearl, 2000).

To illustrate, suppose that you notice that the houseplant sitting in a sunny spot on the windowsill has wilted, and the soil in the pot is dry. Multiple causal structures are consistent with this pattern of observation (see Figure 1): It could be that the intense sunlight dried out the soil, and the plants wilted due to this lack of moisture (a causal chain: Figure 1b). Or perhaps this is a variety of plant that requires shade, regardless of moisture. In this case, the sunlight is a direct cause of both wilting and dry soil, independently of one another (a common cause: Figure 1a).

While observation of the world alone cannot disambiguate between these two possibilities, taking specific actions on the world can. Due to the conditional relationship between patterns of intervention and causal structure, manipulating the variables in a system can reveal the causal relationships between them. That is, a learner who knows that variable X is the cause of variable Y *also* knows that intervening to change X will lead to a change in Y. Returning to our houseplant example, you could therefore discover the true casual structure by intervening to change the dryness of the soil—perhaps by watering more often—and then check to see if plants in that spot flourish (indicating a causal chain) or continue to wilt (indicating a common cause).

This makes intervention a powerful tool for determining causal structure, but its usefulness critically requires that the learner recognize and carry out *informative* interventions. For example, while intervening on the sunlight (e.g., by shading the flower pot) will always lead to improving the health of the plant, this desirable outcome would not provide information about the true underlying causal structure (i.e., whether wilting was caused by dry soil or by excess sunlight).

Whether young learners are able to engage in this type of systematic experimentation is a subject of substantial debate. On the one hand, research on exploratory play suggests that even preschool-aged children have an intuitive tendency to produce informative actions that facilitate their learning: Children preferentially explore where they have incomplete or inconsistent knowledge (e.g., Bonawitz, van Schijndel, Friel, & Schulz, 2012; Gweon & Schulz, 2008; Schulz & Bonawitz, 2007), and spontaneously select actions with the potential to improve their epistemic status (Cook, Goodman, & Schulz, 2011). On the other hand, this work

contrasts with decades of research on the development of scientific reasoning, which overwhelmingly reports that even much older children *do not* follow the principles of informative scientific experimentation in their spontaneous actions (Zimmerman & Klahr, 2018): Children struggle with the control and isolation of variables, often designing confounded and confirmatory experiments rather than logically informative ones (e.g., Inhelder & Piaget, 1958; Klahr, Fay, & Dunbar, 1993; Siler & Klahr, 2012; Valanides, Papageorgiou, & Angeli, 2014). Critically, children also appear to select interventions based on their tangible outcomes, rather than their informativeness (e.g., Schauble, 1990; Tschirgi, 1980) (e.g., choosing to shade the plant in the above example).

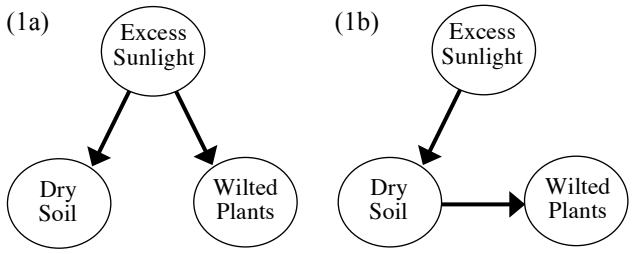

Figure 1: Common cause (a) and causal chain (b) structures.

This apparent preoccupation with producing (or reproducing) effects, rather than testing causal hypotheses, has led some researchers to suggest that children initially do not understand of the goal of scientific experimentation (e.g., Carey, Evans, Honda, Jay, & Unger, 1989; Schauble, Klopfer, & Raghavan, 1991). Instead, Schauble and colleagues (1991) proposed that early experimentation is motivated by an '*engineering'* goal, in which children engage in exploratory interventions in order to "make things happen," rather than the '*science'* goal of learning the underlying causal structure of the world. If true, this early inability or unwillingness to conduct informative experiments poses a major complication for the claim that children's self-directed learning intuitively follows a scientific process.

The current study, therefore, seeks to examine whether young children select and make inferences from their own actions in a way that supports their causal learning. While it is clear from past research that even infants successfully infer causality from observation of the outcomes of interventions that are chosen and performed by others (e.g. Meltzoff, Waismeyer, & Gopnik, 2012), it remains an open question whether the same is true for actions that children take themselves. Schulz, Gopnik, and Glymour (2007), for example, provide evidence that young learners understand and utilize the conditional relationship between causal structure and intervention. Specifically, 3- to 6-years-olds accurately identified the causal structure of a system after observing the outcomes of interventions on it *and* accurately predicted outcomes of interventions on a system when the causal structure was known.

In contrast, more recent findings indicate that even older children (5 to 8 years) may struggle to apply this principle to their *own* actions. Two studies—McCormack, Bramley, Frosch, and Lagnado (2016) and Meng, Bramey, and Xu (2018) – have examined children's causal interventions and inferences during exploration of a 3-node system. While some of the actions children produced in both studies were informative, neither team found evidence for a strong preference for informative actions. For example, according to McCormack and colleagues (2016), only 7- and 8-year-olds *consistently* selected informative interventions significantly more often than chance, while 5- and 6-year-old's did *not* select informative interventions above chance. Similarly, Meng et al. (2018) found that 5- to 7-year-olds average selection of informative interventions was not distinguishable from chance levels.

In fact, both studies found evidence that children select interventions in accordance with a positive testing strategy (PTS)—that is, taking actions that are expected to produce an effect if their current hypothesis is correct (Coenen, Rehder, & Gureckis, 2015; Klayman & Ha, 1987). In McCormack et al. (2015), the most popular intervention was turning on the hypothesized *root node*, which activated all other nodes in the system, regardless of the true causal structure. Meng et al. (2018) also provide evidence for children's use of PTS: Although the model that best captured children's intervention choices in their task relied on a combination of expected information gain and PTS, this mix was heavily skewed towards PTS.

Importantly, however, evidence *for* PTS is not evidence *against* the 'engineering goal' account: While turning on the putative root node of a system positively tests the largest number of causal links with in it (see Coenen et al., 2015), this is *also* the action that 'makes the most things happen'. Indeed, within the scientific reasoning literature, PTS behaviors are often treated as evidence that young learners are focused exclusively on the tangible outcomes of their interventions (Tschirgi, 1980; Zimmerman, 2007; Zimmerman & Glaser, 2001). These previous findings, therefore, cannot rule out the possibility that young children select primarily interventions according to 'engineering,' rather than 'scientific' goals. Thus, our first aim is to look directly at children's intervention preferences. We ask whether young learners will privilege an informative option (one that has the potential to disambiguate between competing causal structures) over an uninformative one in a forced choice design. We then examine whether children maintain their preference when this uninformative alternative is guaranteed to produce a desirable effect.

Our second aim is to examine whether children can utilize the outcomes of their own actions in later causal inference. Despite being older than the children tested by Schulz et al. (2007), participants in Meng et al. (2018) failed to identify the correct causal structure more often than chance, and the 5- to 6-year-olds in McCormack et al. (2015) did so only for certain types of structures. It is unclear whether children's failure to identify the correct causal structure was due to

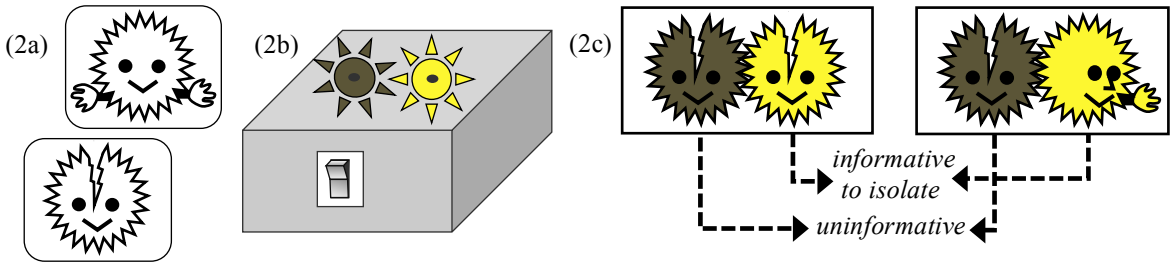

Figure 2: (a) Images used to illustrate 'working' and 'broken' gears. (b) Schematic of the gear toy. (c) Images used to illustrate the multiple causes (left) and single cause (right) structures with the informative option indicated.

their inability to make inferences from self-generated evidence, or due to the challenges associated with these more complex causal structures. In fact, Frosch and colleagues (2012) find that children struggle to make correct inferences about a similar 3-node causal system *even* when an experimenter generated the necessary evidence for them. We therefore designed the current task as a modified version of Schulz et al.'s (2007) paradigm. This is a context in which we know that young learners are able to reason about the conditional relationship between intervention and causal structure.

The current study aims to clarify whether young children preferentially select and successfully learn from their own actions in a way that is sensitive to the informative value of causal intervention. Two experiments examined how 4- to 6-year-olds responded to a forced choice between an informative and uninformative intervention in a causal learning task. Experiment 1 asks whether children will preferentially choose to take the informative intervention when selecting actions on a novel causal system. Then, in Experiment 2, the uninformative intervention is also guaranteed to produce a desirable effect. Choice behavior on this task will therefore distinguish whether children's early interventions are primarily motivated by a '*science'* or '*engineering'* goal. In addition to looking at which interventions young learners choose (and why), these experiments will also consider whether children are able to draw accurate inferences about a simple causal system from evidence they generate themselves.

Experiment 1

To investigate whether children preferentially choose interventions that support their causal learning, we used a task modeled on Schulz et al. (2007). Children were introduced to a gear toy featuring two interlocking gears and a switch. They learned that individual gears may be "working" (they spin when the toy is turned on) or "broken" (they are inert and prevent any interlocking gears from spinning). At test, children observed a pair of gears that failed to spin when the toy was turned on. They were told that this event could have resulted from two possible causal structures.[1] Either both gears are broken (a 'multiple causes' structure), or one gear is broken, preventing the other from spinning (a 'single cause' structure) (see Figure 2). As in the previous houseplant example (Figure 1), it is impossible to determine which of these represents the true causal structure from observation alone. Instead, a specific informative action must be performed: removing the gear that is broken in both structures and observing the behavior of the remaining gear *in isolation*. In contrast, removing the gear that varies between the two structures and observing the remaining (broken) gear would provide no information about the underlying causal structure. Children were given a choice between isolating and observing *only one* of the two gears prior to their inference. If young learners indeed recognize and privilege actions that are most informative for causal learning, then they should prefer to observe the gear that will disambiguate between the two structures. Afterwards, children were given the opportunity to observe the outcome of their chosen action, and were asked to judge which of the two structures was correct. If children are able to infer causal structure from their own actions, those who select the informative action should make the accurate inference.

Methods

Participants Forty-eight children (M = 64.19 months, SD = 9.46 months, range = 46-82 months) participated in Experiment 1. Children were recruited and tested individually at a local science museum in a primarily urban area. Seventeen additional children were run, but excluded due to experimental error (n = 11) or failing to complete the testing session (n = 6).

Stimuli The task used a custom-built electronic gear-toy, colored plastic gears, and picture cards with colored illustrations representing the gears and causal structures.

The toy, previously used in Schulz et al. (2007), consisted of a 12"x12" cube with two metal pegs on top. Each peg was designed to hold one 3" diameter gear, such that two gears would interlock when positioned on top of the toy. Sensors inside the cube detected the presence of a gear on the pegs, causing them to spin when a switch attached to the front of the toy was flipped to the 'on' position. A hidden control on the back of the toy allowed the experimenter to

[1] These structures were also based on Schulz et al (2007) and were originally referred to as 'common cause' and 'causal chain.' However, in the current experiment, it is more appropriate to refer to them as 'multiple cause' and 'single cause' structures, respectively.

surreptitiously control the supply of power (which determined whether or not the switch caused the gears to spin).

A total of six uniquely colored gears (blue, yellow, pink, green, red, orange) were used: four during the training trials and two during the test trial. Gear colors used for each part of the procedure were counterbalanced across participants. Note that in our description of the procedure, we refer to the gears using letters (A-F) in place of the color names that were actually used to identify each gear during the experiment. The picture cards (see Figure 2) each depicted a cartoon illustration of either a single gear (Figure 2a) or a gear pair (Figure 2c). These were used to illustrate the possible causal status (working or broken) and causal structures (single or multiple causes) during the task. The illustrated gears were color-matched to the physical gears used on the toy.

Procedure Each testing session began with the toy on the table in its powered state, with the switch in the 'off' position, and two gears (A and B) in place on the pegs. The experimenter introduced the toy, indicating the switch on the front, and explained that it turned the toy on and off, allowing the child to try both actions. When the child turned the toy on, A and B would spin simultaneously, and when the child turned the toy off, both stopped spinning simultaneously. The experimenter then removed and replaced each gear in turn, explaining that, when turned off, gears can be taken on and off the toy.

The experimenter then put A and B away, saying, "You're going to get to see all the gears. But some of the gears are broken. When a gear is broken, it doesn't spin even when the toy is on, and it gets in the way of other gears spinning too." Children were then shown an example working gear (A) and a broken gear (C) in turn. The experimenter placed the gear on the right peg of the toy and the child observed it either spinning (A) or not spinning (C) when the toy was turned on. Each gear was paired with a matching picture card showing its casual status. Using the pictures, the experimenter explained, "Gears that aren't broken can use their arms to spin themselves," and, "Gears that are broken don't have any arms, they cannot spin, and keep other gears from spinning too." The experimenter then held up A and C in turn and asked the child to tell them, first, whether the gear was broken or working, and second, whether it would spin on the toy on its own. Children received feedback and, if necessary, correction on each response. As part of the feedback for the second question, the experimenter placed the gear on the left peg of the toy and flipped the switch. Thus, children observed that broken and working gears operate consistently regardless of which peg of the toy they are on.

Each child then received training on the two causal structures, presented as different combinations of gears: a multiple cause (C and D) and a single cause (D and B) structure. The order in which the two structures were presented was counterbalanced, as was whether the broken gear (D) in the single cause structure was on the left or right peg of the toy. For each structure, the experimenter placed both gears on the toy and turned it on. The toy was always depowered, and the gears always remained inert. The experimenter said, "The gears aren't spinning. Something is wrong." She then brought out a picture card depicting one of the possible causal structures and described it to the child. For example, for the single cause structure, she said, "The picture shows us that just one of the gears is broken. The D gear is broken and doesn't spin on the toy, and the B gear is not broken so it can spin on the toy. But when they're together, the D gear gets in the way of the B gear, and nothing moves." Each gear was placed on the toy individually, and children were asked to predict (with feedback and observation) whether it would spin when the toy was turned on. This procedure was then repeated for the other structure.

During the test trial, the picture cards used during the training were left visible, one on either side of the toy. Gears E and F were placed on the toy and did not spin when the toy was turned on. This time, however, the experimenter said, "I don't know what's wrong here. I don't know why these gears aren't spinning. Will you help me figure it out?" The experimenter then produced two picture cards, identical to those seen during training, except that the depicted gears matched the colors of E and F. These cards were placed adjacent to the matching card from the training and each was described in the same terms. Children were told that they had to figure out which of the two pictures correctly showed why E and F weren't spinning together. Children were also told that they would get a 'clue' to help them: they could choose to see how *one* of the two gears (*either* E or F) would behave when the other gear was removed and the toy was turned on.[2]

After indicating their choice to the experimenter, children were allowed to remove the unselected gear, turn the toy on, and observe the outcome. If the informative gear was selected, the outcome (spin or inert) was counterbalanced, such that half of the children who selected the informative gear would observe evidence for the single cause structure, and the other half would observe evidence for the multiple causes structure. Regardless of choice or outcome, the experimenter would point to the gear when the toy was turned on and say, "Look!" before holding up the two picture cards depicting the possible structures, and asking children to pick the one that showed how the gears actually operated.

Results and Discussion

Children's responses to all questions were recorded during the experimental session and videotaped. We recorded

[2] As an attention and comprehension check, half of children (n = 24) were prompted to report the possible states of each gear before making their choice. This had no effect on either the number of informative interventions ($t(46) = -0.62$, $p = 0.538$ [*ns*]) or number of correct causal inferences ($t(32) = 1.37$, $p = 0.18$ [*ns*]), so the two scripts were combined.

whether each child chose to observe the informative or uninformative gear, as well as their final judgment about the true causal structure of the gears. For the subset of children who selected the informative gear, judgments were further coded for whether or not they were consistent with the outcome observed.

A significant majority (70.83%) chose the informative intervention, isolating and observing the gear that could disambiguate between the possible causal structures, (p = 0.005, two-tailed binomial). Of the 39 children who observed this disambiguating evidence, *all but two* made the correct causal inference (94.12%, $p < 0.0001$, two-tailed binomial). Together, these results suggest that young learners are not only sensitive to the informative potential of their own causal interventions, but they are also able to use the outcomes of those interventions to accurately infer the causal structure of events in the world.

Experiment 2

The results reported above provide evidence that young children preferentially select and learn from their own informative interventions in the course of causal learning. This is consistent with previous research on children's spontaneous exploration, while also extending this work to show that this preference for informative actions supports later inference. However, children's choice behavior on this task is also amenable to the opposite interpretation. As discussed above, the scientific reasoning literature often characterizes early experimenters as '*engineers*' (rather than '*scientists*') who incorrectly focus on generating effects (rather than information).

The informative gear in Experiment 1 was also the gear that had the potential to *spin* when isolated by intervention. It is possible, therefore, that children did not select the informative action because it would provide disambiguating evidence, but because it was more likely to produce this entertaining and desirable effect. If so, preference for informative action in Experiment 1 would actually be evidence *for* the claim that young children's interventions are motivated by producing effects, rather than learning about the world.

We conducted a second experiment to test this alternative. In Experiment 2, we changed the operation of the gears to include *generative* causes (i.e., working gears cause broken gears to spin), rather than inhibitory causes (i.e., broken gears prevent working gears from spinning): see Figure 3. At test, children observed a pair of spinning (rather than inert) gears that could be explained by appeal to either multiple (both gears spin) or a single cause (only one gear spins, causing the other to spin). Again, participants were given a forced choice between two interventions to determine the true causal structure.

Critically, however, this presents a choice between an uninformative action (isolating the gear that works under both structures), that is *guaranteed* to produce a desirable effect, and an informative action, (isolating the gear that works under one structure and is broken under the other), that has equivalent odds of producing or failing to produce the effect. This means that children must *forgo* the opportunity to produce a desirable effect in order to acquire information about how the causal system works.

If, as suggested by past work on exploratory play, children have an intuitive preference for informative actions, then we should continue to see a preference to isolate and observe the disambiguating gear. If, on the other hand, children show the opposite preference, choosing to select the uninformative gear, then this would suggest they are motivated by an '*engineering* goal'.

Methods

Participants Twenty-four children (M = 65.4 months, SD = 9.59 months, range = 46-82 months) were included in Experiment 2. Recruitment procedures and demographics were identical to Experiment 1. Four additional children were tested, but excluded due to experimental error (n = 1) or for failing to complete the testing session (n = 3).

Stimuli Materials were identical to those used in Experiment 1. However, new picture cards were created to depict the revised causal structures used in Experiment 2.

Procedure Procedures were similar to those used in Experiment 1. The script and outcomes of actions were modified in accordance with the revised definitions of 'broken' and 'working' gears. These changes are described below:

Children were initially told, "Some of the gears are broken. When a gear is broken, it can't spin on its own. It needs a gear that's not broken to make it spin." When shown the example gears and pictures (Figure 3), working gears were described as able to "use their little arms to spin themselves *and* to make other gears spin too!" Broken gears were described as unable to spin by themselves. Instead, broken gears "need a gear that's not broken on the toy with them to make them spin."

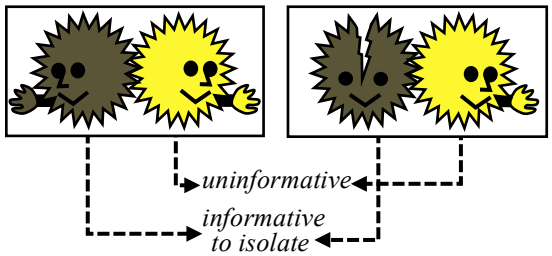

Figure 3: Illustration of the possible causal structures in Experiment 2.

In addition, the gear pairs were presented as operating according to one of two structures: Either both the gears (E and F) are working and can each spin on their own, or just one gear (E) is working, and "uses its little arms" to spin F, causing both to move. As in Experiment 1, whether the broken gear in the causal chain was the right or the left gear of the pair was counterbalanced across participants.

Results and Discussion

There were no age differences between the groups of children tested in Experiments 1 and 2, $t(70) = 0.03$, $p = 0.976$ (*ns*).

Children again selected the informative intervention significantly more often than expected by chance (79.17%, $p = 0.006$, two-tailed binomial). In fact, children's tendency to make this choice was not significantly different from their choice behavior in Experiment 1, $t(70) = 0.77$ $p = 0.442$ (*ns*). In other words, children continued to privilege the informative action *even* when it was pit against an opportunity to produce a desirable outcome.

Performance on the final inference question also did not differ from Experiment 1. Of the 19 children who selected the informative gear, *all but one* of them used this information to infer the causal structure that was consistent with the observed outcomes of their interventions (94.74%, $p < 0.0001$, two-tailed binomial). These results provide evidence against the alternative, '*engineering* goal' explanation for children's success in Experiment 1.

General Discussion

The current research sought to address two outstanding questions about children's intuitive experimentation: (1) Do children successfully identify and select informative interventions during exploration?, and (2) If so, can they draw appropriate causal inferences based on the outcomes they produce? These questions are critical, both for understanding the processes by which self-directed exploration contributes to early learning, and to address the disconnect between the claim that young learners are 'intuitive scientists,' and the claim that children are unsuccessful scientific experimenters.

First, our results demonstrate that 4- to 6-year-olds not only take informative interventions (Experiment 1), but that these actions are not driven by their potential to produce desirable outcomes (Experiment 2). These findings provide strong evidence against previous suggestions that children are initially concerned only with the practical (and not the informative) outcomes of their interventions. In particular, the '*science* vs. *engineering*' account, employed by Schauble and others (e.g., Schauble et al., 1991; Siler & Klahr, 2012) to explain children's choices in scientific reasoning tasks implies that the informative option should be less appealing than the uninformative, but productive one. The fact that the majority of children continued to select the informative action in Experiment 2 indicates instead that their choice of intervention was based on its potential to produce information and not positive outcomes. The apparent tendency to privilege producing effects seen in previous work may therefore be unrelated to children's understanding of the goals of experimentation, and an inaccurate reflection of early ability to identify and select interventions that improve their causal knowledge.

Second, these young children readily and accurately used the outcomes *of their own actions* when making judgments about the causal structure of a novel system. This goes beyond prior work showing that children make appropriate inferences after observing the outcomes of experimenter-generated interventions (Schulz et al., 2007), and contrasts with findings suggesting children may be unable to draw causal inferences from their own interventions (McCormack et al., 2016; Meng et al., 2018). In addition, while research on exploratory learning (e.g., Cook et al., 2011; Schulz & Bonawitz, 2007) has previously shown a preference for informative actions in young children, the bulk of this work has not required children to make subsequent causal inferences from the outcomes of those actions, leaving it uncertain whether and how children utilize self-directed exploration to support their learning.

Ongoing work aims to expand upon the current findings to investigate whether children are able to use the evidence generated by their own informative interventions to draw more sophisticated inferences. Specifically, we present children with cases in which the informative gear is paired with a novel gear after the intervention outcome is observed. Depending on the causal status (working or broken) of the informative gear, we can assess whether children will be able to *use* this information to update their existing causal representations, make predictions, and even draw inferences about the causal status of unknown gears.

This study also goes beyond past research on children's causal interventions (Meng et al., 2018; McCormack, et al., 2015) by directly examining intervention preference, and determining whether it is primarily driven by an action's informative potential or its tangible outcome. In contrast with previous work, the current results provide direct evidence *against* the claim that children select interventions in order to produce effects. Although our findings cannot explain children's previously reported tendency to engage in PTS, we show that this behavior is *not* due to their failure to appreciate the information-seeking goal of intervention and experimentation.

To summarize, the current results demonstrate that young children both preferentially select informative interventions, and make accurate inferences from the outcomes of those actions. These experiments fill a critical gap in the well-worn proposal that early causal learning intuitively follows a process that is analogous to belief revision in science. In sum, our findings suggest that young learners' causal interventions and inferences are sensitive to the principles of informative experimentation long before they are able execute and articulate those strategies in explicit scientific reasoning tasks.

Frequency or Predictability?
The Effect of Entropy on Statistical Learning

Anonymous CogSci submission

Abstract

Do language learners benefit from exposure to a more predictable input (with lower entropy)? Frequency is known to facilitate learning (more frequent words acquired earlier). However, frequency is only one measure of the distributional structure of the linguistic input. Here, we show that entropy also impacts language learning: adults show better word segmentation in an artificial language when the sequence has lower entropy (created by making one word more frequent). Segmentation improved both for the language as a whole, and for the less frequent words: the infrequent words in the low entropy condition were learned better than the words in the high entropy condition, despite appearing half the number of times. This is the first demonstration, to our knowledge, of the facilitative effect of entropy reduction on language learning. We discuss implications for artificial language learning experiments (which often use uniform distributions) and for models of language learning more generally.

Keywords: Statistical learning; Word segmentation; Language Learning; Information.

Introduction

Frequency effects are prevalent across many aspects of language learning and processing. More frequent sounds, words and constructions are acquired earlier (Diessel, 2007; Goodman, Dale, & Li, 2008), and more frequent words are easier to recognize and produce (Jescheniak & Levelt, 1994). These effects are not restricted to single words: more frequent multiword phrases are also processed faster by adults (Arnon & Priva, 2013; Arnon & Snider, 2010), and produced more accurately by children (Bannard & Matthews, 2008). Frequency also impacts the structure of the lexicon: more frequent words tend to be phonologically shorter (Zipf, 1936).

While frequency affects many domains in language, it captures only one aspect of the distributional structure of the linguistic environment. Frequency alone does not tell us about the co-occurrence patterns of words; the contexts in which words tend to appear; or how predictable the input is overall. In order to quantify such aspects of the linguistic input, other measures are required. Here, we focus on one such measure, Shannon's Entropy (Shannon, 1948). Shannon's entropy quantifies how unpredictable a variable is, with higher entropy assigned to less predictable variables. For instance, a toss of a fair coin has higher entropy than a toss of an unfair coin. Entropy tells us something about the entire distribution of words, beyond the properties of each individual word.

In the past decade, there has been growing interest in applying more complex measures like entropy to the study of language, and growing evidence for their impact on language structure and use. For example, information content is a better predictor of word length than frequency, with less predictable words tending to have longer lexical forms (Piantadosi, Tily, & Gibson, 2011). Similar effects are found in online processing where reading times are affected by entropy (Linzen & Jaeger, 2015), and speakers' production of less predictable words is slower (Cohen Priva, 2017) and less contracted (Frank & Jaeger, 2008). Children are also sensitive to such measures: two-year-olds show better repetition of unfamiliar four-words sequences when the final word "slot" has higher entropy (Matthews & Bannard, 2010), and earlier acquisition of words that have greater contextual diversity (appearing with more unique words) (Hills, Maouene, Riordan, & Smith, 2010).

However, very little work to date has looked at the impact of entropy on learning novel linguistic information: will entropy reduction lead to better learning? Here, we examine this question by looking at statistical learning, and in particular, at the classic word segmentation task of Saffran et al., (1996). Statistical learning (SL) has been studied extensively over the past 20 years, demonstrating human's ability to use distributional information to learn about various aspects of language structure (Romberg & Saffran, 2010). One of the first demonstrations of SL was in the domain of word segmentation, where infants were shown to use the lower transitional probabilities between words as a cue to word boundaries (Saffran, Aslin, & Newport, 1996). Research since has shown that humans can also make use of such distributional information to learn more complex relations such as non-adjacent dependencies (Gomez, 2002) or multimodal associations (Cunillera, Laine, Càmara, & Rodríguez-Fornells, 2010; Lavi-Rotbain & Arnon, 2017).

Interestingly, even though SL of word segmentation has been studied extensively, almost all such studies present learners with a uniform distribution where all elements appear an equal number of times (e.g., each of the words in the Saffran segmentation task appear equally often). However, using a uniform distribution has two inherent drawbacks. First, such a uniform distribution deviates from

that of natural language where words follow a highly skewed Zipfian distribution (Zipf, 1936). A Zipfian distribution has a narrowed peak for the small number of words that are the most frequent, and a very long tail for the rest of the words that have low frequencies. Words show a Zipfian distribution across many languages, in both adult-to-adult speech (Zipf, 1936; Piantadosi, 2014) and child directed speech (Lavi-Rotbain & Arnon, under review). That is, unlike word segmentation studies, words in natural language do not have a uniform distribution.

Second, uniform distributions have low predictability. Elements that show a uniform distribution are harder to predict, since they are equally likely to appear: no guess is better than the other. Sewed distributions, such as a Zipfian distribution, are more predictable: when only a small number of words are highly frequent, they make a better guess than the rest. That is, the uniform distributions used in word segmentation experiments differ from those of natural language in ways that may impede learning. The difference in predictability between uniform and Zipfian distributions can be captured using entropy: the uniform distribution is the least predictable and therefore has maximal entropy, while a Zipfian distribution has lower entropy.

Here we ask if entropy reduction can lead to better learning of word segmentation in the classic Saffran segmentation task. Such a finding would illustrate the sensitivity of learners to more complex distributional measures, and their potential impact on learning outcomes. Only one study, to our knowledge, used a non-uniform distribution in a word segmentation task. In that study, adults learned from either a "Zipfian" distribution or a uniform one. No difference in segmentation scores was found between the two, despite the reduced entropy of the latter (Kurumada, Meylan, & Frank, 2013). These findings seem to go against the idea that entropy reduction is facilitative. However, another possibility is that no facilitation was found because entropy was not reduced enough. In the "Zipfian" condition in Kurumada et al., the word's frequency was inversely proportional to its rank. However, the sharp contrast found in natural language between the narrowed peak and the long tail was not present in this condition. This sharp contrast (the existence of few very frequent words and many low frequency words) shifts the distribution further from being uniform, and reduces entropy to lower levels. We suggest that this contrast between frequencies is beneficial for learning.

Here, we expand on the findings of Kurumada et al. (2013) in several ways to test the prediction that entropy reduction will facilitate learning. First, we compare performance in several levels of entropy: high, medium and low. Segmentation might be facilitated in the low entropy level, which was not tested in Kurumada (2013), and is more similar to natural language. Second, we compare learning of items with the same frequency, across several levels of entropy. We predict that reduced entropy can facilitate learning of low frequency items beyond what is expected from their frequency: words with lower frequency will be learned better when they appear in a more predictable environment (one with lower entropy), compared to in a uniform distribution.

The current study

In the current study we ask if entropy reduction can be beneficial for words segmentation (1) in general, and (2) of infrequent words. We examine the first prediction by looking at adults' segmentation scores across several levels of entropy: high, medium and low, with the same exposure durations. Entropy was reduced by making one word more frequent than the rest. If language learners are mostly sensitive to frequency of novel words, performance on the segmentation test should be affected by word frequency rather than entropy level. However, if learners are sensitive to more than mere frequency, e.g. to the predictability of the input, than segmentation score in the low entropy condition should be better than in the high entropy condition.

We examine the second prediction by comparing segmentation of items with the same low frequency, across different levels of entropy. We expect that low entropy will boost learning of low frequency items, such that low frequency words will be learned better when they appear in a more predictable sequence (with lower entropy), compared to when they appear in a uniform distribution (with high entropy). Previous work has shown that previously learned words can serve as anchors for word boundaries and facilitate segmentation (Cunillera, Càmara, Laine, & Rodríguez-Fornells, 2010). We hypothesize that a similar effect can happen when making one word more frequent. This word is now highly predictable, can be learned early on, and serve as an anchor for learning the segmentation of the infrequent words.

Method

Participants

142 undergraduate students at the Hebrew University of Jerusalem participated in the study (108 females, 34 males, mean age 24;0). Participants were randomly assigned to one of the four experimental conditions. All of the participants were native Hebrew speakers without learning disabilities or attention deficits. Participants received 10 NIS or course credit in return for their participation.

Materials

Auditory stimuli

The task was modelled on the audio-only condition from Lavi-Rotbain & Arnon (2017). Participants were exposed to a familiarization stream corresponding to the condition they were assigned to. All streams were composed of the same four unique tri-syllabic synthesized words: "dukame", "nalubi", "kibeto", and "genodi". The syllables making up the words were taken from Glicksohn & Cohen (2013). They were created using the PRAAT synthesizer (Boersma

& van Heuven, 2001) and were matched on pitch (~76 Hz), volume (~60 dB), and duration (250–350 ms).

The four words were created by concatenating the syllables using MATLAB to ensure that there were no co-articulation cues to word boundary. The words were matched for length (mean word length=860ms, range=845-888ms). The words were then concatenated together using MATLAB in a semi-randomized order to create the auditory familiarization streams. Importantly, there were no breaks between words and no prosodic or co-articulation cues in the stream to indicate word boundaries. The only cue for word boundaries was transitional probabilities (TP's): TP's between words were lower compared to TP's within words.

Experimental conditions

We created auditory sequences with three levels of entropy: high, medium and low, but with the same number of tokens (128) and length (1:50 minutes), in order to see if reduced entropy can facilitate segmentation. In the high entropy level, words followed a uniform distribution with each word appearing 32 times in a semi-randomized order (no word appeared twice in a row). TP's within a word were 1, and TPs between words were 0.333. In the medium entropy level, words appeared with a skewed distribution: one word appeared 55% of the time (71 appearances) while each of the other three words appeared 15% of the time (19 appearances for each word). In the low entropy level, words appeared with an even more skewed distribution: one word appeared 80% of the time (101 appearances) while each of the other three words appeared only 7% of the time (9 appearances for each word). In both the low and medium entropy conditions, the identity of the frequent word was counterbalanced across subjects. In addition, in both conditions the TP's within a word were 1, but the TP's between words varied depending on the next word (since the frequent word in these conditions was more likely to occur). These conditions were used to examine the effect of entropy on the general segmentation score.

In order to look at the segmentation of the low frequency items, we added a uniform condition with high entropy but with shorter length (uniform-short). In this condition, each word appeared 19 times (76 tokens, lasting 1:05 minutes). The frequency of each word in this condition was matched to that of the infrequent words from the medium entropy condition. By comparing the two we can examine the impact of entropy on words with the same low frequency. See Table 1 for full details of the experimental conditions.

Segmentation test

16 two alternative forced choice trials appeared in a random order, with the constraint that the same word/foil did not appear in two consecutive trials. Participants heard two words and were asked to decide which belonged to the language they heard. We used non-words as foils ("dunobi", "nabedi", "kilume", and "gekato", average length: 860ms; range 854-868ms), created by taking three syllables from three different words, while keeping their original position. Each of the four words appeared once with each of the four foils to create 16 trials. The order of words and foils was counter-balanced so that in half the trials, the real word appeared first and in the other half, the foil appeared first.

Procedure

Participants completed the experiment on a computer while seated in a quiet room. They were told that they are going to listen to an alien language and will then be asked about it. A check-board image was displayed while they listened to the familiarization stream. After the exposure phase, participants completed the segmentation test.

Results

Participants were divided as follows between the four conditions: uniform, N=31; uniform-short, N=30; medium entropy, N=41; low entropy, N=40. In the medium and low conditions, each of the four words was the frequent one for ten subjects. A one way ANOVA (on each entropy rate separately) revealed that segmentation did not differ due to which word was the frequent one (for the medium entropy condition: $F(3)=0.72$, $p=0.55$; for the low entropy condition: $F(3)=1.7$, $p=0.18$). Consequently, in all subsequent analyses we collapsed the data across the different frequent words, for each of these conditions. Participants showed learning (were above chance) in all four conditions (low entropy condition: $t(39)=12.57$, $p<.001$; medium entropy condition: $t(40)=7.0$, $p<.001$; uniform condition: $t(30)=7.0$, $p<.001$; uniform-short condition: $t(29)=5.8$, $p<.001$) (see Fig. 1).

We used mixed-effect linear regression model to examine the effect of condition on performance. Following Barr et al. 2013, the models had the maximal random effect structure justified by the data that would converge. Our dependent binominal variable was success on a single trial of the segmentation test. We had experimental condition (dummy coded, meaning that each condition is compared to the

Trial number (centered)	-0.03469	0.01061	-3.271	**<.01 ****
Order of appearance (word)	0.59277	0.09781	6.061	**<.001 *****

uniform condition) as a fixed effect, as well as: log frequency of the word (centered); gender; trial number (centered); order of appearance in the test (word-first trials vs. foil-first trials). The model had random intercepts for participants and for items (Table 2). To examine the overall effect of experimental condition and word's frequency, we used two model comparisons.

As predicted, experimental condition had a significant effect on performance (chi(3)=42.07, p<0.001). Participants showed better learning in the low entropy condition compared to the uniform condition (β=1.25, SE=0.22, p<0.001). However, performance in the medium entropy condition, and in the uniform-short condition, did not differ from the uniform condition (uniform-short: β=0.19, SE=0.2, p>0.1; medium entropy: β=0.19, SE=0.19, p>0.1).

In addition to the entropy effect, frequency also had a significant effect on segmentation (chi(1)=18.9, p<0.001). Participants showed higher accuracy for more frequent words (β=0.4, SE=0.09, p<0.001). Trial number significantly affected performance: better accuracy in the beginning of the test (β= -0.03, SE=0.01, p<0.01). Order of appearance in the test significantly affected performance: better accuracy on trials where the word appeared before the foil (β=0.59, SE=0.1, p<0.001), as has been found in previous studies (Lavi-Rotbain & Arnon, 2017; Raviv & Arnon, 2017). Since the order of presentation of words and foils was counter-balanced this could not reflect a preference for pressing 1 or 2. Gender did not affect performance (β= -0.02, SE=0.16, p>0.1).

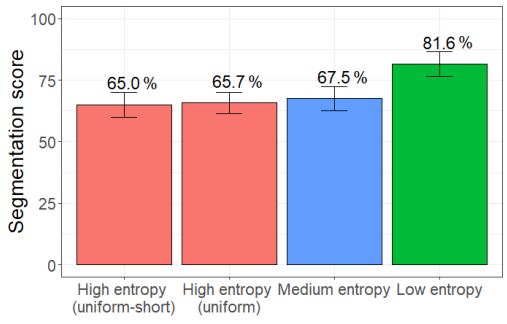

Fig. 1: Mean segmentation score by condition with 95% confidence intervals

In order to examine the effect of entropy on low frequency words, we compared accuracy in learning: (1) the words in the uniform-short condition; (2) infrequent words from the medium entropy condition; and (3) infrequent words from the low entropy conditions. The first two sets of words appeared 19 times during exposure, while the third set appeared only nine times. We used all trials (16 per subject) from the uniform-short condition (since they all had the same frequency). However, for the medium and low entropy conditions, we included only trials in which the correct answer was one of the infrequent words (denoted as 'infrequent trials'). In these conditions, there were 12 infrequent trials for each subject. Participants showed learning of infrequent items (above chance) in all conditions (low entropy condition: t(39)=9.59, p<.001; medium entropy condition: t(40)=5.3, p<.001).

We used a mixed-effect linear regression model to look at the effect of entropy level on learning infrequent words. Our dependent binominal variable was success on a single trial. We had experimental condition as a fixed effect (each condition was compared to the uniform-short condition) as well as: gender, trial number (centered); and order of appearance in the test. The model had random intercepts for participants and for items. To examine the overall effect of condition, we used model comparisons.

As predicted, experimental condition had a significant effect on learning infrequent words (chi(2)=16.9, p<0.001). Low frequency words were learned better in the low entropy condition (M=78.8%) than in the uniform-short condition (M=65%) (β=0.78, SE=0.22, p<0.001). This effect is opposite to what would be expected based on mere frequency: these words appeared only nine times in the low entropy condition as opposed to 19 times in the uniform-short condition. Performance on infrequent trials in the medium entropy condition (M=64.8%) did not differ from the uniform-short condition (β=0.0, SE=0.2, p>0.1). Trial number affected performance, with better accuracy in the beginning of the test (β= -0.03, SE=0.01, p<0.05). Order of appearance in the test also affected performance, with better accuracy on trials where the word appeared before the foil (β=0.53, SE=0.1, p<0.001). Gender did not affect performance (β=0.06, SE=0.2, p>0.1).

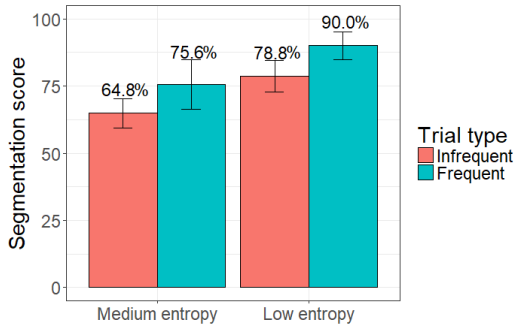

Fig. 2: Mean segmentation score by condition by trial type (frequent VS infrequent) with 95% confidence intervals

How can we reconcile the general effect of frequency with the finding that words that appeared only nine times were learned better than those appearing 19 times? Our data suggests that what matters is not absolute frequency, but relative frequency: within each condition, the more frequent words were learned better. This is best illustrated in Fig. 2 in which we plotted segmentation means by condition (medium and low entropy) and by trial type (infrequent versus frequent trials). Frequency affect performance within conditions: frequent words are learned better in both entropy levels. However, this does not hold across conditions. For example, infrequent trials from the low entropy condition are numerically better than frequent trials from the medium entropy condition, despite of the sharp difference in frequency in the opposite direction: only nine appearances compared to 71. That is, only the relative frequency within each condition affected performance.

One possible explanation for the entropy effect we found is that participants only learned the frequent word, and used it to rule out foils by elimination. If this is what they did, we should see a difference in segmentation scores across foils: foils that share a syllable with the frequent word should be easier to reject compared to foils that do not. For example, if the frequent word for a participant is 'nalubi', we should see better accuracy in rejecting 'nabedi' that shares the first syllable with 'nalubi', compared to rejecting 'gekato' that does not share a syllable with 'nalubi'. However, we see no such effects. A one-way ANOVA showed no difference between trials in the low entropy condition where the foil shared one syllable with the frequent word (M=79.2%) and trials where it didn't (M=77.5%) ($F(1)=1.2$, $p>0.1$). No difference was found even when we compared performance between foils that share the first syllable with the frequent word separately from these who share the second, the third or none at all ($F(3)=1.57$, $p>0.1$). That is, the boost for the infrequent words in the low entropy condition seems to reflect the better learning of those words.

Discussion

We set to ask if reduced entropy can improve segmentation in a classic auditory SL task (1) in general, and (2) of infrequent words. In addition, we wanted to see if the lack of facilitation in previous findings (Kurumada et al., 2013) was due to a not large enough decrease in entropy. To do so, we examined adults' word segmentation in an artificial language across three levels of entropy (high, medium and low). Entropy was reduced by making one word more frequent than the rest, so that it appeared 55% (medium entropy) or 80% (low entropy) of the time. As in the "Zipfian" condition in Kurumada (2013), reducing entropy to medium level did not facilitate segmentation. However, lower levels of entropy did facilitate learning compared to uniform conditions with the same length. This effect was not driven only by improved learning of the frequent words. The low frequency words also benefitted: they were learned better in the low entropy condition compared to medium and high levels, despite appearing half the number of times (nine vs. 19). Further analyses ruled out alternative explanations: the facilitation cannot be explained by ruling out foils that share syllables with the frequent word. In addition to the effect of entropy, our findings highlight the importance of relative, rather than absolute frequency on learning. Frequency effects were present only within conditions and not across conditions. For example, infrequent words from the low entropy condition, that appeared only nine times, were learned better than the infrequent words in the medium entropy condition (appearing 19 times). Moreover, they were learned numerically better (though this did not reach significance) than the frequent word in the medium entropy condition despite appearing much less (nine vs. 71 times).

This is the first evidence, to our knowledge, that humans are sensitive to complex measures such as entropy in the process of language learning, and that a more predictable distribution, as the one found in natural language, can be beneficial for learning compared to a uniform one. In addition, we provide novel evidence showing that low frequency items can 'overcome' their frequency when appearing with higher frequency items, in a more predictable distribution. These results have implications for artificial language experiments. The vast majority of artificial language experiments use a uniform distribution in which all items have equal frequency. It is already known that this uniform distribution is not ecological since the natural language we are exposed to shows a Zipfian distribution (Zipf, 1936; Piantadosi, 2014) even in speech directed to infants at their first stages (Lavi-Rotbain & Arnon, under review). Our results highlight an additional drawback of using uniform distributions in the lab: such distributions can impede performance compared to more skewed, low entropy distributions. That is, we may be significantly underestimating learners' abilities when using uniform distributions. This is of particular importance when such tasks are used to determine what learners can (or cannot) learn. We are currently investigating the impact of entropy on learning in children, and for other kinds of SL tasks.

Beyond artificial language experiments, these results have implications for our understanding of the factors that impact language learning. While frequency effects on language

learning have been studied extensively (Goodman et al., 2008; Jescheniak & Levelt, 1994), the effect of more complex measures remain understudied. Our results highlight the role of entropy in learning and open up new research directions on the impact of entropy on real-life language learning. What is the informative structure of child-directed speech? Does variance in entropy predict the age of acquisition of words? Can we see similar effects of the environment words appear in on natural language learning? We are currently engaged in a series of studies investigating these questions, which can further deepen our understanding of infants' first steps into language and the formation of their vocabulary.

The Inductive Benefit of Being Far Out: How Spatial Location of Evidence Impacts Diversity-based Reasoning

Abstract

Inductive reasoning is constrained by several principles that govern how we choose to generalize evidence to new cases. Here we focus on diversity principle of induction, which describes the tendency to favor inductive arguments that include a diverse sample of evidence over those that include a homogenous sample of evidence. Several studies reveal that adherence to the diversity principle is influenced by a range of conceptual processes, such as an individuals' prior knowledge or expectations about the categories and properties represented in the evidence. In the two experiments reported here we examined a contextual factor of the available evidence – the spatial separation of evidence exemplars – that we expected would impact how people reason about diverse samples. We found that when the pictures (Experiment 1) or labels (Experiment 2) used to represent evidence exemplars were presented far apart (approximately 10 cm), participants showed a greater willingness to endorse arguments with diverse exemplars than those with homogenous sample, relative to when these exemplars were placed in close proximity (approximately 1 cm apart). We discuss these results as they relate to existing models of induction.

Keywords: Inductive reasoning; Generalization; Diversity principle; Situated cognition

Introduction

Inductive reasoning, the process by which we use specific facts to arrive at general conclusions, is critical to our cognitive lives. For example, learning that hawks have hollow bones serves as evidence to support the inductive inference that other birds are likely to have hollow bones. Given the powerful role of induction for a range of cognitive processes there has been considerable interest in determining the constraints that guide the inferences we make. For example, in their classic work, Osherson and colleagues (1990) outlined several inductive principles that systematically constrain how we use evidence to arrive at inductive decisions. The present study focused on one such principle – the diversity principle of induction. Consider the two arguments below in which the two statements above the lines represent evidence and the statement below the lines represents a conclusion:

Hawks have hollow bones
Penguins have hollow bones (1)
Larks have hollow bones

Hawks have hollow bones
Eagles have hollow bones (2)
Larks have hollow bones

When asked to judge which of these two represent stronger inductive arguments, participants tend to select those that include a diverse sample of exemplars (1) rather than those that include a homogenous sample of exemplars (2) (Heit, Hayes, & Feeney, 2005; Kim & Keil, 2003; Osherson, et al., 1990; also, Lopez, 1995).

Most explanations of diversity effects focus on the ways individuals represent the content (i.e., categories and to-be-generalized properties) of the available evidence. For example, Osherson et al. proposed the similarity-coverage model to account for diversity effects. This perspective posits that individuals first consider the overarching category about which the inductive judgment should be considered. In the two inductive arguments presented above the coverage category in *bird*. Participants then assess the extent to which the evidence in each set of arguments covers this overarching category. According to this model individuals rely on their calculation of the similarity between exemplars to assess the extent to which each sample covers the conclusion category. Greater dissimilarity between exemplars within the evidence sample reflects greater coverage of the category, and therefore facilitates diverse-based reasoning.

Diversity effects have also been explained as Bayesian inference. From this perspective individuals rely on their prior beliefs about categories and properties to test hypothesis about the scope of property projection (Heit, 1998; Lo, Sides, Rozelle, & Osherson, 2002). Our prior experience may lead us to believe that some categories (e.g., hawks and eagles) share many features in common and others categories (e.g., hawks and penguins) share fewer features. Thus, we are not surprised to learn about a new property that happens to be shared by two categories we have heretofore expected share many properties. In contrast, we are surprised to learn about a property that is shared by two categories that we believed had very little in common. This surprising sample of evidence, coupled with our expectation that samples of

evidence tend to be selected purposefully (Lawson & Kalish, 2009), makes the diverse sample a better argument to support a conclusion about a superordinate category.

There are notable cases in which individuals fail to adhere to the diversity principle. For example, several studies have shown that individuals with rich domain knowledge are less likely to consider taxonomic diversity in lieu of other evidence (Lopez, Atran, Coley, Medin, & Smith, 1997; Proffitt, Coley, & Medin, 2000). Moreover, when experts do engage in diversity-based reasoning they rely on a range of strategies that appeal to their knowledge about the domain, such as the types of properties that are transmitted across categories, or the relative size of the category that is represented in the samples of evidence (Proffitt et al., 2000). Thus, experts will depart from using taxonomic diversity as a basis for induction under conditions in which their rich domain knowledge suggests an alternative inductive strategy is optimal.

In related work Medin and colleagues (2003) showed that non-experts (college students) prefer to generalize from a sample of evidence that highlights a relevant relation between two evidence exemplars rather than a sample that includes taxonomically diverse exemplars. For example, participants judged an argument in which fleas and butterflies were attributed the same property as better support to conclude that the property is true of sparrows, than an argument in which fleas and dogs were the same property. This latter sample signals a relevant causal relationship that draws attention away the greater taxonomic diversity of the two exemplars, thereby leading individuals to favor the inductive argument with less diverse exemplars.

These exceptions are notable for two reasons. First, they highlight the role of prior knowledge about categories and properties when reasoning about the content of an inductive problem. Second, they bring to light an important methodological point: specific task modifications, such as the type of property or the relationship between categories presented in the evidence, impact how people reason about diverse samples. In support of this point, Feeney and Heit (2011) showed that the content of the to-be-generalized property serves as a prime to either encourage or discourage diversity-based responses. In their study participants exhibited diversity effects when they were primed with a general property that can be construed as common across a wide range of category members (e.g., are warm-blooded), but did not show these effects when they were primed with an idiosyncratic property (e.g., lives in the water).

In the present studies we examined whether contextual factors, such as how evidence exemplars are presented, may impact the extent to which participants obey the diversity principle. We were particularly interested in the potential influence of the spatial location of exemplars for two related reasons. The first concerns findings from research demonstrating that taxonomic categories tend to be, in many ways, represented within a multidimensional space which can be described as reflecting psychological distance between exemplars (Collins & Quillian, 1969; Hutchinson & Lockhead, 1977; Rips, 1975; Schaeffer & Wallace, 1969). Among other things this psychological distance can be created by similarity relations; for example, relative to their membership within the bird category robins and sparrows can be considered *close* (they share many properties) whereas robins and ostriches are *far* apart (they share few properties). From this perspective, diverse samples are likely to be those that represent items that have greater representational distance.

The second, related, idea comes from research on situated cognition and embodiment (Barsalou, 2006; Wilson, 2002), in which it has been argued that the way we think about and represent concepts is determined, at least in part, by the way we experience and engage with concepts. For example, in addition to activating semantic features, many of the concepts we reason about (e.g., dogs) activate motor and sensory features (e.g., throwing to-be-retrieved items, going for walks, tugging on a leash, etc.) that reflect simulations of how we might interact with concepts (Barsalou, 2006). At a broad level, the embodiment framework challenges cognitive models to consider the role of the environment for a cognitive system (e.g., Hutchins, 1995).

With theses issues in mind we examined whether creating greater physical distance between exemplars within a sample would impact diversity-based reasoning. In two experiments participants were given inductive problems in which three evidence exemplars were presented either in close proximity to each other (within 1 cm), or far from each other (approximately 10 cm apart) (See Figure 1). Half the evidence samples included a diverse range of exemplars and the other half included a homogenous set of exemplars. Our main prediction was that the greater separation of items would encourage participants to consider the coverage, or range, of the exemplars and therefore would lead to higher ratings for inductive arguments that included diverse samples compared to conditions in which the items were spaced close together.

The experiments assessed two additional factors. The first concerns the contents of the evidence samples. In Experiment 1 the items were represented by pictures of animals used to represent the categories presented in the evidence, whereas in Experiment 2 the items were represented by category labels (see Figure 1). This manipulation allowed us to test whether any potential effects of evidence spacing were due to perceptual processed that governed the way participants compared the physical features of the exemplars (i.e., differences

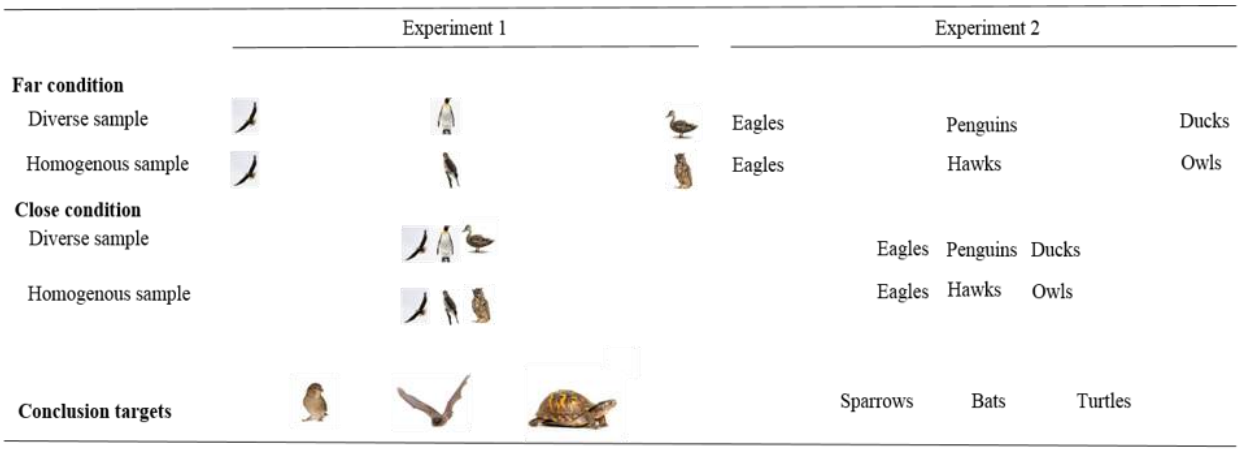

Figure 1. Schematic representation of the design of Experiments 1 and 2.

between the pictured items), rather than differences in how they represented the categories.

Finally, we asked participants to make inductive judgments about three different targets, each of which varied in similarity to/taxonomic distance from the category represented by the evidence exemplars. For example, for the item in which evidence exemplars were represented by birds, participants were asked to make a judgement about a new bird (e.g., sparrow), a bat, and a reptile (e.g., turtle). We expected that the spacing effects would be limited to the category that represents the lowest level of abstraction covered by the evidence and target exemplars (e.g., Osherson et al., 1990). However, if the spatial manipulation has a more general effect on how individuals compare stimuli, it is possible the spaced presentation could lead to an overall increase in one's willingness to generalize from diverse samples to any targets. Thus, this manipulation allowed us determine the extent to which varying the spatial location of the evidence influenced participants' adherence to the diversity principle, in particular.

Experiment 1

Participants. Fifty-three undergraduate students participated for extra credit in a college course. Participants were recruited from, and were representative of, a medium-sized Midwestern US city.

Design. This experiment employed a 2 x 2 x 3 design with Spatial location of evidence exemplars (Close, Far) manipulated between subjects and Sample composition (Diverse, Non-diverse) and Conclusion target (Same basic-level, Similar superordinate, Dissimilar superordinate) manipulated within subjects. Participants were randomly assigned to either the Close condition or the Far condition such that there was an approximately equal number of participants in the two conditions: Close (N = 27), and Far (N = 26).

Materials. Participants were presented 12 inductive reasoning problems each of which included a sample comprised of 3 evidence exemplars. Half of the samples included a diverse set of exemplars (e.g., eagles, penguins, ducks) and the other half included a homogenous set of exemplars (e.g., eagles, hawks, owls). A novel biological property (e.g., Enzyme A) was attributed to the exemplars within the sample. A different novel property for each of the twelve problems.

For each reasoning problem participants were asked to make judgements for 3 different conclusion targets each of which varied in relation (taxonomic and/or perceptual relatedness) to the category covered by the evidence exemplars (see Figure 1 for a sample item). One target was drawn from same basic-level category that was represented by the evidence exemplars (e.g., sparrows). The other two target categories were drawn from superordinate categories (e.g., bats and turtles). Each of the evidence exemplars and targets were represented by photographs of a single animal (2cm x 2cm).

Procedure. The experiment was conducted on a desktop computer with a 24" screen. The spatial arrangement manipulation involved varying the location of the evidence exemplars as they appeared on the screen. In both conditions the exemplars were presented in row on the top of the screen. In the *Far* condition the exemplars were spaced so that there was an approximately 10 cm gap between each. In the *Close* condition the exemplars were bunched together so that there was an approximately 1 cm gap between each. For each item the three evidence exemplars were presented at the same time and were accompanied by a statement (appearing below three exemplars) that attributed a property to all the animals (e.g., "these animals have Enzyme A").

After the evidence exemplars were presented participants were asked to make a judgment about each of the three conclusion targets. A photograph of an

animal used to represent the category was presented approximately 6 cm below the evidence exemplars and was accompanied by a prompt to judge the likelihood that the target category would have the property that was attributed to the evidence exemplars (e.g., "How likely is it that sparrows have Enzyme A?"). Participants were instructed to use a scale, ranging from 0 ("not at likely" to 100 ("very likely), to determine their likelihood judgment. The three target categories were presented in random order.

Note that because sample diversity was manipulated within subjects we counterbalanced across participants which category was represented by a diverse sample or homogenous sample of exemplars. Also the order of presentation of diverse and homogenous samples (within participants) was randomized.

Results

Average likelihood ratings were submitted to a mixed ANOVA with Spatial arrangement of evidence (Close, Far) as the between subjects variable and Sample composition (Diverse, Homogenous), and Conclusion target as the within subjects variables. The only significant main effect was Conclusion target, $F(2, 102)=374.93$, $p<.001$, $\eta^2>.87$, due to a stepwise decrease in likelihood ratings as a function of the decrease in similarity/increase in taxonomic distance from the evidence exemplars to the target categories, all ps<.001 Tukey's HSD.

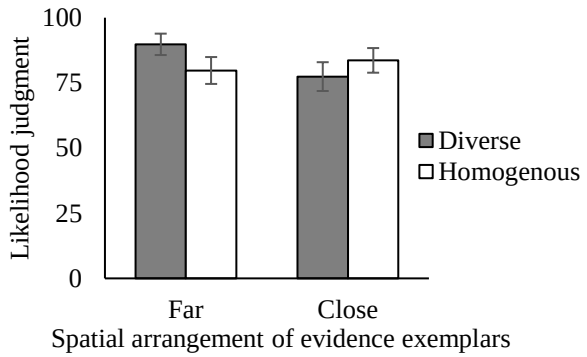

Figure 2. Mean likelihood judgements for basic-level targets for Diverse samples and Homogenous samples in both Spatial arrangement conditions in Experiment 1. Bars represent 1+/- SE from the mean.

The analysis also yielded several noteworthy interactions, all of which were captured by a 3-way interaction, $F(2,102)=4.72$, $p<.02$, $\eta^2=.09$. Analyses of the effects of spatial location on the ratings for each target revealed different patterns of responses for only the Basic-level targets. Simple effects analyses indicated there was a sample location by sample diversity interaction for basic-level targets $F(1,51)=8.49$, $p=.005$, $\eta^2=.17$. As suggested by Figure 2, this interaction was due to differences in responses for Diverse samples of evidence, for which the ratings were significantly higher in the Far condition than the Close condition, $p<.001$. Additional comparisons indicated that were significant differences in ratings between diverse samples and homogenous samples in the Far condition $F(1,25)=7.89$, $p=.01$, $\eta^2=.12$, but not in the Close condition ($F<1.50$). No other effects or interactions were significant (all Fs<1.60).

Discussion

These results indicate that the spatial location of evidence exemplars had a consistent and precise effect on judgments about diverse, but not homogenous, samples. Adults consistently gave higher likelihood ratings for diverse samples when the evidence exemplars were separated from each other than when they were presented in close proximity to each other. However, the effect of spatial location was only present for targets from the same, basic-level, conclusion category as the evidence exemplars. Thus, these results provide preliminary evidence in support of our prediction that contextual factors, such as the way evidence is presented, can facilitate diversity-based reasoning.

Experiment 2

This experiment was designed to address at least two concerns raised by Experiment 1. First, because the items were represented by a photograph of a single animal it remains unclear if participants interpreted the exemplars as representative of the categories they were intended to represent or if they interpreted the evidence as representative of single individual concepts. Second, because the materials included photographs it is possible the effects were due to differences in how participants compared the stimuli, rather than their assessment of the diversity represented by the categories in the evidence. We addressed both of these concerns in this experiment by replacing the photographs with category labels.

Method

Participants. Forty-nine undergraduate students participated for extra credit. Participants were recruited from, and representative of the population of, a medium-sized Midwestern US city.

Design, Materials, and Procedures. This experiment was identical to Experiment 1 in every respect except the stimuli. In this case, rather than presenting photographs to represent the evidence and target items, participants were presented category labels. Participants were randomly assigned to the Far (N=24) or Close (N=25)

conditions. See Figure 1 for a schematic of the study design.

Results

The analysis replicated the pattern of results that was found in Experiment 1. Again there was a three-way interaction between Spatial arrangement, Sample Composition, and Conclusion target, $F(2, 92)=3.48$, $p=.02$, $\eta^2=.078$. Further analysis revealed a significant Sample composition by location effect interaction for Basic-level targets, $F(1, 46) = 10.32$, $p=.002$, n=.18. As suggested by Figure 3, the interaction was due to higher ratings for Basic-level targets for diverse samples than homogenous samples in the Far condition, $F(1, 47) = 12.12$, $p<.001$, $\eta^2=.13$, but not in the Close condition, $F<1.00$. Also, participants exhibited higher likelihood ratings for diverse samples in the Far condition than in the Close condition, $F(1,97)=6.42$, $p=.03$, $\eta^2.09$ As was the case in Experiment 1, no other effects or interactions were significant.

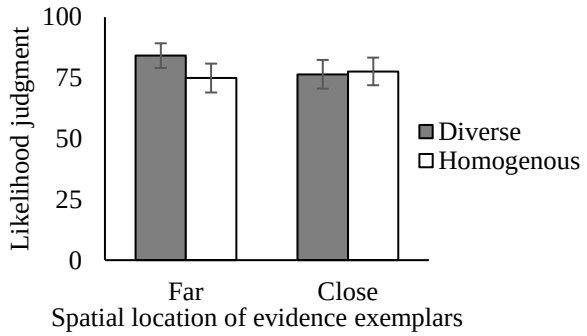

Figure 4. Mean likelihood judgements for basic-level targets for Diverse samples and Homogenous samples in both Spatial location conditions in Experiment 2. Bars represent 1+/- SE from the mean.

Discussion

These results replicated those found in Experiment 1. Participants rated arguments with diverse samples as providing better support for conclusions than arguments with homogenous samples when the exemplars were spatially distant from each other but not when these same evidence exemplars were in close proximity. Moreover, the diverse sample were given higher ratings when the evidence exemplars were more distant than when they were close. These results suggest that the findings from Experiment 1 were not due to participants' interpretation of the evidence as applying to specific individuals, rather than categories, nor their reliance on perceptual features of the task.

General Discussion

Prior research indicates that diversity-based reasoning is dictated by our knowledge or expectations about the categories, or the to-be-generalized properties that are represented in the evidence (Feeney & Heit, 2011; Heit, 1998; Osherson et al., 1990). Thus most existing models account for diversity effects by focusing on how people reason about the content of an inductive problem. In the two experiments reported here we demonstrated that certain contextual factors, such as the way exemplars are presented, also contribute to diversity-based reasoning. Specifically, participants showed a greater willingness to endorse arguments that included diverse samples when these samples were presented in such a way that there was a large spatial separation between each of the evidence exemplars relative to when the same exemplars were presented without a large separation between evidence exemplars. In other words, diversity effects were strongest when the evidence covered more physical space.

It is difficult to reconcile these results with current explanations for diversity effects. One could argue that the spacing effects in Experiment 1 are consistent with the feature-based induction model of induction (Sloman, 1993) insofar as the presentation impacted the way participants compared stimuli, or identified overlapping or unique features, and thus impacted their calculation of diversity. However, this interpretation does not account for the observed effects in Experiment 2 in which the stimuli were represented by labels rather than images. The results are also inconsistent with the idea that a calculation of similarity between the evidence exemplars is sufficient to assess category coverage (Osherson et al., 1990). The similarity coverage model does not account for the finding that participants gave higher ratings for diverse samples when the evidence exemplars were spread far apart compared to when they were positioned close together.

Those in favor of the Bayesian or Relevance accounts of induction might interpret the results as the outcome of pragmatic factors. It could be argued that participants assumed that the exemplars were purposefully placed in close proximity or far apart. According to the Relevance theory of induction (Medin et al., 2003), participants rely on standard rules of communication (e.g., Grice, 1975; Sperber & Wilson, 1995), such as the notion that people present information in such a way as to highlight a relevant piece of information. Thus, it could be argued that participants reasoned as-if the exemplars were deliberately placed apart to draw attention to the coverage of the exemplars (or placed together to highlight the similarities between them). Although these models can accommodate these effects of spatial location, they do not explain them. Assuming participants reasoned that exemplars were spread apart purposefully, why would they interpret this decision was

intended to highlight the coverage of evidence exemplars?

Our interpretation of these results is that they provide some support for the grounded, or situated, aspect of diversity-based reasoning. Most models of situated cognition tend to focus on the influence of different modalities (e.g., motor sequences) on conceptualization. Diversity refers to a feature of samples, not isolated concepts. Diverse samples are those that include exemplars that provide coverage of a category; diverse samples occupy greater psychological space. Here we showed that presented evidence in such a way that the sample occupied greater physical space facilitated diversity-based reasoning. That the spacing effects were not observed for homogenous samples, or for targets from more distant conclusion categories, suggests that spacing did not influence *whether* participants interpreted samples as diverse. Rather, the results indicate that the broad spacing of exemplars primed cognitive processes that can draw attention to sample diversity, and thereby strengthen diversity effects.

Clearly, more work is needed to better understand the scope of these effects. For example, to clarify the potential impact of participants' pragmatic assumptions it will be important to determine whether we can replicate these effects in conditions in which participants are made to believe that the location of the exemplars was not chosen deliberately. Additionally, because participants did not show the diversity effect in the Close condition it will be important to replicate these findings with a different set of stimuli. Also, it will be important to explore other ways in which individuals might be primed to consider the breadth or scope of evidence. For example, we are currently exploring the impact of gestures on adults' and children's adherence to diversity and sample size principles of induction.

There are several notable limitations of these experiments. First, the methods were different from those typically used on the inductive reasoning literature. Participants are often given arguments and asked to determine the sample that provides the best support for a conclusion. Here the evidence exemplars were presented as single photographs or category labels, rather than premises in an inductive argument. The effect of spacing might have been pronounced because this method encouraged participants to compare the stimuli. Also, although the observed effects were consistent, they were rather small. It will be important to replicate these results with stimuli from different domains to be sure these effects are not exclusive to the set of items.

Despite these limitations, these results raise important questions about the impact of contextual factors on inductive reasoning. In particular we showed that presenting evidence in such a way that it covered a broad physical space provided greater support for diversity-based reasoning than when the same evidence was presented in a narrow physical space. While we do not deny that there is still much to learn about the influence of category knowledge, and prior beliefs, on inductive reasoning, these experiments call for more work on understanding the impact of contextual features on induction. As much as inductive reasoning is influenced by *what* is presented in an inductive problem, it seems intuitive that it would be influenced, at least to a certain degree, by *how* evidence is presented.

Exploring the Representation of Linear Functions

Abstract

Function learning research has highlighted the importance of human inductive biases that facilitate long-range extrapolations. However, most previous research is focused on aggregate errors or single-criterion extrapolations. Thus, little is known about the underlying psychological space in which continuous relationships are represented. We ask whether people can learn the distributional properties of new classes of relationships, using Markov Chain Monte Carlo with People, and find that (1) people are able to track not just the expected parameters of a linear function, but information about the variability of functions in a specific context and (2) in many cases these spaces over parameters exhibit multiple modes.

Keywords: generalization, function learning, representation

Inductive biases are at the heart of the human ability to generalize and extrapolate from sparse evidence. For instance, when we infer labels and properties of new objects or entities, we rely not just on our experience of past examples, but on our implicit and explicit expectations about the nature of categories. Similarly, when we learn relationships between quantities in *function learning*, inductive biases make it possible to distinguish between the boundless possible relationships behind a set of observations (Lucas et al., 2012, 2015).

In order to characterize a person's inductive biases, it can be useful to first focus on spaces of possible mental representations – sometimes called hypothesis spaces – and the kinds of inferences they support or preclude. As with categorization, there have been many proposals about the mental representations supporting function learning, including exemplar-based approaches (McDaniel & Busemeyer, 2005), rule-based approaches (Brehmer, 1974), and hybrids or generalizations of these (DeLosh et al., 1997; Lucas et al., 2015). These models are typically evaluated by comparing their predictions to averaged human judgments, either via direct correlations, error relative to the true underlying function, or qualitative features including multiple modes (Kalish et al., 2004), or monotonicity (Bott & Heit, 2004; Kalish, 2013).

While this line of research has shed light on function learning and the representations and inductive biases that make it possible, some fundamental questions remain. For example, while models that take a distributional approach to function learning have successfully explained human behavior, there is little direct evidence that people track distributional information – uncertainty or variability – when faced with function learning problems. This question has been unanswerable in previous work that relied on aggregated judgments or assumed that individual inductive biases are broadly similar (Kalish et al., 2007). Even the few studies that have focused on inference patterns (Kalish, 2013; Wilson et al., 2015; Schulz et al., 2017), including analyses of per-participant extrapolations (León-Villagrá et al., 2018), still neglected this question about the tacit beliefs behind participants' judgments. Only recently, experiments have started to explore the role of uncertainty in function learning. In Schulz et al. (2015) participants judged functions to be more predictable when they were smooth or when they exhibited low variance, much in accordance with the preferences of a probabilistic model. Similarly, Stojic et al. (2018) showed that participants' predictive accuracy in a function learning task correlated with their confidence ratings, again resembling the uncertainty estimated by a probabilistic model.

Here we expand on this work and attempt to directly characterize how people represent uncertainty when they learn functions.

Markov Chain Monte Carlo with People

To uncover the psychological space that participants learn when learning functions we apply Markov Chain Monte Carlo with People (MCMCP; Sanborn et al., 2010). Sanborn et al. showed that Markov Chain Monte Carlo can be used as an experimental method to elicit posterior distributions from people using a simple forced-choice task. Thus, MCMCP offers a method to explore the psychological representational space and has been successfully applied to elicit the representations of complex stimuli, such as facial affect categories (Martin et al., 2012). Previously, MCMCP has been used in a function learning setting[1] to examine if participants prefer compositional over non-compositional functions (Schulz et al., 2017). Since Schulz et al. were interested in preferences for types of functions (compositional vs. non-compositional), the samples presented consisted of discrete varieties of functions and did not explore the distribution of function parameters.

In contrast, in this work, we directly explore the distributional space of the parameters governing the realizations of linear functions. This allows us to uncover how learned functions are represented, without constraining the participant's choices to pre-specified sets of materials.

Adopting MCMCP also allows us to explore novel questions – do participants represent variability in the training relationships? Do they form a single, deterministic functional relationship or do they form posterior distributions over parameters, reflective of the variability in the training? This question about representation, in turn, can inform more general future questions about extrapolation – are typical extrapolation patterns maximum a posteriori judgments given a

[1]Function learning has been more extensively studied in a closely related paradigm, *iterated learning*. Iterated learning experiments can elicit participants' shared expectations and have revealed strong inductive biases for positive linear functions (Kalish et al., 2007).

learned distribution over parameters? Or do they correspond to samples from a range of probable parametrizations?

In this work we:

- Evaluate if MCMCP can be successfully adapted to a function learning paradigm.
- Contrast how functions are represented depending on the variability of the example sets provided.

Experiment

In this experiment, we examine how participants represent linear functions when presented with sets of training examples. We hypothesize that participants learn both the parameters generating the function, as well as the variability of the relationship, i.e. they will learn both how much slopes and intercepts vary, while also learning the specific modes of slopes and intercepts. Therefore, we expect participants to form posterior distributions over the training parameters, with the variance of that posterior reflective of the training.

We distinguish between training functions with positive and negative slopes, since previous research has highlighted strong inductive biases for these relationships. Similarly, while it has been shown that people are biased to extrapolate in a linear fashion, especially preferring linear functions where both stimulus and criterion are matched (DeLosh et al., 1997), extrapolations appear to be influenced by their proximity to the extrapolation boundaries. In areas of the extrapolation range that are closer to zero, participants seem to adjust the slope of their extrapolations towards this boundary (Brown & Lacroix, 2017; Kwantes & Neal, 2006). To test how different offsets and different degrees of steepness are represented we contrast steep and shallow linear functions. Finally, we expect that highly salient functional relationships, like positive functions for which target and criterion are matched, will be easier to learn and result in more peaked posterior distributions if the training exhibits low variability. For high variability training, and especially if the function is not favored as strongly (for instance a function with a shallow negative slope) we expect broader, less peaked posteriors. Finally, we hypothesize that especially in high variability conditions, some participants will not exhibit unimodal posterior distributions and consider several potential generating functions broadly consistent with the learned function.

Contrasting these functions resulted in a $2 \times 2 \times 2$ between-subjects design (direction of the function: positive or negative, steepness: shallow or steep, variability of the training data: low or high).

Participants

The study was self-certified in accordance with the School of Informatics Ethics Guidelines. We recruited 454 participants ($M_{age} = 33$, $SD_{age} = 8.63$, 91 female, 176 male, 1 other, 186 refused information on gender) on Amazon Mechanical Turk. Participants had to have more than 50 approved HITs and an approval rate of 95% or larger. They received \$1.33 for participation and took an average of 17 minutes ($M = 17.25, SD = 8.59$) to complete the experiment. Participants were randomly assigned to one of the 8 conditions.

Materials

The parameters generating the functions in the experimental conditions differed in the sign of the slopes, as well as in their steepness. In addition, parameters in the training set exhibited either low or high variance for intercepts and slopes. For the full set of experimental conditions, see Table 1.

Table 1: Parametrization for the generating linear functions.

Condition	β_0	SD_{β_0}	β_1	SD_{β_1}
$C_{.5,\text{low}}$	0.25	0.05	0.5	0.025
$C_{1.0,\text{low}}$	0	0.05	1	0.025
$C_{-.5,\text{low}}$	0.75	0.05	-0.5	0.025
$C_{-1.0,\text{low}}$	1	0.05	-1	0.025
$C_{.5,\text{high}}$	0.25	0.3	0.5	0.15
$C_{1.0,\text{high}}$	0	0.3	1	0.15
$C_{-.5,\text{high}}$	0.75	0.3	-0.5	0.15
$C_{-1.0,\text{high}}$	1	0.3	-1	0.15

To create the 25 training sets, corresponding to iid realizations of $\beta_0, \beta 1 \sim \mathcal{N}(\mu, \sigma)$, with μ and σ matching the experimental condition, we systematically sampled 10,000 pairs and selected the most normal and uncorrelated sets[2]. Then we generated the corresponding linear function for a range of 15 points for x in 0–1 for all sets. One of those 15 values was picked at random and constituted the interpolation target.

MCMCP Proposals were generated by two symmetric Gaussian distributions, to allow both for local, as well as far-off proposals, $\sigma_{\beta_0} \in [0.14, 0.98]$, $\sigma_{\beta_1} \in [0.21, 1.47]$. At each iteration these proposals had a probability of .8 and .2 to be selected. Proposals were further restricted to be in bounds $\beta_0 \in [-0.5, 1.5]$, $\beta_1 \in [-1.5, 1.5]$, and if less than 4 points of the function realization were visible on screen, the proposal was automatically rejected and a new proposal was resampled. Participants traversed three different, interleaved chains, since multiple chains allow a wider application of convergence diagnostics and reduce the impact of the particular starting state. The starting values for these chains were obtained by k-means clustering of pilot data ($n = 8$, one participant per condition). This resulted in the following starting values $\beta_0 = \{0.12, 0.1, 0.58\}, \beta_1 = \{0.92, -0.94, -0.28\}$, for chains 1 to 3.

Procedure

Participants were instructed that they would learn the relationship between two proteins, Zenopin and Mepradin. Participants were told that the concentration of Zenopin was related to Mepradin, but that the extent of that relationship var-

[2] All Shapiro-Wilk tests yielded $p > 0.99$, and all correlation coefficients were in the range $[-.01\ .01]$.

ied between humans. Participants were also instructed that they would be presented with examples of the relationship as observed in different people and that they would be asked to interpolate the relationship. They were then instructed that after the training phase they would be presented with pairs of proposed relationships, all observed for a new person, and would have to choose which of the two were more likely to resemble the learned relationship. After reading the set of instructions, the participants were tested on their comprehension. If participants did not respond correctly in the questionnaire they had to restart the instructions.

Training Phase In the training phase, participants were presented with 25 interpolation tasks, presented as scatter plots. In each task, they were instructed that the scatter plot depicted the relationship between the two protein concentrations for a new person. They then had to guess the concentration of the protein by selecting the height of the corresponding value on the plot (on the y-axis). Participants were shown the correct value as feedback for one second, and, if their choice deviated by more than ± 0.05 from the true value, had to readjust their selection.

Test Phase The test phase consisted of 240 forced-choice tasks, corresponding to 80 interleaved iterations of the three Markov chains. On each trial, participants were presented with two adjacent scatter plots, one corresponding to the current state of the chain and the other reflecting the proposed new state (in randomized order). Participants had to select the plot they believed most likely to depict the relationship in the training phase. After the test phase, participants completed a short survey, were debriefed, and compensated. See Figure 1 for a depiction of both training and test phase.

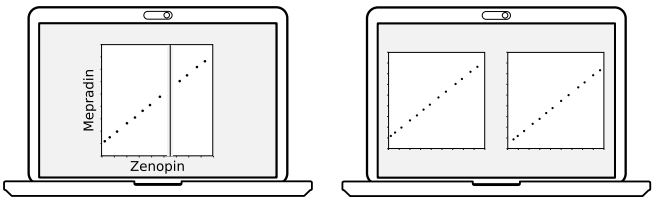

Figure 1: Participants had to complete a training and a test phase. In the training phase they were asked to interpolate the concentration of a fictitious protein for 25 different people (with feedback). In the test phase, they were presented with 240 forced-choice tasks, for which they had to choose the scatter plot that most resembled the relationship in the training phase. The choices were presented in random order and corresponded to a Markov chain, in which the participant implemented the acceptance function.

Results

We excluded participants from the analysis if their chains did not converge to the stationary distribution. Many criteria for convergence checks have been suggested in the literature, here we applied one of the most commonly used evaluations, $\hat{R}$ (Gelman et al., 2013; Vehtari et al., 2019). $\hat{R}$ estimates the ratio between within-chain variances and between-chain variance and thus provides a measure of how (self-)similar chains are. In general applications $\hat{R}$ should not exceed a value of 1.1. However, such a strict application of this diagnostic is not realistic in most MCMCP experiments, since human judgments might exhibit more correlated choices and the number of iterations in experiments is usually considerably lower than in standard statistical applications. Therefore, we incrementally calculated $\hat{R}$ values for chains for each participant and selected the lowest overall $\hat{R}$, with the additional constraint that the first 20 samples of the chain were always discarded and the resulting chains had to be at least 20 iterations long. We then used the maximum of the intercept and slope $\hat{R}$ values to apply exclusion criteria and determine burn-in.

Similar to Ramlee et al. (2017), we excluded participants who exhibited $\hat{R} \geq 2$. Furthermore, we excluded participants who required more than one correction in the interpolation task. Given that the interpolation function was deterministic, most participants did not require many corrections ($Mdn = 0, \mathrm{Q1} = 0, \mathrm{Q3} = 1, max = 44$).

In total, these methods led to the exclusion of 262 participants (convergence exclusions: 224, interpolation exclusions: 72). This high number of exclusions was to be expected given the correlated, bi-variate parameter space and previous results (Sanborn et al., 2010). For group sizes after exclusion, see Table 2. For an overview of how the forced-choice task results in the posterior distribution, see Figure 2.

Determining Burn-in

To determine how many trials were required on average for the Markov chains to converge, we used the iteration for which $\hat{R}$ was optimal for each participant. On average, chains required 33 iterations to reach optimal burn-in and the resulting optimal $\hat{R}$ values were well below 2, $M_{\hat{R}} = 1.4, SD = 0.2$. Conditions did not differ considerably in terms of the optimal iterations or the resulting $\hat{R}$ values. For the full list of per-condition burn-in values, see Table 2. For all subsequent analysis, we discarded all points of the chain before the per-participant burn-in.

Table 2: Participants in each condition before (N_{total}) and after exclusion (N). $M_{\text{burn-in}}$, $SD_{\text{burn-in}}$, as well as mean acceptance probabilities averaged over participants (M_{acc}, SD_{acc}).

Condition	N_{total}	N	$M_{\text{burn-in}}$	$SD_{\text{burn-in}}$	M_{acc}	SD_{acc}
$C_{.5,\text{low}}$	48	25	34.88	14.49	35	17
$C_{1.0,\text{low}}$	63	21	31.37	12.01	42	10
$C_{-.5,\text{low}}$	52	19	34.37	13.73	37	13
$C_{-1.0,\text{low}}$	64	22	29.59	11.59	38	15
$C_{.5,\text{high}}$	59	35	32.29	13.22	38	14
$C_{1.0,\text{high}}$	57	26	32.08	12.24	45	9
$C_{-.5,\text{high}}$	56	29	35.66	12.75	42	13
$C_{-1.0,\text{high}}$	55	15	29.40	10.67	36	12

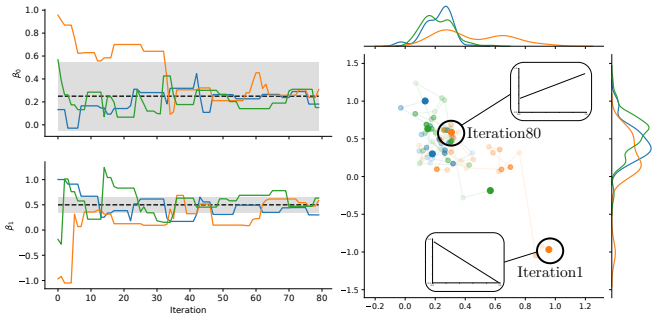

Figure 2: The 240 choices submitted by the participants corresponded to three Markov chains. By accepting or rejecting proposed parametrizations for the functions, participants traversed this representational space and eventually converge to a region reflecting the posterior over parameters. For this participant, the chains converge after 35 iterations for β_0 and after 15 iterations for β_1. The corresponding distribution after this burn-in period closely matches the true relationship learned in the training phase, both in terms of its mean and variance (dashed line and grey range).

Acceptance Probabilities

Acceptance rates for MCMC samples should range between 20–40% (Roberts, Gelman, & Gilks, 1997). Mean acceptance probability was in that range, $M = 39\%, SD = 13$, indicating that the proposals were wide enough to traverse the parameter space. Between conditions, the mean acceptance probabilities for participants varied, ranging from 35 to 45%, for all acceptance probabilities, see Table 2. For each condition, acceptance probabilities for each chain did not vary substantially and were similar to the general acceptance rates (not shown).

Posterior Distributions

Slopes differed significantly between positive- and negative-slope conditions, with participants trained on negative slopes preferring negative slopes, $M_{\beta_1} = -0.16, SD_{\beta_1} = 0.53$, and participants trained on positive slopes preferring positive slopes, $M_{\beta_1} = 0.19, SD_{\beta_1} = 0.45$, $t(165.33) = -4.74, p < .0001$[3].

For conditions with negative slopes in the training sets, steep and shallow conditions exhibited significantly different posterior slopes, with lower slopes for steep compared to shallow conditions, $M_{-.5} = -0.05, SD_{-.5} = 0.45, M_{-1.0} = -0.29, SD_{-1.0} = 0.59$, $t(65.58) = 2.08, p = .041$. For conditions with positive slopes in the training sets there was also a significant difference in posterior slopes. However, this difference was not in the predicted direction, as slopes in the shallow condition were on average larger than in the steep condition, $M_{.5} = 0.29, SD_{.5} = 0.4, M_{1.0} = 0.05, SD_{1.0} = 0.47$, $t(89.75) = -2.89, p = .005$. Posterior intercepts in conditions with negative training slopes did not differ significantly between steep and shallow conditions, $M_{-.5} = 0.52$, $SD_{-.5} = 0.21$, $M_{-1.0} = 0.6$, $SD_{-1.0} = 0.3$, $t(62.84) = 1.38$, $p = .174$, nor for conditions with positive training slopes, $M_{.5} = 0.35, SD_{.5} = 0.2, M_{1.0} = 0.5, SD_{1.0} = 0.25, t(88.71) = 3.31, p = .001$.

[3] All tests are unequal variance, two-sided t-tests.

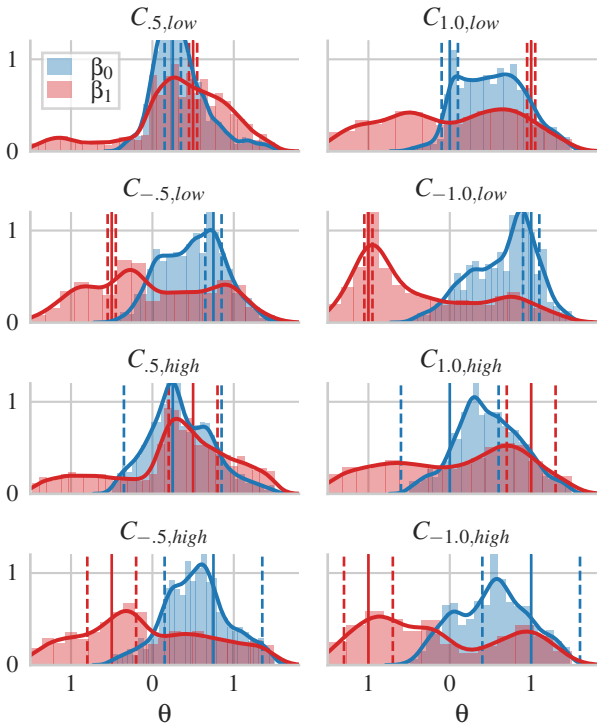

Figure 3: Posterior densities for intercepts and slopes and true values and standard deviation (dashed lines) in the experimental conditions. The posterior densities exhibited multiple modes, some centered in close proximity of the true parameters.

Equally, per-participant SD for slopes did not differ significantly between high and low variability conditions, $M_{low,\beta_1} = 0.49$, $SD_{low,\beta_1} = 0.26$, $M_{high,\beta_1} = 0.55$, $SD_{low,\beta_1} = 0.25$, $t(180.07) = -1.39$, $p = .166$. However, for intercepts, per-participant SD did differ significantly between high and low variability conditions, with high variance conditions resulting in higher SD, $M_{low,\beta_0} = 0.26, SD_{low,\beta_0} = 0.11, M_{high,\beta_1} = 0.31, SD_{low,\beta_1} = 0.11, t(182.48) = -2.46, p = .015$.

Visual inspection revealed that in all conditions posterior distributions were multimodal and heavily skewed, which complicated the analysis. In general, the posterior densities suggested that the modes of the posterior distributions were often close to the learned parameters, see Figure 3, for a selection of posterior distributions for one participant in each condition, see Figure 4.

Since the mean and standard deviations of multimodal, heavily skewed distributions are not good representations of the underlying data and we were interested in characteristic modes of the distributions, we used mixture models to identify dominant modes of the posterior distributions.

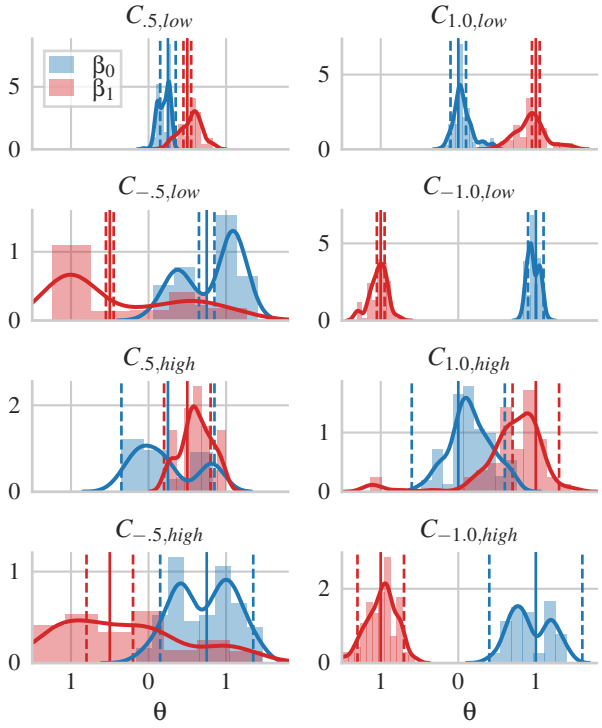

Figure 4: Posterior densities for one participant in each condition. Lines represent the true values and standard deviations (dashed lines) in the experimental conditions.

Table 3: Posterior means and variances per condition, for function intercepts (β_0) and slopes (β_1).

Condition	M_{β_0}	SD_{β_0}	M_{β_1}	SD_{β_1}
$C_{.5,\text{low}}$	0.34	0.32	0.32	0.62

$C_{-.5,\text{high}}$	0.54	0.40	−0.07	0.77
$C_{-1.0,\text{high}}$	0.52	0.44	−0.20	0.83

Estimating Posterior Density Clusters We estimated Gaussian mixture models that best described the distributions for each experimental condition. We incrementally increased the number of components and selected the model with the lowest BIC[4]. The clustering produced a moderate number of clusters, reflecting the multimodal nature of the data. In general, each condition was estimated to correspond to a mixture of 1–8 clusters ($M = 4.5, SD = 2.56$), and the largest clusters closely matched the different training conditions. For KL-divergences between training distribution and the inferred clusters, see Table 5, for the number of clusters, weights, means and covariances for the largest clusters, see Table 4, for plots of the clusters, see Figure 5.

[4]Estimating the mixtures with a Bayesian Dirichlet process mixture model yielded very similar results.

Table 4: The total number of clusters (N_c) assigned was generally low and the weight of the largest clusters was relatively large (16–100%).

Condition	N_C	$w_{c=1}$	$\mu_{\beta_{0,c=1}}$	$SD_{\beta_{0,c=1}}$	$\mu_{\beta_{1,c=1}}$	$SD_{\beta_{1,c=1}}$
$C_{.5,\text{low}}$	8	0.2	0.15	0.02	0.69	0.14
$C_{1.0,\text{low}}$	8	0.17	0.07	0.01	0.84	0.1
$C_{-.5,\text{low}}$	1	1.0	0.49	0.14	-0.01	0.53
$C_{-1.0,\text{low}}$	4	0.42	0.93	0.03	-0.98	0.04
$C_{.5,\text{high}}$	2	0.81	0.24	0.10	0.54	0.21
$C_{1.0,\text{high}}$	3	0.46	0.24	0.1	0.75	0.13
$C_{-.5,\text{high}}$	5	0.31	0.93	0.09	-0.65	0.2
$C_{-1.0,\text{high}}$	5	0.39	0.9	0.08	-0.95	0.07

Table 5: KL-divergence between the training distribution and the three largest clusters. In general, one of the largest clusters corresponded well to the training distribution.

Condition	$KL_{c=1}$	$KL_{c=2}$	$KL_{c=3}$
$C_{.5,\text{low}}$	2.18	1.1	1.95
$C_{1.0,\text{low}}$	1.74	42.1	5.85
$C_{1.0,\text{low}}$	1.35	–	–
$C_{-1.0,\text{low}}$	0.31	1.76	24.16
$C_{.5,\text{high}}$	0.83	10.37	–
$C_{1.0,\text{high}}$	1.06	9.76	2.95
$C_{-.5,\text{high}}$	1.49	2.66	4.25
$C_{-1.0,\text{high}}$	1.02	59.27	11.09

Per-Participant Clusters To evaluate if the source of the multimodality in our data was due to averaging over diverse cohorts of participants, or if individual participants produced multimodal posteriors, we performed the same clustering procedure on a per-participant basis. Participant posterior distributions were characterized by 1–12 clusters ($M = 3.11, SD = 1.96, Q1 = 1, Q2 = 3, Q3 = 4$), suggesting that the posterior distributions were composed of multimodal individual distributions. Furthermore, some participants with optimal $\hat{R}$ (≤ 1.1) also exhibited multiple clusters, indicating that the multimodality was not simply due to poor convergence ($M = 1.89, SD = 1.36, N_{\hat{R}\leq 1.1} = 9$).

The number of clusters did not differ significantly between low- and high-variance conditions, $M_{low} = 2.98, SD_{low} = 1.94, M_{high} = 3.1, SD_{high} = 1.57, t(164.24) = -0.49, p = .312$. Neither did the variance of the largest cluster for slopes differ significantly, $M_{low} = 0.1, SD_{low} = 0.13, M_{high} = 0.1, SD_{high} = 0.11, t(172.43) = 0.11, p = .545$. However, for intercepts the variance of the largest clusters was significantly different, with smaller cluster variances for low-variance conditions, $M_{low} = 0.04, SD_{low} = 0.03, M_{high} = 0.05, SD_{high} = 0.04, t(189.85) = -2.09, p = .048$.

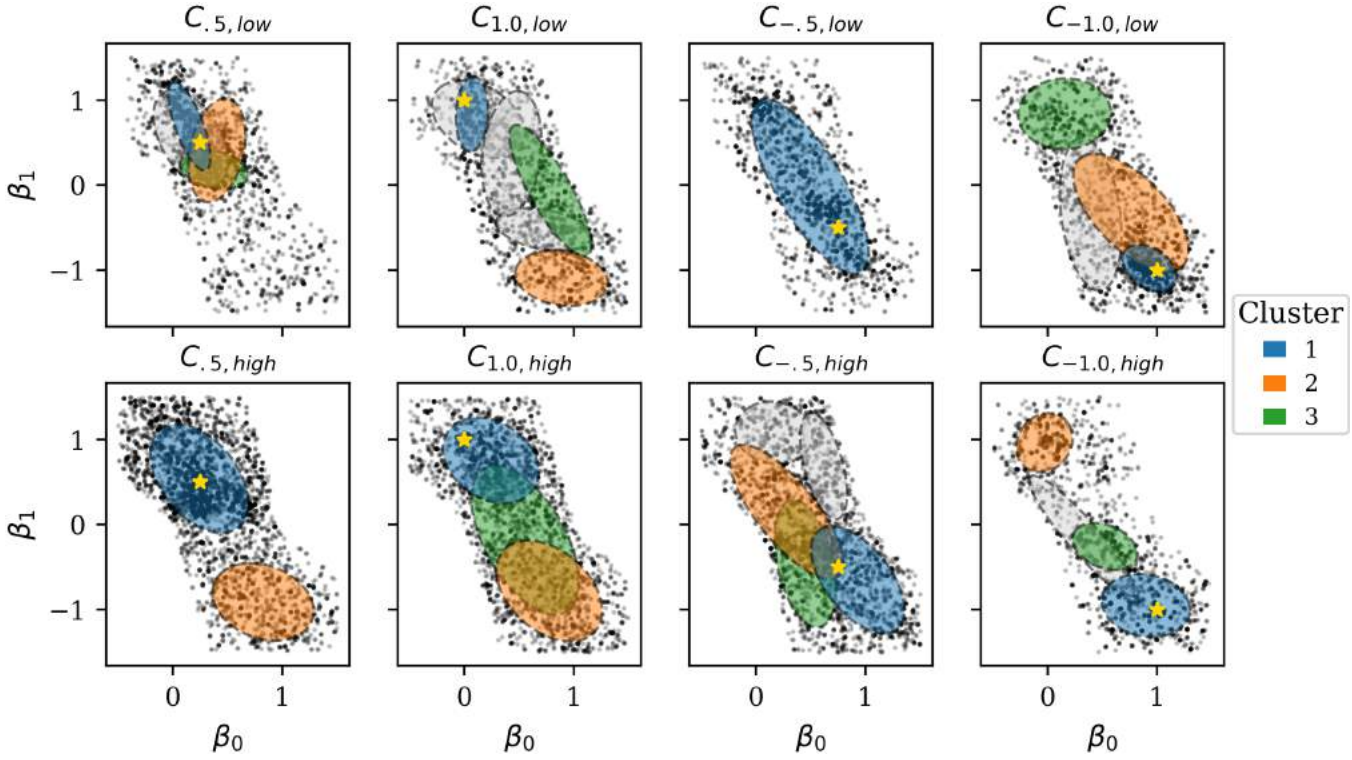

Figure 5: Clusters obtained by fitting a Gaussian mixture model (oval shapes). The top three clusters (colored shapes) accounted for a large proportion of the data and in general matched the distribution learned in the training phase well (mean parameters of the true distribution in yellow).

Discussion

We have found some evidence that participants represent the functions learned in training as distributions over parameters. Furthermore, the modes of these distributions were, in many cases, aligned with the true parameters. In addition, for intercepts, but not for slopes, these distributions were affected by differences in the variability of training. Finally, our results suggest that the learned distributional spaces over function parameters can exhibit multiple modes.

The multimodality in the posterior distributions allows for two interpretations. First, it is possible that participants truly evaluated distinct candidate representations, and thus multimodal posterior distributions characterized their hypothesis space. It is plausible that highly salient relationships, in addition to the implied parameters in the training, constitute the psychological space when learning sets of varying functions. However, the multimodality might also arise from our experimental method. One issue could be the number of iterations. Theoretically, MCMCP is well suited to discover complex, multimodal distributions, but practically many more samples could be necessary to achieve convergence to the posterior distribution. Since extremely large numbers of iterations might not be feasible from an experimental perspective, one practical test of our results could be starting the chains of later participants at the endpoints of previous participants (Martin et al., 2012).

Future research should clarify the source of multimodality, for instance by comparing our results with results obtained by multidimensional scaling (MDS). If such a comparison corroborates our results, these insights into the structure of psychological spaces could, in turn, provide invaluable guidance for future generalization research. In addition, MDS would also allow us to address two shortcomings of the current study: its exclusive focus on linear functions, and the potential influence of perceptual similarity of functions on participants' forced choices. First, similarity judgments obtained via MDS could be used to determine if participants are well described by linear models, or if non-linear representations underlie their judgments. These results would allow us to determine if the multimodal representations observed in our experiment were the result of a lack of satisfactory choices or a genuine characteristic of learning. Second, MDS would allow us to chart sets of perceptually similar samples. It is plausible that intercepts and slopes can affect notions of similarity of linear functions differently. For example, if functions sharing the same slope but very different intercepts are judged more similar than functions with similar slopes and intercepts, such non-linear interactions could explain the multimodality observed in our experiment.

While more research is required, our results also highlight the importance of a plurality of experimental approaches and methods in the study of human generalization. Most of previ-

ous research has focused on averaged errors or single extrapolations. Here, we suggest that to fully understand human generalization, characteristic errors, in combination with extrapolation patterns, and evaluation and exploration of the underlying hypothesis spaces are required.

Generalizing Functions in Sparse Domains

Pablo León-Villagrá Christopher G. Lucas
School of Informatics, University of Edinburgh, United Kingdom

Abstract

We propose that when humans learn sets of relationships they are able to learn the abstract structure or *type* of a family of relationships, and exploit that knowledge to improve their ability to learn and generalize in the future, especially in the face of sparse or ambiguous data. In two experiments we found that participants choose patterns and extrapolate in ways consistent with sets of previously learned relations, as measured by extrapolation judgments and forced-choice tasks. We take these results to suggest that humans can detect shared abstract relations and apply this learned regularity to perform rapid and flexible generalization.

Keywords: generalization, function learning, transfer

Introduction

Many everyday situations require us to generalize from past experience, even if we are faced with a specific problem we have never seen before. For example, in cooking, one regularly has to infer the relationship between ingredients, ratios or quantities, like the amount of sweetener and resulting pleasantness of a dessert, and generalize this relation to new recipes or ingredients. Often, we learn a general relationship that helps us understand related problems. If we learn that as we increase the amount of sugar in a recipe, the sweetness will not change immediately, then increases rapidly and then saturates, one can use this knowledge to reason about similar relationships, as when deciding how much xylitol to add to a cake.

Our example requires two types of generalization. The first, sometimes called transfer or transfer learning, involves transferring information about a relationship between two quantities to help us understand a new and different relationship. The second, extrapolation, involves understanding a single relationship and extrapolating to new instances or data points within, e.g., to new amounts of xylitol. The latter depends on the former – our past experiences shape the inductive biases we bring to a new problem.

Transfer learning expands the task the human learner faces and requires further-reaching and more abstract inferences. Given a set of prediction tasks, how can we capitalize on statistical regularities to aid future prediction? If the tasks exhibit some shared structure, learning a representation capturing this latent structure of the environment (Gershman & Niv, 2010), or learning which aspects of a task change (R. C. Wilson & Niv, 2012) can enable the learner to perform wide-ranging and data-efficient generalization.

The value of transferring knowledge across different tasks is receiving growing attention in machine learning communities. For example, abstract learning and transfer have been successfully applied to challenging control tasks (Hamrick et al., 2017). From a cognitive science perspective, the study of such general learning mechanisms has a long tradition, e.g., Harlow (1949). Research in this tradition has highlighted how hierarchical representations can allow for the "blessing of abstraction" (Gershman, 2017), where abstract knowledge is acquired faster than detailed information. In recent years several proposals have been put forward on how hierarchical and structured inductive biases can be acquired through development and how they allow for rapid generalization (Goodman et al., 2008; Tenenbaum et al., 2011).

The second type of generalization has been widely studied in psychology, most commonly in classification tasks in which participants have to learn to predict class labels for unknown objects or entities. Similarly, tasks in which the target to be learned is a continuous quantity have been studied in the domain of function learning research. Research in function learning has emphasized particular human inductive biases. For example, humans learn functions more quickly if the relationship is linear (Brehmer, 1976), and struggle with cyclic functions (Bott & Heit, 2004; Kalish, 2013). More importantly, human extrapolations are strongly biased towards linear relationships, in particular positive linear functions (Brehmer, 1976; DeLosh et al., 1997; Busemeyer et al., 1997; McDaniel & Busemeyer, 2005; Kalish et al., 2004). While this line of research emphasizes simple types of functions, results from experiments with less taxing memory demands have shown that a wide variety of relationships can be learned and inform extrapolation (Lucas et al., 2015; A. G. Wilson et al., 2015; Schulz et al., 2017; León-Villagrá et al., 2018).

In function learning, the hierarchical and abstract representation of the learned relationships has traditionally been reduced to mechanisms that allow generalizing a mapping from criterion to targets. Multiple proposals have been put forward for the nature of these mappings, ranging from rule–like parametric forms (Carroll, 1963; Brehmer, 1976), associative, neuronal network architectures, and hybrids thereof (Busemeyer et al., 1997).

Here we will adopt a general perspective and express the task as Gaussian process regression. A Gaussian process specifies a distribution over functions $f(x) \sim GP(\mu, k)$, where $\mu(x) = E[f(x)]$ and k is the covariance kernel. The kernel specifies a similarity measure over x and allows us to express abstract beliefs about the shape of the function, such as periodicity or smoothness. Gaussian processes have been successful in accounting for both the flexibility in learning, as well as long-range extrapolations (Lucas et al., 2015).

While Gaussian processes allow us to express inductive biases for functions in flexible, non-parametric fashion, only recently more attention has been given to structural and hierarchical aspects of function generalization. This work has emphasized the importance of inductive biases over different

function types (Lucas et al., 2015), the compositional structure of functions (Schulz et al., 2017), or the generalization of functions into dimensions outside the learned space (Lucas et al., 2012).

Here we expand on this line of research and propose that when humans learn relationships they do not maintain sets of data, parametrizations or fixed parametric forms, but that they form flexible and abstract hypothesis spaces. Based on this abstract encoding, we suggest, they are able to capitalize on statistical co-occurrences of abstract information about the *type* of relationship learned. As a result, repeated exposure to similar functions should result in learning about the shared type of relationship, as well as its relevant features. Such exposure should then facilitate extrapolation in sparse contexts and allow far-ranging generalization. We hypothesize that this application of past knowledge does not simply amount to remembering previous data, but extrapolation depends on the induced function type and adapted to the context at hand.

Experiment 1

In this first experiment, we examine if participants prefer functions consistent with the previously learned function type and its shared, defining, features. We train participants on three sets of samples from the same type of function and assess if they subsequently choose extrapolations in concordance with this type and parameters.

Participants

The study was self-certified in accordance with the School of Informatics Ethics Guidelines. We recruited 99 participants ($M_{age} = 32.1$, $SD_{age} = 10.87$, 34 female, 65 male) on Amazon Mechanical Turk. Participants had to have more than 50 approved HITs and an approval rate of 95% or larger. They received \$0.55 for participation and took an average of 7 minutes ($M = 6.46$, $SD = 5.19$) to complete the experiment. Participants were randomly assigned to one of the six conditions ($n_{Cos_1} = n_{Lin_2} = n_{Ou_1} = 17$, $n_{Cos_2} = n_{Lin_1} = n_{Ou_2} = 16$).

Procedure

Participants were instructed that they would learn the relationship between two substances, substance x, and substance y. They were told that they would be presented with three sets of patterns, each depicting one realization of the same relationship and that they would have to predict the relationship for 10 new points. They also received a visual depiction explaining how they would predict the points. They were instructed that they would see one more pattern from the same relationship, consisting of three points. Then they were instructed to select the pattern from six options that most likely depicted the learned relationship.

Training Phase Each training block took the form of an extrapolation task, where participants saw scatterplots and had to guess the value of the substance on the y-axis in an extrapolation range, by selecting the height of the corresponding value on the plot. Participants were shown the correct value as feedback for one second, and, if their choice deviated by ± 0.025 or more of the true value, had to readjust their selection. Training blocks were presented in randomized order.

Choice Phase After the training blocks, there was a forced-choice task where participants saw the three-point pattern and read that this pattern belonged to the same relationship as the training. Then they saw with six scatterplot patterns, corresponding to one conditional sample for each of the six kernels, in randomized order. Participants had to select the pattern that they deemed the most likely extrapolation for the learned relationship. After the choice tasks, participants completed a short demographic survey.

Materials

The functions in the six conditions corresponded to samples from Gaussian Processes (GPs), with three different types of kernels and mean functions, each with two distinct parametrizations, see Table 1. To allow for characteristic periodic samples, we elected a "pure" cosine kernel, *cos* with $k(r) = \sigma \times cos(r)$, $r(x,x') = \frac{(x-x')^2}{\ell_q^2}$, with an additional intercept. We generated linear samples from a linear kernel *lin* with explicit slope and intercept terms. Finally, we used a Ornstein-Uhlenbeck kernel (*OU*) with an additional intercept, to generate non-smooth samples. The noise variance was fixed to 0.01 for all GPs.

Training Sets We generated the training data by sampling three sets of 35 points each in the range 0.05–0.95 for each of the six conditions. The first 25 points constituted the evidence provided in each training set. Participants had to extrapolate the target value for the last 10 points and received feedback for their choices. To ensure that samples were clearly perceptible and the samples were distinct (within function type and between function types) we generated a set of 20 candidate patterns for the 18 sets. We then selected samples from these candidates for which all points were in the presentation range $[0,1]$, that were ≥ 0.05 of the three transfer points, and rejected uncharacteristic samples[1]. For a full list of kernels and kernel parametrizations, see Table 1, for the training data and the conditional samples, see Figure 1.

Forced Choices In the transfer set three points, $x = \{0.05, 0.1, 0.2\}$, $y = \{0.475, 0.525, 0.5\}$ were. These points were selected to be inconsistent with any of the training materials, in terms of specific point locations. We then generated three samples conditional on the transfer points for each of the six functions. Participants received one of these three samples at random for each of the six kernels in the forced choice task.

[1]For example, *OU* samples that did not exhibit any discontinuities and thus looked visually identical to linear relationships, or *cos* samples that had very low amplitudes.

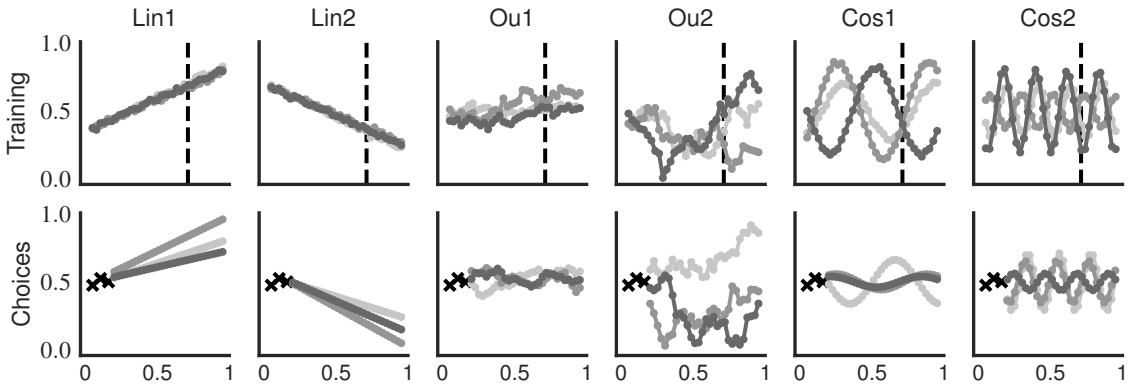

Figure 1: Top row: Training data in the six conditions. For each condition, there were three data sets to be learned. Participants received the first 25 points and had to extrapolate for the 10 remaining points, dashed is the cutoff between presented evidence and training. Bottom row: Samples that constituted the forced-choice options in Experiment 1 & 2. Samples were generated by the particular GP, conditional on the three points in the transfer set.

Table 1: Kernels and kernel parameters generating the training data. For all models we set $\sigma_{noise} = 0.01$.

Kernel	variance	lengthscale	β_0	β_1
Lin_1	0.02	–	0.35	0.47
Lin_2	0.02	–	0.7	-0.47
Cos_1	0.05	0.1	0.5	–
Cos_2	0.05	0.04	0.5	–
OU_1	0.01	1	0.5	–
OU_2	0.08	1	0.5	–

Results

Error Rates

The training functions differed considerably in their mean absolute errors (MAEs)[2], as well in the change of error over blocks, see Table 2.

Only for conditions with linear functions did errors differ significantly between the first and the last block, $t(42.94) = 2.21$, $p = .032$[3]. For OU conditions, errors were lower for the last block, but did not differ significantly, $t(62.21) = 0.95, p = 0.345$. For periodic conditions, error was again lower for the last block, but blocks did not differ significantly $t(57.17) = 0.66$, $p = .509$. The two OU and periodic conditions were highly heterogeneous. While errors for the low variance condition Ou_1 decreased over blocks, errors in Ou_2 remained high. Equally, while errors in Cos_1 decreased, errors for Cos_2 remained high throughout training. For error rates for all conditions, see Figure 2.

[2]All MAEs were calculated on extrapolations before the participant had received feedback for that particular value.

[3]All tests are two-sided, unequal variance t-tests. For means and SDs, see Table 2

Selecting an Extrapolation Pattern

About 35% of the participants selected the choice corresponding to the correct function type and parametrization. Both for positive and negative linear training conditions, the proportion of chosen true functions was significantly larger than chance (1/6), Lin_1 = 44%, $p = .01$, Lin_2 = 53%, $p < .001$[4]. For periodic functions, Cos_2 was selected significantly above chance, Cos_2= 50%, $p = .002$, but $Cos_1$was not, Cos_1 = 12%, $p = .802$. Instead, participants mostly selected the

[4]All tests are one-sided, exact Binomial tests.

other periodic function. The proportion of generally periodic functions over the alternatives for condition Cos_1 was significantly above chance $(1/3)$, $Cos_1 = 59\%$, $p < .027$.

For OU conditions, Ou_1 was not selected significantly above chance, $Ou_1 = 18\%$, $p = .556$, nor did participants prefer OU functions in general, $Ou_1 = 47\%$, $p = .172$.

However, participants trained on Ou_2 selected the true pattern at rates significantly higher than chance $Ou_2 = 38\%$, $p = .05$. For all participant choices, see Figure 5.

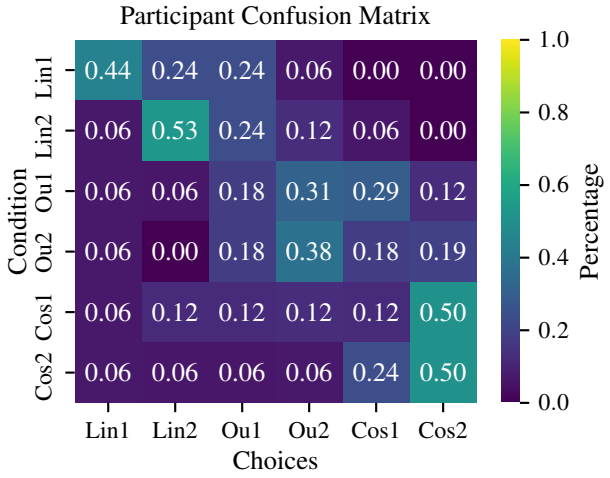

Figure 3: Confusion matrix for choices in Experiment 1

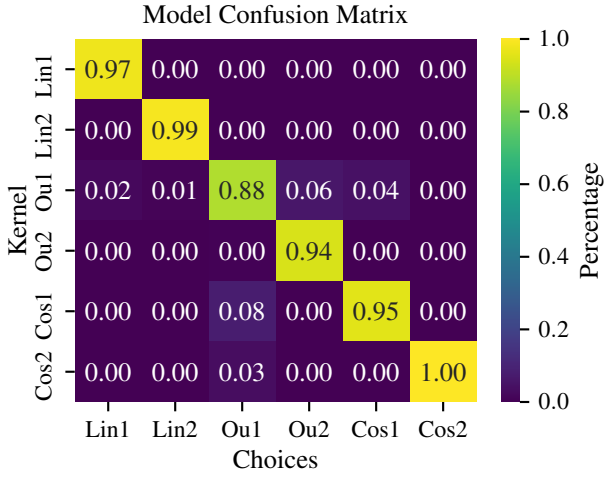

Figure 4: Confusion matrix for the generating functions and the choices presented in Experiment 1.

We also calculated the confusion matrix resulting from the likelihood assigned to each of the presented samples for each of the functions generating the materials. We then converted these likelihoods into proportions via the softmax function[5].

[5]We also evaluated these proportions for a model with an additional temperature parameter T that we fitted to the human choices. Unsurprisingly, this temperature parameter was estimated to be low, $T \approx 10$, and produce less peaked distributions.

While the model consistently favors the true generating function and does not produce preferences resembling the participants' choices, some interesting parallels are apparent. First, both kernels resulting in the strongest preference for the true function (Cos_2 and Lin_2) also correspond to conditions with fairly peaked human preferences. In contrast, kernels resulting in more dispersed likelihoods, and as a result, lower preference for the true function (Ou_1, Ou_2) resemble the systematic preferences for alternative functions by human participants. For a confusion matrix displaying the asymmetric choices of participants, see Figure 3, for model confusions, see Figure 4.

Experiment 2

In Experiment 1, participants were able to select from a set of candidates realizations corresponding to the learned type of function and, in many cases, the specific features of the set of training examples. In this control experiment, we contrasted participants' choices in Experiment 1 with a condition in which no training was provided.

Participants

We recruited 50 participants ($M_{age} = 34.7$, $SD_{age} = 10.53$, 25 female, 24 male, 1 other) on Amazon Mechanical Turk. Participants received \$0.2 for participation and took an average of 1.5 minutes, ($M = 1.46$, $SD = 6.05$) to complete the experiment.

Procedure

Participants were instructed that they would be presented with a relationship between two substances, consisting of three pairs of values. Then they were instructed that they would have to select a pattern from six options that most likely depicted the relationship. The choices were the same as in Experiment 1.

Results

In the absence of training data participants preferred periodic functions over OU and linear, $Lin_1 = 10\%$, $Lin_2 = 0\%$, $Ou_1 = 18\%$, $Ou_2 = 14\%$, $Cos_1 = 28\%$, $Cos_2 = 30\%$, see also Figure 1. Given the low rates of choices of Lin_1 and the high proportion of chosen periodic functions, these results suggest that participants interpreted the three points presented as generated from a deterministic, non-monotonic relationship, rather than a low-noise linear or low-variance OU relationship.

These results suggest that the strong preference for periodic samples in Experiment 1 did not solely result from the training but were also reflective of a higher preference to ascribe periodicity to the test points.

Experiment 3

We have shown that participants can use the knowledge acquired in the training sets, to inform their choices about which

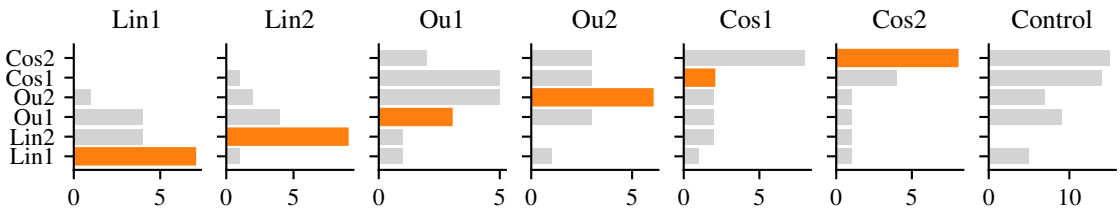

Figure 5: The selected choices (correct choice in orange) for Experiment 1 and Experiment 2 (Control). Participants generally selected the function type and parametrization consistent with their training. When instead they preferred other options they mostly selected samples from the same type of function. Without training, participants favored periodic and OU.

particular type of function generated the data. However, it is possible that these choices do not reflect participant's true belief about the underlying functions, but are merely best guesses given a set of unsatisfactory options. In this last experiment, we will analyze if these choices correspond to actual extrapolation behavior.

Participants

We recruited 91 participants ($M_{age} = 30.53$, $SD_{age} = 6.941$, 34 female, 57 male) on Amazon Mechanical Turk. Participants received \$0.65 for participation and took an average of 10 minutes (M=10.29, SD=10.56) to complete the experiment. Participants were randomly assigned to one of the 6 conditions ($n_{Cos1} = n_{Cos2} = n_{Lin1} = 15$, $n_{Lin2} = n_{OU1} = 16$, $n_{OU2} = 14$).

Procedure & Materials

Instructions and training were identical to Experiment 1. However, instead of the forced-choice task participants performed an extrapolation task. In the extrapolation task, participants received the same three points that generated the conditional samples in experiment 1 and had to extrapolate for 30 values of x, without feedback, following the same procedure as in the training sets. The 30 extrapolation criteria were the same as the ones used to generate the forced-choice patterns in Experiment 1.

Results

Error Rates

As in Experiment 1, conditions differed considerably in their MAEs, as well in the decrease in error, depending on the particular function, see Table 3, for errors, see Figure 6. In contrast to Experiment 1, errors in conditions with linear functions did not differ significantly between the first and the last block $t(56.04) = 0.81$, $p = .423$. Neither did errors differ significantly in OU conditions, $t(50.13) = 0.37$, $p = .716$. However, errors for periodic conditions differed significantly between the first and the last block, $t(42.62) = 2.38$, $p = .022$. As in Experiment 1 most conditions exhibited very low errors. In contrast Cos_2 and Ou_2 were characterized by large MAEs. For error rates for all conditions, see Figure 6.

Table 3: MAEs in Experiment 3.

Function	MAE_{b1}	SD_{b1}	MAE_{b2}	SD_{b2}	MAE_{b3}	SD_{b3}
Lin	0.03	0.02	0.02	0.02	0.02	0.02
OU	0.06	0.03	0.05	0.04	0.05	0.05
Cos	0.09	0.08	0.06	0.04	0.05	0.04

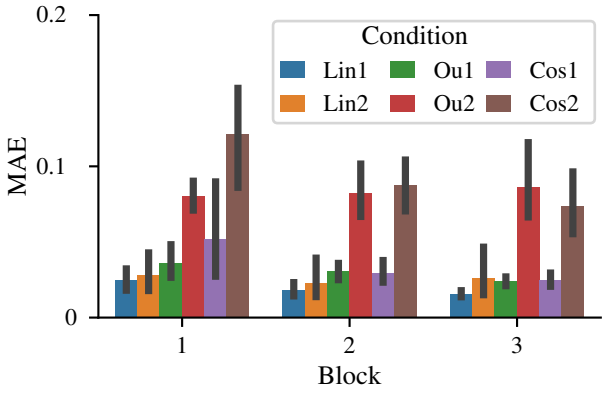

Figure 6: MAEs and 95% confidence intervals for each condition in Experiment 3.

Extrapolating

Visual inspection of the extrapolation strongly suggested that variances between OU-, frequencies for periodic- and slopes for linear conditions reflected training functions, see Figure 1. To evaluate if these patterns were also well aligned with the generating models, and if samples reflected the differences in function parametrization, we performed maximum-likelihood estimation (MLE) for each individual participant and each generating GP. We then used the type of the generating GP with the highest likelihood to predict which training samples the participant had been assigned to. This approach allowed us to evaluate if the experimental manipulation resulted in extrapolation patterns consistent with the generating GPs. Our classification procedure classified 22 out of 30 participants in the OU conditions correctly, a proportion that was significantly larger than expected by chance (1/3),

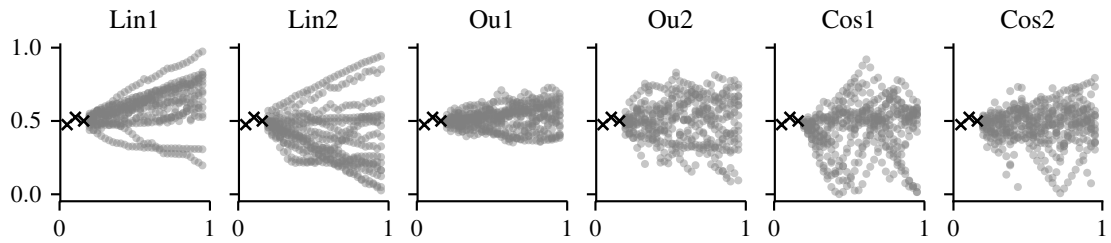

Figure 7: Participant extrapolations in Experiment 3. Extrapolations closely matched the learned type of function and its detailed parametrization, see Figure 1

$p_{OU} < .001$[6]. In the periodic conditions, 17 out of 30 participants were classified correctly, $p_{Cos} = .007$. However, for linear samples, only 10 out of 31 participants were classified correctly, $p_{Lin} = .617$. For the full confusion matrix, see Figure 8.

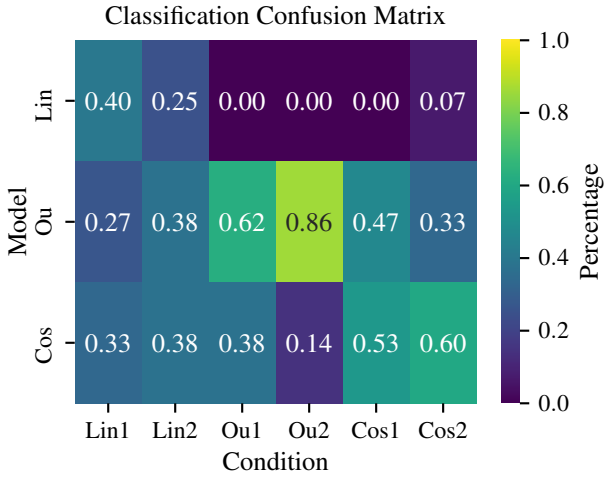

Figure 8: Confusion matrix for the proportion of participants assigned to each model. Our method was able to accurately recover which type of function participants were trained on for OU and periodic, but not linear conditions.

To compare the inferred parametrizations across training conditions of one function type, we contrasted the parameters obtained via MLE for the true model. For linear functions, the MLE parameters for slopes differed significantly between conditions, $M_{Lin1} = 0.2$, $SD_{Lin1} = 0.25$, $M_{Lin2} = -0.1$, $SD_{Lin2} = 0.34$, $t(27.49) = 2.82$, $p = .009$[7], with the signs of the inferred slopes matching the training. Neither intercept, variance or noise estimates differed significantly between conditions (all $p > .1$). The inferred parameters for variance in the OU conditions did not differ significantly, but were reflective of differences in training, $M_{OU1} = 0.002$, $SD = 0.002$, $M_{OU2} = 0.007$, $SD_{OU2} = 0.008$, $t(15) = -1.95$, $p = .071$. The inferred length scale did not differ significantly between conditions, but was slightly higher for $OU1$, $M_{OU1} = 0.38$, $SD_{OU1} = 0.39$, $M_{OU2} = 0.21$, $SD_{OU2} = 0.28$, $t(26.31) = 1.46$, $p = .157$. Both intercept and noise estimates did not differ significantly between conditions (all $p > .5$). The inferred parameters for periodic conditions did not differ significantly for length scale, $M_{Cos1} = 0.08$, $SD_{Cos1} = 0.06$, $M_{Cos2} = 0.08$, $SD_{Cos2} = 0.1$, $t(22.47) = 0.27$, $p = .79$. Instead, conditions differed significantly for variance $M_{Cos1} = 0.02$, $SD_{Cos1} = 0.02$, $M_{Cos2} = 0.01$, $SD_{Cos2} = 0.01$, $t(20.1) = 2.25$, $p = .036$. Estimates for intercepts and noise were not significantly different between conditions (all $p > 0.1$).

Discussion

We found evidence that participants choose patterns and extrapolate in ways consistent with the learned function type. Furthermore, contrasting the extrapolations in the transfer set within function conditions, suggested that these patterns differed in ways consistent with our experimental manipulation.

While participants' judgments generally reflected the functions they learned during training, our results also highlight characteristic human biases. In the Cos_1 condition, participants preferred high-frequency periodic samples over the true low-frequency samples. Similarly, participants in the Ou_1 conditions, preferred the higher variance samples, or even periodic samples over the trained low-variance samples. One explanation for this biases could be that people have a strong preference for particular functions because these parametrizations are well adapted to environmental regularities. As a result, these functions would be robust and applicable to a wide range of task in the environment. This explanation would be consistent with recent results in human exploration, where participants exhibited a tendency to undergeneralize spatial correlations, but this undergeneralization resulted in comparable or even better performance than a ground-truth matching model (Wu et al., 2018).

To better describe these characteristic human biases and explore their potential rational grounding, future research should more closely examine which statistical patterns can be generalized and under which circumstances these generalizations are performed. For example, while our experiment imposed that all patterns followed the same relationship, in

[6] All tests are one-sided, exact Binomial tests.
[7] All tests in this section are unequal variance, two-sided t-tests.

reality this information is rarely available. Thus, future research should examine under which circumstances task regularities are inferred to be similar, and what kinds of notions of similarity can guide these generalizations. One exciting prospect is to link notions of hierarchical- and compositional representations and function generalization. We are currently exploring how such compositional regularities can aid transfer and generalization in sparse domains.

When Sleep-Dependent Gist Extraction Goes Awry: False Composite Memories are Facilitated by Slow Wave Sleep

Itamar Lerner (itamar.lerner@rutgers.edu)

Abstract

Contemporary evidence suggests that sleep contributes to the extraction of gist from previously encoded experiences, a process that relies on compressed memory replay. While the functional significance of the time compression is not fully understood, a recent 'temporal scaffolding' model suggested that compression allows associating encoded events that happened in disparate times, a critical feature when extracting gist of a temporal nature. We examined this hypothesis using a novel behavioral paradigm. Subjects were first presented with word pairs that could form a new composite word if combined (e.g., car, pet --> carpet), and then tested on whether they falsely recognize seeing the composite word. When subjects napped in between exposure and testing, false memories of composite words increased, with reaction times for false recognition correlating to time spent in slow wave sleep. These results confirm the functional role of time compression in memory replay, supporting the temporal scaffolding model.

Keywords: Sleep; Memory Replay; Gist Extraction; False Memories; Temporal Scaffolding

Introduction

Numerous studies over the last two decades support the notion that sleep facilitates memory consolidation (Rasch & Born, 2013). There is now compelling evidence from human and rodent studies that during one particular sleep stage, Slow Wave Sleep (SWS), recently encoded memories are replayed in the hippocampus as part of a hippocampal-cortical dialogue (Wilson & McNaughton, 1994; Diba & Buzsaki, 2007). Theoretical models suggest this replay may contribute to the strengthening of common features within those memories while eroding their idiosyncratic elements, effectively leading to the extraction of "gist" and their integration within general knowledge structure in the cortex (McCelland, McNaughton, & O'reilly, 1995; Lewis & Durrant, 2011).

Perhaps the most striking example of gist extraction is exemplified by demonstrations that SWS can support insightful discovery of hidden rules. In these studies, subjects were presented with a sequence of stimuli and asked to respond to each stimulus as quickly and accurately as possible by following a simple rule (Fischer, Drosopoulos, Tsen, & Born, 2006; Wagner, Gais, Haider, Verleger, & Born, 2004). Unknown to subjects, a hidden temporal structure governed the series of presentations such that, if discovered, it could improve performance significantly. Following sleep, subjects were more likely to discover the hidden rule and improve performance compared to subjects that stayed awake, an effect that was correlated with the time spent in SWS (Wilhelm, Rose, Imhof, Rasch, Büchel, & Born, 2013; Yordanova, Kolev, Verleger, Bataghva, Born, & Wagner, 2012). While sleep-dependent discovery of hidden rules fits the general theory of gist extraction during sleep, the particular mechanism, and its relation to SWS, remain unclear. Recently, a 'temporal scaffolding' model was proposed to account for the effects of sleep on insightful processes (Lerner 2017a, 2017b; Lerner et al., 2019). The model suggests a key property of memory replay that allows for these effects to emerge: its time-compressed nature. In particular, hippocampal memory replay is known to occur in an accelerated form, up to twenty times the speed of the original experience (at least in rodents; Rasch & Born, 2013). When encoded sequences of events are reactivated in this accelerated manner, Hebbian learning mechanisms can associate events that were otherwise too temporally distant from each other to fall within the typical neural learning timescale (50-200ms for Hebbian mechanisms; August & Levy, 1999). Consequently, discovery of hidden rules that relies on the detection of temporal structure within sequential stimuli should, according to the model, be particularly prone to facilitation by SWS.

One surprising prediction of this model is that temporal associations resulting from time-compressed replay during sleep might also hurt memory, not just facilitate it. If two distinct events are replayed in a compressed timescale one after the other during SWS, this may lead to their assimilation into one single memory following the consolidation process, even if such assimilation is unwarranted. In particular, such phenomena might occur if the two events have a special meaning when compiled together, thus signaling to the cortex to maintain the combined meaning rather than the separated memories (a gist extraction of sorts, albeit one that occurs under the wrong circumstances). An example of this theoretical

process can be demonstrated by presenting a subject with two consecutive words, such as *car* and *pet*, which could be combined into a composite (or compound) word: *carpet*. Due to the temporal scaffolding mechanism, the proximal but distinct events of seeing *car* and *pet* might be integrated following sleep to become a false memory of seeing *carpet*.

In the current study, we tested this hypothesis by exploring how an afternoon nap affects the probability of falsely recognizing composite words whose components were previously encountered, as if they were actual memories. Since memory replay during SWS is known to occur predominantly in a forward manner (i.e., replay of encoded events proceeds in the same order as the original experience, albeit in accelerated form; Diba & Buzsaki, 2007), we predicted that sleep would facilitate false memories of composite words whose components were presented sequentially in the forward direction (e.g., car -> pet), but not of those presented backwards (pet->car), or when the components were presented in totally separate trials. Confirming that SWS facilitates the formation of such false memories substantially supports the idea that accelerated forward replay plays a part in gist extraction

Methods

Participants

Forty young adults (ages 18-24, n=19 females) from Rutgers University and the New Jersey Institute of Technology participated in this study for monetary compensation. Subjects were recruited via protocol flyers, in-class announcements and on-campus active recruitment. All subjects were screened for exclusion criteria, which included personal or family history of sleep problems, neurological or psychiatric disorders, drug or alcohol abuse, and/or intake of medications that have any effect on sleep. Furthermore, all recruited subjects had normal or corrected vision/hearing and were fluent in English. Subjects were also asked not to increase daily caffeine and to abstain from caffeine and alcohol before testing. All participants provided informed consent in line with the procedures approved by the Institutional Review Board of Rutgers University.

Sleep Monitoring

We recorded sleep using the Zmachine ® Insight device (Model DT-200; General Sleep Corporation), a sleep monitoring apparatus designed for use in clinical and home environments, and has been shown to reliably detect sleep stages at a level comparable to Polysomnography (Wang et al., 2016). It consists of three self-applicable, single-use, disposable electroencephalography (EEG) sensors, two located on the mastoids (signal electrodes) and one on the back of the neck (ground electrode). The machine detects and records three sleep stages, in addition to wake stage: light sleep (combined Stages N1 and N2), SWS, and Rapid Eye Movement (REM) sleep for each 30-second epoch of sleep. Following the completion of each subject testing, the collected data was transferred from the device's micro SD card to a secure desktop computer for further analysis.

Behavioral Task

Stimuli We compiled three groups of word pairs, 6 pairs per group, such that the words of each pair, if combined together, create a "composite" word (e.g., *car, pet* --> *carpet*; *under, stand* --> *understand*). Words of each pair were selected such that they were not semantically related to each other, nor were they related to the composite word they create together. In addition, we compiled a group of 32 non-composite words. The average length and frequency of the composite words (i.e., the combination of the two components together) in each of the three groups, as well as each single word in the non-composite group, was roughly equal, with M=~7.5 letters and M=~18,000 occurrences for length and frequency, respectively (Frequency data was based on the database found in: https://corpus.byu,.du/coca/)

Based on these four groups, two word-pair lists were created for the "exposure" phase of the experiment. The first exposure list was comprised of the following: (1) 'Forward' composite items: the word pairs of the first composite group appearing in the order that corresponds to the composite word (e.g., *car, pet*); (2) 'Backward composite items: the word pairs of the second composite group appearing in the reverse order to the one corresponding to the composite word (e.g., *stand, under*); (3) 'Separate composite items: each of the two words of the third composite group paired with random words from the non-composite group (e.g., *honey, moon*, forming the composite word *honeymoon*, were paired with *pharmacy, sad*, to create the pairs *pharmacy, honey* and *moon, sad*); (4) the remainder of the words from the non-composite group, randomly paired. The total number of items (pairs) in the list was 34, and their order within the list was pseudo-randomized with the restriction that items containing words that belonged to the same word-pair of the Separate composite group would not appear sequentially. The second exposure list was identical to the first, except that the Forward and Backward composite items were switched such that the first group composed the backward items and the second group composed the forward items. The order of the items within the list was switched as well, such that the location of the forward and backward pairs was similar in the two lists.

We next created two testing lists, matching the two exposure lists. The first testing list contained all 18 composite words made of the Forward, Backward and Separate composite items, as well as 24 additional non-composite words from the exposure list, and 6 totally new, non-composite words (48 items in total, half of which are old). The totally new words were chosen such that the average length and frequency of the new and old words across the testing list remained roughly equal. The order of these words within the list was chosen pseudo-randomly. The second testing list was identical to the first, except that the location of the forward and backward composite words was switched to match the first testing list.

Composite Word task The behavioral task included an exposure session and a testing session, separated by an intermission during which subjects were either allowed to sleep or remained awake (see Figure 1). The objective of the exposure session was to allow subjects to encode the components of the composite words consecutively, without driving their attention to their composite nature (by using a distracting task). The testing session included a surprise memory test, where subjects' tendency to incorrectly recognize the composite words as words they have been exposed to earlier was examined.

Figure 1: The behavioral task used in the study. During an exposure session, subjects saw two colored words in succession and were asked to indicate whether the words appeared in the same or different color. Unknown to subjects, some of those word pairs could be concatenated to create a third, unrelated word. Following an intermission during which some of the subjects took a 90 minute nap and some remained awake, they received a surprise memory test requiring to indicate whether a series of presented words are new or appeared in the earlier exposure session. Some of those words were the composite words whose components were previously displayed.

Exposure Session In each trial of the exposure session, subjects were presented with two consecutive words. Each of the words appeared in one of 3 colors: red, green, or blue. Subjects were required to indicate whether the two words appeared in the same or different colors by pressing one of two buttons on the keyboard. The two words presented in each trial were taken from the items in the exposure list, with half of the subjects receiving the first list and the other half – the second list. To facilitate the probability that Forward and Backward composite items will be combined in memory during sleep, word pairs belonging to these two conditions were always presented in the same color. Other word pairs were presented in either the same or different colors, and the total number of 'same' and 'different' trials was counterbalanced across the session. Subjects were not informed that some of the word pairs could construct a composite word if combined.

Testing Session During the testing session, subjects were presented with single words appearing on the screen one at a time. After each word presentation, subjects were required to indicate whether they recognize seeing this word in the first session or not, by pressing one of two buttons on the keyboard. These words could either be old words appearing in the first session, composite words whose components appeared as single words in the first session, or totally novel words. Subjects that received the 1st exposure list also received the 1st testing list, and subjects receiving the 2nd exposure list also received the 2nd testing list. Following the testing session, subjects were administered a post-experimental questionnaire, designed to determine if they explicitly recognized the existence of composite words in either of the sessions. The questionnaire was designed as a series of questions of escalating details, which avoided revealing the hidden structure of the task unless subjects came up with it by themselves. Three subjects who explicitly recognized the presence of composite words during the exposure session were removed from the study.

Procedure Subjects first arrived to the lab to collect the sleep-monitoring device and were given detailed instructions on how to use it. They then monitored their sleep at home for two nights to allow them to adapt to sleeping with the device on their scalp, and to allow the sleep stage detection algorithm of the device to accommodate to the subjects' individual EEG patterns. After two nights, subjects returned to the lab at the afternoon to begin the experiment, which included the 2 sessions of behavioral measurements, exposure and testing, separated by a 120-minute intermission. The experiment was ran in a quiet room using a MacBook Air (v.2014) laptop, with subjects situated in a convenient distance of 30cm from the screen. Subjects first received detailed instructions on screen regarding the task. Each trial of the exposure session began with the presentation of small white fixation cue appearing on a black screen for 500ms. The screen then remained black for 1500ms until the presentation of the first word for 500ms. After an Inter Stimulus Interval of 100ms, the second word appeared for 500ms, followed by a black screen that remained until the subject's response. Following the response, the next trial initiated. Five practice trials preceded the exposure, using different word pairs. Practice trials were similar to the exposure trials, with the exception that subjects received feedback immediately after responding (a smiley face for a correct response and a sad face for an erroneous response), which replaced the fixation cue. Following the exposure session, subjects put on the sleep monitoring device and went into the intermission period during which they were allowed to take a nap for 90 minutes in a designated sleep testing room (Sleep group; N = 19) or watched a non-stimulating movie in the same testing room (Wake group; N = 18). Following the intermission (which lasted 2 hours for both groups, to allow half an hour of wake time for the Sleep group to eliminate sleep inertia), subjects underwent the testing session. Subjects received instructions on screen regarding the memory recognition test before starting the task. Each testing trial consisted of a word appearing on the screen in white, until the subject's response. After responding, the screen remained black for 1000ms, after which the next word appeared, and so on until the end of testing.

Data Analysis For each subject, we assessed the performance of each of the four critical experimental conditions (Forward composite items, Backward composite items, Separate composite items, Novel items) using two behavioral measures, Error Rate and Normalized Error Reaction Time (RT). Error rates were defined as the total number of erroneous responses in each condition, divided by the number of trials in that condition (an error was defined as responding "Old"). Normalized Error RTs were defined as the mean RTs for wrongly identified items divided by the total mean RT, for each condition (calculated after removal of outlier RTs, defined as values above or below 3 standard deviations from an individual's mean, across conditions). We used the normalized RT measure rather than raw RTs because pilot data collected prior to the experiment suggested that between-subject individual differences in RTs were substantially higher than within-subject differences in this task, potentially blurring the effects of interest. We expected that the more false memories an individual has, the higher will the error rate and the lower will the Normalized Error RT be (based on a common interpretation of RTs as indicating confidence in the responses; Wiedemann & Kahana, 2016). We compared these two measures between the Sleep and Wake groups, and within the groups themselves, using Bonferroni-corrected independent and paired t-tests, respectively. In addition, for the Sleep group, we also correlated these measures across subjects with the individual time spent in sleep, and in each sleep stage, during the nap (as well as the percent of time spent in each sleep stage out of total sleep time).

Results

Mean error rate values for each condition and subject group are presented in Figure 2.

Bonferroni-corrected t-tests showed that error rates in recognizing Forward composite items as "Old" were significantly higher for the Sleep group compared to the Wake group ($t(35) = 2.61$, $p < 0.05$). No other condition showed a difference between the groups. Within the Wake group, Bonferroni-corrected pairwise comparisons showed that error rates for the Backward composite items were significantly higher than those of the Separate composite items ($t(17) = 4.19$, $p < 0.004$), as well as higher, on a trend level, than those of the Forward composite and Novel items ($t(17) = 2.91$, $p < 0.06$, and $t(17) = 2.87$, $p < 0.07$. respectively). Within the Sleep group, in contrast, error rates for the Forward and Backward composite items were significantly higher than those of the Separate composite and Novel items (all ps < 0.03), but there was no difference between the Forward and Backward composite items ($p = 0.47$). Repeating the same analysis with Normalized Error RTs, we found no significant effects between or within the groups.

We also compared the error rates of the Sleep and Wake group in the Old words condition (i.e., non-composite words that appeared during the exposure session and for which the correct answer was "Old" and an error response was "New"). There was no difference between the groups in this condition (M = 50.9 and M = 54.2 for the sleep and Wake group, respectively; $p = 0.526$).

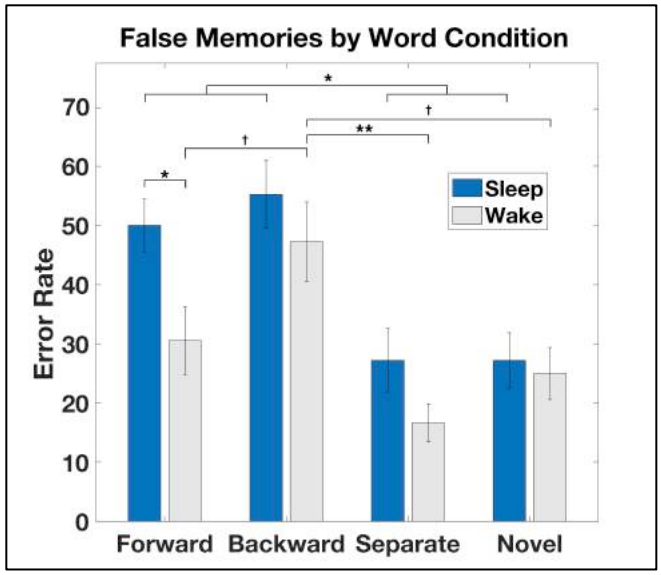

Figure 2: Error rate by word condition for the sleep and wake groups. Subjects who slept exhibited more false memories (higher error rate) for composite words that were presented in the forward direction during training compared to the wake group. ** $p<0.005$; * $p<0.05$; † $p<0.07$. Error bars represent standard error of the mean.

We next examined whether the performance measures were influenced by any of the recorded sleep parameters for subjects in the sleep group (see sleep statistics in Table 1). First, we computed the Pearson correlations between the total time subjects spent in sleep and each of the two performance measures in each of the four experimental conditions (8 comparisons in total). We found a significant correlation of total sleep time with the Normalized Error RT of Forward composite items ($r = -0.6717$, $p = 0.0023$; $p = 0.018$ after correcting for 8 multiple comparisons). No other correlation was significant.

Table 1: Recorded sleep statistics. TST = Total Sleep Time.

Sleep Measure	Mean (std)
TST (minutes)	40.41 (22.3)
N1/N2 (minutes)	23.97 (13.0)
% N1/N2 out of TST	66.46 (23.7)
SWS (minutes)	11.32 (13.1)
% SWS out of TST	19.59 (21.6)
REM (minutes)	5.10 (5.8)
% REM out of TST	13.92 (18.1)

Next, to investigate the contribution of particular sleep stages, a multiple regression analysis was carried out for each condition, with the performance measure of interest as

the dependent variable and time in each recorded sleep stage (N1/N2, SWS, REM) as predictors. A significant regression was found, once again, for Normalized Error RT of Forward composite items ($F(3,14) = 8.11$, $p = 0.0022$; $p = 0.0178$ after correcting for 8 multiple comparisons) with $R^2 = 0.6348$. Normalized Error RTs were equal to 1.2208 – 0.0068 (N1/N2) – 0.0095 (SWS) + 0.0093 (REM), with SWS contributing significantly to the model ($p = 0.0078$). The more SWS subjects had, the faster was their erroneous response in identifying Forward composite items as "Old" (Figure 3, inset). This effect remained highly significant in a follow-up analysis, computing the Pearson correlation between Normalized Error RTs of Forward composite items and the percent of time spent in SWS out of total sleep time ($r(17) = -0.647$, $p < 0.004$; Figure 3, main). No other effects were significant in the multiple regression analyses.

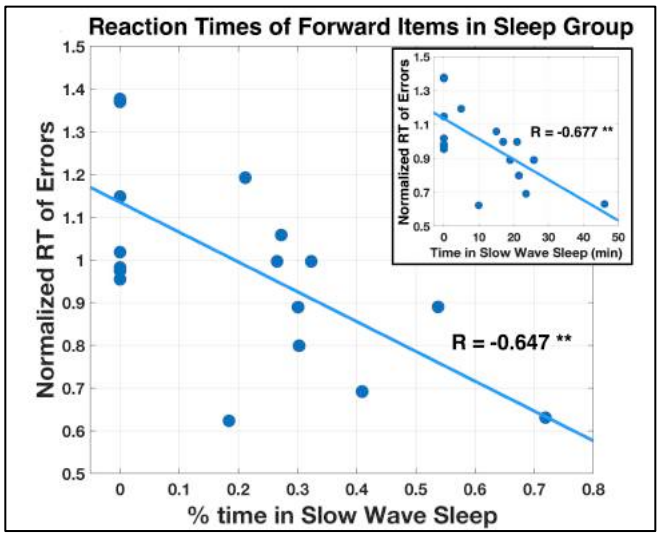

Figure 3: Normalized reaction times of error responses for Forward composite items as a function of minutes spent in slow wave sleep (inset) and percent of time spent in slow wave sleep out of total sleep time (main), for subjects in the sleep group. ** $p<0.008$.

Discussion

We found that subjects who take a nap following exposure to components of a composite word are more likely to falsely recognize being presented with that composite word compared to subjects who did not nap. Moreover, the more time subjects spent in SWS during the nap, the quicker it took them to make that error, likely indicating a higher confidence in their response (Wiedemann & Kahana, 2016). These effects, however, were apparent only if subjects were exposed to the component words one after the other, and only if they were presented in the order that matches their appearance in the composite word, but not if they were presented in the reverse order.

Our findings are consistent with the prediction of a recent "temporal scaffolding" model of memory consolidation during SWS, which emphasizes the role of time compression in memory replay (Lerner et al., 2017a). Specifically, the model predicts that compressed replay of a recently encoded sequential experience may lead to elements within this experience to bind together and create a unified memory that no longer preserves the original sequential nature of the experience. Given that memory replay during SWS is predominantly in the forward direction (Diba & Buzsaki, 2007), the model predicts that such unified memories would be created if the sequence presentation order matches that of the unified memory, but not otherwise. Consistent with the model, we only found a difference between the Sleep and Wake groups in the Forward composite condition, but not when component words were presented in the backward direction. Moreover, consistent with the model's emphasis on replay of stored sequences, there was no difference between the groups when the component words were separated to different trials during the exposure session, a condition that yielded only few false memories on average (Figure 2). Finally, and also consistent with the model, there was no difference between the groups in a baseline condition consisting of totally novel words, which, as expected, also yielded few false memories on average.

One important contrast with the model's predictions was the finding that, for Backward composite items, both the Sleep and the Wake group had increased levels of false memories (compared, for example, to the Novel words condition). This unexpected effect suggests that backward items tend to be combined together irrespective of sleep. This finding might be accounted for if taking under consideration the fact that memory replay could also occur during waking. Rodent studies suggest that compressed replay in the hippocampus is elicited at wake as well, often during resting periods following completion of a task, and, unlike sleep, it tends to include backward replay of recently encoded memory sequences and not just forward replay (Diba & Buzsaki, 2007). While the function of wake replay is still debated, some suggest it could contribute to memory consolidation in the same manner as sleep replay does (Rasch & Born, 2013). Since both Sleep and Wake subjects in our task had a period of rest following the completion of the task (before they went to bed or saw a movie, respectively), such backward replay could potentially have been elicited and contribute to the formation of false composite memories for the Backward items (i.e., replaying the sequence of events pet->car backwards could result in the activation of "carpet" in its regular order). Another possibility is that composite memories of both Forward and Backward items were already formed during the initial experience simply because of their close temporal proximity (and aided by the fact they were always presented in the same color), but sleep was essential in maintaining the Forward composite memories. Further research is needed to explore these possibilities.

Several previous studies have suggested that false memories could arise following sleep. Specifically, using the Deese-Roediger-McDermott (DRM) paradigm (e.g.,

Payne et al., 2009), it was shown that sleep following exposure to a group of words with a related theme (e.g., *Pillow*, *Bed*, *Night*) could lead to the formation of a false memory for the theme word (*Sleep*). However, these effects are not always found (e.g., Fenn, Gallo, Margoliash, Roediger, & Nusbaum, 2009) and they seem to decrease rather than increase with time spent in SWS (Pardilla-Delgado & Payne, 2017; Payne et al., 2009). In other words, the mechanism contributing to the effect seen in the DRM paradigm is likely different than the one presented here, and relates to deep semantic processing of the stored stimuli rather than the time-compression property of replay during SWS (Pardilla-Delgado & Payne, 2017). A more related effect to the one presented here is the demonstration that sleep in humans preferentially facilitates memory of sequences when they are presented during test in the original forward direction compared to backwards, a finding that was interpreted as resulting from memory replay during sleep (Drosopoulos et al., 2007). Our findings add to that previous demonstration by introducing the element of time compression in the process, and by showing it specifically relates to SWS.

Conclusion

In the current study, we demonstrated that an afternoon nap could lead to the formation of false composite memories made of events that were previously presented sequentially. The importance of these results is twofold. First, our novel behavioral paradigm potentially allows for tapping replay compression mechanisms during sleep, opening the door for various future investigations of this phenomenon in humans. Second, our findings provide evidence for the functional role of time compression in memory replay, suggesting it contributes to the association of disparate yet proximal events and showing that in addition to the regular facilitation seen in the majority of studies, this mechanism could also lead to impairments in memory.

Abstract

We describe a cognitive mechanism of moral judgment, universalization, that has received little attention up to now. Under universalization, an action's moral permissibility is determined by calculating what the outcome would be if all people who are similarly situated to the actor also acted in that way. This mechanism is particularly well-suited to capture our moral judgments of free-rider cases, where one person doing the action increases utility but many people doing it decreases utility. Universalization fits into an agreement-based (contractualist) theory of moral cognition, and explains properties of our moral judgments that an outcome-based or rule-based approach cannot. We show patterns of universalization reasoning in young children as well as adults.

Active physical inference via reinforcement learning

Abstract

When encountering unfamiliar physical objects, children and adults often perform structured interrogatory actions such as grasping and prodding, so revealing latent physical properties such as masses and textures. However, the processes driving and supporting these curious behaviors are still largely mysterious. In this paper, we develop and train an agent able to actively uncover latent physical properties such as the mass and force of objects in a simulated physical "micro-world'. Concretely, we used a simulation-based-inference framework to quantify the physical information produced by observation and interaction with the evolving dynamic environment. We used model-free reinforcement learning algorithm to train an agent to implement general strategies for revealing latent physical properties. We compare the behaviors of this agent to the human behaviors observed in a similar task.

Keywords: physical simulation; active learning; probabilistic inference; reinforcement learning

Human adults have an intuitive understanding of the physical world that supports rapid and accurate predictions, judgments and goal-directed actions. For example, we can quickly estimate how heavy a door is by how it responds to a push, judge whether a tower is stable with a glance, or predict where to stand to catch a baseball by watching its trajectory. These abilities are so ingrained in everyday life, we are rarely aware of the complexity of identifying physical properties of objects from brief experiences and interactions with their dynamics.

Bramley, Gerstenberg, Tenenbaum, and Gureckis (2018) explored the strategies people use to actively infer masses and forces of attraction and repulsion that relate objects in a simple simulated environment. Their learning environment consisted of a bounded two-dimensional "hockey puck" world, containing four circular objects of varying masses and related with pairwise attractive or repulsive magnet-like forces. For subjects, the world was displayed on a computer screen and updated in real time using a physics engine that approximates Newton's laws of motion (see Figure 1a). Subjects could hold-click to "grab" onto any object then move their cursor to "drag" that object around the scene, so altering how the scene played out and often better revealing the physical property they had been tasked with inferring. Bramley et al. (2018) used a simulation-based inference model to assess what information was generated by subjects, and contrasted trials in which the subject's goal was to identify the relative masses of two objects against trials in which their goal was to identify the pairwise force between two objects. They found that learners were able to gather information selectively relevant to their learning goal, and exhibited markedly different behaviours dependent on the goal that could be classified into a classes of frequent experimental strategies such as staging collisions by *throwing* objects at one another, *shaking* them back and forth, bringing pairs of objects close together (dubbed *encroaching*). However, they did not model how such strategies were learned or generalised successfully across learning instances

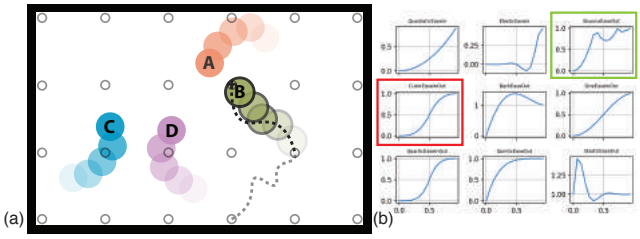

Figure 1: Visualisation of task environment adapted from Bramley et al. (2018). Gray circle overlay shows grid of target locations and dashed line give an example control trajectory in which B is grabbed and moved toward A. (b) Sample of the interpolation functions used to create smooth control trajectories. The *cubicEaseInOut* in the red box and the *bounceEaseOut* in the green box are most frequent interpolations selected by force focused and mass focused agents, respectively, as reported in Figure 4.

In the current work, we take a step toward understanding this ability. We use reinforcement learning, to train an artificial agent to minimize its own uncertainty about these specific physical parameters by composing action sequences from an action space qualitatively similar to human subjects' mouse movements, training this ability across a diverse set of ground truth and initial conditions. We are interested whether, with sufficient training and subjective information as a reward signal, an agent can learn to produce robustly informative action sequences, or strategies, for revealing particular physical properties, and whether these will reflect the behaviors previ-

ously seen in human subjects.

Related Work

Understanding what drives information-seeking behavior has long been a goal in psychology (see Schulz & Gershman, 2019, for a recent review). Some approaches attempt to tie information seeking directly (e.g., Guez, Silver, & Dayan, 2012) or incidentally (e.g., Thompson, 1933) to the familiar goal of extrinsic reward maximisation. Explicit approaches require intensive preposterior planning, that is averaging behavioral prescriptions over many potential future learning and reward trajectories (Raiffa, 1974), so are infeasible for complex problems. Incidental approaches are computationally cheaper but fail to capture information seeking behaviours that depart from noisy extrinsic goal seeking (cf., Schulz, Klenske, Bramley, & Speekenbrink, 2017).

The idea that the brain seeks information as a form of *intrinsic* reward captures a middle ground idea that that for humans, discovery is an "end in itself" driven by something we intuitively understand as "curiosity" (Gottlieb, Oudeyer, Lopes, & Baranes, 2013; Schmidhuber, 2010).

While some learning problems only occur once in a lifetime (e.g., we only need to figure out the laws of physics once), many others occur repeatedly (we encounter new objects daily and would like to be able to rapidly infer their most important properties). For these problems, there is space to *learn to actively learn* by training reusable active learning strategies through repeated experience,making them amenable to reinforcement learning (Kober & Peters, 2012).

The task we explore is challenging in part because of the continuous and complex nature of physical dynamics. However, combined with adequate function approximators such as a deep neural network, reinforcement learning has proven successful for optimising control in rich state spaces (Mnih, Heess, Graves, et al., 2014). For example, Bachman, Sordoni, and Trischler (2016) developed agents that can solve a collection of tasks which require active information seeking using deep neural networks and reinforcement learning, including cluttered MNIST (Mnih et al., 2014), Blockworld, CelebA (Liu, Luo, Wang, & Tang, 2015) and Hangman. Misha et al. (2017) also proposed and trained a deep reinforcement learning agent that can make judgments about physical properties in a simulated environment.

This project sets apart from prior work on intrinsic curiosity in that it focuses on interventional rather than observational information seeking. In our physics learning task, actions have extended complex and far reaching consequences, compounding the complexity of inference, but better mimicking the challenges of learning in the natural world.

The task

Our interactive physical environment adapts the two-dimensional physics-based environment from Bramley et al. (2018) and is implemented using the `pybox2d` library.[1] The world is limited to a 6×4 meter bounded rectangle containing four circular objects, each with radius 0.25 meters. The objects interact with one another and with the static walls according to Newtonian physics and the latent properties of mass and the pairwise forces. The complete fixed settings of the simulator are detailed at `https://bit.ly/2B4TOAf`.

Possible settings and initial uncertainty

As with Bramley et al. (2018), we will contrast actions focused on identifying objects' *masses* against actions focused on identifying the *forces* relating each pair of objects. However, we explored a larger set of possible settings of these values and correspondingly larger initial hypothesis space for the agent than human participants. To ensure the agent had equivalent initial uncertainty about both masses and forces, we defined a discrete space of 2^5 mass combinations and 2^5 force combinations and initialised the agent with a uniform prior across all 2^{10} distinct mass-force combinations. The space of mass combinations is a subset of $\mathbb{R}^4$, in which each parameter represents the mass of an object and is in the range of [1, 3]kg. Meanwhile, the space of force combinations is a subset of $\mathbb{R}^{4\times4}$, in which each force parameter takes a value $\in (-3, 0, 3)^{\mathrm{m}}/_{\mathrm{s}^2}$, representing repulsive force, no interactive force, and attractive force respectively for each pair of objects. Under the Newton's second law of motion, different mass-force combinations yield different accelerations, leading to distinct simulated trajectories, interactions and collisions.

Like the human participants in Bramley et al. (2018), the agent could "grab" one object at a time. The cursor would exert an elastic force (i.e., scaling continuously with the inverse square of the distance between the object and the cursor) attracting the controlled object to the cursor's location until it was released. All interactions and resulting trajectories were simulated by the Box2D engine.

The Agent

Learning Framework

Reinforcement learning (RL) focuses on how agents learn sequential control policies to maximize cumulative reward. We assume (S, A, R, T) defines a Markov Decision Processes (MDP) with state space S, action space A, reward function R and transition dynamics T. Modern RL can be divided into model-based and model-free approaches, where the former first learns a predictive world model then uses the model to learn a policy, while the latter learns an optimal policy directly from experience. We position our learning agent somewhat like a developing child learning about the physical properties of the world through experience but without much *a priori* knowledge. Thus, we do not assume the agent has a complete internal physics engine from which to draw samples (model-based learning) but instead is learning how best to reveal information in a model-free manner evaluated against its own learning progress (Oudeyer, Kaplan, & Hafner, 2007).

[1] `https://github.com/pybox2d/pybox2d`

Action space

As mentioned above, human subjects exhibited rich and informative behaviors when interacting with the objects in this environment. However, many of the strategies identified in Bramley et al. (2018) appeared to be composed of multiple simpler movements. For instance, "shaking" involved grabbing then moving an object rapidly back and forth between two locations while "throwing" involved grabbing an object and releasing it at speed and in a direction such that it went on to collide with another. To encode an action space expressive enough to incorporate these realistic and extended human behaviors, we combined a a grid of target locations (Figure 1a) with pool of easing (interpolation) functions (see Figure 1b). Concretely for each action, the agent chose an object to control (none, 1,2,3 or 4) and a cardinal direction (up, down, left ,right), or a quadrant (up-right, up-left, down-left, down-right) which determined a target location adjacent to its current location. It then followed a path to that location determined by its selected interpolation function. Figure 1b shows these functions in the first quadrant such that the path would be appropriately mirrored in the other three quadrants.[2] Together with horizontal and vertical movements, and no movement — i.e., the cursor pausing at its current position — our action generator output a contiguous mouse trajectory, following the policy learned by our agent via the learning framework demonstrated in the following section.

A complete learning episode consisted of a sequence of these actions and would terminate when the agents' uncertainty about a target property of the environment reached a threshold, or a timeout limit was reached. For simplicity we assumed each action occurred across a fixed time window, and to ensure continuity of mouse movement, the start point of each action was the end position for the last action. This resulted in a continuous action trajectory decomposed into a sequence of discrete action choices.

State definition

We defined the motion of an object at every time step t with scalars m_t and ϕ_t, where m_t represents the magnitude and ϕ_t the direction of the object. Given a two-dimensional space, $m_t = \sqrt{v_{x_t}^2 + v_{y_t}^2}$ and $\phi_t = \arctan \frac{v_{y_t}}{v_{x_t}}$, where $v_t = [v_{x_t}, v_{y_t}]$ is the velocity vector of the object at time step t. Together with the location tuple (x_t, y_t), the object state $s_t \in S$ is thereby a four-dimensional vector $[m_t, \phi_t, x_t, y_t]$.

Intrinsic Reward Signal

Our agents' goal was to minimise its final uncertainty about either mass or force. Thus its reward signal was based on computing its reduction in entropy with respect to the target property (Shannon, 1951). Following Bramley et al. (2018), we assumed likelihoods were computed based on divergence between mental simulations and the observed trajectories.

[2] All together there were (stay + $\rightarrow$ + $\uparrow$ + $\leftarrow$ + $\downarrow$ + 31[functions] $\times$ 4[quadrants]) $\times$ (4[objects] + no object)=645 possible actions.

Concretely, to infer how likely a mass-force combination, w, is we assume actual observed dynamics are compared against dynamics simulated assuming those properties. Let $w \in W$, where W is the space of all possible mass-force combinations. Before an episode starts, the agent has a uniform prior over settings $p(W)$. After a period of action and observation d, we assess the likelihood of the observed trajectory o under all possible w, and use this to update the prior distribution $p(W|d)$.

Following Vul, Frank, Alvarez, and Tenenbaum (2009), we modelled the likelihood of observing the object trajectories o given the potential property setting w and the mouse trajectory a using a Gaussian error distribution:

$$p(o \mid w, a, \beta) = \prod_{t=1}^{T} \exp^{-\frac{\beta}{2\Sigma}(s_t - d_t)^\top (s_t - d_t)}, \tag{1}$$

where d_t is the observed $[m_t, \phi_t]$ produced by the true environment w', and s_t is the velocity vector of the trajectory simulated under w. The covariance matrix was $\Sigma = \begin{bmatrix} \sigma_m^2 & 0 \\ 0 & \sigma_\phi^2 \end{bmatrix}$ where σ_m^2 and σ_ϕ^2 were set to the empirical standard deviations of the disparities between simulations and the actual observations in Bramley et al. (2018). β was a scaling parameter determining how confidently the agent could perceive divergences between the objects' true and simulated trajectories.[3]

According to Bayes' rule, once we measure the likelihood through Equation 1, we can calculate the posterior of the potential latent physics properties w by:

$$p(w \mid o, a, \beta) = \frac{1}{Z} p(o \mid w, a, \beta) p(w), \tag{2}$$

where $p(w)$ is the prior and Z is a normalizing constant. Using Shannon entropy (1951) as a measurement of the amount of remaining uncertainty about w', we formulated the immediate reward after action t as:

$$r_t = -\Big(\sum_{w \in W} p(w) \log p(w) - \sum_{w \in W} p(w \mid o, a, \beta) \log p(w \mid o, a, \beta)\Big). \tag{3}$$

For particular parameters of interest (here masses of the four objects), the posteriors and priors are marginalized over the remaining parameters (in this case, the pairwise forces) when estimating the parameter specific uncertainty reduction. The resultant reward signal r embodies the amount of information about the latent physics parameters (mass or force) a particular agent's action has obtained.

Deep Q-Learning

Q-learning is a model-free learning algorithm that estimates the expected cumulative discounted rewards of performing an

[3] Intuitively, $\beta = 0$ would result in no learning and $\beta \lim \infty$ would lead to an implausibly powerful learner with infinite perceptual precision. In our experiment, we assumed a constant β of $\frac{1}{50}$. We also held a fixed size of the time window T of $\frac{1}{6}$ seconds, over which forward simulations were compared against observations before being corrected.

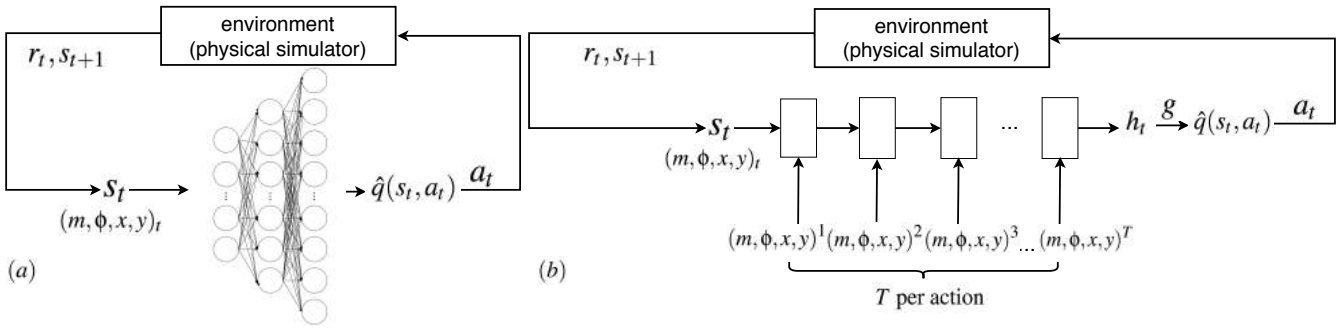

Figure 2: Proposed (a) MLP and (b) RQN structures of our Q-learning framework. For every time period, the network takes a sequence of object states and return the estimated Q-values. The control policy of the next time period, a sequence of mouse trajectories, is determined by selecting the action corresponding with the largest Q-values over the action space.

action from a given state (Watkins & Dayan, 1992). These estimated cumulative discounted rewards are often called returns and represented as Q-values (state-action values). One way to iteratively learn Q-values is by using a *Temporal Difference* (TD) algorithm (Sutton, 1988). TD updates Q-values by:

$$\hat{Q}(s,a) := (1-\alpha)Q(s,a) + \alpha(r + \gamma \max_{a'} Q(s',a')), \qquad (4)$$

where (s,a) is the current state-action pair, (s',a') is the state-action pair at the next time step, γ is the discounted factor, and α is a learning rate.

A challenge for conventional Q-learning is to estimate Q-values over continuous states and action spaces. For our task, despite creating a discrete action space with interpolation functions, the object's locations and motion $[m,\phi]$ was continuous throughout the world. Computing separate Q-values for every possible (s,a) pair at every time window is infeasible and naïve given the smooth relationships between nearby states. We hence adapted the *deep* Q-learning method, which instead of updating Q-values of each discrete pair (s,a) in tabular form, approximates $\hat{q}(s,a)$ with deep neural network. Denoting the parameters of the network as θ, a mean squared error loss of the Q-values approximator can be written as:

$$l(s,a \mid \theta) = \frac{1}{2}(r + \gamma \max_{a'} \hat{q}(s',a' \mid \theta) - \hat{q}(s,a \mid \theta))^2, \qquad (5)$$

where $r + \gamma \max_{a'} \hat{q}(s',a' \mid \theta)$ is the *target* of our estimation. Below, we present two neural network models, serving as the function approximators $\hat{q}_\theta$. Optimal control strategies can be discovered following this general learning structure.

Multilayer Perceptron First, we used a Multi-Layer Perceptron (MLP) with three layers to approximate Q-values (Figure 2a). For every time period t, the simulator fed the agent a sequence of object states s_t that spanned over T time-steps and offered a reward r_t to the MLP. The network outputs a deterministic cursor trajectory that was the action $a_t \in A$ with largest Q-value at t. We used ε-greedy exploration and optimized Equation 5 via stochastic semi-gradient descent (Watkins & Dayan, 1992). Note that the same network $\hat{q}$ producing the next state target Q-values was used for computing the loss of the current predictions. Such optimization can yield erratic gradients when the control policy oscillates. To deal with this potential instability, we redefined the *target* as a *target network*. Instead of using the same network to compute the next state target and the current state Q-values, another network $q_{\hat{\theta}^-}$, sharing the same structure as $\hat{q}_\theta$, was utilized to compute target Q-values during the update. The loss function in Equation 5 was then modified as:

$$l(s,a \mid \theta,\theta^-) = \frac{1}{2}\left[r + \gamma \max_{a'} \hat{q}(s',a' \mid \theta^-) - \hat{q}(s,a \mid \theta)\right]^2. \quad (6)$$

Following the 'hard-copy' update proposed in Mnih et al. (2015), we froze θ^- and copied θ into θ^- once after a few episodes. Experiments demonstrated that the MLP with *target network* model produced convergent and stable policies faster than the simple MLP model.

Recurrent Q-Network For every forward pass, the function approximator $\hat{q}_\theta$ should receive a sequence of object states with length $16T$ (four objects, each carrying a four-dimensional vector $[m,\phi,x,y]$ that depicts the object's motion per time step). An MLP approximator, as introduced in the previous section, consists of multiple fully-connected layers, where each layer contains multiple neurons that accept and send information across the network. The input motion vectors are stacked and reshaped into a $16T$-dimensional vector, and then fed into the first layer of the MLP. However, the state vectors encode the objects' movement information over a period of time, and simply flattening them may fail to capture some parts of the underlying dynamics or spatial correlations among the objects. We thereby propose a second RNN-based function approximator (Figure 2b).

Instead of treating all the motion vectors equally without order, RNN chronologically receives the motion vectors and updates its hidden cells accordingly. The output hidden vector at the last time step included not only the object state information but also their latent interconnections with the environment. To alleviate the vanishing gradient issue, we adapted the Long Short-Term Memory cell (Hochreiter & Schmidhuber, 1997) as the recurrent unit. A linear mapping function $g : S \to A$ mapped the state representation to actions. We optimize this recurrent Q-network (RQN) by semi-gradient

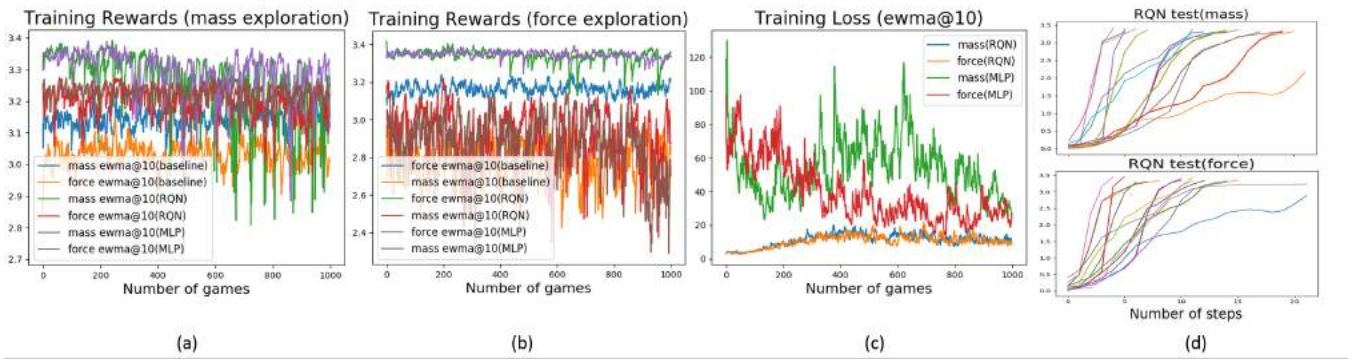

Figure 3: Reward and loss. (a) and (b) show total target and mismatched reward for each game, for the mass and force exploration tasks respectively. (c) reports the training loss associated with all proposed models. For each test game, the cumulative target rewards over actions are recorded and presented in (d).

descent using the *target network* method.

Experiments

In this section, we present some preliminary attempts at training these networks and comparing their behavior to that of humans performing the same task. We compare the achieved reward with respect to the agent's goal against its reward for the mismatched alternative goal to assess to what extent the actions were selectively informative.

Training

For our physics simulator, 60 time-steps was equivalent to 1 second. We set the time-window T as 40 time-steps, implying that each atomic action would take roughly 0.7 seconds. It is nontrivial to determine when a simulated game should stop, since uncertainty typically continues to diminish indefinitely, approaching but never reaching zero. For our agent, the total uncertainty of the latent physical parameter of interest could be obtained by computing the Shannon entropy of the initial prior distribution $p(W)_0$, denoted $\mathrm{H}(p(W)_0)$. We denoted a reward threshold factor $\gamma_r = 0.95$. Then, every time the cumulative reward reached $\gamma_r \mathrm{H}(p(W)_0)$, the game would stop. Otherwise, the agent would continue playing until the current game approached a timeout limit.

The three-layer MLP had 150, 250, and 450 neurons per layer. The input state s_t of MLP was in R^{640}, while for RQN, it was $R^{16\text{x}40}$. The approximated Q-values $\hat{q}_\theta(s,a) \in R^{645}$. We initialized the exploration rate ε as 0.5, discounted by a factor of 0.95 every 20 games until ε reached 0.01. The discount factor γ was 0.99, and the weights of *target network* were cloned from $\hat{q}_\theta$ every 20 games.

A training set with 60 distinct ground truth w, initial object locations, velocities, cursor positions, and initial velocities was created, and a holdout test set containing 20 different configurations, are defined beforehand to ensure the robustness of the models. For each proposed model, we trained the agent for the mass exploration task and the force exploration task separately with 1000 episodes, and the training errors and rewards are illustrated in Figure 3(a)-(c). Within each task, both the target reward and the mismatched reward (i.e., force in a mass exploration task) are recorded. For comparison purposes, we also ran a baseline policy (randomly selected actions) for each task. To better illustrate the moving trends, we weighted the training rewards and the loss by exponentially weighted moving average (ewma) with span 10.

Compared with the MLP-based models, RQN converged faster with small and stable loss, as shown in Figure 3(c). Both models produced swinging errors in the training process. The intuition is that 'hard' copying weights from θ into θ^- yielded a time interval when θ^- was frozen and the predicted Q-values diverged from the target Q-values. Such oscillations would not distort the optimization of the objective function, as the time interval was small and θ^- was constantly updated, ensuring steady amounts of information explored by the agent. Given a flexible timeout limit, both methods were able to uncover the uncertainty of the environment, and outperforms the baseline policy with higher and more stable cumulative rewards, as depicted in Figure 3(a) and (b). Mass reward was more variable. This is in line with the Bramley et al. (2018) finding that evidence about *mass* tends to come in sporadic spikes when objects collide or are moved rapidly, while *force* information typically accumulates more smoothly whenever objects are in close proximity. Thus, gathering mass information reliably have depended on more specific and targeted actions while moving objects closer together may have been sufficient for force information. Overall, the RQN exhibited continuing amounts of achieved information on all latent physics parameters. We applied the trained RQN agent on the test configuration set for mass and force exploration separately, each with 20 games. As reported in Figure 3(d), in most of the cases the agent could effectively capture the underlying properties of the environment within 20 steps. Since explorations were excluded from the testing, few 'abnormal' actions appeared. For those rare cases, our agent quickly came back to the right track and could still complete the learning task within the timeout limit.

Using the trained models we created a small dataset of 10 *force*-focused episodes and 10 *mass*-focused episodes using a holdout set of new worlds and starting locations. See `https://bit.ly/2FYTjvD` for videos. Comparing these episodes, we found that achieved information reward was similar for mass or force focused trials 2.82 ± 0.54, $2.96 \pm$

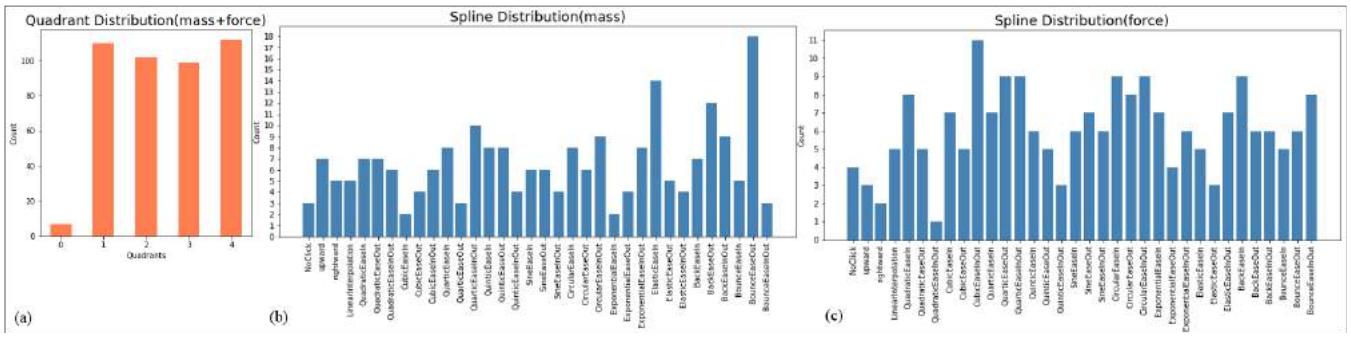

Figure 4: Distributions of emerged actions in 20 test games (10 for mass focused and 10 for force focused). (a) Sum of the quadrant distribution of mass and force tasks. '0' means the agent staying over at its position within the time-windows. (b) Spline distribution of mass task (c) Spline distribution of force task

$0.39, t(18) = .98, p = .32$ but that significantly more information was generated for the property matched with the agents' goal than the alternative property (see also lower orange and blue lines in Figure 3a and b). That is, the agent generated more evidence and reward on average about the target property 3.1 ± 0.35bits than the mismatched property 2.7 ± 0.52 bits $t(18) = 2.4, p = 0.021$ similarly to human subjects in Bramley et al. (2018).

Trained agent behaviour

The agent frequently moved the controlled object closer to the other objects, reducing the distance to the closest object from 1.28 ± 0.24m to 1.01 ± 0.23m on average during each control action $t(38) = 3.6, p < .001$. As we see in Figure 4a, the agent learned that moving was normally more informative than staying still. There were also hints of goal dependent control strategies similar related to those identified in Bramley et al. (2018). For example, the most frequently selected interpolation by the mass focused agent was *bounceEaseOut* (Figure 4b and green highlight in Figure 1b), a particularly dynamic motion consistent with the rapid changes of direction associated with shaking or knocking observed frequently in the human data on *mass* focused trials. The intuition both there and here is that these actions strongly reveal objects mass by causing rapid changes in objects' directions. Meanwhile, the most frequent interpolation selected by force focused agent was *cubicEaseInOut* (Figure 4c and red highlight Figure 1b), a smooth motion intuitively consistent with the "encroaching" behavior observed frequently in force trials in Bramley et al. (2018) and effective in providing strong evidence about mass.

Discussion and Conclusions

Humans display sophisticated intervention strategies when actively inferring the properties of physical objects. We used model-free reinforcement learning, deep function approximation, and simulation based inference to build an agent able to efficiently reveal the latent physical properties in human-like ways without external input. Part of the insight gleaned from this project comes from our solutions to the engineering challenges involved in creating a successful agent. To produce extended actions with richness and qualitative correspondence with humans', we found success with an action space that combined a discrete set of target locations with a discrete set of smoothing splines. We found that learning to associate action sequences with successful resolution of uncertainty was much more effective with a recurrent network architecture, but that robust strategies could be learned through model-free Q-learning. Following the predicted optimal control policies, not only did the agent uncover the latent parameters of interest, but there were also hints of behavioral correspondence with human subjects in that our mass trained agent would select more jagged and dynamic trajectories aligned with the strategies observed in Bramley et al. (2018).

While this study provides a valuable first step to understanding how humans learn and apply rich interrogatory behaviours when interacting with the natural world, it also has its limitations. One of these is the use of the physics simulator to calculate the reward signal. This is a rational idealisation of physics inference, but embodies the overly strong assumption that the agent is able to simulate the world accurately and perform approximate Bayesian inference with its own interaction data. A more plausible and practically viable approach to rewarding informative control would be to train a separate prediction network to anticipate upcoming dynamics, and use some function of its loss over time as a reward signal (cf. Oudeyer et al., 2007; Pathak, Agrawal, Efros, & Darrell, 2017). A more integrated agent could also use the predictor network approximation to plan actions that are likely to be informative through preplay Chentanez, Barto, and Singh (2005). Following Haber, Mrowca, Fei-Fei, and Yamins (2018), a complex adversarial-based learning framework may be helpful. In future work we plan to combine more realistic intrinsic rewards, richer action space and model based planning to better mimic the ability of humans to create intuitive physical experiments.

Abstract

Suspense is an affective state that contributes to our enjoyment of experiences such as movies and sports. Ely, Frankel, and Kamenica (2015) proposed a formal definition of suspense which depends on the variance of subjective future beliefs about an outcome of interest (e.g., winning a game). In order to evaluate this theory, we designed a task based on the card game Blackjack where a variety of suspense dynamics can be experimentally induced. By presenting participants with identical sequences of information (i.e., card draws), but manipulating contextual knowledge (i.e., their understanding of the rules of the game) we were able to show that self-reported suspense follows the predictions of the model. Follow-up model comparison further showed an advantage for the "suspense as variance of future beliefs" account over a number of alternative definitions of suspense, including some that depend only on current uncertainty (not the future). This paper is an initial attempt to link aspects of formal models of information and uncertainty with affective cognitive states.

Keywords: suspense; affect; prediction; expectation; probabilistic modelling

Introduction

Suspense refers to sensations of hopeful or anxious anticipation. These familiar affective states often precede the revelation of important information—exam results, paternity tests, election outcomes and so forth. However, we also feel suspense in situations where there are no direct personal consequences. For example, children enjoy listening to stories that happen in imagined kingdoms, adults spend time watching televised sports, and Hollywood movies are a multi-billion dollar industry. A key feature of these experiences is that information is incrementally revealed over time to the observer, often with the goal of building anticipation and suspense. The goal of this paper is to empirically study the relation between self-reported feelings of suspense and the dynamics of information and uncertainty.

Suspense as the variance in future beliefs

A recent theory in the economics literature proposes that suspense can be explained as an increasing function of the "variance of future beliefs" (Ely et al., 2015). Here the beliefs refer to the probability of a significant outcome (e.g., which team will win a game) that is updated in time with information as an experience unfolds. People are assumed to also estimate how their belief may change in the future. For example, if a doctor arranges to call a patient at a particular time with test results, in the period leading up to the phone call the patient might expect that their belief about their health could soon change (although they may not know what they will learn). Conditioned on the information one expects to receive, if the subsequent future beliefs would be very different from one another they would be said to have high variance. For example, if the test the doctor performed was routine, the patient would not expect their future knowledge state to change much after the call (low variance). As a result they would experience low levels of suspense. In contrast, if the test was a cancer screening, then the call might either alter the person's life or leave them reassured (high variance), and thus they would experience high levels of suspense in that moment.

To formalize these intuitions, we assume belief change is Markovian in that a viewer's subjective belief μ about some outcome evolves over a series of discrete time points t, such as individual points in tennis, card draws in a game, or time passing in a movie. At each time point, relevant information may be encountered and people update their beliefs μ_t (e.g., by Bayesian updating). In addition, viewers also anticipate future information using their understanding of the situation. For example, a viewer might anticipate that their favorite team will score on the next play or that the opposing team will score, each representing a state s. The state s has a probability of being realized $P(s)$ and will result in a future belief μ^s_{t+1}. The variance among these beliefs indicates how different the future might be, and therefore how much suspense might be evoked.

Formally, Ely et al. defined the momentary suspense at time t, S_t as:

$$\begin{aligned} \mathcal{S}_t &= \mathrm{E}_s[(\mu^s_{t+1} - \langle \mu_{t+1} \rangle_s)^2] \\ &= \mathrm{E}_s[(\mu^s_{t+1} - \mu_t)^2] \\ &= \sum_s P(s)(\mu^s_{t+1} - \mu_t)^2 \end{aligned} \tag{1}$$

and we adopt the same notation throughout this paper.

Note that the term $(\mu^s_{t+1} - \mu_t)^2$ may be also interpreted as a metric of variance of belief change or "surprise" that follows learning a piece of information. As a result, the value, S_t can be also be interpreted as the expected future surprise or expected future belief change from the next time period.

Figure 1 gives a graphical overview of the model applied to a hypothetical tennis game. Here μ is the probability of winning the game ($\mu = 1$ if team A wins and $\mu = 0$ if they lose), each point is one time step, and s is whoever wins the

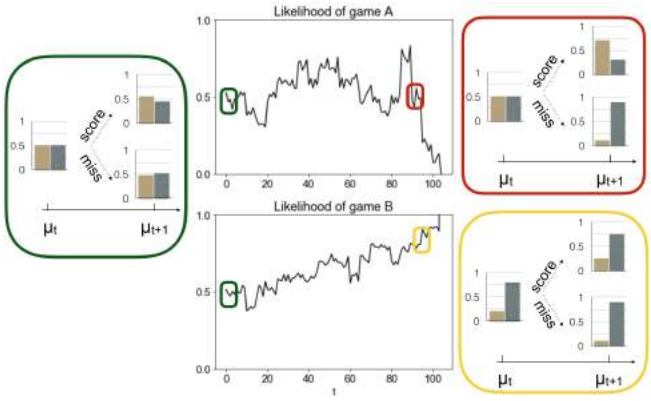

Figure 1: Demonstration of the belief trajectory during watch tennis games and the related suspense predicted from our model. Details see the main text.

next point. In the center of Figure 1 we show the unfolding of belief about who will win for two different games (A and B) with the x-axis representing time. The beginning of both games is not very suspenseful, since whoever wins the first few points has little impact on predictions about the final outcome. However, the end of the game A is more suspenseful since whoever wins a point will greatly swing the final outcome, while game B is less suspenseful since one side has already virtually secured victory.

An experimental test of the theory

Ely et al. (2015) articulated the basic outline of the theory described above and explored a number theoretical analyses of the optimal structure for games to maintain suspense. However, to our knowledge, this operational approach to suspense has not yet been examined empirically. We propose that a useful behavioral paradigm for testing this theory needs to have at least two features:

1. The experiment context should be quantifiable in a probabilistic model. This tends to exclude tasks like reading stories and watching movies because it is not trivial to convert these complex situations into accurate probability models.

2. The experiment paradigm should allow the decoupling of the external stimulus and internal belief. In most prior work, changes in suspense are always confounded with incidental features of the stimuli. To validate the belief-based account of suspense, the ideal experiment would manipulate an observed internal belief through some prior knowledge while holding other aspects of the stimulus and task identical.

With these criteria in mind, we designed a card game related to the classic casino game Blackjack. Participants are asked to draw cards from a small deck with a known distribution of cards and report their moment-by-moment suspense. Intuitively, suspense builds in the task when the sum of the drawn cards approaches a boundary value (21 in Blackjack). If the sum exceeds or hits this value the game is lost. Because the distribution of cards and the probability of drawing any card can be determined exactly, the game is an ideal test bed for exploring information-theoretic models of suspense. In addition, the game is relatively fun, intuitive, and easy to explain to participants.

To address the second concern from above, participants were given one of two different rules for how the game would be scored. In one version, the game was lost anytime the sum of the cards drawn so far met or exceeded the boundary value. This is the traditional concept of "bust" from Blackjack. In a second version, the game was lost only if the sum met or exceeded the boundary value on the final draw of the game. Due to the presence of negatively valued cards, it was possible for the sum to exceed and then return to safety. The differences between these two rules allows us to compare identical sequences of cards, but to modulate if a given card draw was more or less suspenseful about the game outcome according the the Ely et al. theory. To optimize the power of our design, we used a computer-aided method to search for best rules, card decks, and card sequences that result in strong predicted suspense differences under the two rules.

Methods

Participants 263 people (113 female), age 36.7±20.4 (mean±SD) were recruited from Amazon Mechanical Turk using psiTurk (Gureckis et al., 2016) and paid 90 cents (60 cents of this was a bonus that in actuality was the same for all participants). The task took 12±3 minutes to complete.

Procedure Participants were told that we were interested in their feelings of suspense while playing a simple card game. Each participant went through an extensive tutorial covering the rules of the game, and could only continue if they correctly answered a series of comprehension questions. They then played two rounds of training games which were identical to the real games except they were told there would be no bonus. After completing these tasks, participants played a sequence of three games with a $0.60 bonus payment for each game that was won (as describe below, all participants won one game). Afterwards they answered a questionnaire about their strategies and about their perception of the task.

Similar to Blackjack, in each round of a game, the player draws cards from a deck of nine cards. To increase the trial-by-trial suspense dynamics, we use a two-step process for choosing each card: first, the participant sees the animation of nine cards shuffling (Figure 2A); next, the first two cards at the top of the deck were selected (Figure 2B); next, the participant uses the keyboard to spin an animated wheel which (depending where it lands) decides the identity of the final card (Figure 2C). The wheel was programmed so that it spins more when the participant presses the key longer but, unknown to subjects, the spinner always ends up selecting a predetermined card. The purpose of the spinner was to give

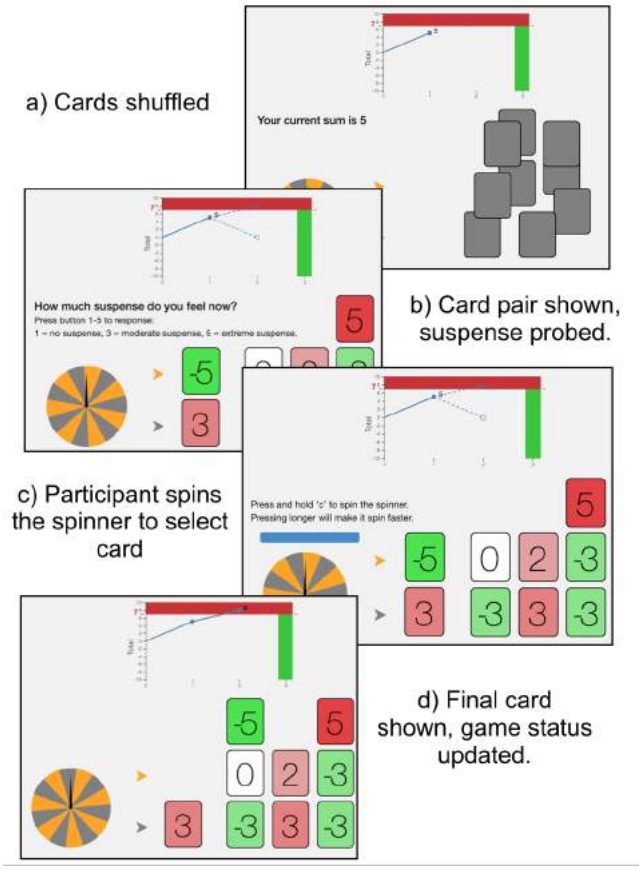

Figure 2: The game interface. a) Card shuffle is an animation that the participant cannot control. b) Participants see the selected card pair and are probed about their suspense on a scale of 1-5. c) Participants press and hold a key to spin the animated wheel. d) When the wheel stops one of the two selected cards is chosen. The whole process repeats until the game has ended.

participants a feeling of control and chance thus they do not lose interest early, although in fact the sequence of cards to be chosen was fixed for the purposes of experimental control. After a card is selected the participant's current card total (the sum of the face value of all of the cards they have drawn so far) was automatically updated in a graph at the top of the screen (Figure 2D).

To measure suspense, after the two candidate cards are shown and before spinning the wheel, we directly asked the participant to rate their current suspense with the keyboard from number 1 to 5 where 1 means no suspense and 5 means very suspenseful. Previous studies on suspense have also chosen a 7-point scale (Gerrig & Bernardo, 1994; Knobloch-Westerwick, David, Eastin, Tamborini, & Greenwood, 2009) and 11-point scale (Comisky & Bryant, 1982; Cupchtk, Oatleyb, & Vorderee, 1998), yet we are unaware of any systematic comparison of different response scales for suspense measurement. No other instructions were given about the use of the scale. However, we asked participants to report how they personally defined suspense in the post-task questionnaire.

Implementing the belief updating model To calculate the belief μ (probability of winning) at a given moment t, we use an exact enumerative strategy. We first enumerate all the possible future card draws remaining in the game according to the known card distribution of the deck. Summing these values, we get the predicted card sum probability. The winning probability calculation is rule-dependent: if the game is played according to the bust rule, we get the card sum distribution for one future step, keep the surviving card sums, continue to the next step and so forth until the game end. If the rule is no-bust (i.e. only the sum of cards at the end of the game matters), we directly calculate the card sum distribution at the end of the game and count the proportion of winning relative to losing sums.

Since the suspense is reported after the pair of possible cards are shown, we assume that suspense is the variance of future probabilities of winning after spinning the wheel and the card being finally drawn. Given that the wheel has equal area for both options, the probability of both future states are equal: $p(s) = 0.5$. The suspense prediction can then be calculated utilizing the equation 1.

Design We will introduce the design of card sequences, then the condition and counterbalance structure.

Belief manipulation: Model-based stimuli design. One key aspect of the theory is that suspense is the result of an active prediction about future stimuli and future beliefs, not the mere reaction to current stimuli. To test this, we looked for rule-dependent differences in suspense responses for the identical card sequences. Given the inherently noisy nature of self reports, we looked for sequences with large predicted differences by maximising a score:

$$\begin{aligned} \text{score}(\text{seq}, \text{deck}, \text{rulepair}) = S^{\text{rule1}} + S^{\text{rule2}} \\ -\alpha \cdot r(S^{\text{rule1}}, S^{\text{rule2}}) \end{aligned} \quad (2)$$

where α is a positive weight constant and $r(\cdot)$ is Pearson's correlation coefficient. The first two terms ensure the average suspense level is not too low while the third encourages anti-correlation between the suspense trajectory under two rules. We set α to a positive constant that makes the two terms have similar magnitude.

We searched the space of rules by generating 5000 random combinations of deck and card sequence valid under both rules and scoring them, then filtered with restrictions to ensure the game also feels like plausible random draws from the deck (details on *Github*). The result of this search was a set of 3 deck/card sequence combinations that evoke strongly different suspense trajectories under two rules: *Bust* with a bound of 7—i.e., the card sum should never exceed 7—and *No-bust* game with a bound of 3—i.e., the sum of cards should not exceed 3 at the end. The full sequences are shown in in Figure 3a.

Participants were randomly assigned to one of the two rule conditions. Two of the games were selected from *high suspense 1-3*.

Besides sequences with interesting suspense dynamics, we also designed two *no suspense* games where the card pairs have similar or identical values, or values that are non-consequential to the games outcome (Figure 3, "no suspense" 1-2), thus should intuitively induce low suspense. According to Ely et al. model, the predicted suspense at every point in these games is zero.

Task duration and manipulation. Each participant was assigned to one rule condition (rule was a between subject manipulation) and played two rounds of training games (with no bonus regarding the game consequence) then three rounds of gambling games. This is to make the task short enough to avoid boredom. Among the three rounds, two are of *high suspense* and one was a *no suspense* game. The order of games were all counterbalanced. The sign of cards and requisite bound values were also counterbalanced (for example, "cards sum must not exceed 3" was flipped to "card sums no smaller than -3" for half of participants).

Results

Given that each subject may use the scale differently, we *z*-scored the raw suspense ratings for each subject for all analyzes except the likelihood analysis. We also collapsed across the counterbalanced conditions of positive and negative card values. Figure 3 shows a detailed summary of the model predictions and point-by-point empirical suspense ratings for each of the games.

To first assess if the *no suspense* and *high suspense* game type altered people's ratings we ran a paired t-test for each participant's averaged suspense rating from the *no suspense* vs *high suspense* games. The suspense level in the *high suspense* games (0.1 ± 0.3, Mean $\pm$ SD) is significantly higher than the *no suspense* games (-0.7 ± 0.7): $t(262) = 14.18, p <$ .001, verifying the basic effectiveness of this very heavy-handed manipulation. Visual inspection of Figure 3 confirms this as well. Participants responded with the lowest increment on the scale for 71.9% and 53.4% of the two *no suspense* games.

To study the direction and magnitude of suspense differences for identical card sequences under different rules, we computed the average z-scored rated response for each point in each of the high suspense games and calculate the difference between in the two rules, comparing this empirical difference to the difference in suspense generated by the model. In Figure 4 we see that most point differences are in the same direction (quadrant 1 and 3). The self-reported suspense difference has an correlation coefficient of $r = 0.80$ ($p = 0.01$) with the model with zero free parameters which is impressive given the inherently noisy measurements of self-reported suspense.

Alternative models

So far we have focused on the formulation of suspense proposed by Ely et al. (2015). In this last section we explore alternatives that may also capture the empirical patterns in suspense.

Alternative probability distance metrics To measure the expected belief change, Ely et al used a squared distance between probabilities while alternative metrics such as information gain and absolute change are common in other contexts (Nelson, 2005). It is unclear in the context of suspense judgment which metrics will best describe people, thus we explore these alternatives.

In the Ely et al model the suspense is defined with an L-2 norm distance for belief update:

$$S_{\mathrm{L2}} = E[(p_{t+1,i} - p_t)^2] \tag{3}$$

where $i = 1, 2$ for each possible card to be drawn and $E[\cdot]$ denotes the average over i.

We explore alternative metrics to quantify the belief update with a KL norm:

$$S_{\mathrm{KL}} = E[KL(p_{t+1,i}, p_t)] \tag{4}$$

an information gain norm:

$$S_{\mathrm{IG}} = E[\mathrm{IG}(p_{t+1,i}, p_t)] \tag{5}$$

$$= E[H(p_{t+1,i}) - H(p_t)], \tag{6}$$

and an absolute error norm

$$S_{\mathrm{L1}} = E[abs(p_{t+1,i} - p_t)] \tag{7}$$

Uncertainty The second theoretical proposal is that people may feel more suspense simply when they have high uncertainty or the estimated chance of winning is close to 1/2. In studies of drama, to keep the story captivating, it has been proposed that "the protagonist and the obstacles he encounters must be fairly evenly matched" (Mabley, 1972). Also in the realm of psychology, uncertainty has been found to sustain attention since people demand the reduction of uncertainty (Berlyne, 1960). By looking at our post-task questionnaire, we also found that around 10% of participants reported they define suspense with uncertainty (although it is unclear whether they use this term in the mathematical sense).

Uncertainty should be the highest when the probability of winning is 0.5 and lowest when it is 0 or 1. To capture this idea, we use the entropy of the belief distribution:

$$S_{\mathrm{uncertainty}} = \mathrm{H}(p_t) \tag{8}$$

Suspense when close to losing The last alternative theory is that people may feel more suspense if the negative outcome is very likely to happen or the estimated chance of winning is close to 0. Previous studies in film narratives (Comisky & Bryant, 1982) and sports viewing (Knobloch-Westerwick et al., 2009) both empirically found that when there is a bigger

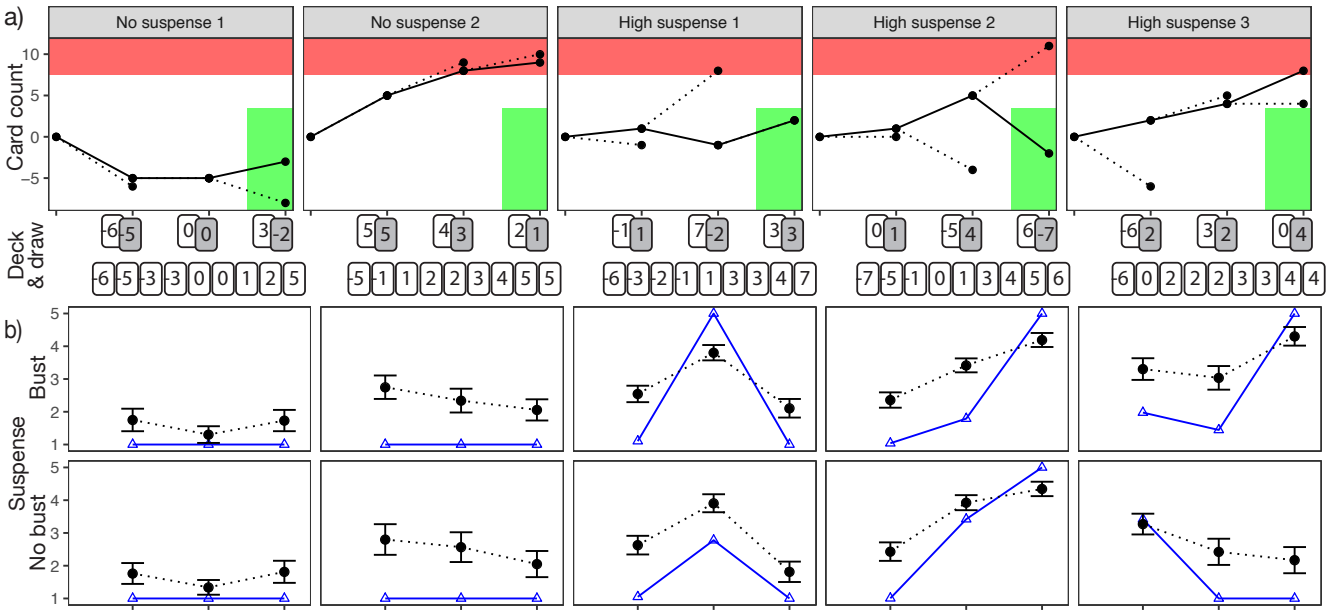

Figure 3: a) Stimuli: Panels show the five games; red indicates the bust region for *Bust* rule and green indicates win region for *No-bust* rule. The card pair at each turn is shown on x-axis with final draw in gray and the full game deck is shown below. Black lines show the actual score and dotted lines show potential score if the alternative card is drawn. b) Results and model predictions: Black circles show M±SE for participants with rule type separated by row. Blue triangles show Ely et al. (2015) predictions scaled to the full response range.

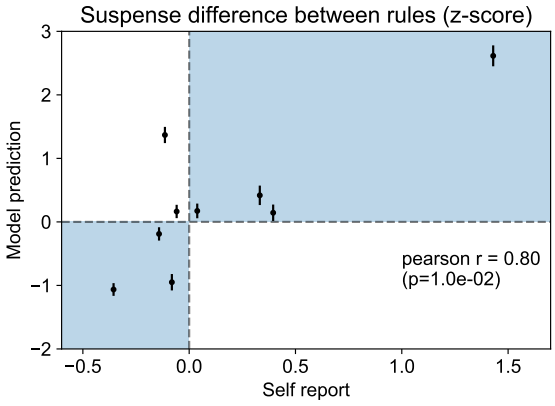

Figure 4: Suspense difference under two rules. Mean±SE differences in z-scored judgments (x-axis) scattered against z-scored model predicted differences (y-axis). Reported suspense differs in the direction the model predicted differences for points in the 1st and 3rd quadrants.

chance for the unwanted outcome to happen, more suspense is felt. In our data we also found this hint: for example, in the two *no Suspense* games, people feel more suspense in *no Suspense* 1 (-0.9 ± 0.5), where the chance of losing is always low than in *no Suspense* 2 (-0.5 ± 0.7) where the card total is always close to the bound and it indeed ends up losing. The difference of average suspense between the two games being significant ($t(261) = -4.98, p < 0.01$) indicates that people may feel more suspense when there is a high chance of losing.

We introduce two models to estimate this "pessimistic" belief about how close one is to losing the game. First, consider a heuristic: how far is the largest of the two cards drawn from the deck is from the boundary:

$$S_{\text{toBound}} = \begin{cases} 1 - |\langle V \rangle_{t+1,i} - \text{bound}|/M \\ 0, \text{if} |\langle V \rangle_{t+1,i} - \text{bound}| > M \end{cases} \quad (9)$$

Where $|\cdot|$ denotes absolute value, $i = 1,2$ representing the card pair and M is the maximum card value (7 in the current design). This piecewise definition assigns zero suspense when the current card sum is too far away from the boundary.

The other model is belief-based which is how big is the probability of losing:

$$S_{\text{pLose}} = \begin{cases} 1 - p_t, \text{if} p_t > 0 \\ 0, \text{if} p_t = 0 \end{cases} \quad (10)$$

$p_t = 0$ represents there is no hope of winning at all thus no suspense.

Likelihood model for fitting discrete responses Fitting the raw suspense scores requires an additional response

Table 1: Model Fits

	Aggregate	Individual	N best fit
L2 (Ely et al)	8.70	0.82	7
L1	**10.06**	**1.00**	**131**
KL	5.97	0.23	13
IG	8.62	0.83	14
toBound	6.65	0.03	40
pLose	8.36	0.20	6
uncertainty	7.47	0.55	52

Note: 1st column: Log likelihood improvement for each fit relative to baseline for average subject judgments (rounded into an integer response). 2nd column: Mean individual log likelihood improvement under optimal shared parameterization. 3rd column: Number of subjects best fit by each model under optimal shared parameterization. Best fitting model indicated in bold

model to convert the continuous suspense predictions to a integer output in the range of 1 to 5. We treat the response as a multinomial sampling process, with the probability of choosing each value related to a beta distribution:

$$p_k = \int_{(k-1)/5}^{k/5} pbeta, k = 1,2,\ldots,5 \tag{11}$$

whose beta parameters are defined such that the mean of beta distribution is equal to the suspense prediction (scaled to [0,1]):

$$pbeta(x) = \frac{x^{a-1}(1-x)^{b-1}}{B(a,b)}, \tag{12}$$

where

$$a = A * \tilde{S} + 1, b = A * (1-\tilde{S}) + 1 \tag{13}$$

$A \in [0,\infty)$, and $\tilde{S}$ is the suspense S rescaled to $[0,1]$.

We define our baseline model where all p_k are equal equivalent to choosing each response randomly. All the model log likelihood results in Table 1 are improvements from this baseline.

For individual participant data we fit this model with A determined by fminbound function of scipy package ($A \in [0,\ldots,15]$). We compare this maximum log likelihood to that from baseline model and summarize over all subjects. The result of all model comparison is in Table 1.

Our model fitting suggests there is considerable heterogeneity in what drives self-reported suspense in this task. The belief based suspense model with linear belief update distance (L1 norm) fit best overall, suggesting that Ely et al's choice of predictive variance may not be the most natural way of capturing human suspense. However all of the models we considered received some support, with the L2 and information gain models fitting almost identically. Consistent with the self reports in which some participants reported suspense in proportion to their current uncertainty, 20% of individual subjects were best fit by the *uncertainty* model, while a further and 15% best fitted by the heuristic "distance to boundary" model, indicating another potential heuristic sub population distribution.

General Discussion

In this study we designed a paradigm to manipulate the revelation of information about if a player will win a game (and thus earn a monetary bonus) in order to modulate participant's subjective feelings of suspense. We used the model and a computer aided search to select game sequences and rules with high predicted differences in suspense. To our knowledge, this is the first such empirical evaluation of the Ely et al. proposal.

By comparing a range of model variants, we found that most participants were fit by a model that related the rating of suspense to the anticipation of belief change, in line with Ely et al. (2015). However, we also found that belief variability predictions may be better explained by potential absolute (L1) change rather than variance. Heuristic models such as "probability to an unwanted outcome" also captured subsets of the participants.

In sum, this study suggests that suspense is systematically related to meta-cognitive predictions of future belief change. Such preposterior planning (Raiffa, 1974) issues arise in active learning and control contexts. For example, in order to identify the most useful query, one should consider the possible answers one might receive under different possible queries, and how one's beliefs would change as a result (Nelson, 2005). Suspense is thus a quantity that is tantalisingly closely related to such prospective meta-cognition, yet also distinctly low level in that it manifests as a reportable affective state.

Future iterations of our paradigm can be readily adapted to test other interesting hypotheses about suspense, such as the influence of (perceived) control, positive or negative rewards, or the role of suspense in driving attention or engagement (Bezdek et al., 2015).

Abstract

Outcome bias describes the tendency of people to alter their rating of a decision's quality according to whether the outcome is good or bad – despite equivalencies in available information and decision processes – which has the potential to undermine learning about causal structures and diagnostic information in many fields, including medicine. Herein, a sample of 181 doctors and medical students is shown to display outcome bias in medical and non-medical scenarios – with their susceptibility correlating across the domains, r = 0.38. Analyses showed that rational and intuitive decision styles and a medical risk tolerance measure offered little predictive power. Instead, the strongest drivers of bias susceptibility were the Age and professional Level of participants, with more senior personnel showing less outcome bias. We argue that this could reflect improved learning across a doctor's career or result from increasing confidence making them less likely to change their initial judgement of decision quality.

Keywords: medical decision making; outcome bias; individual differences; expertise; decision style.

Introduction

Outcome bias (Baron & Hershey, 1988) describes people's tendency to judge decision quality by outcome rather than the quality of the decision making process. Baron and Hershey demonstrated this across five studies, starting with an experiment where people judged the quality of pairs of decisions about medical treatment that differed only in terms of whether the treatment succeeded or failed. That is, the background information and the decision made remained the same but the outcome differed. The key finding was that almost half of participants rated the decision made in the good outcome scenario as superior to the same decision when a bad outcome occurred (with most of the remainder giving the same rating and a handful rating the good outcome decision as worse). This was despite a within-subjects design, which maximises the chance of participants working out what an experiment is about and remembering their answers to previous scenarios. Participants' own statements also indicated that the outcome *should* not affect ratings of decision quality.

Outcome bias has since been demonstrated in different fields; for example, ethical decision making (Gino, Moore, & Bazerman, 2009), where people's condemnation of ethic breaches is weighted according to the harm done rather than the nature of the ethical breach.

It is distinguished from the similar hindsight bias (Fischhoff & Beyth, 1975) in that outcome bias affects judgements of how good the decision process was, while hindsight affects people's ratings of how likely or predictable the outcome was. (That said, these processes can be linked in situations where, having seen the outcome, hindsight bias leads to the conclusion that the person making the decision should have been able to predict the outcome and thus that their decision making was flawed.)

Of course, judging decisions by their outcomes is natural– particularly given that we often can not access other people's decision-making processes, only the outcomes of their decisions. Thus, we need to *infer* their decision processes (Gino et al., 2009). The fact that people show outcome bias in circumstances when they are specifically made aware of others' decision process and even for their own decisions, however, indicates a problem in decision making - specifically, the overuse of the generally applicable rule that outcomes are linked to decision quality.

Outcome Bias in Medical Decisions

As noted above, the original outcome bias paper used medical scenarios amongst its materials but was conducted on an undergraduate student population. Follow-up work, however, has looked directly at whether medical practitioners are affected by this bias. For example, Caplan, Posner and Cheney (1991) demonstrated anesthesiologists' ratings of the appropriateness of care provided by other medical practitioners was affected by the outcome of that care not just the quality of the decision about treatments.

Similarly, Sacchi and Cherubin (2004) found outcome bias affected doctors' judgements regarding the quality of their own diagnostic decisions and pointed out the difficulties this causes for doctors trying to learn from their own experiences – as good outcomes can artificially inflate confidence while bad luck can deflate it. In either case, background knowledge can be updated incorrectly – inferring causal relationships from random effects.

The problem of learning from experience in the face of outcome and hindsight biases has also been raised for nurses (Jones, 1995) and is key to answering the question of whether these biases can be overcome in order to improve medical decision making.

Experience and Individual Differences

A gap in the above research is in the examination of experience and other individual differences on doctors' outcome bias susceptibility. As noted above, outcome and hindsight biases make learning from experience difficult and

it is, therefore, valuable to consider whether experience helps eliminate or exacerbates these biases. No previous studies, however, include doctors' experience as a covariate.

A related question is whether the level of outcome bias shown by doctors on medical and non-medical decisions is similar. If so, this would argue for a general propensity within an individual towards (or away from) outcome bias, which could be linked to personal traits. If not, however, it may be that outcome bias is domain specific – its strength determined by prior experience within a field.

A second line of enquiry is whether there are traits that predict susceptibility to outcome bias. While range truncation in such a highly selected population is likely to prevent measures of intelligence from being useful predictors, it is possible that decision styles (a person's preference for how to make decisions; see, e.g., Hamilton, Shih, & Mohammed, 2016) could affect the level of outcome bias shown. Gino et al (2009) argue exactly this in the context of ethical decision making – that a rational mindset helped to overcome outcome bias. This makes sense particularly for a within-subjects design, where more rational participants could be more likely to notice the pairs of outcome bias scenarios and may feel a greater propensity for ensuring that they are consistent across scenarios.

Another possible covariate is a doctor's tolerance for risk (see, e.g., Grol, Whitfield, De Maeseneer, & Mokkink, 1990). While this may not directly affect outcome bias, it could do so indirectly - by pushing a participant's responses towards the floor or ceiling of a rating scale, thereby potentially preventing outcome bias. For example, if a doctor is particularly risk averse, they could judge a scenario as too risky and thus a bad decision even when it has a good outcome, leaving no space for them to judge it as worse when it occurs with a bad outcome.

Aims and Objectives

The aims of this study are, thus, to: compare doctors' susceptibility to outcome bias on generic and medicine-specific questions; explore whether and how this susceptibility is related to individual traits; and to establish whether outcome bias susceptibility varies across different groups of participants in a meaningful way.

Methodology

Participants

Participants were medical students and practitioners, recruited via Facebook and direct emails to ACGME accredited departments of 100 institutions around the US (universities and large medical groups). In total, 181 completed responses were obtained. Table 1 summarises the participant demographics.

Materials

An online survey was developed in UCSF's Qualtrics, asking participants for demographics and measuring predictor variables and outcome bias as detailed below.

Table 1. Participant demographics

Gender	114 F, 60 M & 7 no-response
Level	66 students, 22 residents, 12 fellows, 56 attendings & 25 no-response
Experience	M = 9.1 years (*SD = 13.2);* 16.9 years (SD = *13.8)* excluding students
Age	21 x '18-25'; 40x '26-35'; 27 x '36-45'; 33 x '46-55'; 59 x '56+'; and 1 x no-response

Demographics. Participants provided their gender, age range, level, years of experience and medical specialty.

Predictor Variables. Two measures with the potential to predict bias susceptibility were included in the survey:

Decision Styles Scale (Hamilton et al., 2016). The DSS is 10-item questionnaire that measures people's preferences as to how they make decisions on separate Rationality and Intuition subscales. Scores on each subscale can range from 5-25 and, in both cases, higher scores reflect greater comfort with decisions being made in that style.

Medical Risk Tolerance Scale (Grol et al., 1990). The MRTS is a 5-item response scale assessing medical practitioners' tolerance for risk in medical decisions. Scores range from 5-25, with lower scores reflecting greater tolerance for risks. Herein, however, we have reversed the scoring such that high values reflect higher risk tolerance.

Outcome Bias Questions. Nine decision scenarios were written for this experiment to enable testing for outcome bias – six describing simple, betting scenarios and three describing medical decisions. (While more scenarios could provide a finer measurement of an individual's degree of outcome bias, this was weighed against limiting the length of the survey in order to maximise responses.)

Betting Scenarios. The basic structure of the betting scenario questions was as follows, with participants responding on a 5-point, 'Very bad' to 'Very good' scale.

Your friend is playing a simple game. He has the choice to not bet on a coin flip, and automatically win $10, or bet on the coin flip and win $15 if it comes up heads, but nothing for tails. He chooses to bet. The coin comes up heads and he wins, gaining $15. In your opinion, how good a decision was this?

In all variant scenarios, the friend ignores the certain $10 and bets on the coin toss. The pay-offs and whether the outcome was good or bad varied as shown in Table 2.

This gives three pairs of questions with the same decision quality (good, neutral or bad, based on simple, economic calculation when compared to the certain, $10 option). Differences between responses to these pairs thus reflect the impact of the outcome of people's responses (outcome bias).

An individual's level of outcome bias is measured as the sum of these differences - that is: (GDGO-GDBO) +

(NDGO-NDBO) + (BDGO-BDBO), yielding scores from -12 to 12 with scores above zero reflecting outcome bias.

Table 2. Decisions scenarios

Code	Outcomes of bet	Decision	Actual outcome
GDGO	$0 or $40	Good	$40
GDBO	$0 or $35	Good	$0
NDGO	$0 or $20	Neutral	$20
NDBO	$0 or $20	Neutral	$0
BDGO	$0 or $15	Bad	$15
BDBO	$0 or $15	Bad	$0

Note: the codes are anagrams. E.g., GDGO = good decision, good outcome. The difference between payoffs in two good decision scenarios was an uncorrected error but analysis suggested it had little impact on results.

Medical Scenarios. Three scenarios were written for this study. In each, a patient opts for a surgery rather than non-surgical management of their condition. Given their length, they are summarized in Table 3 rather than described in full.

Table 3. Medical Scenarios

Patient	Surgery	Risk	Outcome
♀24yr	Pacemaker	Low	Successful surgery
♀42yr	Panniculectomy	Low	Major complications
♂72yr	Hip replacement	High	Successful surgery

As these were written to be realistic for a sample of medical professionals, they are not as easily categorized as the simple, betting scenarios – with the riskiness (and thus the 'goodness' of the decision) depending not on simple probabilities but interpretations of patient history. However, the authors' view (on writing them) was that they corresponded most closely with GDGO, GDBO and BDGO situations, which allows two comparisons: (GDGO-GDBO) as per the above; and also (BDGO-GDBO), which represents the strongest test of outcome bias. As for the simple outcome bias, medical outcome bias was calculated from sum of these two scores, yielding a possible score of -8 to 8, with scores above zero reflecting outcome bias.

Procedure

The Facebook and email invitations included a direct link to the survey, allowing participants to take part without direct contact with the experimenters. The survey started with a standard consent request before proceeding to demographics, then the DSS and MRTS. Finally, the nine outcome bias questions were presented – intermixed to limit direct comparisons between the betting scenarios.

Results

Figure 1 shows participants' mean ratings of decision quality on the Betting scenarios with 95% confidence intervals. This serves as an initial proof of concept – demonstrating that participants recognised differences between good, bad and neutral decisions but were also affected by outcome bias – as scenarios with good outcomes are consistently rated higher than their matched, bad-outcome scenarios. (NB – the smaller number and greater difficulty in designating good versus bad in the medical scenarios meant that a similar figure would not be helpful.)

Figure 1. Mean responses on Betting questions

Descriptive Statistics

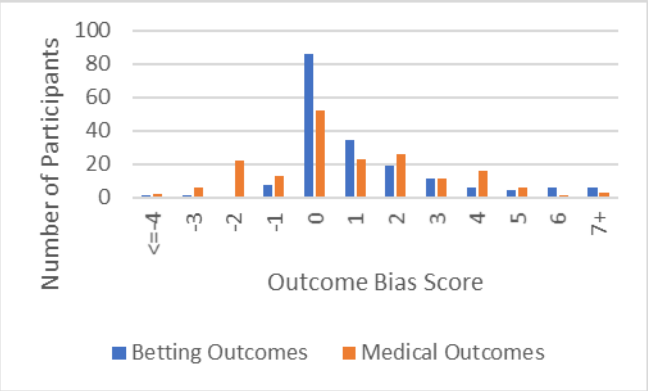
Table 4 summarises descriptive statistics for the individual differences measures and the two measures of outcome bias.

Table 4. Descriptive Statistics

Measure	Range	Mean	SD
Rationality (DSS)	10-25	19.7	3.3
Intuition (DSS)	5-24	11.3	3.4
Risk Tolerance (MRTS)	5-25	12.7	3.7
Outcome Bias (Betting)	-8-11	1.2	2.2
Outcome Bias (Medical)	-4-8	0.8	2.2

NB – the DDS and the MRTS are measured on 5-25 scales. The outcome bias measures are measured on -12 to 12 and -8 to 8 scales for Betting and Medical respectively.

Figure 2. Frequency counts of outcome bias scores



Looking at the table, one can see that both outcome bias measures, although low, are positive – as expected after seeing Figure 1. This impression is strengthened on examination of Figure 2, depicting the distribution of individual's scores. While a number of participants score around zero, there is a right skew, with more participants scoring above zero than below. Overall, 86 of the 181

participants have positive scores reflecting outcome bias for each of the Betting and Medical outcome bias measures (with 86 and 52 scores of zero and 9 and 43 scores below zero, respectively). These are similar proportions to those reported by Baron and Hershey (1988).

Outcome Bias

To test the significance of the above observations, single sample t-tests compared participant results to the expected score of zero if no outcome bias were present. These confirmed that outcome bias scores in both cases are significantly higher than zero, $t(180) = 7.39$ and 4.89, for the Betting and Medical questions respectively, $p < .0001$ in each case. A Pearson correlation was also calculated between the two outcome bias measures, indicating a moderate correlation, $r(179) = 0.38$, $p < .0001$, suggesting a stable tendency for people to show outcome bias (or not) regardless of the scenarios used. This suggests that, despite differences between scenarios, overall outcome bias susceptibility could be calculated in future work.

Individual Differences

Table 5 shows the Pearson correlations between the three individual difference measures and the Betting and Medical outcome bias scores.

Table 5. Pearson correlations between predictor and outcome bias variables

	1	2	3	4	5
1. Rationality	-		*		
2. Intuition	-.02	-	*	*	
3. Risk Tolerance	**-.17**	**-.19**	-		*
4. Betting	-.05	**.16**	-.09	-	***
5. Medical	-.10	.07	**-.19**	**.38**	-

* - sig. at .05 level, 2-tailed; *** - sig. at .001 level, 2-tailed

In Table 5, relationships between the predictor variables and the outcome bias measures are weak but a number are statistically significant. Specifically, Intuition correlates positively with people's Betting outcome bias score, while Risk Tolerance correlates negatively with Medical outcome bias. That is, people with more belief in their own intuitions and less tolerance for risk (or a greater desire to consult with others) seem to have a weak tendency to show more outcome bias (in the Betting scenario).

Overall, however, the results provide little hope for those seeking to use these individual differences to predict levels of outcome bias, with the strongest relationship explaining less than 4% of the variance in outcome bias scores.

Finally, analyses looked at participants' raw responses on the 1-5 ratings across both the Betting ($M = 2.95$, $SD = 0.65$) and Medical ($M = 3.63$, $SD = 0.58$) questions. This established that participants tended to think the medical decisions were better overall but is reassuring in that the majority of results are clear of floor and ceiling in both cases. Comparison of participant's mean ratings with their Risk Tolerance also found no correlation - $r = .04$, $p > .05$ in both cases - undermining the suggestion that risk tolerance might contribute to floor or ceiling effects.

Group Differences

Further analyses were undertaken to determine whether demographic differences between the participants predicted outcome bias or differences in the predictor variables.

Gender

Table 6 shows the data divided by gender.

Table 6. Mean (and *SD*) of measures by gender

	Female (n=114)	Male (n=60)
Rationality	20.0 (*3.37*)	18.6 (*3.63*)
Intuition	10.8 (*3.21*)	10.9 (*3.15*)
Risk Tolerance	12.3 (*3.74*)	13.7 (*4.26*)
Betting	1.54 (*2.39*)	0.58 (*1.62*)
Medical	1.08 (*2.46*)	0.35 (*1.79*)

Looking at Table 3, males and females score similarly on the individual difference traits but show clear differences in terms of the extent to which they show outcome bias, with females showing the bias at higher rates in both the Betting and Medical conditions. Independent samples t-tests were used to assess the significance of these apparent trends. These confirmed that the differences between male and female scores on the DSS Rationality and Intuition measures were not significant. Differences in Risk Tolerance, however, were, $t(172) = 2.3$, $p = .023$ (two-tailed), with males showing higher risk tolerance.

Similarly, the differences in outcomes bias were significant for both the Betting and Medical questions, $t(172) = 2.8$ and 2.0, $p = .006$ and .044, respectively, with males showing less bias in both cases.

Practitioner Level

Table 7 shows the data divided according to the level of the participants (as medical practitioners).

Table 7. Mean (and *SD*) of measures by practitioner level

	Student	Resident	Fellow	Attending
Rationality	20.7	18.7	19.6	19.8
	(*3.0*)	(*3.3*)	(*2.6*)	(*3.3*)
Intuition	11.6	11.6	11.6	10.0
	(*3.4*)	(*2.9*)	(*5.1*)	(*2.6*)
Risk Tol.	11.3	13.8	12.2	14.2
	(*2.9*)	(*3.9*)	(*4.4*)	(*3.9*)
Betting	1.8	1.1	1.1	0.6
	(*3.0*)	(*1.8*)	(*1.1*)	(*1.6*)
Medical	1.2	0.1	1.4	0.3
	(*2.2*)	(*2.7*)	(*2.4*)	(*2.0*)

Note: n = 66, 22, 12 and 56, respectively.

The table shows noticeable differences between the groups on a number of measures. In particular, Attending physicians seem to show less trust in their Intuition, higher risk tolerance and less outcome bias, while Students tend to

lie at the opposite extremes on these measures. The Resident group also shows extremely low outcome bias on the Betting scenarios but, given the very small size of this group, the reliability of the result is questionable.

One-Way ANOVAs were conducted in SPSS, comparing the groups' mean performance across all five measures. These confirmed significant differences between groups for: Intuition; Risk Tolerance; and Betting; $F(3, 152) = 2.67$, 7.45 and 2.91, $p = .050$, $<.001$ and .036, respectively. The other ANOVAs just failed to reach significance $F(3, 152) = 2.58$ and 2.55, $p = .056$ and .058, for Rationality and Medical outcome bias, respectively. Bonferroni post-hoc tests confirmed that significant results were driven by differences between the Attending and Student groups.

Given the effect of practitioner level on results, a χ^2 test was conducted to see whether a relationship between practitioner level and gender was driving the gender effect observed above. This revealed a significant relationship between gender and level, $\chi^2(3) = 10.1$, $p = .014$, with the sample containing more female Students and fewer female Attendings that would be expected based on the overall gender/level breakdown. Thus, multiple regressions (described below) were required to tease these effects apart.

Medical Specialty

Participants listed many specialties – making analysis difficult given space and power constraints. A result that stood out, however, was the difference between surgical and non-surgical specialties. Specifically, despite similar Risk Tolerance scores, surgical specialties (defined as those that make decisions in the operating room on a regular basis, including surgical specialties and anaesthesia) rated the decision to undergo the higher risk surgery (i.e., the bad decision, good outcome Medical scenario) as a worse decision than did non-surgical specialists, Mdiff = -0.42; confirmed as significant by an independent samples t-test, $t(102) = 2.0$, $p = .048$. As a result, the surgeons, overall, did not display outcome bias on this question.

Predicting Outcome Bias

In light of the multiple relationships shown above, linear regressions were run in SPSS using the Forward entry method ($p = .05$ inclusion criterion and $p=0.1$ removal criterion) using Age (converted to a 1-5 scale), Decision Making Training (0 or 1), Experience, Gender (converted to a 0 or 1 scale), Level, Rationality, Intuition and Risk Tolerance on Betting and Medical outcome bias scores. Tables 8 and 9, below, show the models produced for the Betting and Medical outcome bias scores, respectively.

Examination of these tables shows that both produced significant models (albeit with low proportions of variance explained at 7.9% and 11%) with the same predictors for the Betting and Medical versions of outcome bias - Age and Level. Participant's Medical scores were also affected by their Risk Tolerance score. Specifically, the models suggest that participants at higher Levels tend to show *less* outcome bias despite a tendency for older people to show *more*. Greater medical Risk Tolerance also decreased outcome bias, but only for the Medical outcome bias questions.

Table 8. Regression model for Betting scores

Model
Significant Predictors: Level and Age Formula: Betting = 1.74 – 0.96*Level + 0.77*Age $F(2, 149) = 7.48$, $p <.0001$; Adj $R^2 = .079$
Note: regression conducted using forward entry method. Standardised βs = -.297 (Level) and .204 (Age).

Table 9. Regression model for Medical scores

Model
Significant Predictors: Risk Tolerance, Age and Level Formula: Medical = 1.59 – 0.11* Risk + 0.40*Age - 0.329*Level $F(3, 148) = 7.23$, $p <.0001$; Adj $R^2 = .110$
Note: regression conducted using forward entry method. Standardised βs = -.189 (Risk) .253 (Age) and -.198 (Level).

Interestingly, once the effects of Age and Level are partialled out, the gender differences do not reach significance in either model. Neither is previous decision training or either of the DSS measures (Rationality and Intuition) having a significant effect.

Discussion

The results presented above reconfirm the existence of outcome bias in doctors and medical students and add to this knowledge in a variety of ways.

Firstly, the stability of outcome bias across scenarios of different types was established, with participants' outcome bias on Betting and Medical scenarios correlating significantly together. This supports the idea that there could be particular traits that predict the degree of outcome bias an individual will show.

Our analyses, however, failed to support the finding from Gino et al (2009) that a rational mindset decreases outcome bias. This may, however, simply reflect a range truncation effect, with participants' Rationality scores tending towards the higher end of the scale and none scoring below 10 on the 5-25 range. This is, perhaps, unsurprising, given the need for medical students and practitioners to use rational decision making and reflects a common difficulty in finding predictors of biases in highly selected populations.

The fact that Intuition emerged as a significant predictor in correlations with outcome bias does shine some light on the solution to this – the need to find traits that affect decision making but which are less strongly selected for through medical training. Intuition scores, while as low on average as Rationality scores were high may have been less truncated, spanning almost the scale's full range – from 5 to 24. The combination of range truncation and skew in these measures may also explain the somewhat surprising observation that Rationality and Intuition did not correlate

in our sample – unlike in the majority of data presented by Hamilton et al (2016) where a negative relationship is seen.

Overall, amongst the potential covariates examined herein only a handful of weak relationships were shown. Overall, the decision styles and Risk Tolerance measures showed little predictive power for outcome bias and, what little they did, disappeared when demographic variables of participant Level and Age were included in regressions. This suggests that participant Level may be affecting both a person's (trust in their own) Intuition and level of outcome bias rather than Intuition directly affecting outcome bias.

Caveats and Future Research

The fact that Level and Age proved the most consistent predictors of outcome bias, combined with the correlations involving Intuition and Risk Tolerance, could indicate that doctors, across the course of their careers, are learning in such a way as to help them overcome outcome bias. Alternately, however, it may suggest that a measure of confidence (see, e.g., Stankov, Kleitman, & Jackson, 2014) could be useful predictor in future work. The idea being that more senior doctors may be performing better because they are more confident and thus less swayed away from their initial rating as to whether something is a good or bad decision by outcomes. Of course, this might apply differentially in situations where they were rating their own decisions rather than those of others, which would need to be tested as well.

This could be regarded as a Bayesian explanation of the expertise effects. Specifically, outcome bias among students could reflect weaker priors which are, therefore, more affected by the new evidence provided by the outcome. More experienced people, by comparison, could have stronger priors as a result of that experience. Such an effect could also shed light on the difference between results for the Betting and Medical scenarios. A possibility we did not consider, for example, is whether people assumed that the coin described in the betting scenarios was 'fair'. We intende for them to do so but did not specifically state it and so participants could have, intuitively, been considering the possibility that the coin was not fair – with the result that their prior beliefs were weaker than in the medical scenarios. If true, an explicit statement or demonstration of the fairness of the coin should reduce outcome bias in these cases.

Another potential trait that could be considered is Need for Cognitive Closure (Webster & Kruglanski, 1994), which measures person's tolerance for ambiguity and/or their need to quickly resolve it – the expectation being that people high in NFCC might show less outcome bias as, having made a decision, they are less likely to revisit it once the outcome becomes known. In either case, however, whether medical personnel show a truncated range on such traits will also need to be tested.

Another interesting possibility raised by the data is that surgical and non-surgical specialists interpret surgical risk differently. This could be directly examined in future work.

A potential concern regarding the data is that the lack of control over online survey data may have resulted in errors or deliberate mistakes in personal data. In particular, it was noted that participant age data was strangely distributed – with more medical students selecting an age of 56+ than seems likely at first glance. This is likely to have eroded the predictive power of Age – by adding noise to the data. Given this, it may be that Age would be a stronger predictor in a future study with greater control over participant inputs. An alternative recruitment strategy could also aid in statistical analysis by ensuring equal numbers of participants in all groups.

Additionally, while prior Decision Making training was not a significant predictor of performance in our data, future research could explore this further by requesting further details on the type of training received and when it was received – given work in other areas showing that the durability of such training can be low over the course of years (see, e.g., Welsh, Bratvold, & Begg, 2005).

Finally, while the findings suggest that outcome bias is reduced by medical expertise, additional work is required to see whether these effects replicate when considering experts in other, non-medical fields. This could shed light on which of the possible explanations described above are most likely.

Conclusions

Doctors and medical students showed outcome bias in medical and non-medical decision scenarios, rating decisions with good outcomes significantly better than those with bad outcomes. The degree of outcome bias shown in these different sets of questions was similar and correlated, indicating a stable susceptibility to outcome bias.

The individual differences traits tested herein showed little predictive power, possibly due to range truncation, but outcome bias decreased with the Age and employment Level of participants. This could represent learning across a doctor's career but could also, we suggest, relate to their overall level of confidence, which is likely to inure them against changing their opinion on what the right decision is in light of new information like outcomes.

Novel categories are distinct from "Not"-categories

Abstract

The categorization literature often considers two types of categories as equivalent: (a) standard categories and (b) negation categories. For example, category learning studies typically conflate learning categories A and B with learning categories A and NOT A. This study represents the first attempt at delineating these two separate types of generated categories. We specifically test for differences in the distributional structure of generated categories, demonstrating that categories identified as *not* what was known are larger and wider-spread compared to categories that were identified with a specific label. We also observe consistency in distributional structure across multiple generated categories, replicating and extending previous findings. These results are discussed in the context of providing a foundation for future modeling work.

Keywords: categorization; category generation; contrast; category learning;

Introduction

People are remarkable in their capacity to innovate new and different ideas. Is creating a new idea the same as creating a different idea? Consider a restaurant that serves one meal per night. Their chef cooked red curry last night and wants to create and cook a new dish tonight. Is that the same as wanting to create and cook a new dish that is *not* red curry? While the former is identified as its own category, the latter is identified in relation to a known category.

While categorization researchers have primarily focused their effort on classification (associating an exemplar with a category given its features), and inference (predicting exemplar features given its category), work on category generation – predicting all exemplar features for a novel category – is relatively scarce. This is surprising because category generation is not an uncommon phenomenon – people are constantly challenged to generate novel categories, such as a new meal plan for the week, a new music playlist for an upcoming road trip, or a new exercise regimen to stay healthy.

Recent category generation work has established a few key findings. Earlier studies have shown that generated categories tend to share distributional statistics with learned categories (Jern & Kemp, 2013; Thomas, 1998; Ward, 1994). More recently, Austerweil, Conaway, Liew, and Kurtz (in preparation) and Conaway and Austerweil (2017) have found that category contrast is an important factor in category generation and learning – computational models sensitive to the differences between categories were a better fit to generated categories than models which did not take categories contrast into account.

Although previous work has established a few key findings, the basic phenomena and processes involved in category generation are still not well understood. In this article, we examine whether given a known category in a domain, generating a new category is different from generating a category that is not the learned category. If the only category is A, most formal accounts of categorization would consider generating a new category B as equivalent to generating not A. In order to better understand the nature of generated categories, it is necessary to distinguish between these two possible types of generated categories: one driven by its own identity – an *independently identified category*, and another driven by a motivation to be not what is known – a *category-by-negation*.

Current models of category generation do not explicitly make this distinction. One of the first computational models of category generation, Jern and Kemp (2013)'s hierarchical sampling model, is a Bayesian model that reproduces distributionally similar categories by assuming that the covariance matrix of features of exemplars from generated categories is generated by the same prior that generated the covariance matrix of the known categories. An alternative proposed model, PACKER (Conaway & Austerweil, 2017), is an extension of the classic Generalized Context Model (GCM; Nosofsky, 1984, 1986). It explicitly incorporates contrast into the similarity function by including a penalty for being similar to exemplars from a known category. A contrast parameter allows candidate categories that are more different from the known category to be weighted more heavily than candidate categories similar to the known category. Both models are flexible enough to describe how generated categories can be distributionally similar (or different) from an experimenter-defined category. However, they do not distinguish between generating an independently identified category and a category-by-negation because there is no mechanism to account for these different identities.

This issue also extends to the methodology applied in category generation (as well as most categorization studies.) In Ward (1994), participants were told to generate aliens that belonged to a different species from a prior group of aliens, without applying any specific label to this new group of aliens. Similarly, Jern and Kemp (2013) instructed participants to generate a new, different type of crystal after having

observed two different types of crystals. In contrast, Conaway and Austerweil (2017) prompted participants to generate exemplars from a novel "Beta" category, while avoiding an explicit instruction for participants to create something "different". In each of these studies there appears to be an implicit assumption that generating an independently identified category is equivalent to generating a category-by-negation.

In this paper, we challenge this null assumption by positing that the explicit association of categories-by-negation to its known counterpart (i.e., the explicit identification of the to-be-generated category as *not* a known category) should result in the observer taking advantage of the entire area of the feature space not occupied by the known category. In contrast, observers generating independently identified categories should be less focused on the unoccupied feature space and instead construct their categories based on the structure of known categories. From this we can predict that categories-by-negation should occupy larger areas of the feature space compared to independently identified categories. In addition, the similarity in distributional statistics should extend not only from the learned category to the first independently identified category to be generated (as previous studies have found), but also between subsequent independently identified categories. We test these predictions by adapting and extending a category generation experiment by Conaway and Austerweil (2017) and explore the implications of its results.

Experiment

Our current experiment closely mirrors the the experimental design of Conaway and Austerweil (2017), where participants are first trained on a category named 'Alpha' before being tasked to generate exemplars from a new category. While Conaway and Austerweil (2017) were primarily interested in the measuring the location of generated categories relative to learned categories, our current investigation focuses on analyzing the differences in distributional statistics across different generated categories. Consequently, in addition to varying the shape and location of the Alpha category (i.e., across different Alpha conditions where the position of the Alpha exemplars are systematically varied) in three distinct ways, we include an additional independent variable comprising three different generation conditions: a Not-Alpha condition, where participants generate a new category that is not the learned Alpha category; a Beta-Only condition, where participants generate a new category named 'Beta'; and a Beta-and-Gamma condition, where participants generate a category 'Beta' as well as a category 'Gamma'. The resulting 3-by-3 design is applied in a between-subjects fashion – participants can be in only one of the nine unique conditions.

The main advantage of adapting the experiment by Conaway and Austerweil (2017) is that the simplicity of their stimuli allow for a straightforward test of the distributional similarities across known and generated categories. In addition, the variety of Alpha categories used (i.e., the different shapes of the Alpha categories) also allows us to observe the effect of generated category identity across multiple scenarios.

In line with our earlier predictions, we expect that the Not-Alpha conditions on average generate categories that are larger in area and more widely dispersed than categories from the Beta-Only as well as Beta-and-Gamma conditions. In addition, we predict that within the Beta-and-Gamma conditions, the generated Beta and generated Gamma categories should be distributionally similar.

Method

Participants and materials We recruited 240 participants through Amazon Mechanical Turk and randomly assigned them to one of the nine unique conditions. Sample sizes of each condition are presented in Table 1.

Stimuli were squares that varied along two dimensions: color (grayscale 9.8% – 90.2%) and size (3.0 – 5.8cm on each side). The assignment of perceptual features (color, size) to axes of the domain space (x, y), as well as the direction of variation along each axis (e.g., increasing or decreasing size) was counterbalanced across participants. Feature values were evenly-spaced on a 50-by-50 grid, giving a near-continuous space from which exemplars can be generated. An example of the feature space is presented in Figure 1a.

The three Alpha conditions are Cluster, Row, and Diagonal. In the Cluster condition, Alpha exemplars occupy a small area towards one corner of the feature space. In the Row condition, the exemplars are nearly equal along one feature, while equally spread out along the other feature. The Diagonal condition has Alpha exemplars equally spaced along the diagonal of the feature space in a similar fashion to the diagonal conditions of Jern and Kemp (2013). In order to ensure that exemplars are not completely identical along any one feature, exemplar feature values are slightly jittered. The exact same amount of jitter is applied to all Alpha exemplars within a given Alpha condition. The locations of these different Alpha categories in the feature space are presented in Figures 1b to 1d.

Procedure In the first phase of the experiment (Figure 2), participants learned the Alpha category exemplars by observing a unique exemplar on each trial. This was repeated over a total of three blocks (four trials per block – one corresponding to each unique exemplar,) with the order of exemplar presentation randomized within each block. Prior to the presentation of each exemplar, a fixation cross was shown for 1000 ms. Participants were allowed to spend as much time as they wanted on each trial and were also shown the full range of possible feature values prior to training.

The next phase comprised a series of generation trials (Figure 3). Depending on their generation condition, participants generated either eight exemplars from a category that was 'Not-Alpha' (Not-Alpha generation condition), eight exemplars from a category called 'Beta' (Beta-Only generation condition), or four exemplars from a category 'Beta' *and* four exemplars from a third category 'Gamma' (Beta-and-Gamma

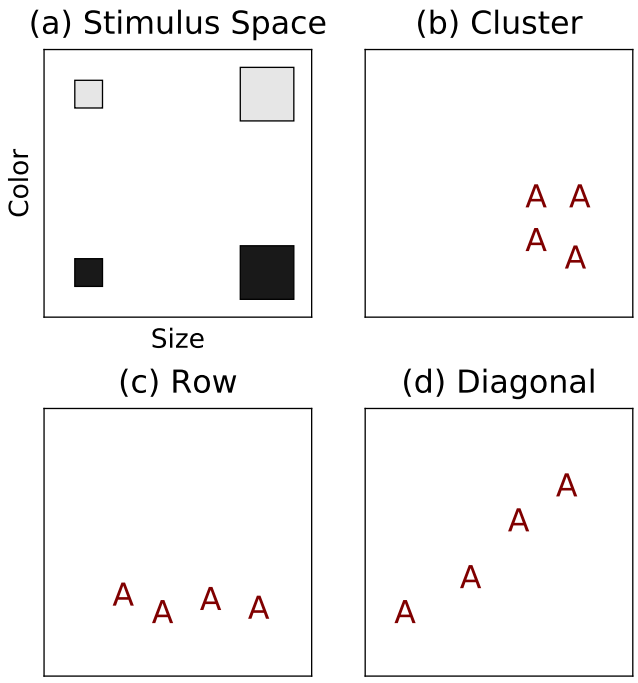

Figure 1: (a) Example of stimuli located at the corners of the feature space. (b-d) Locations of Alpha category exemplars for each Alpha condition.

generation condition). More specifically, participants in the Not-Alpha generation condition were asked to produce "what [they] think is likely to NOT be in the Alpha category", while participants in the other conditions were asked to produce "what [they] think is likely to be in the Beta [or Gamma] category". Exemplars were generated on each trial using two on-screen sliding scales, with each scale controlling the individual features (color and size) of the generated exemplar. Feature values could take any one of 50 evenly-spaced values between the specified boundaries. Previously generated exemplars were not allowed to be generated a second time. Participants were shown an on-screen preview of their exemplar on each trial as they interacted with the sliders, but could not see previously generated exemplars or exemplars from the Alpha category.

Table 1: Sample sizes for each condition.

Generation Condition	Cluster	Row	Diagonal
Not-Alpha	26	28	25
Only Beta	30	27	25
Beta-and-Gamma	26	27	26

Analyses We analyze our data in two stages. First, to provide a coarse overview of the distribution of different patterns of generated categories, we classify the generated categories into six different profiles: Positives, where the correlation between the dimensions is more than r; Negatives, where the correlation between the dimensions is less than $-r$; Rows, where the range of values across the x dimension is at least d times more than the range across the y dimension; Columns, where the range of y dimension values is at least d times more than the range of x dimension values; Clusters, where the ranges across both dimensions are less than a; and Dispersed, where the ranges across both dimensions are more than a. Next, we compare the generated categories on four key distributional measures: ranges of each feature, the feature correlations, and the area enclosed by the generated exemplars in the feature space (i.e., their convex hull). Differences along each of these statistics are performed using Bayesian t-tests (Rouder, Speckman, Sun, Morey, & Iverson, 2009), yielding Bayes factors (BF_{01}) which indicate evidence for the null hypothesis when $BF_{01} > 1$, with larger values indicating greater evidence for the null hypothesis. $BF_{01} < 1$ indicates evidence for the alternative hypothesis. Interpretations of the sizes of Bayes factors are guided by Jeffreys (1961).

Results

We took a subset of the data and tuned each of the profiling parameters such that the profiles of this subset were adequately captured. Subsequently, we applied this profiling scheme to the entire dataset. Overall, we found that setting $r = .7$, $a = .25$, and $d = 5$ was useful in capturing the different profiles of generated categories. The results were robust to moderate variations in the profiling parameters (e.g., setting $.5 < r < .9$, $.1 < a < .4$, and $d > 1$ returned very similar results.) A representative sample of each profile is shown in Figure 4 and the frequency plot of the different profiles is presented in Figure 5.

The most striking patterns to note here are the high frequencies of Row category profiles from participants in the Row conditions, and the high frequencies of Dispersed category profiles from participants in the Not-Alpha conditions. The former indicates that the distributional similarities between learned and generated categories are especially strong in the Row conditions, while the latter provides preliminary evidence that generated categories from the Not-Alpha conditions tends to be more widely dispersed. Also noteworthy are the low counts of both Positive and Negative category profiles across the whole data set – in contrast to the Row conditions, this indicates low similarity in distributional structure between the learned and generated categories for the Diagonal condition.

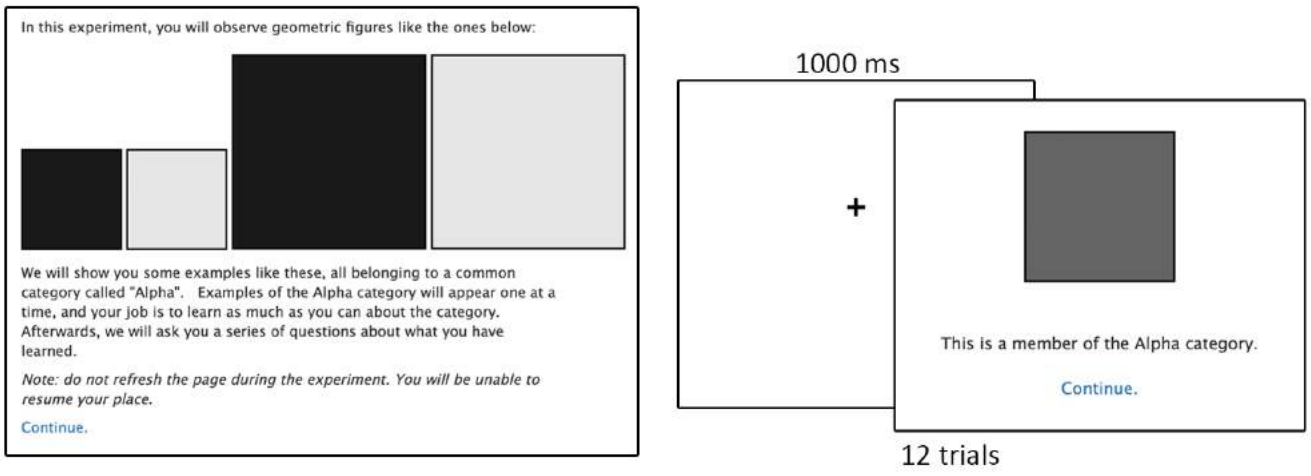

Figure 2: Instructions and trials observed by each participant during the category learning phase. The instructions screen is shown once, followed by 12 presentations of Alpha exemplars (4 exemplars across 3 blocks.)

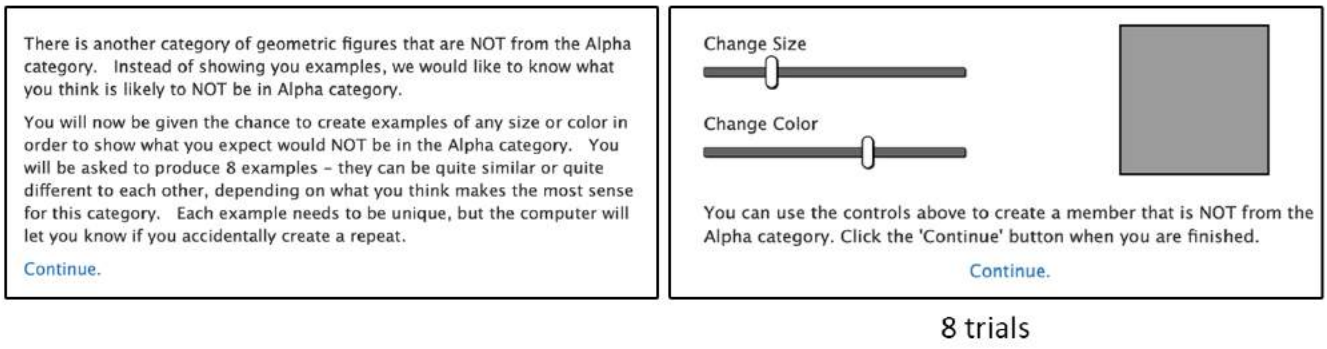

Figure 3: Instructions and trials during the generation phase, observed by a participant in the Not-Alpha condition. Participants in the Beta-Only and Beta-Gamma conditions experienced similar trials, with the exception that those in the Beta-Gamma condition were asked to generate 4 Beta exemplars then 4 Gamma exemplars.

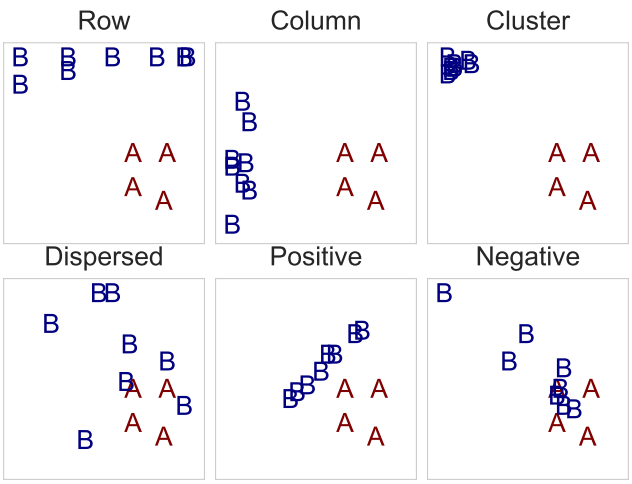

Figure 4: Representative samples of the six different category generation profiles.

Focusing on the distributional statistics, when broken down by the Alpha conditions (Figure 6), we found that the Cluster conditions tended to have categories with a smaller range of both features, and with correspondingly small sizes. The Row conditions produced categories that are high on the x dimension but not the y dimension. These observations indicate that the distributional statistics were carried over from the known category to the generated category in these two Alpha conditions. However, the Diagonal conditions did not have similar distributional statistics observed – instead of a positive correlation, the Diagonal conditions tended to produce large, dispersed categories. Austerweil et al. (in preparation) also observed a similar effect (although they found more evidence for a negative correlation). Overall, in alignment with previous research, at least two out of the three Alpha conditions in our experiment generated categories that share distributional statistics as the known category.

More interestingly, when the data is broken down by the generation conditions (Figure 7), we found that compared to the Not-Alpha conditions, there is moderate evidence showing Beta-Only conditions with a lower y dimension range ($t(162) = 3.00$, $BF_{01} = 0.16$) and moderate to strong evidence that their generated categories are smaller in area ($t(162) = 3.16$, $BF_{01} = 0.10$). There is moderate evidence that the Not-Alpha and Beta conditions share equal range of x dimension values ($t(162) = 1.33$, $BF_{01} = 4.82$). With Beta-and-Gamma conditions, we find greater evidence for smaller and tighter categories compared to the Not-Alpha conditions. Specifically, there is very strong evidence that both Beta and Gamma categories from the Beta-and-Gamma condition are smaller in both x ($t(156) = 4.83$, $BF_{01} = 2.55 \times 10^{-4}$; $t(156) = 4.21$, $BF_{01} = 2.94 \times 10^{-3}$, respectively) and y ($t(156) = 4.57$, $BF_{01} = 7.40 \times 10^{-4}$; $t(156) = 7.56$, $BF_{01} = 4.30 \times 10^{-10}$, respectively) ranges compared to the Not-Alpha conditions. Similarly, there is very strong evidence that both categories in the Beta-and-Gamma conditions are smaller in area than the Not-Alpha conditions ($t(156) = 5.70$, $BF_{01} = 5.41 \times 10^{-6}$; $t(156) = 7.69$, $BF_{01} = 2.07 \times 10^{-10}$, respectively). Overall, when comparing the Not-Alpha conditions to categories from other generation conditions, we consistently find moderate to very strong evidence that Not-Alpha categories are more widely dispersed (in their range values) and also larger (in their area), with the only exception being the comparison of x dimension ranges between the Not-Alpha and Beta-Only conditions.

When comparing the distributions of the Beta and Gamma categories generated within the Beta-and-Gamma conditions, we find an overall weak-to-moderate evidence for equal distributional statistics. Specifically, there was moderate evidence for equal x dimension ranges ($t(150) = 0.56$, $BF_{01} = 9.47$) and weak evidence for both feature correlations and area size ($t(150) = 1.85, BF_{01} = 2.10; t(150) = 1.77$, $BF_{01} = 2.40$, respectively). When measured on their y dimension ranges, we found weak evidence for lower values from Gamma categories compared to the Beta categories ($t(150) = 2.47$, $BF_{01} = 0.59$).

Discussion

At first glance, it seems reasonable to assume that generating a new category Y after learning category X is the same as generating a new category Not-X. An independently identified category should already be a category-by-negation (in that an independently identified category is not what was previously known.) Further, if the categories are already identified by arbitrary labels, then it may be easy to assume that identifying the negation of a known category cannot add any additional information in category generation.

Our results have indicated otherwise. Specifically, when tasked to produce categories-by-negation, participants tended to generate wider and larger new categories compared to when tasked with producing independently identified categories. To our knowledge, this paper represents the first piece of evidence distinguishing these separate types of categories.

Aside from demonstrating a new effect, this study has continued to show the robustness of the distributional similarities between learned and generated categories. In this sense, the results from the different Alpha conditions are similar to those observed in Austerweil et al. (in preparation). The generated categories from the Cluster condition tend to possess lower x and y ranges, with a correspondingly smaller area, and the generated categories from the Row condition tend to adopt Row-type profiles. There is also similar lack of categories with positively correlated features from the Diagonal condition.

However, one notable difference is that while Austerweil et al. (in preparation) found evidence of negatively-correlated generated categories in their XOR condition, we found no evidence of negatively-correlated generated categories in our comparable Diagonal condition. Austerweil et al. (in preparation) explained that the presence of negatively-correlated

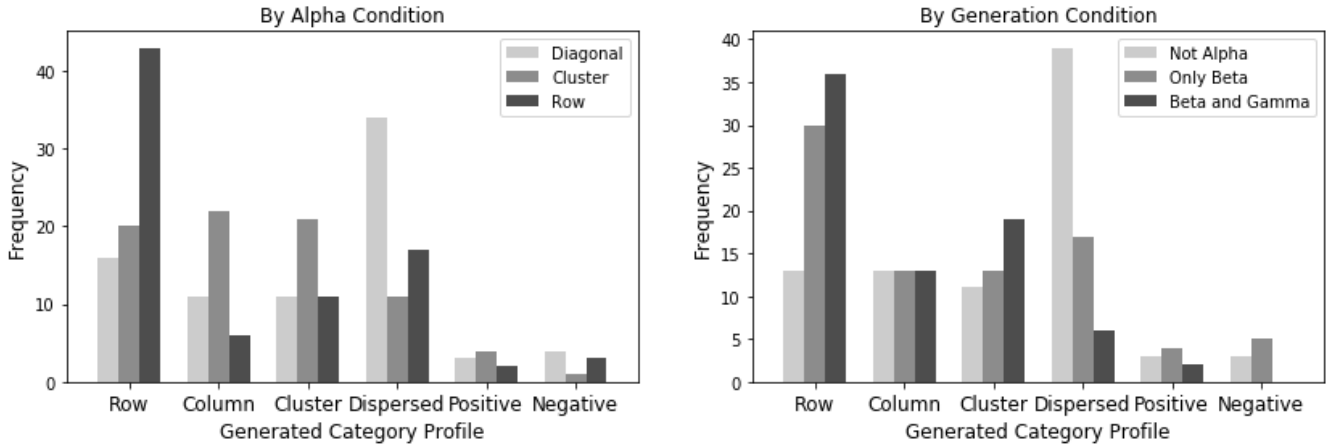

Figure 5: Frequencies of category generation profiles broken down by Alpha condition (left plot) and generation condition (right plot).

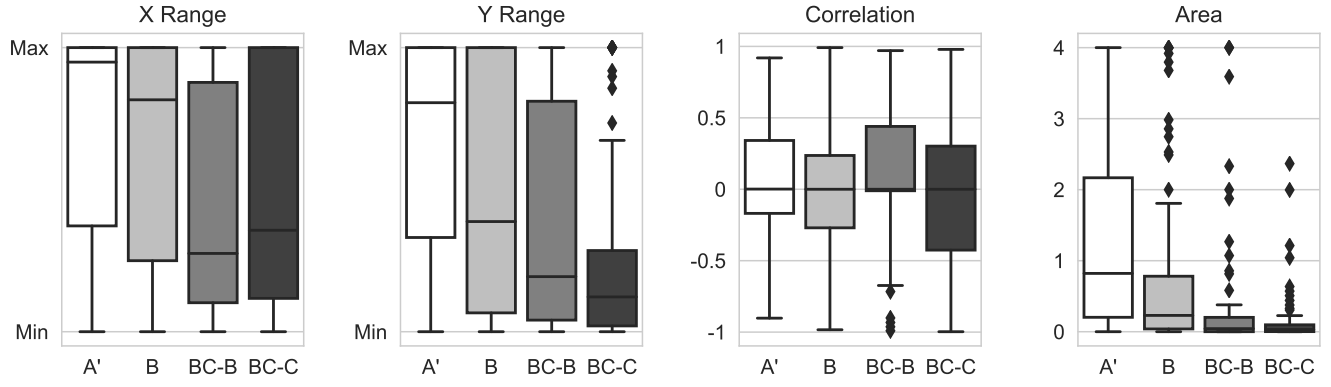

Figure 7: Box-plots of the distributional statistics from the generated categories. Boxes depict the median and quartiles of each generation condition, with the Not-A condition denoted by A' and the Beta-Only condition denoted by B. Data from the Beta-and-Gamma conditions are separated into the Beta groups (denoted BC-B) and the Gamma groups (denoted BC-C) generated in that condition. Whiskers are placed at 1.5 inter-quartile range. All points outside this region are marked individually.

features in this condition was indicative of the effect of category contrast – that is, categories with negatively correlated features are generated because they are particularly different to categories with positively correlated features. It is possible that due to the reduced strength of the positive correlation in our study compared to Austerweil et al. (in preparation) (because of the addition of noise to the feature values), participants were no longer as sensitive to the negative correlations in the experimenter-defined category and therefore started to produce uncorrelated but widely dispersed categories.

Beyond replicating previous studies, the current study has demonstrated that the consistency in distributional statistics can persist beyond the first generated category. However, evidence showing this was ultimately weak. One possible reason for this is the relatively small feature space employed in the tasks. The generation of a second novel category is necessarily more constrained in the feature space than the generation of the first novel category, possibly contributing to differences in distributional structure. By exploring stimuli features with less defined boundaries (e.g., orientation), we may expect to see greater consistency in distributional structure over multiple generated categories.

Although we have observed participants generating multiple independently identified categories, we do not want to imply that categories-by-negation can only happen once. It would be worth investigating how participants might proceed to generate additional categories-by-negation (e.g., by asking observers to generate a category that is Not-Alpha and Not Beta). Packing Theory (Hidaka & Smith, 2011) – a hypothesis that suggests categories can be neatly 'packed' into the feature space – may indicate that successive categories-by-negation are generated in a fashion that preferentially occupies spaces between observed categories. Further, although none of the current models of category generation can directly account for the effects observed in this study, they may be useful components in a larger category generation framework. For instance, future work may consider implementing the hierarchical sampling model from Jern and Kemp (2013) in a framework of overhypotheses (Kemp, Perfors, & Tenenbaum, 2007), where a prior can be placed over a category identity space, allowing models to behave differently under different regions of generated category identity.

Ultimately, the nature of newly generated categories appears to vary depending on the identity they were associated with. The extent to which they may differ, and the mechanisms driving these differences represent fascinating areas for future research.

Abstract

Mounting evidence suggests that human category learning is achieved by multiple qualitatively distinct biological and psychological systems. In an information-integration (II) categorization task, optimal performance requires switching away from rule and adopting a procedural response strategy. However, many participants perseverate with rules. This article attempts at understanding the difference between optimal and suboptimal participants in II categorization. To this end, we collected data in the Iowa Gambling Task (IGT) and an II categorization task. Performance in the IGT was used to estimate each participant's sensitivity to reward, punishment, and propensity to explore. The results show that optimal participants in the II task explored more in the IGT than suboptimal participants. However, optimal participants in the II task did not show higher sensitivity to punishment or lower sensitivity to reward. We conclude by discussing the implications of these findings on system-switching and theoretical work on multiple-systems model of perceptual category learning.

Keywords: perceptual categorization; decision-making; dual systems; exploration-exploitation

Introduction

Categorization is an important part of daily life. From categorizing objects as edible or not to categorizing people as friends or enemies, everyday life is filled with thousands of category decisions. Over the past 20 years, mounting evidence has been gathered that category learning is achieved using a number of different psychological and biological systems (e.g., Ashby et al., 1998; Ashby & Valentin, 2017; Erickson & Kruschke, 1998; Hélie et al., 2010; Nosofsky et al., 1994; Waldschmidt & Ashby, 2011). However, much less is known about the interactions between the multiple categorization systems (Hélie, 2017). For example, the COVIS theory of categorization (Ashby et al., 1998) assumes that participants begin by guessing or using simple rules generated by hypothesis testing. Only after these rules have failed will participants abandon rule-based strategies and proceed to using alternative, more intuitive and less verbal methods of categorization.

One task where the primacy of rule-based strategy is often observed is the information-integration (II) categorization task. In II categorization tasks, participants need to integrate information from more than one dimensions at a pre-decisional level in order to maximize accuracy. Example for the II category structures are shown in Figure 2B. In this figure, each symbol represents the coordinate of a stimulus in perceptual space and specify one specific rotation angle and frequency that allow for drawing a unique sine wave grating (see Figure 2A). In this example, participants need to learn to categorize the 'o' and '+' in separate categories. This can be achieved by drawing a line in Figure 2B, but notice that the line would not correspond to a meaningful verbal description. The verbal description would be: 'o' are stimuli where the rotation angle is larger than the frequency, which is not meaningful given that rotation angle and frequency are not commensurable.

In an II categorization task like the one presented in Figure 2, the most accurate verbal rules can produce an accuracy of about 75%. In order to perform optimally, participants need to abandon rules and rely on a non-verbal procedural strategy. Decision bound models (DBM) (Hélie et al.,2017; Maddox & Ashby, 1993) can be used to identify the type of strategy that participants are using, and a consistent finding over the past 30 years is that a substantial number of participants perseverate with rule-based strategy in II category tasks and as a result perform suboptimally.

Reward Processing

The goal of this study is to understand why certain participants fail to abandon rule-based strategies and adopt non-verbal procedural strategies. To generate predictions, we first used the COVIS model of categorization (Ashby et al., 1998; Hélie, Paul, & Ashby, 2012) to fit published II categorization data collected in our lab. The COVIS model implements a multiple-systems theory of category learning that includes an explicit hypothesis-testing system and an implicit procedural-learning system. The explicit system learns through declarative memory by choosing and testing simple verbally expressible rules, whereas the implicit system employs non-declarative memory whereby learning is mediated by reinforcement learning as the system gradually assigns motor responses to regions of perceptual space. On each trial, the model compares the confidence in both systems and produce one response, either from the explicit system or from the implicit system.

The COVIS model was fit to data from Experiment 2 in Hélie & Cousineau (2015) (Condition = 0.5) to understand the switching of learning system between explicit and

implicit system in a perceptual categorization task. Decision bound models were fit to the data from each participant to separate participants using an optimal strategy from participants using a suboptimal strategy. The COVIS model was then fit to each group separately in order to identify which model parameters differed between simulations matching optimal participants and simulations matching suboptimal participants. Two hundred simulations were run for each subgroup of participants and the results are shown in Figure 1. The fit was excellent, with a RMSD of 1.5%. The model was able to differentiate optimal from suboptimal participants by changing the parameters odelta_e and odelta_c, which are the magnitude of the effect of the (negative and positive, respectively) feedback to adjust confidence in the hypothesis-testing system (Hélie, Paul, & Ashby, 2012). The simulations for optimal participants had a higher odelta_e value and a lower odelta_c value compared to the simulations of suboptimal participants, indicating that optimal participants are more sensitive to negative feedback while suboptimal participants are more sensitive to positive feedback. As a result, we hypothesize that optimal participants in II categorization tasks are more sensitive to negative feedback than participants who perseverate with rule-based strategies.

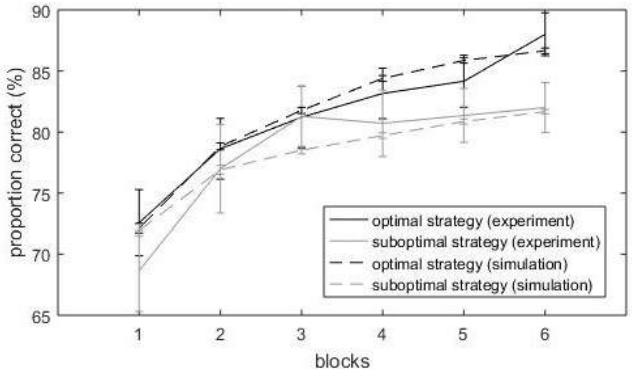

Figure 1: Average accuracy in Hélie & Cousineau (2015) and model results for each block of 100 trials. Black lines shows data for participants that use an optimal strategy, while grey lines indicate participants that use a suboptimal strategy. The participants' accuracy collected from the experiment are shown as solid lines, while the data from simulation are shown as dashed lines.

The Exploration-Exploitation Dilemma

One useful way to think about strategy switching and selection is to consider them in the context of the exploration-exploitation dilemma (Berger-Tal et al., 2014). Exploration and exploitation are seen as two opposing ways in the means of attention and resources allocation (Benner & Tushman, 2003; Gupta, Smith, & Shalley, 2006). Exploration entails risk taking, flexibility, discovery, and disengaging from the current task to allow for more room for experimentation, which is frequently associated with innovation. In contrast, exploitation is described with high-level engagement, choice-selection, efficiency and improvement (Laureiro-Martínez et al., 2015). The behavior of gathering information and exploiting are viewed as mutually exclusive events in many cases (Mettke-Hofmann, Winkler, & Leisler, 2002). When exploring, the agent seeks information about its environment as a way to improve performance, but in many situations it has to pay an opportunity cost (March, 1991). Agents that only exploit using current knowledge might be stuck in a suboptimal stable equilibrium, unable to adapt fully to the environment (March, 1991; Uotila et al., 2009). Thus, an optimal strategy in decision-making is to have balance between exploration and exploitation, allowing resource allocation between the two behaviors to yield the 'best' long-term rewards (March, 1991).

The exploration-exploitation dilemma to some extend resembles the results observed in the II categorization task. Assuming that participants begin by using a rule-based strategy, 'exploiters' may perseverate with a rule-based strategy since it allows for responding correctly in about 75% of the trials. Exploration is required to abandon rule-based strategies and try procedural strategies that are more optimal. As a result, we hypothesize that participants who explore more are more likely to perform optimally in an II categorization task.

Methods

To test for the hypotheses, we used the Iowa Gambling Task (IGT) (Bechara et al., 1994) to measure reward sensitivity and exploration tendencies. Each participant performed both an II categorization task and the IGT. Performance in the IGT was used to predict whether participants would use an optimal or suboptimal strategy in the II categorization task.

Participants

Fifty participants were recruited from the Purdue University undergraduate population. Each participant was given credit for participation as partial fulfillment of a course requirement. Participants gave written informed consent and all procedures were approved by the Purdue University Human Research Protection Program Institutional Review Board.

Materials and Procedure

Each participant did both the Iowa Gambling Task (IGT) and the perceptual categorization task (PCT) in random order of IGT-PCT (n = 27) and PCT-IGT (n = 23). The experiment was run on a Desktop PC equipped with a regular mouse and keyboard. Stimuli were displayed in a 21-inch monitor with 1,920 × 1,080 resolution. The experiment was controlled by in-house programs written using PsychoPy.

Iowa Gambling Task Participants were presented with four blue rectangles. The blue rectangles were labeled as "Deck A", "Deck B", "Deck C", and "Deck D". The task required participants to repeatedly draw 'cards' from the four decks, by clicking on the blue rectangle on the screen with a mouse. Participants were required to select a deck on each trial within

four seconds. If a participant failed to select a deck before the deadline, the program randomly selected a deck. The participant could only select one deck for each trial.

The expected values of the decks differed so that two decks were associated with high immediate rewards but long-term overall loss (disadvantageous decks A and B), and two other decks yielded lower immediate rewards but long-term overall gains (advantageous decks C and D). The experiment was designed to record the participant's affinity towards each deck given the rewards and penalties presented in each trial upon selection of a particular deck. The reward and penalty from the selected deck in the particular trial, as well as the total accumulated gain from the rewards and penalty gathered thus far was presented to the participant at the end of each trial. The rewards and penalties were generated to meet the requirements listed in Table 1. Each deck contained 10 different cards and was re-shuffled after all 10 cards had been drawn. Each participant performed 120 trials grouped into six blocks of 20 trials each. Completing the IGT took about 10 minutes.

Table 1: Deck properties (Bechara et al., 1994)

Card	Deck A	Deck B	Deck C	Deck D
P(penalty)	0.5	0.1	0.5	0.1
Penalty	-150 to -350	-1250	-25 to -75	-250
Reward	100	100	50	50
Expectation	-250	-250	250	250

Perceptual Categorization Task (PCT) The stimuli used in the PCT were circular sine-wave gratings of fixed contrast and size, as shown in Figure 2. The stimuli differed in terms of bar width and orientation. The bar width was derived as the frequency of lines in a 2D space in cycles per degree, while the orientation is the counterclockwise rotation of the lines from horizontal in radian. The stimuli were categorized as A and B, with a diagonal line as a category bound as shown in Figure 2. Perfect accuracy was possible and optimal performance required responding to the A-B stimuli using a procedural strategy.

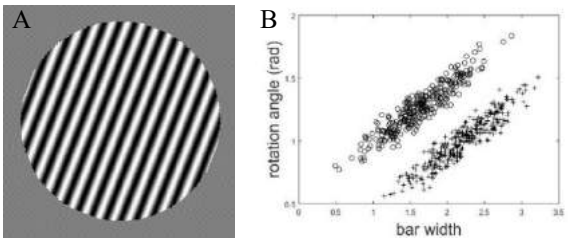

Figure 2: (A) Example stimulus shown to the participants for PCT, (B) Category structures used in PCT.

The participants were informed that they were taking part in a categorization experiment and that they needed to learn to categorize the stimuli presented into either category A or B with trial-and-error. In each trial of this task, a "crosshair" was presented on the screen for one second, followed by a single stimulus presented in the center of the screen. Participants were required to choose a category for the stimulus. Responses were given on a standard keyboard: "s" key for category A and "k" key for category B. After each trial, visual feedback showing "Correct", "Incorrect", or "Wrong Key" was given to the participant according to the response they pushed. The response for stimulus on each trial was recorded, as well as the response time. The participants did 600 trials grouped into six blocks of 100 trials each. The PCT took about 35 minutes to complete.

Decision bound models

The objective of the study was to explore the difference in sensitivity to reward and punishment between participants that used an optimal strategy and participants that did not use an optimal strategy. To allow for the classification of participants into optimal strategy users and suboptimal strategy users, Decision Bound Models (DBM) were applied to the perceptual categorization task to identify how participants learned to assign responses to regions of perceptual space. In DBM, it is assumed that participants determine the region of the percept and give the associated response. The decision bound is described as a partition segregating competing response regions. Three general classes of decision bound models were fit to response data of the PCT (Hélie et al., 2017; Maddox & Ashby, 1993): (1) guessing models, (2) explicit rule-reasoning models, and (3) procedural learning models.

The guessing models assumes that participants do not use the information on the screen and randomly responded "A" or "B" in each trial. The explicit models set a boundary to segregate participant's responses with a vertical line or horizontal line (or the combination of both vertical and horizontal lines). An adjusted diagonal line is used as the boundary instead in the procedural learning models. For each participant's data set, the best model is selected using the Bayes information criterion (BIC). Participants whose data were best-fit by the optimal models, which is the procedural learning model in this case, are labelled as "optimal strategy" and all other participants are labelled as "suboptimal strategy".

Rescorla-Wagner Model

The data recorded in the IGT were fitted with the Rescorla-Wagner (1972) model (RW). The RW was used to calculate a value for each deck and estimate a participant's sensitivity towards reward and punishment.

Data for each participant was fed into the RW model. For each trial, t in a particular task block, the parameter for sensitivity to reward, b_{rew} was multiplied with the magnitude of reward, R received following the participant's response in each trial, while the parameter for sensitivity to punishment, b_{pun} was multiplied with the magnitude of punishment, P received following the participant's response in each trial.

The key equations to update reward and punishment sensitivity were:

$$B_{rew} = \frac{b_{rew} \times (R(t) - P(t))}{\max(R)} \quad (1)$$
$$B_{pun} = \frac{b_{pun} \times (P(t) - R(t))}{\max(P)}$$

where, B_{rew} and B_{pun} are the sensitivity to reward and punishment, for the perceived net gain and loss in each trial. The key equations to update reward and punishment sensitivity were:

$$\text{Qdeck(t)} = \text{Qdeck(t} - 1) + \alpha\big(B_{rew} - \text{Qdeck(t} - 1)\big) \quad (2)$$
$$\text{Qdeck(t)} = \text{Qdeck(t} - 1) + \alpha(B_{pun} - \text{Qdeck(t} - 1))$$

where, Qdeck is the Q-value for each deck and α is the learning rate. The equation on top in Eq. 2 updates the deck value with B_{rew}, while the equation below updates with B_{pun}. In trials where an overall reward was received, the equation with B_{rew} was used to update the deck value; in trials where overall punishment was received, the equation with B_{pun} was applied to update the deck value. All parameters were estimated using Maximum A Posteriori (MAP).

The sensitivity towards reward and punishment b_{rew} and b_{pun} for each participant were then normalized. The weighted proportion of b_{rew} and b_{pun} with respect to the summation of b_{rew} and b_{pun} were computed with Equation 3.

$$W_{rew} = \frac{b_{rew}}{b_{rew} + b_{pun}} \quad (3)$$
$$W_{pun} = \frac{b_{pun}}{b_{rew} + b_{pun}}$$

where, W_{rew} and W_{pun} are the weighted proportion of b_{rew} and b_{pun}, respectively.

Results

Effects of sensitivity to punishment and rewards

Participants in the PCT were categorized into participants who found the optimal strategy and participants who did not using DBM. The sensitivity to punishment (b_{pun}) and reward (b_{rew}) were computed with the RW. W_{rew} and W_{pun} were computed as the weighted proportion of sensitivity to reward and punishment, respectively, and the mean estimates of the proportion of W_{rew} and W_{pun} for participants that used an optimal strategy and a suboptimal strategy are shown in Figure 3. Confirming our hypothesis, W_{rew} [t(48) = 1.901, p = 0.032] of participants that used an optimal strategy was lower than that of participants that used a suboptimal strategy, whereas W_{pun} [t(48) = -1.901, p = 0.032] of participants that used an optimal strategy was higher than that of participants that used a suboptimal strategy. These results show that participants using an optimal strategy in the PCT have a greater sensitivity to punishment, while participants using a suboptimal strategy in the PCT have a higher sensitivity to reward.

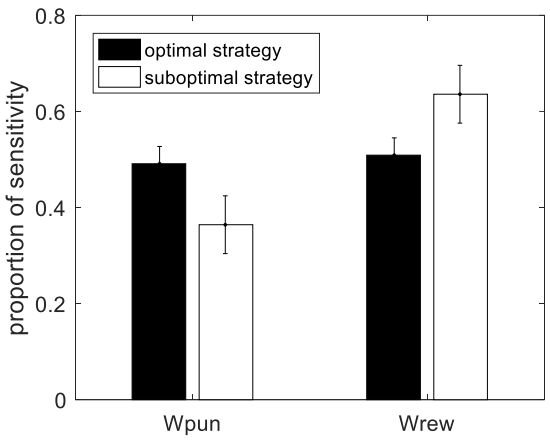

Figure 3: Estimated sensitivity to reward and punishment (IGT) for optimal and suboptimal participants (PCT). Error bars are standard error of the mean.

Exploration affects category learning

Exploration was quantified as the number of deck switches in the IGT and was compared between the two groups of participants. The number of deck switches was subjected to an independent samples t-test to test the effect of using optimal or suboptimal strategy in PCT. The average number of deck switches for the two groups is shown in Figure 4. The main effect of the strategy used [t(48) = 1.684, p = 0.049] was significant. The number of deck switches for participants that used an optimal strategy in the PCT (mean = 71.91) was higher than the number of deck switches for participants that used a suboptimal strategy in the PCT (mean = 60.38). The results suggest that, as predicted, participants who conduct more exploration are more likely to perform optimally in an II categorization task.

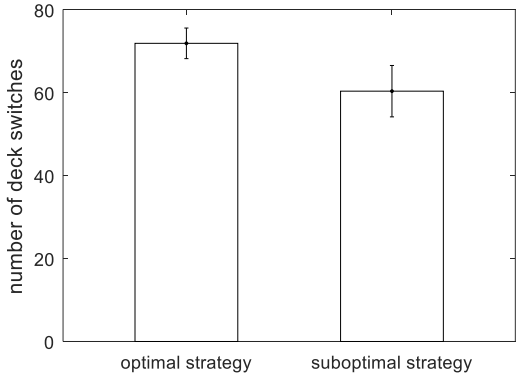

Figure 4: Average number deck switches in the IGT for optimal and suboptimal participants in the PCT. Error bars are standard error of the mean.

To further assess the role of exploration in strategy selection, we measured the entropy of choosing different decks: A, B, C and D. Entropy gives a sense of disorder and uncertainty. Hence higher entropy means that all decks were sampled equally often, whereas an entropy of 0 means that participants always selected the same deck. We first calculated the correlation between entropy and number of deck switches in the IGT (Figure 5A). This analysis informs whether participants always switch between a subset of the decks or if all decks are sampled. The correlation was 0.513, which is statistically significant [$t(48) = 4.136$, $p < 0.001$]. This result suggests that participants with more deck switches sample from all decks.

Next, we computed the linear relationship between entropy and sensitivity to feedback in the IGT ($b_{pun} + b_{rew}$). Here, b_{pun} is negative, so a negative number means higher sensitivity to punishment while a positive number means a higher sensitivity to reward (0 means equally sensitive to both types of feedback). This analysis informs about the relationship between the breadth of exploration (sampling from some or all the decks) and feedback sensitivity in the IGT. The correlation was -0.665, which reached statistical significance [$t(48) = -6.168$, $p < 0.001$] (Figure 5B). This suggests that higher sensitivity to punishment leads to sampling from more decks, which is consistent with our hypothesis that greater sensitivity to punishment leads to more exploration.

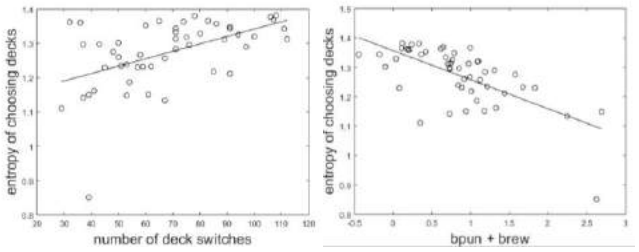

Figure 5: (A) Relationship between entropy and number of deck switches in the IGT. (B) Relationship between feedback sensitivity and entropy in the IGT.

Discussion

This article presents the results of an experiment aimed at understanding why some participants fail to select an optimal procedural strategy in II categorization and instead perseverate with using suboptimal rule-based strategies. By fitting the COVIS model to published II categorization data, we hypothesized that participants using an optimal strategy in II categorization would be more sensitive to punishment whereas participants using a suboptimal strategy would be more sensitive to reward. We further hypothesized that participants with a tendency to explore would be more likely to use an optimal strategy in the II task.

We tested these predictions by running participants in an II categorization task and the IGT. Decision-bound models were fit to II categorization data to classify each participant as optimal or suboptimal. The RW model was fit to the IGT to estimate each participant's sensitivity to reward and punishment. The number of deck switches and entropy of choice in the IGT were used to estimate the propensity of each participant to explore. The results partially supported our hypotheses. As predicted, exploration was related to the selection of an optimal strategy in II categorization. Sensitivity to punishment was also related to propensity to explore, but only in the IGT. The hypothesis that sensitivity to punishment would be related to the selection of an optimal strategy in II categorization was not supported in the experiment.

System-Switching vs. Rule-switching

Individuals vary considerably in terms of their sensitivity to reward and punishment. Sensitivity to reward can be described as how an individual's behavior is driven by reward-related stimuli, while sensitivity to punishment is described as how an individual's behavior is subdued by punishment-related stimuli. Studies suggest that individuals with greater sensitivity to reward are more reactive to rewarding outcomes but are less sensitive to monitoring loss, while greater sensitivity to punishment are linked to avoidance and giving up actions in absence of immediate reward (Kim et al., 2015).

As predicted by COVIS, the selection of certain strategies and the abandonment of others depends on the evaluation of how rewarding the strategy is. The implementation of one system over the other depends on the confidence and trust in the system. The trust is a function of the effect of received feedback when using a particular system. Thus, the switching of strategies from a rule-based to aa procedural strategy depends on the feedback received when using the particular strategy, which can be explained in terms of the reward and punishment the system or strategy gets when providing a response.

Our study confirms the finding that the selection of an optimal strategy in II categorization task is associated with greater sensitivity to punishment and perseveration with suboptimal strategies in II tasks is associated with greater sensitivity to reward. If the participant focuses more on the effect of punishment, losses in the task leads to giving up and avoidance of certain strategies, which leads to the possibility of adopting a strategy that leads to the optimal outcome. If the participant has greater sensitivity towards reward, s/he is less sensitive to immediate loss and tend to perseverate with strategies that bring a certain degree of rewards. In the II categorization task, participants tend to perseverate with a rule-base strategy since the strategy allows for a certain degree of accuracy (typically about 70%). However, additional research is required to determine how participants change from attending to specific stimulus dimension(s) to an integrated procedural-based strategy.

Exploration in the IGT

Deck switch is used as a measure of exploration. A larger number of deck switches indicates that participants were willing to disengage from the current strategy or deck, and

were willing to explore other possible options, despite the uncertainty and risk of getting punished. As seen in Figure 4, both optimal and suboptimal participants explored greatly in the IGT. The difference in exploration between optimal and suboptimal participants may have been caused by several factors, which includes willingness to take risk to maximize gain. The tendency for exploration appears to be robust and may be predictive of both rule-switching and system-switching. This was shown by the number of switches being both related to entropy in the IGT and the selection of an optimal strategy in II categorization. COVIS does not explicitly model exploration but a tendency to explore would be characterize by noise in system selection.

One observation is that many participants tend to choose Deck B in the IGT. With an expected value of a net loss of $250 and a relatively large loss of $1250 as compared to the other decks in the task, it would normally inhibit participants from selecting Deck B. The basic assumption is that the largest loss would trigger an alarming signal from the intact somatic system, thus inhibiting further selection of deck B as it guides the process of decision-making (Lin et al., 2007). However, Deck B has a low loss-frequency owing to a small number of trials with large losses (or can be seen as a high gain-frequency), which may explain why participants choose the deck despite great immediate loss when a penalty card is drawn from the deck. Most participants' behavior are driven by the high gain-frequency, instead of inhibited by the great loss while choosing Deck B (Dunn et al., 2006; Lin et al., 2007).

Participants that used suboptimal strategies tend to fixate on specific deck(s) and were not willing to explore for more reward, which might cause them to be stuck in a local minimum, and lose the chance to seek out strategies that are more efficient. The fixation can be due to contentment, unwillingness to take risks, or pros-to-cons weighing. Additional research is needed to determine why certain participants are reluctant to explore.

Future Work

This experiment came with a few limitations. Some of the advantage and disadvantage decks used in the IGT were difficult to identify through limited interactions with the decks, which might misguide participants while performing the tasks. For example, exploiting Deck B in IGT results in an overall loss, the frequency of loss is small. Hence, participants may consider Deck B to be an advantageous deck and continue choosing the deck along with other advantage decks. Questionnaires could be given to participants to ask for the decks the participants believed to be advantageous. This would allow for better understanding whether participants considered each deck as "risky" or not and disentangle risk taking from bad estimation of deck expectation.

Finally, a task needs to be designed that shares properties with the IGT but requires system-switching instead of rule-switching (or deck switching). This new task would allow to more directly estimated sensitivity to reward and punishment between-system and would provide a more definitive test of the hypothesis that optimal participants, who switch system in an II categorization task, are more sensitive to punishment then suboptimal participants, who are more sensitive to reward.

Abstract

Curiosity plays a critical role in our daily behaviors and interactions. Yet, very little is known about its psychological and neural underpinnings. By reframing curiosity as the motivation to obtain reward – where the reward is information –, and using frequency-based metrics of frontal brain lateralization, we aimed to investigate the neural correlates of curiosity in the frontal cortex and its effects on subsequent learning. Twenty-one undergraduate students participated in this two-day study by answering 35 general interest trivia questions, while EEG data was being recorded, also indicating their curiosity towards the question. One week later, participants were asked to write down the correct answers to each one of the questions. The results of this study suggested that frontal brain asymmetry (FBA) predicts memory recall, but is not directly correlated with self-reported curiosity. Study limitations and future directions are discussed.

Keywords: curiosity; EEG; frontal brain asymmetry; learning; memory

Introduction

Curiosity plays a critical role in many of our daily pursuits, actions, and interactions. It drives learning and promotes discovery, increasing our understanding of the world. Albert Einstein once said, "I have no special talents. I am only passionately curious" (Hoffmann, 1972, p. 7). Yet for something that drives much of our daily behavior and knowledge, very little is known about its psychological and neural underpinnings. Lowenstein (1994) was the first one to propose an information gap theory, suggesting that curiosity arises from a perceived information gap, that is, the disparity between what one knows and what one wants to know. According to him, curiosity seeks a subjective value: information.

Innovating from this theory, Marvin & Shohamy (2016) reframed curiosity as the motivation to obtain reward, where the reward is information. This information-as-reward framework was supported by the fact that curiosity shares behavioral and neurobiological properties with other reward-motivated behaviors, as the same dopaminergic neurons that signal changes in the value of the reward also code changes in the value of information (Hare, O'Doherty, Camerer, Schultz, & Rangel, 2008; Kang et al., 2009). Furthermore, high-curiosity information is associated with activation in brain areas known to respond to reward, which includes the caudate and the nucleus accumbens (Gruber, Gelman, & Ranganath, 2014; Kang et al., 2009), and there is a strong link between how valuable information is and the likelihood of remembering it (Gruber et al., 2014; Kang et al., 2009; Mullaney, Carpenter, Grothehuis, & Burianek, 2014). Research has also found that learning is driven not only by the absolute value of given information but also by an information prediction error (IPE), which is the difference between the reward expected and the reward received (Daw & Doya, 2006; Schultz, 2006; Marvin & Shohamy, 2016).

Although these studies demonstrate that curiosity conforms to basic characteristics of reward-motivated behavior, they leave open critical questions related to the extent to which this analogy is valid at a deeper level. The greatest problem is that almost all current studies that investigate curiosity rely primarily on self-reports as a way to measure it, which, despite being convenient and affordable, is knowingly not the most reliable technique currently available. This is due mainly to the lack of a well-known, comprehensive, and more credible method to investigate and measure curiosity.

Over the last decades, however, neuroscience research has developed significantly, and analyses of EEG data have become much more advanced. One of the more sophisticated frequency-based metrics is frontal EEG asymmetry, or frontal brain asymmetry (FBA). This index is commonly used as a tool to measure engagement and motivation, typically using alpha power (8 – 13 Hz) in electrodes over frontal cortical regions (channels F3 and F4). Previous studies have consistently found that greater activity in the left (F3) versus the right (F4) frontal cortex indicates positive feelings, higher engagement, and motivation (Davidson, 2004; Harmon-Jones & Gable, 2017). Evidence suggests that frontal lateralization can, in fact, be used to analyze people's engagement to media advertisements, market products, and services (Vecchiato et al., 2011; Yilmaz et al., 2014). Furthermore, research findings confirm the idea that frontal brain asymmetry modulates the probability to engage in reward-motivated behavior (Pizzagalli, Sherwood, Henriques, & Davison, 2005; Schmid, Hackel, Jasperse, & Amodio, 2017).

Therefore, our study aimed to expand from previous investigations on both curiosity and frontal brain asymmetry. By using the same information-as-reward approach, and reframing curiosity as the motivation to obtain reward – where reward is information –, we wanted to investigate if the same frameworks and methods currently used to study engagement and motivation can be used to measure curiosity in a more reliable way, serving as an alternative to the current self-reported measures. If this held true, we expected to see higher activation in the left frontal cortex – a greater frontal brain asymmetry – when people were exposed to high-curiosity information. We would also be able to correlate higher FBA scores to a higher likelihood of remembering the information. Hence, we aimed to investigate if frontal EEG alpha left asymmetry is (1) in any way related to self-reported curiosity and (2) a stronger predictor of subsequent learning. Our study may provide an initial framework for future studies on curiosity, as well as help to shed light on the functional significance of frontal EEG asymmetry on curiosity, learning, and other reward-motivated behaviors.

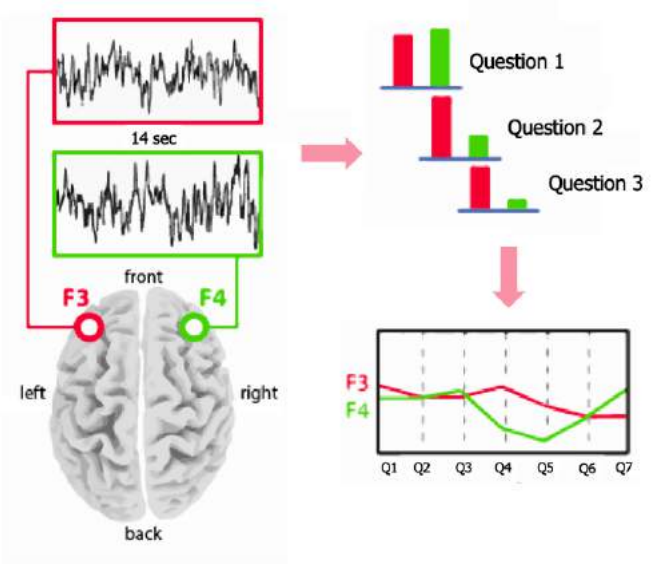

Figure 1: Illustration of EEG data collection. Raw EEG data was extracted from regions F3 and F4 (10/20 System Positioning) during the 14-second period in which each question was presented. The Fast Fourier Transform algorithm (FFT) was used to calculate the alpha power from each raw signal.

Methods

Participants

21 undergraduate students (mean age = 18.8 ± 1.1 year; 12 female, 9 male) at a college of liberal arts in the greater New York City area participated in this two-day study for partial course credit.

Materials & Equipment

Brain electrical data from this experiment was collected using electroencephalography (EEG) equipment, iWorx IX EEG 10-20 (iWorx Systems, Dover, NH) culled from two scalp sites (F3 and F4). The questions were presented on Apple Macintosh computers, using Qualtrics (2013) and the QuickTime Player (Cupertino, CA) to present stimuli and collect responses. The analysis of the EEG data was done on LabScribe Software, and all subsequent statistical analyses were done on R (R Core Team, 2013).

Procedure

The first session was about 45 minutes long, and the second one (a week later) was about 15 minutes long. On the first session, after providing written informed consent and answering a quick demographic questionnaire (which included age, gender, race and/or ethnicity, and handedness), participants were prepared for EEG recording. Before the primary task, two electrodes were placed on the participant's scalp (regions F3 and F4, 10/20 System Positioning; see Figure 1), and two minutes of EEG baseline was recorded. The experiment was a within-subjects design, where all participants were presented with a set of 35 general interest trivia questions culled from Internet sources (e.g., "What is the capital of Brazil?). Each question was presented on the laptop screen for 14 seconds. Participants were instructed to, after reading each question, type the answer down, and indicate their curiosity about the correct answer and their confidence in their guess. Then the question was presented again, followed by the correct answer (Kang et al., 2009). The same procedure was repeated for each and all of the 35 trivia questions, and the order of the questions was the same for all participants. EEG data was recorded for the entirety of the experiment. All participants were expected to come for a follow-up session one week later, although they were not aware of the purpose of the second session. For this session, the same 35 questions from the first day were presented and participants were asked to write down the answer to each one of them.

EEG Data Analysis

Alpha frequency band power was calculated by extracting frequency domain features from both left and right raw EEG signals (channels F3 and F4, respectively; see Figure 1). Since each question was presented for 14 seconds, we extracted the first seven 2-second epochs from each segment, and averaged them. The frequency domain analysis was performed using the Fast Fourier Transform (FFT) algorithm (with a frequency resolution of 1 Hz). The power spectra were reduced to the alpha frequency band, defined as between 8–13 Hz.

The frontal brain asymmetry index was calculated by dividing the alpha power values from the F4 (right) electrode by the values from the F3 (left) electrode. The results were computed using a natural log transformation to normalize the data as frequency power values tend to be severely skewed. This is illustrated by the following formula:

$$FBA\ Index = ln\left(\frac{F4\ right\ \alpha\ power}{F3\ left\ \alpha\ power}\right)$$

Since alpha power is inversely related to brain activity, positive asymmetry scores represented relatively greater alpha (less activity) over right than left hemispheres (Coan & Allen, 2004).

Data Preprocessing

The quality of the signal received from each electrode was evaluated during the entire EEG recording in order to make them both comparable and to avoid the influence of artifacts on the analysis. Offline visual artifact rejection was used to remove eye blinks, head movements, muscle activity, and other noise from the data. A subsequent round of artifact rejection was also conducted in which single trials containing voltage deviations of over 50 μV from normal baseline were manually rejected. Therefore, only artifact-free data from electrodes F3 and F4 were extracted and used in the analysis.

In addition to the EEG signal filtering, we also excluded trials based on whether or not the participant already knew the answers to the presented trivia, such that questions that were correctly answered by the participants during session one were not included in the EEG analysis. Therefore, our preprocessing filter yielded a total of 519 trials (332 correctly recalled, 187 not correctly recalled) across all 21 participants of this study.

Results

Self-Reported Curiosity and Frontal Brain Asymmetry

A correlational approach was used to assess links between reported curiosity and frontal brain asymmetry. Pearson's correlation coefficient indicated no statistically significant correlation between self-reported curiosity and FBA, neither for correctly remembered answers, $r(N = 21) = -.008$, $p = .486$, nor for incorrectly remembered answers, $r(N = 21) = -.290$, $p = .101$. Therefore, reported curiosity values were not linked to higher asymmetry values, on average (see Figure 2).

Frontal Brain Asymmetry and Learning

Participants on average remembered 62.1% of the answers correctly (range: 30.2% – 82.7%). A paired-samples t-test was conducted to compare FBA index, self-reported curiosity, and confidence level for both correctly remembered and incorrectly remembered answers (see Table 1). For confidence scores, there was a significant difference between incorrect ($M = 2.14$, $SD = 1.05$) and correct ($M = 2.69$, $SD = 1.17$) answers; $t(20) = 2.97$, $p = .008$. For curiosity scores, on the other hand, there were no statistically significant differences between incorrect ($M = 6.29$, $SD = 1.83$) and correct ($M = 6.63$, $SD = 1.43$) answers; $t(20) = 1.17$, $p = .254$.

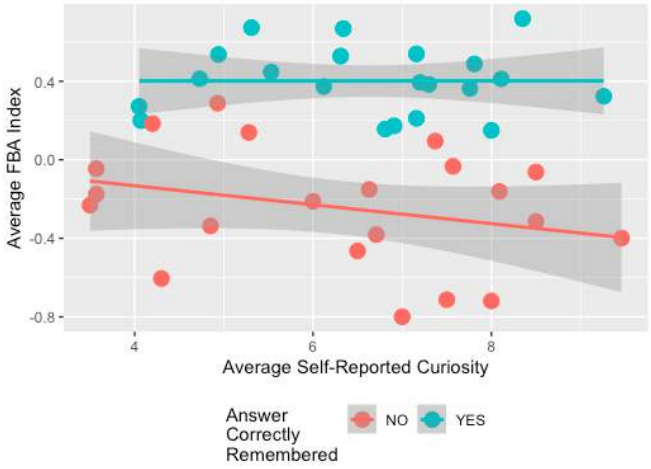

Figure 2: Scatterplot of self-reported curiosity and FBA. Each participant is represented by two dots, one orange and one green. Pearson's correlation coefficient indicated no statistically significant correlation between self-reported curiosity and FBA for neither correct nor incorrect answers (p=.486, $p = .101$).

For frontal brain asymmetry scores, the difference for incorrect ($M = -0.24$, $SD = 0.30$) and correct ($M = 0.40$, $SD = 0.17$) answers was statistically significant; $t(20) = 7.20$, $p < .001$. Specifically, participants' recall was better for trials in which they had higher asymmetry scores than those in which they had lower asymmetry scores (see Figure 3). These results suggest that FBA is linked to whether or not an individual remembered the information from the trivia questions correctly.

Discussion

This experiment investigated if frontal EEG alpha left asymmetry was (1) in any way related to self-reported curiosity and (2) a better predictor of subsequent learning. By using the information-as-reward approach, and after reframing curiosity as the motivation to obtain reward – where reward is information –, we investigated if the same methods currently used to study engagement and motivation can be used to measure curiosity in a more reliable way, serving as an alternative to the current self-reported measures. If asymmetry measurements in EEG recording were indeed a more reliable way to measure curiosity, we expected to see higher neural activity in the left frontal cortex – a greater frontal brain asymmetry – when people were exposed to high-curiosity information. This asymmetry index, then, would be a better predictor of whether or not the participant would remember the correct answer – if compared to the participant's self-reported curiosity levels.

The data indeed showed that there was a relationship between frontal brain asymmetry and subsequent learning:

Table 1
Descriptive Statistics and Paired t-test Results for Confidence, Curiosity, and FBA Index

	Not Correctly Remembered		Correctly Remembered			95% CI for Mean Difference		
Measure	M	SD	M	SD	n		t	df
Confidence	2.14	1.05	2.69	1.17	21	0.16, 0.92	2.97*	20
Curiosity	6.29	1.83	6.63	1.43	21	-0.27, 0.95	1.17	20
FBA Index	-0.24	0.30	0.40	0.17	21	0.46, 0.83	7.20*	20

* $p < .05$.

Table 1: Descriptive statistics and paired t-test results for confidence, curiosity, and FBA index. There are statistically significant differences, at the .05 significance level, in the correctness scores for confidence and frontal brain asymmetry, but not for curiosity. Results show that both confidence levels and FBA scores were higher for correctly remembered answers than for incorrectly remembered answers.

participants were significantly more likely to remember the correct answers for trials in which they had higher FBA scores (see Figure 3). Self-reported curiosity, on the other hand, was not associated with subsequent learning. For the second half of our research question, we utilized a bivariate correlational analysis to investigate whether frontal brain asymmetry and reported curiosity were linked to each other. We found that self-reported curiosity and FBA were not statistically significantly correlated, meaning that higher values of left hemisphere activation were not linked to higher self-given scores of curiosity (see Figure 2).

Because our study did not find any link between self-reported curiosity and frontal brain asymmetry, it is not possible to infer any relationship between these two variables. In other words, frontal brain asymmetry might not be a neural correlate of curiosity, as we had initially hypothesized. However, although our experimental study design avoids claiming causality, our results support the idea that frontal brain asymmetry might be a better predictor of subsequent learning and correct information recall than the curiosity scores reported by the participants. Differently from Marvin & Shohamy (2016), self-reported curiosity did not correlate with subsequent learning in our study. These data leave open critical questions related to the reliability of self-reports measures on research investigating curiosity. Given that the current studies on the topic rely primarily on self-reports as a way to measure curiosity due to its convenience and affordability, more research is needed in order to confidently state the effects of curiosity on memory and learning.

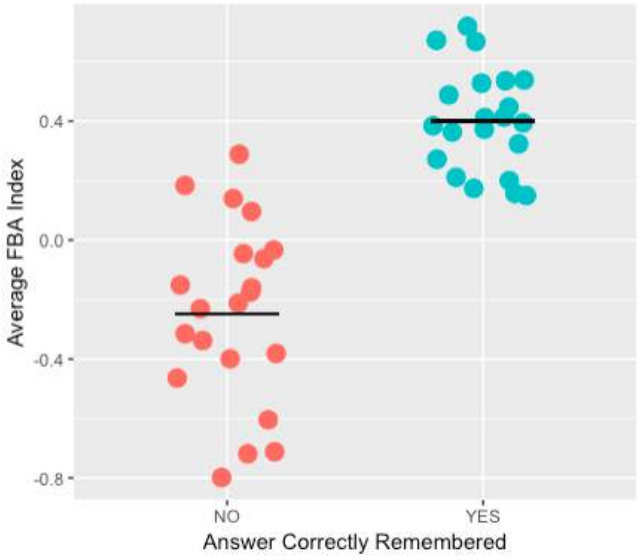

Figure 3: Plot of the mean differences in FBA between questions that were and were not remembered correctly (the black lines indicate the mean for each). Each participant is represented by two dots, one orange and one green. Participants' recall was better for trials in which they had higher asymmetry scores than those in which they had lower asymmetry scores ($p < .001$).

Moreover, the variable confidence level showed a significant effect on the correctness of the responses in the retest ($p = .008$). Subjects were more likely to provide a correct answer during the retest when the same question on the pretest was answered incorrectly but with a high level of confidence. These results are in accordance to previous studies on hypercorrection, which suggest that high-confidence errors tend to be corrected at a higher rate on retests, when compared to low-confidence ones (Metcalfe & Finn, 2011; Metcalfe & Miele, 2014).

Our study also found that there is a positive relationship between frontal brain asymmetry and subsequent learning (see Figure 3). More specifically, correct answers have a significantly higher FBA index than incorrect answers ($p < .001$). Future research is necessary, however, in order to investigate *why* this relationship exists. Previous studies have suggested that greater activity in the left versus the right frontal cortex indicates positive feelings, higher engagement, and motivation (Davidson, 2004; Harmon-Jones & Gable, 2017). Although these correlates of FBA might play a role in whether a participant will remember the correct answer or not, only future studies might be able to indicate if this is true.

The present study is not without limitations. The number of participants included in the final analysis was relatively

small ($N = 21$). Future work should aim to collect and analyze data from a more extensive poll of participants in order to examine if findings will hold true with more data. Furthermore, the equipment used in this study was quite rudimentary if compared to more expensive and sophisticated EEG equipment and software used in first-class clinical settings and research labs.

By any means our study intends to be a definitive verdict or conclusion for the topic. Instead, it aims to provide an initial – but valuable – framework, upon which future studies can be built. Additionally, our study may have implications in the field by providing a helpful framework for more advanced research on the functional significance of frontal EEG asymmetry on learning and other reward-motivated behaviors such as curiosity. More broadly, given the importance of curiosity in our daily decisions and behaviors, these works could have important implications for studies in several different academic areas, including psychology, neuroscience, medicine, marketing, and education, and may contribute to the development of new strategies for improving memory and learning in both school and therapeutic settings.

Acknowledgments

The authors would like to thank Dr. Christopher Medvecky, Dr. Patrick Dolan, and Dr. Graham Cousens for their help and insightful feedback. Gabriel Lima was responsible for the conception and design of this study, data collection, analysis and interpretation of the data, and manuscript writing. Fabiana Rocha was responsible for data computing and manuscript writing. This research was made possible by the funding support from the Psychology Department at Drew University.

Rapid information gain explains cross-linguistic tendencies in numeral ordering

Abstract

One previously unexplained observation about numeral systems is the shared tendency in numeral expressions: Numerals greater than 20 often have the larger constituent number expressed before the smaller constituent number (e.g., *twenty-four* as opposed to *four-twenty* in English), and systems that originally adopt the reverse order of expression (e.g., *four-and-twenty* in Old English) tend to switch order over time. To explore these phenomena, we propose the view of Rapid Information Gain and contrast it with the established theory of Uniform Information Density. We compare the two theories in their ability to explain the shared tendency in the ordering of numeral expressions around 20. We find that Rapid Information Gain accounts for empirical patterns better than the alternative theory, suggesting that there is an emphasis on information front-loading as opposed to information smoothing in the design of large compound numerals. Our work shows that fine-grained generalizations about numeral systems can be understood in information-theoretic terms and offers an opportunity to characterize the design principles of lexical compounds through the lens of informative communication.

Keywords: language universals; numeral system; lexical compound; information theory; informative communication

Number is a fundamental domain of human cognition (Spelke & Kinzler, 2007), but numeral systems vary substantially across cultures (Comrie, 2013). For instance, some cultures in the Amazon lack exact numerals for expressing numbers beyond 5 (Gordon, 2004; Pica, Lemer, Izard, & Dehaene, 2018). Some languages use body parts to describe numbers (Comrie, 2013). However, the majority of languages in the world define numbers precisely and over a large range through recursive numeral systems (Comrie, 2013). Recent work has suggested that the diversity of numeral systems is constrained by the need for efficient communication (Xu & Regier, 2014; Kemp, Xu, & Regier, 2017). By this account, numeral systems are designed to facilitate highly informative communication of numbers, despite their differences in complexity.

The proposal of informative communication helps to explain why numeral systems vary the way they do, but it does not directly account for fine-grained generalizations about numeral expressions. In particular, many languages express compound numerals by specifying the larger constituent number first (e.g., *twenty-four* in English or Mandarin), and fewer languages express these in the reverse order (e.g., *vierentwintig* in Dutch, interpreted as "four twenty"). Moreover, numeral systems that originally use the reverse order of expression (e.g., Old English expresses 24 as *four-and-twenty*) tend to switch order over time (Berg & Neubauer, 2014). This preference of having the larger constituent number expressed before the smaller constituent number is prevalent in numerals for the range above 20 but less prominent for smaller numbers (Calude & Verkerk, 2016). Here we ask what principles might account for this shared tendency in numeral ordering.

This problem has been discussed by Greenberg in his cross-linguistic generalization about the design of recursive numerals (Greenberg, 1978). Recursive numeral systems represent numbers based on the canonical expression $x_1 n^k + ... + x_k n + y$. Here n is called the base and the values of x_i's and y are in the range of 1 to the base (Comrie, 2013). For numbers in the range $1-100$ in a base-10 system such as English or Mandarin, xn will be considered the *base* term (i.e., 10, 20, ..., 90) and y (i.e., 1, 2, ..., 9) will be considered the *atom* term. Greenberg observed that if a numeral system has both atom-base (e.g., *fifteen*) and base-atom (e.g., *twenty-four*) orderings in its numeral expressions, the system will always begin with atom-base, and then switch to base-atom at some number on the number line (Greenberg, 1978). In English and many other languages, this switch takes place at 20.

Independent work from Hurford has sought to address this phenomenon in light of the "packing strategy" (Hurford, 2007). According to this proposal, numeral expressions should allow one to go as far as possible along the number-line with a given set of terms (Hurford, 2007). This would imply that terms should be arranged in decreasing order, with the larger constituents coming first, and it confirms that the base-atom order should be preferred over the atom-base order. Although this work provides an intuitive theory for the ordering preference in large numerals, it leaves open two important questions: 1) why the base-atom order is preferred across languages for numbers above 20, but this preference is substantially less for smaller numerals (e.g., 11 to 19), and similarly, 2) why ordering switch should typically take place in numerals above 20 and in particular, why it occurs only in one direction (atom-base→base-atom) but not in the other (base-atom→atom-base).

We examine the problem of numeral ordering through the lens of informative communication. Consistent with the growing literature on this topic, we suggest that language design is driven by the basic need for efficient communication (Gibson et al., 2013; Kemp et al., 2017). Extending this line of research, we propose the view of *Rapid Information*

Gain (RIG) that focuses on explaining the design of compound numerals, particularly the ordering of constituent expressions in terms of the need to optimize information flow. We hypothesize that lexical ordering of a compound numeral expression should maximize information gain for the listener in the process of reconstructing the speaker's intended referent. We contrast this view with the established theory of Uniform Information Density (UID) postulating that information smoothing should be preferred (instead of information front-loading) in word ordering in sentences, online (Levy & Jaeger, 2007) or offline (Maurits, Navarro, & Perfors, 2010). We show that RIG explains empirical patterns better than UID in the domain of numerals, and we believe this work has the potential for developing a domain-general account of the design principle of lexical compounds.

Two theories of informative communication

We present the numeral ordering problem in a simple communicative scenario, illustrated in Figure 1a. Here the speaker has the target number 85 in mind and wishes to convey that number to the listener. We consider two possibilities in the ordering of constituent expressions of that numeral, using English as an example: 1) "Eighty-five", which is the *attested order* or base-atom; 2) "Five-eighty", which is the *alternate order*, or atom-base in this case. The problem is to determine which order should be generally preferred in natural languages and in what range of the number line this preference might be most prominent.

We postulate that the preferred numeral order should tend to minimize the listener's uncertainty in reconstructing the target number as the speaker's utterance is processed. We consider how uncertainty arises over time in the listener's mind as the constituent expressions are uttered sequentially by the speaker. Based on the ordering of "eighty-five", upon hearing the first constituent "eighty", the listener would consider numbers in the range 80-89 as possible candidates for the target, because numerals for numbers within that range all begin with the same constituent. In this case, uncertainty depends on the probability ratio between the actual target and the candidate set. Based on the ordering of "five-eighty", upon hearing the alternative first constituent "five", the listener would instead consider numerals that begin with "five" (e.g., 5, 15, ..., 85, 95) as the candidate set for the target. We illustrate these alternative candidate sets in Figure 1a.

We consider two alternative theories that quantify uncertainty given choices of numeral ordering based on Shannon's information theory (Shannon, 1948). The first view is based on Uniform Information Density (Levy & Jaeger, 2007), which predicts that uncertainty incurred should be as smooth as possible. This view suggests that the listener would experience a uniform information flow as a compound expression is uttered. We propose a second view, Rapid Information Gain, that makes the alternative prediction. We hypothesize that the preferred order in compound numerals should tend to front-load information as opposed to smoothing information, such that uncertainty in the listener can be reduced as quickly as possible. We illustrate the predicted uncertainty profile from each theory in Figure 1b. As we show later, the property of information front-loading is more salient in the ordering of larger numbers (>20) than in the case of smaller numbers, which explains why the cross-linguistic preference and the ordering switch toward base-atom expressions are stronger for larger numbers. We now describe the details of each theory.

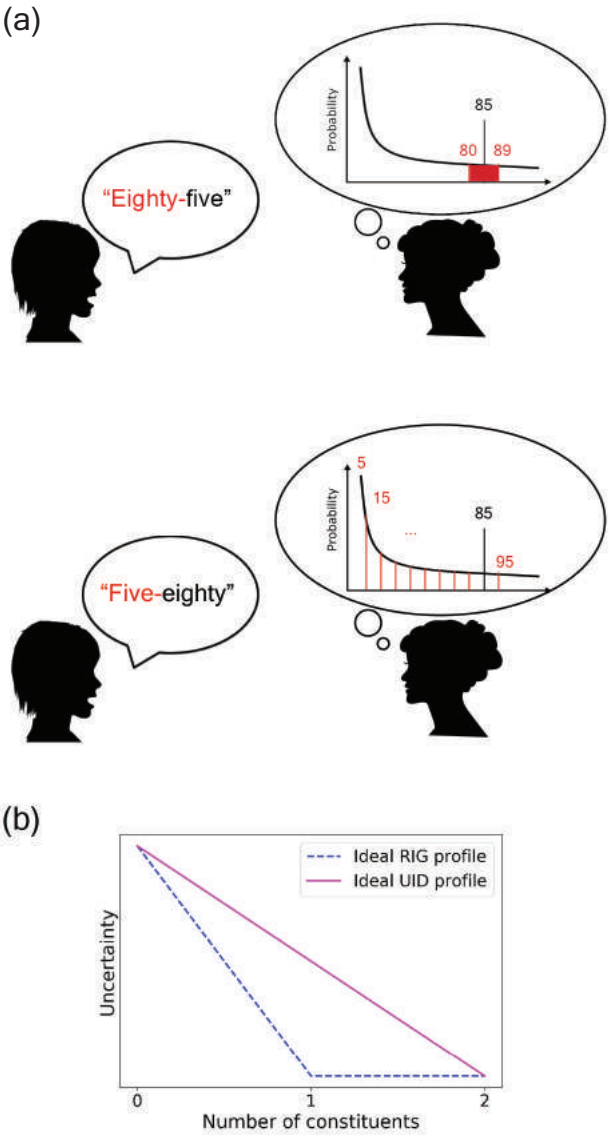

Figure 1: Illustration of the numeral ordering problem and the two theoretical proposals of informative communication.

Uniform Information Density (UID). Following Shannon (1948), we define uncertainty by surprisal or negative log probability $-log_2(p(\cdot)) = log_2(\frac{1}{p(\cdot)})$. We define the information content of a compound linguistic expression by the sum of surprisals from its sequential constituents, following the

formulation of UID (Levy & Jaeger, 2007). The cumulative information conveyed by an expression U with n constituents $w_1...w_n$ in reference to a target t is the following:

$$log_2\frac{1}{p(U)} = log_2\frac{1}{p(t)} + log_2\frac{1}{p(t|w_1)} + ... + log_2\frac{1}{p(t|w_1...w_n)} \quad (1)$$

In the case of two-constituent numeral expressions such as *twenty-four* (i.e., base constituent and atom constituent), this formulation effectively captures the information flow of a compound numeral as it is processed incrementally in terms of its constituent expressions:

$$log_2\frac{1}{p(t)} \rightarrow log_2\frac{1}{p(t|w_1)} \rightarrow log_2\frac{1}{p(t|w_1w_2)} \quad (2)$$

Cumulative surprisal defined in Equation 1 can thus be simplified to

$$log_2\frac{1}{p(U)} = log_2\frac{1}{p(t)} + log_2\frac{1}{p(t|w_1)} + log_2\frac{1}{p(t|w_1w_2)} \quad (3)$$

As such, the cumulative surprisal of hearing "twenty-four" would be $log_2\frac{1}{p(\text{“twenty-four”})} = log_2\frac{1}{p(24)} + log_2\frac{1}{p(24|\text{“twenty”})} + log_2\frac{1}{p(24|\text{“twenty-four”})}$.

Empirical studies of UID typically focus on speaker information modulation given the predictability of different units. This would involve measuring information-theoretic entropy rather than surprisal formulated here. However, the UID principle implies that the flow of information to follow a uniform trajectory in cumulative surprisal, and we test the applicability of this proposal in the case of numeral ordering.

More specifically, UID suggests an even distribution of information (in the design of compound numerals), such that the amount of information conveyed in the sequence of constituents should be identical. This predicts that if the speaker has alternative ways of ordering a numeral expression, she should choose the order in which information is distributed more evenly. Here we are interested in the cost of a numeral order versus its reverse order, and we quantify cost by measuring how a numeral order deviates from the theoretical UID information flow. Prior work has taken a similar approach to examine whether UID predicts preferred word orders (e.g., subject-verb-object) across languages (Maurits et al., 2010). In that work, deviation from UID is defined by the percentage deviation from the theoretical UID information flow. Abbreviating the components of the information flow in Equation 2 by $I_0 = log_2(\frac{1}{p(t)})$, $I_1 = log_2(\frac{1}{p(t|w_1)})$ ..., we measure the deviation from UID following Maurits et al. (2010):

$$d = \frac{n}{2(n-1)}\sum_{i=1}^{n}|\frac{I_{i-1}-I_i}{I_0} - \frac{1}{n}| \quad (4)$$

Here n is the phrase length of an expression (Maurits et al., 2010). In our work, we use the same formula to quantify how the design of a numeral expression deviates from UID. Concretely, we consider $n = 2$ because each compound numeral expression that we use for analyses has two constituents. We also know that $I_2 = 0$ since full certainty is obtained after the second (or last) constituent of a numeral is uttered. UID predicts a linear relationship between information content and number of constituents. If UID explains the shared tendency in numeral ordering across languages, we should expect the attested numeral order to yield a smaller deviation from the linear information profile than the alternate order, more so for the numerical range above 20 than the range under 20.

Rapid Information Gain (RIG). We propose an alternative theory for numeral ordering based on rapid information gain. We postulate that the ordering of numerals should facilitate quick delivery of information to the listener, such that the constituent expression that contains more information should be arranged prior to the constituent that contains less information. This notion of rapid information gain is related to work on optimal data selection. For instance, when performing a series of tasks, optimal data selection implies that people should order the tasks so that they gain the most information possible at each step (Oaksford & Chater, 2003). We believe that similar principles apply to the design of numerals. Our proposal is not equivalent to the claim that the larger numeral should always precede the smaller numeral in a compound (Hurford, 2007; Berg & Neubauer, 2014). Instead, it suggests that the ordering of constituent numerals depends on the amount of information they convey, as opposed to their magnitudes per se. We demonstrate later that our proposal correctly predicts information front-loading to be more critical for high-order numbers than low-order numbers, an aspect that could not be explained fully by a magnitude account that always predicts the larger numeral to be expressed first in a compound numeral.

We evaluate our proposal by measuring the cumulative surprisal of a numeral expression over its constituents:

$$c = \sum_{i=0}^{n} I_i \quad (5)$$

This formulation is the same as Equation 3, and we consider $n = 2$ and since $I_2 = 0$, $c = I_0 + I_1$. The RIG theory predicts an elbow-like information profile which differs from the linear profile predicted by UID (see illustrations of the two theoretical information flows in Figure 1b). We expect that a lower cumulative surprisal should generally be preferred as a consequence of rapid information gain. More specifically, the attested numeral order should yield a lower cumulative surprisal than the alternate order when there is a strong preference toward the attested order (e.g., for numbers >20), but the two possible orders might yield similar cumulative surprisals when there is greater flexibility in the ordering conventions of numerals across languages (e.g., for numbers <20).

Materials and methods

To facilitate the information analyses and evaluation of the two theories, we collected numeral frequencies for estimating surprisals along with cross-linguistic numeral data.

Numeral frequencies. We estimated probabilities of the number terms for the range 1-100 (following Xu & Regier, 2014) in 8 different languages: English, French, German, Hebrew, Italian, Mandarin, Russian, and Spanish. We collected these frequency data from the Google Ngrams corpora (Michel et al., 2011) by averaging numeral frequencies from 1900 to 2000. We used part-of-speech tags for numerals in the corpus if those were available for a given language. For each language, we queried frequencies of numeral terms from a standard set of numeral expressions (data from `www.sf.airnet.ne.jp/ts/language/number.html`). When multiple expressions were available for a numeral, we took the most frequent expression. The frequencies of the numerals for each of the languages were normalized to probabilities so that they sum to 1.

Calculation of surprisals. To calculate surprisals, we decomposed a numeral expression into two separate constituents, atom and base, while ignoring connectives such as hyphens, e.g., "twenty-one" $\rightarrow$ ["twenty", "one"]. Although it is possible to split some terms into multiple constituents, e.g. "quatre-vingts huit" (4x20+8=88) $\rightarrow$ ["quatre", "vingts", "huit"] ([4, 20, 8]), we chose to split only along additive terms for consistency. We did not choose to treat suffixes as separate constituents. We calculated the surprisal based on each constituent expression, where surprisal is the negative log probability of the target number being correctly inferred from the set of candidate targets. Finally, for each numeral expression we computed the deviation from UID according to Equation 4 and the cumulative surprisal for RIG according to Equation 5.

Cross-linguistic numeral data. We tested the theories against numeral data collected from 334 languages in 53 listed language families sampled from *Numeral Systems of the World's Languages* (Comrie & Chan, 2018). We sampled languages evenly from each family whenever possible, taking 10 from each family, or if 10 were not available, taking the maximum number possible. This was so that language families with a large number of languages such as Indo-European or Sino-Tibetian did not bias the sample. For each language, we recorded the attested orders in the numeral expressions, atom-base or base-atom, for the numerical ranges of 11-19 and 21-29 (chosen to be symmetric about 20 where order switch most commonly takes place). If a language did not have sufficient data for the numerical ranges, we would exclude that language and sample other languages from the family until 10 or the maximum possible number were collected.

Results

Empirical patterns in the ordering of numerals. We first present cross-linguistic tendencies and switches in "atom-base" and "base-atom" ordering of numeral expressions in the sample of 334 languages that we considered. Table 1 summarizes the cross-linguistic occurrences for these orders in the numerical ranges 11-19 and 21-29. If the atom-base ordering was used for at least one term in 11-19 in a language, we considered that language as having an atom-base ordering in that range. We observed that the base-atom order is attested in more than 96% of the languages for the range 21-29, whereas this order is attested much less commonly in about 76% of the languages for the lower range 11-19. This finding confirms descriptive generalizations from previous work (e.g., Greenberg, 1978) and indicates an asymmetric preference toward base-atom ordering in larger numerals, and more flexibility in the ordering of smaller numerals.

Table 2 confirms that the same asymmetric preference applies to switches in the ordering of numerals. In particular, out of all languages that were attested to have switched order in numeral expressions, switch took place exclusively in the direction atom-base $\rightarrow$ base-atom but not in the opposite direction. Moreover, out of the 63 languages that use the atom-base order for expressing the numerical range 11-19, 52 (or $\sim$83%) switch the order to base-atom but only for numerals expressing the range 21-29. Together, these empirical data suggest that preference toward the base-atom order is more prominent in larger but not smaller numerals.

Numeral frequencies across languages. Figure 2 summarizes the meta-mean and language-specific probabilities of numerals, estimated from the corpus-based frequencies over the past 200 years. These probability profiles show a consistent near-logarithmic decay that confirms previous findings in cross-linguistic numeral and digit-based frequencies (Greenberg, 1978; Calude & Verkerk, 2016): Numerals in the lower numerical range tend to be referred to more frequently than numerals in the higher range. We used these probabilities for surprisal calculations for the two theories.

Table 1: Ordering conventions in numerals across languages.

Number of languages	Range 11-19	Range 21-29
atom-base ordering	63	11
base-atom ordering	271	323

Table 2: Switch in numeral ordering conventions. For each language, the original numeral order is the same as that in the lower range 11-19, and ordering switch is attested in numerals for the upper range 21-29.

Number of languages	No switch	Switched
atom-base $\rightarrow$ base-atom	11	52
base-atom $\rightarrow$ atom-base	271	0

Evaluation of the two theories. We evaluated UID and RIG by first considering a "template" language that reflects the cross-linguistic tendency in numeral ordering we and other scholars have observed: Atom-base order in numerals

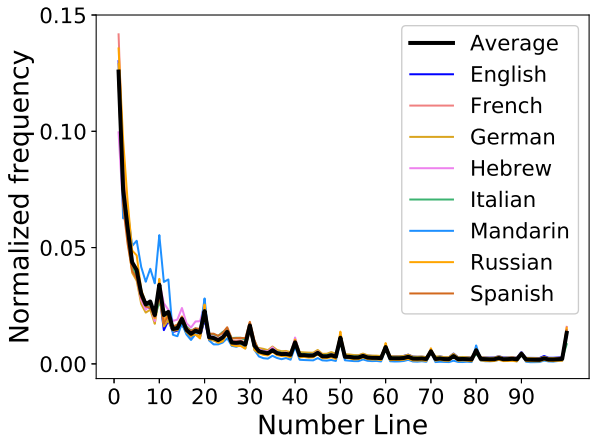

Figure 2: Numeral frequencies across 8 languages.

for the range 11-19, and base-atom order in numerals for the range above 20. An ideal theory should explain 1) why there is a strong preference for the attested base-atom order over the alternate atom-base order in the upper numerical range; 2) why this preference between the attested and alternate orders is much weaker in the lower range. As such, we expected a greater discrepancy in the attested and alternate orders for the theoretically predicted information profile we described (e.g., under UID or RIG), and a substantially smaller discrepancy in these orders for the same measure of information. To test these ideas, we calculated the information profile for each of the numerals within the range 1-100 based on the mean numeral probabilities we had obtained. We performed these calculations for both the attested order and the alternate order, resulting in two sets of measures for UID deviation and two sets of measures for RIG cumulative surprisal.

Figure 3 (a) and (d) summarize the results. At the broad level, both UID and RIG identify the attested order to be closer to their theoretical information profiles than the alternate order. However, a closer examination of these results reveals variation in the precision of these theories. For the numerical range beyond 20, UID shows an ambivalent preference toward the base-atom order over the atom-base order, manifested in the noisy deviation scores between the two orderings. In contrast, RIG provides a clearer advantage of the base-atom order over the atom-base order for numerals in the same range, indicating that there is a dominance toward the first order as predicted by this theory. Moreover, for numerals in the range 11-19, UID shows a strong support for the base-atom order, but RIG shows that both orderings render roughly equal cumulative surprisals—this suggests that information front-loading is less relevant to ordering variation in this lower numerical range.

To further examine the precision of the two theories, we examined their predictions for two sample languages, English and Mandarin. For these cases, we used language-specific numeral probabilities for calculations of UID deviation and RIG cumulative surprisals. Figure 3 shows that the results for these individual languages are consistent with our findings with the template language, such that RIG provides a more precise explanation for the asymmetric preference in ordering of larger and smaller numerals. Figure 4 illustrates the information profiles in the attested and alternate orders with two example numerals, *fifteen* and *twenty-four* in English, along with the theoretical predictions from UID. In both cases, the attested order shows an elbow-like information profile that deviates from the ideal linear profile of UID, providing evidence against the idea that numerals are designed under the criterion of information smoothing. Importantly, the information profile under the alternate order for *fifteen*—a low-order numeral—is almost identical to the elbow-like profile under the attested order, reflecting the fact that information front-loading is insensitive to ordering of numerals in this range. It is worth noting that both alternate and attested profiles deviate from the UID prediction. In addition, for *twenty-four*, the alternate order produces an information profile that approaches the UID prediction. This profile yields a cumulative surprisal higher than the attested order, suggesting information front-loading is desirable for larger numerals in English.

As a final analysis, we examined whether the preferred ordering switch from atom-base to base-atom can be explained away by the theory of RIG. In particular, we performed a focused analysis that compares cumulative surprisal between these two orders for the numerical ranges 11-19 and 21-29 respectively. We expected that the cumulative surprisal might be comparable under the two orders for the smaller range, but substantially discrepant for the larger range, which would explain why switching of order tends to occur beyond 20 and only in the atom-base $\rightarrow$ base-atom direction.

For each of the numerical range in question, we conducted a permutation test that shuffles the numeral expressions between the base-atom and atom-base orders. We then repeated the shuffle 100,000 times and for each repetition, calculated the mean difference in cumulative surprisal between the two orders. This effectively helped construct the null hypothesis that there should be no between-order difference in cumulative surprisal. We also calculated the same quantities for the unshuffled data, and compared those against the null distributions for the two numerical ranges of interest. Figure 5 shows that there is no statistical significance ($p = 0.56$) to reject the null for the range 11-19, but there is high statistical significance ($p < 0.004$) in rejecting the null for the range 21-29. These results provide evidence for the idea that information front-loading is equally prominent under atom-base or base-atom orderings for smaller numerals, but it is more prominently represented in the base-atom order as opposed to the atom-base for larger numerals. Possibly due to this reason, historical changes in ordering convention of numerals tend to occur uni-directionally beyond but not below 20.

Discussion

We investigated two theories for explaining the shared tendency in the ordering of numeral expressions. We found that

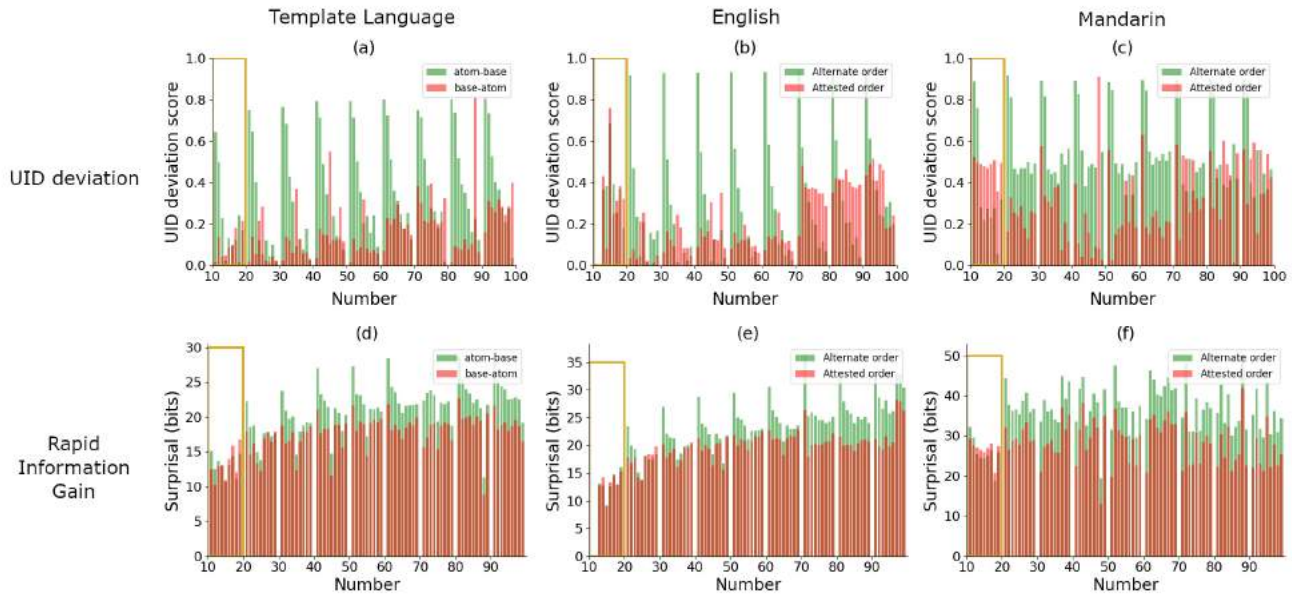

Figure 3: UID deviation (top row) and cumulative surprisal (top row) for template language, English, and Mandarin.

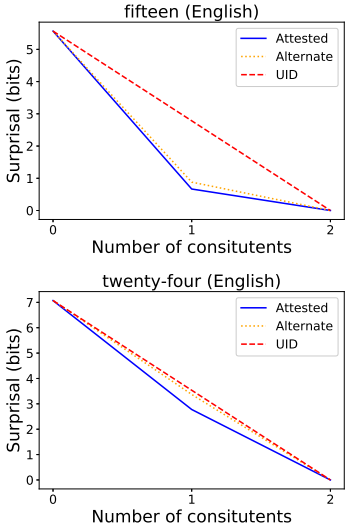

Figure 4: Information flows under alternative orders of expression for English numerals 15 and 24. The attested order for 15 is atom-base ("fifteen"), and the alternate order is base-atom ("teenfif"). The attested order for 24 is base-atom ("twenty-four"), and the alternate order is atom-base ("four-twenty"). "UID" refers to the UID theoretical prediction.

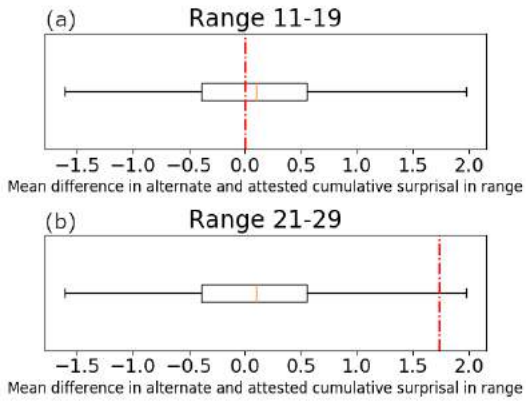

Figure 5: Permuted surprisals with attested ones marked.

the proposal of rapid information gain provides a better account for the empirical data across languages than the existing theory of uniform information density. Our findings suggest that the dominant preference toward the base-atom ordering in larger numerals reflects the need for information front-loading as opposed to information smoothing, and greater flexibility in the ordering of smaller numerals is explained partly by the fact that information flow is less affected by ordering conventions in numerals for the lower range. Our study differs from existing research in UID that focuses on information processing at the sentence level. Our emphasis is to characterize the design principles of complex lexical items, particularly compounds. This difference in the level of analysis might provide one explanation as to why UID does not predict as well in the current study. An alternative possibility is that the domain of numerals has characteristics that make a uniform information flow less desirable than information front-loading. Future research should delineate when UID might apply and when alternative principles such as RIG are more appropriate. It is also worth exploring whether the RIG principle can be applied to compounds in other domains.

Abstract

Verb learning is important for young children. While most previous research has focused on linguistic and conceptual challenges in early verb learning (e.g. Gentner, 1982, 2006), the present paper examined early verb learning at the attentional level and quantified the input for early verb learning by measuring verb-action co-occurrence statistics in parent-child interaction from the learner's perspective. To do so, we used head-mounted eye tracking to record fine-grained multimodal behaviors during parent-infant joint play, and analyzed parent speech, parent and infant action, and infant attention at the moments when parents produced verb labels. Our results show great variability across different action verbs, in terms of frequency of verb utterances, frequency of corresponding actions related to verb meanings, and infants' attention to verbs and actions, which provide new insights on why some verbs are harder to learn than others.

Keywords: verb learning, motion verb, attention, head-mounted eye-tracking, infant-parent dyads

Introduction

Language learning depends on both the internal learning mechanisms and the data on which those mechanisms operate. Many experimental studies have focused on examining the internal learning mechanisms by using well-controlled and well-balanced stimuli as the input. A recent trend in the field of language acquisition is to examine natural statistics in everyday learning contexts (e.g. Pereira, Smith, & Yu, 2014). For example, recent studies have shown that both the quantity and quality of parent language input are predictive of children's later language development (Hart & Risley, 1995; Hoff, 2003; Weisleder & Fernald, 2013). In the present study, we used the same approach to examine the input for early word learning. One of the challenges in early word learning is to figure out the correct mapping between a word and a referent (Quine, 1960). Given many possible referents in the moment when a word is heard, young learners need to attend to the right referent at the right time in order to learn the meaning of a word. However, we do not yet know what input from the environment is available to the child and what input attended by the child is therefore processed by the internal learning mechanisms.

A large proportion of early vocabulary is composed of concrete nouns and concrete verbs. Previous studies on learning concrete nouns found that children need to select and attend to the right object at the right time from an ambiguous learning environment when hearing its name (Golinkoff, Hirsh-Pasek, Bailey, & Wenger, 1992; Yurovsky, Smith, & Yu, 2013; Yu & Smith, 2007; Gleitman & Trueswell, 2018). In addition, Pereira, Smith and Yu (2014) found that when the named target is visually large and more centered in the child's view and when these optimal visual properties last longer before and after parent's naming, children are more likely to attend to the named object and learn its label. Thus, learning object names with perceptually grounded meanings requires not only hearing the words from parent speech but also showing sustained attention to the intended referent. However, little is known about whether learning concrete verbs also requires young learners' sustained attention when mapping verbs to visually grounded actions. Most experimental studies on verb learning have been focused on testing how well young children build verb-action mappings when presented with a verb and an action in well-controlled laboratory settings (Imai et al., 2008; Hirsh-Pasek & Golinkoff, 1996; Maguire et al., 2008; Golinkoff et al., 2002; Pulverman, Golinkoff, Hirsh-Pasek, & Buresh, 2008; Monaghan, Mattock, Davies, & Smith, 2015, Messenger, Yuan, & Fisher, 2015; Scott & Fisher, 2012). The learning tasks for young children in those experimental setups were well-controlled to minimize distraction, which is very different from learning verbs in the real world. Referential uncertainty created during naturalistic interactions may be different from that created for traditional lab tasks, thus it may influence how children process information differently.

Imagine a naturalistic context for early verb learning such as toy play, when a parent names a verb (e.g. "Can you shake it?") while demonstrating the shaking action. The meaning of "shake" is presented briefly as the parent is not likely to keep shaking the object. If the infant does not attend to the action when hearing the word "shake" and when the action is produced, it would be impossible for the infant to build the association between the word "shake" and the action "shake". This example reflects the transient nature of the action referent and lead to important research questions related to early verb learning that have not been examined at the

perceptual and attention levels. For example, compared with object names, how frequently do parents mention action verbs in their speech in everyday learning contexts? When parents produce a verb in speech, how likely there is a corresponding action in the learning environment that reveals the meaning of the verb? If there is an action in accompany with parent speech, how likely do infants attend to the action to build a verb-action mapping?

To answer these questions, we need to examine parents' and children's behaviors from natural learning environments. We used head-mounted eye-tracking techniques to record fine-grained multimodal behaviors during parent-infant joint play. We analyzed parent speech, parent and infant action, and infant attention at the moments when parents produced verb labels. By doing so, we will be able to provide new evidence on how easy or hard for young children to learn early verbs and discover new elements -- at the attentional level -- that matter to early verb learning. Our overarching goal was to quantify word-referent co-occurrence statistics in parent-child interaction from the learner's perspective and examine what information infants select to attend when a verb is heard.

Method

Participants

Thirty-three infant-parent dyads with infants (12 female) ranging from 15.2 to 25.3 months (M = 19.52, SD = 2.42) were included in the final sample.

Stimuli and Experimental Setup

Parents and their infants were invited to play with a set of 24 toys in a playroom (Figure 1A). The toys were randomly spread out across the floor at the beginning of each play session. Parents and infants both sat on the floor and parents were told to sit in any orientation with their child but were instructed to try to keep their child sitting on the ground as much as possible during the play session. We observed that parents and infants naturally generated various types of manual actions during toy play. For example, they used a toy saw to pretend to cut other objects; they put a doll on a toy bed; they played with a car toy to generate actions like turning; and they stacked one toy on top of others, etc. While playing, parents also verbally described those manual actions generated by themselves or by infants.

Figure 1A: Experimental setup

Figure 1B: Examples from the infant egocentric view. The crosshair in each example indicates the infant's gaze direction.

Eye-tracker and Calibration

Parents and infants wore head-mounted eye trackers (Positive Science LLC). The tracking system has been successfully used in both infant and adult experiments (Franchak & Adolph, 2010; Yu & Smith, 2017). The eye-tracking system includes an infrared camera mounted on the head and pointed to the right eye of the participant that records eye images and a scene camera that captures and records images from the participant's perspective. The visual field of the scene camera is 108° (Figure 1B). Each tracking system – the infants' and parents' – recorded egocentric video and the x- and y-position of the right eye in the captured scene at a sampling rate of 30Hz. For eye-tracker setup, one experimenter engaged with the infant with an enticing toy while the second experimenter affixed the eye-tracker on the parent. After the parent's eye-tracker was secure and the scene and eye cameras were properly adjusted and oriented, both experimenters and the parent worked together to place the headgear and eye-tracker on the infant. The parent and one of the experimenters played with the infant while the other experimenter placed the infant's headgear (a small hat with Velcro stickers on the forehead) on the infant.

Instructions and Procedure

After the calibration phase, one of the experimenters distribute the set of toys on the floor and leave the parent and infant to play. The experimenters watch the interaction in an adjoining room and monitor the parent's and infant's eye and scene live streaming videos. If infants touch the camera or bumped the camera with a toy, the experimenter would go into the room, readjust the cameras, complete a new calibration phase, and leave the room so the parent and infant could complete the rest of the toy play session. Parents were asked to engage with their infants and toys as naturally as possible for ten minutes.

Data Annotation

Parent speech and infants' egocentric video were used in data analysis. We first transcribed speech and then identified spoken utterances containing action verbs. For those utterances, we further coded subject, verb, and (direct and/or indirect) object for each verb utterance. Since the main interest of this paper is on early verb learning and most verbs learned early by young children are action verbs, we focused only on action verbs with concrete meanings that can be revealed by manual actions (e.g. stack and shake) instead of abstract verbs (e.g. think and imagine).

For each parent utterance containing an action verb, we defined a window ranging from 3 seconds before to 3 seconds after the verb was generated. Within this temporal window, we first coded whether an action event was accompanied by the action verb, using infants' egocentric video. For example, in Figure 2, when a parent said, "shaking it", whether the parent or the infant used an object to generate a "shaking" action at the same time. If so, we next coded which target object was action-related for the action event. Figure 2 showed three example verb utterances, two accompanied by an action, and the other without any action. For the two utterances with action (Figure 2B, Row 1), we also coded target objects at the moment (Figure 2B, Row 2). Finally, an in-house coding program was used to code frame by frame which object infants attended moment by moment and gaze data were used to measure infants' attention when hearing verb utterances (Figure 2B, Row 3).

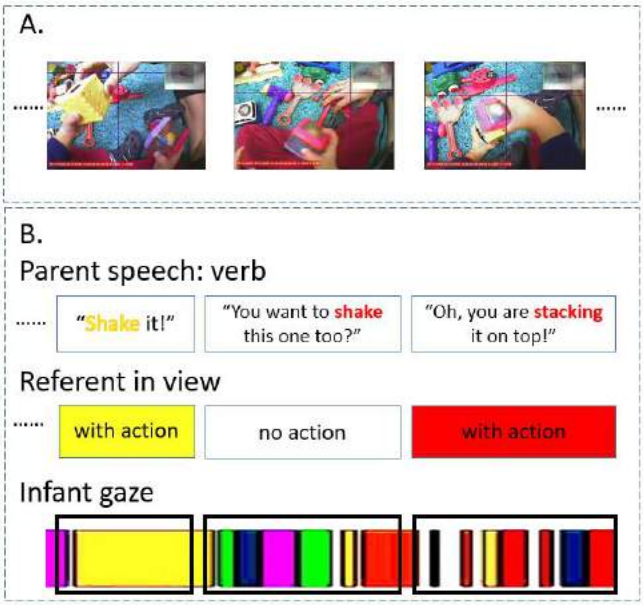

Figure 2: (A) Infants' first-person view and point of gaze during verb utterances. Purple crosshair in the image indicates where the infant was attending in the first-person view. (B) Row 1: Speech transcription of parents' verb utterances; Row 2: Coding of whether a verb utterance was accompanied by an action revealing the meaning of the verb. Colors indicate which object is carrying out the action; Row 3: Gaze coding. Different colors in the infant gaze stream indicate different objects attended by the infant moment by moment. If an infant attended to the named object, the colors in Row 2 and 3 would match in time.

Results

Verb utterance in parent speech. Parent speech contains 4406 utterances (1498 contain object names, 1381 contain action verbs). On average, parents generate roughly the same amount of nouns (5.09 nouns/min) and verbs (5.12 verbs/min, $t(32) = .72$, $p = .47$, ns). Among all the verbs, 705 were action verbs and 268 were abstract verbs. Thus, action verbs took roughly 72.4% of the total of 973 verbs, suggesting that parents most often used concrete verbs in their speech when they played with their children. Among all the action verbs that were coded from parent speech, we selected the top 25 verbs with relatively high frequency (except "look" and "see" as these two verbs were mostly used for attention getting in free play) to form a list of target action verbs for further data analysis. Figure 3A shows a skewed frequency distribution of those top 25 action verbs with two statistical properties. First, even for those top 25 verbs, most of them were produced fewer than 30 times, suggesting that a large proportion of those action verbs were hardly repeated by parents in a play session. Second, the skew distribution also revealed that some verbs were mentioned in parent speech much less frequently than others. Both the frequency difference between action verbs and object nouns, and the variability within action verbs suggest that those quantitative discrepancies are one of the many reasons why (some) verbs might be harder to learn than nouns.

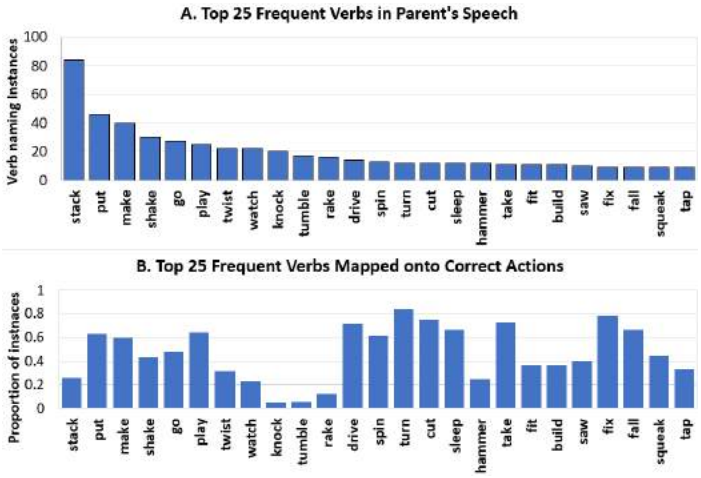

Figure 3: (A) A skewed frequency distribution of the top 25 action verbs. (B) A distribution of the percentage of verb utterances that were accompanied by an action.

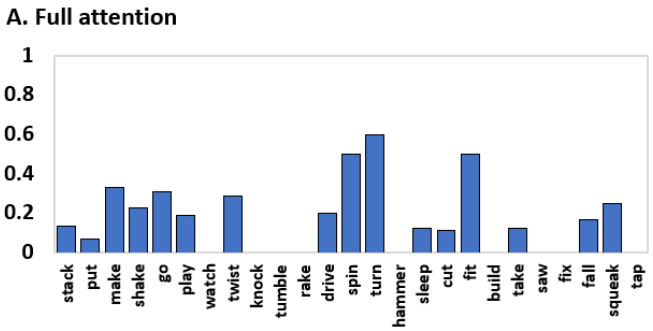
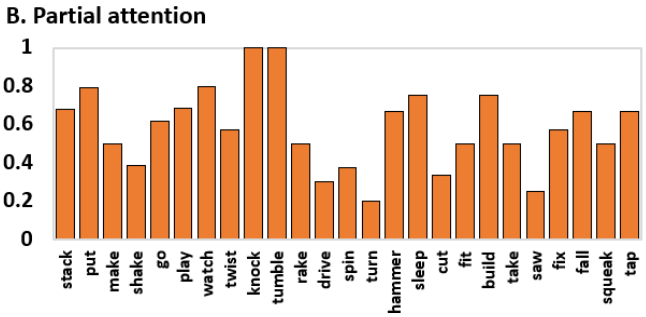
Verb-Action co-occurrence. Learning the perceptually grounded meaning of an action verb requires not only hearing the verb but also perceiving the action. One critical question is how often a verb and its corresponding action co-occur in the learning environment? We answered this question by directly measuring verb-action co-occurrence and counting how often an action revealing the meaning of a verb was generated – either by parents or infants – when parents produced a verb utterance. Figure 3B showed the percentage of verb utterances that were accompanied by the corresponding action. There are two noticeable patterns. First, there is variability in verb-action co-occurrence across action verbs as when some verbs (e.g. "drive", "turn", "cut") were mentioned in parent speech, it was very likely that the corresponding actions were also generated at the same time; while for some other verbs (e.g. "knock", "tumble", "rake"), they were produced in parent speech most often without the corresponding actions. In those situations, either parents failed to demonstrate the corresponding action while a verb was generated, or parents failed to name the actions

conducted by infants. Second, there is no correlation between verb frequency and verb-action co-occurrence (r = -0.161, *n.s.*), suggesting that producing action verbs more frequently would not necessarily create more verb-action co-occurrences, which are critical for building verb-action mappings than just hearing action verbs alone.

Attention to verb-action co-occurrence. Infants' visual attention in free play was dynamic as they sometimes followed parents' attention and sometimes went with their own goals. Even with the presence of verb-action co-occurrence in the learning environment, they may or may not attend to the action when hearing a verb label. Given that attending the corresponding action when hearing a label is critical for verb learning, we next measured the proportion of infant gaze attention on the corresponding action within a verb utterance. Prior research shows that infants' learning of an object name depends on sustained visual attention to the object during a window that lasts from the onset of the utterance containing the name to several seconds after the offset of the utterance (Yu & Smith, 2012). Therefore, we operationally defined a verb event starting at the onset of a parent verb utterance and lasting for 3 seconds – the temporal interval including both the utterance itself (on average 1.5 sec long) and roughly 1.5 seconds after the utterance. We quantified infants' attention during and after hearing a verb utterance by defining three attentional states based on infant gaze: **Full attention** -- infants attended to the action 100% of time within a 3s window; **Partial attention** -- infants attended to the action sometimes but also to elsewhere when hearing a verb label. **No attention** -- infant did not attend to the action at all. Figure 4 showed the percentages of verb-action co-occurrences that received full attention (4A), partial attention (4B) or no attention (4C) from infants. As observed in the distributions of verb utterance frequency and verb-action co-occurrence, there is large variability among different action verbs. Infants seemed to attend to some actions (e.g. "turn" and "spin") much more than others (e.g. "saw" and "rake") when hearing verb labels. Also, in most cases, they seemed to attend to the correspond action sometimes but not the whole time within a 3s window as the percentages in partial attention are much higher than the percentages in full attention and no attention.





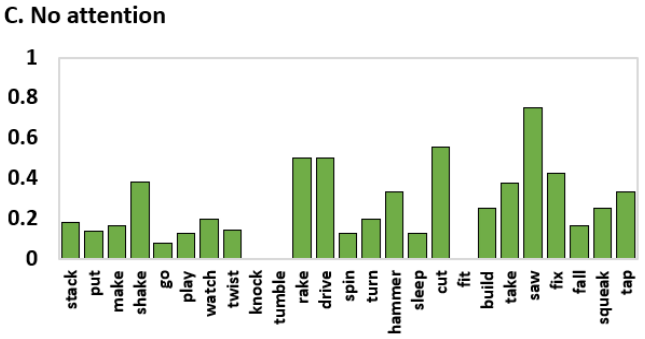


Figure 4: The distribution of infants' attention on the target of the actions that matches with the verbs of the top 25 verbs. (A): Infants' full attention on the targets; (B): Infants' partial attention on the targets; (C): Infants' no attention on the targets.

If an action verb was mentioned more frequently in parent speech, would a higher frequency attract infant attention more on the corresponding action when it was available in the environment? To answer this question, we correlated both verb utterance and verb-action co-occurrence with the three attentional states. As shown in Table 1, we found no correlation between verb frequency and infant attention. Producing more verb utterances did not attract infant attention more toward actions when those verb utterances were accompanied by the corresponding actions. However, there is a significant correlation between verb-action co-occurrence and full attention as shown in both Table 1 and Figure 5, suggesting that infants were more likely to attend to the action 100% of time when a verb and its corresponding action consistently co-occurred together. The higher percentage that manual actions and verb labels co-occurred together; the more likely infants showed full attention to the action event when hearing its label.

Table 1: The correlations between infants' attention, and verb utterance and verb-action co-occurrence (*p<0.05)

	verb utterance	verb-action co-occurrence
full attention	0.015	**0.475***
partial attention	0.206	-0.386
no attention	-0.242	-0.015

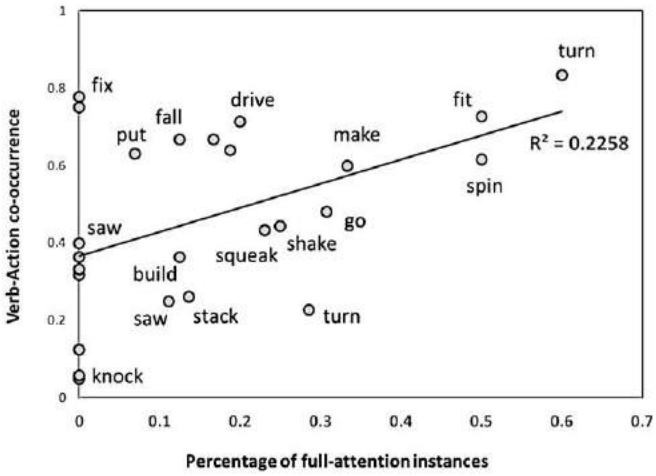

Figure 5: A significant correlation between verb-action co-occurrence and full attention.

Discussion

Recent studies show the overall speech input perceived by the young learner is predictive to later learning outcomes (Weisleder & Fernald, 2013). The input for learning concrete verbs includes not only spoken words but also their perceptually grounded meanings to build word-referent mappings. In light of this, the present study quantified both speech input and verb-action co-occurrences in the learning environment. Critically, the input to the language learning system is not the objective properties available in the learning environment but instead the information in the environment selected by the learner. Therefore, we measured the statistical regularities from the learner's perspective by using the learner's gaze data. Our result showed that the overall frequency distribution of verb generated by the parent during free play is right-skewed, which is similar to what has been observed in the recent studies of object names (Smith, Jayaraman, Clerkin, & Yu, 2018; Bambach, Crandall, Smith, & Yu, 2018). Moreover, the mere frequency of verb utterances was not related to how often the corresponding action was generated. It is not the case that more frequent verbs have more chances to be learned due to more frequent verb-action co-occurrences. In fact, some lower frequency verbs may have more chances to be learned as they co-occurred more frequently with the corresponding action. Further, it is not the case that more verb-action co-occurrences lead to more attention from the learner to the corresponding action.

The infant's attention adds a critical factor to variability of the learning input. We found that it is unlikely that young learners look at the target action during the entire time of a verb utterance. Instead, in most cases, they spent only some time looking at the corresponding action while hearing its label. It is also unlikely that they would completely miss the co-occurring action when a verb is heard. Although there isn't a significant correlation between verb frequency and infant attention, verb-action co-occurrence is positively correlated with the infant's full attention. For those verbs that co-occur more with the corresponding actions, infants are more likely to spend more time looking at the corresponding actions. The great variability within the concrete verbs examined here offers an explanation on why some concrete verbs are harder to learn than others.

What exactly makes verb learning difficult? Based on our findings, we argue that actions to which verbs refer are usually transient in context. Unlike concrete nouns whose perceptual information is usually available to the child when the object label is uttered, the corresponding action of a verb is not very likely to be perceptually available for the child continuously before, during, and after the verb utterance. Given the verb's transient nature and the infants' developing attentional system, if infants failed to attend to the right action at the time a verb was generated, they would miss the target action and once they miss the action, it is impossible for them to recover from other perceptual inspection of the immediate visual context at the moment. Despite the fact that verb learning is challenging, it is also important to keep in mind that verb learning happens in rich naturalistic contexts. Besides solely observing the action accompanying the verb, children also receive other cues that could help them figure out the correct mapping. For example, parents often provide socio-attentional cues, such as pointing to guide the child's attention (Goldin-Meadow, 2007). In addition, verbs are likely to co-occur with nouns and other parts of speech. Infants can also utilize the syntactic structure of the sentences to bootstrap the verb meaning (Naigles, 1996; Yuan, Fisher, & Snedeker, 2012).

The present study is the first step towards understanding the input for early verb learning. There are several future directions to advance our understanding on this topic. First, the current study does not have an outcome measure of verb learning as a way to directly assess the infant's knowledge of the heard verbs. Adding a verb learning test at the end of the play session would allow us to directly examine how the quantity and quality of co-occurrence statistics impact verb learning. Another way to link the input with learning outcomes is to collect and use the parent report of the child's vocabulary (i.e. MCDI, the MacArthur-Bates Communicative Development Inventories). Many studies have showed that both the quality and quantity of parent object naming are correlated with the child's MCDI results. However, little is known about how input quantity and quality impact early verb learning.

Second, toy play is only one of the everyday contexts in which children learn words. It would be interesting to study other learning contexts, such as storybook reading. Talking about objects on a page during book reading and manually manipulating objects during toy play are two very different types of interactions. Therefore, parent and children tend to generate very different learning statistics. Given that word-learning outcomes heavily depend on the structure of the input, it would be interesting to examine what types of input infants receive in those two contexts and compare how different types of input influence verb learning in those contexts.

Finally, another idea for follow-up studies is to compare the actions generated by infants versus by parents. There are studies showing that infants' own egocentric views contain unique properties and distributions that are critical for successful learning (Yurovsky, Smith, & Yu, 2013; Bambach, Crandall, Smith, & Yu, 2018). Actions generated by the parent may contain different visual properties from actions generated by the child. We could further investigate how the infant's body and associated visuomotor processes influence how the information is perceived and processed for learning verb-action mappings.

Abstract

The nature of morphological processing has remained a controversial topic in psycholinguistic research. Some studies (e.g., Rastle, Davis, & New, 2004) have argued that when we read words like *corner* and *talker*, we automatically decompose them into existing morphemes like *talk*, *corn*, and *-er*, regardless of whether it is semantically plausible (e.g., *talker*) or not (e.g., *corner*). Recent studies, however, have challenged this view, by showing early semantic effects of the whole complex word (Järvikivi & Pyykkönen, 2011; Lõo & Järvikivi, 2019; Milin, Feldman, Ramscar, Hendrix, & Baayen, 2017). Using a masked priming paradigm, the present study only found effects of morphological decomposition for true morphological relations (e.g., *talker*) as well as effects of frequency and affective properties of whole words, further challenging automatic decomposition accounts. Finally, we also report that individual differences such as participants' self-reported scholarly reading and openness to new experience, affect processing.

Keywords: morphological processing; masked priming; affective properties; individual differences

Introduction

A large body of psycholinguistic research has focused on the question of how people read words like *cats* or *puppy*. More precisely, the question is whether these words are understood by accessing their morphemic components, for example *cat*, *-s*, *pup*, and *-y* or whether they are processed as any simple word, without recourse to internal structure.

From early on (Taft & Forster, 1975; Manelis & Tharp, 1977) both views have been represented in various forms. Recently, a particularly prominent view has been a variant of the former which states that all morphologically complex words are automatically decomposed in lexical access (Beyersmann et al., 2016; Lázaro, Illera, & Sainz, 2016; Longtin, Segui, & Hallé, 2003; Marslen-Wilson, Bozic, & Randall, 2008; Rastle, Davis, Marslen-Wilson, & Tyler, 2000; Rastle et al., 2004; Rastle & Davis, 2008). Most strikingly, this view takes the decomposition process to operate on the word form alone, without access to any semantic aspects of the word, with the prediction being that all word forms with apparent internal structure should be processed alike.

This approach has found support from masked priming studies (see e.g., Rastle et al., 2004) demonstrating that both pseudo-complex words, where the potential morphemic parts (e.g., *corn* and *-er*) do not make up the meaning of the whole word (e.g., *corner*), as well as transparent complex words with morphemic parts (e.g., *talk* and *-er*) that clearly contribute to the meaning of the whole word (e.g., *talker*), equally facilitate the recognition of their stems (*corn* and *talk*, respectively). Not only that, this research has also shown that words that are not exhaustively divisible into two morphemes, like *turnip* (where *-ip* is not an English affix), do not behave this way, suggesting that automatic decomposition is not only agnostic to semantics but is also driven by online analysis of linguistic structure.

However, not all recent research aligns with this view. Recent studies considering semantic and whole-word properties of the words have started to question this rather simplistic approach to language processing, especially in the case of morphologically complex languages, such as Serbian, Finnish and Estonian (Milin, Filipović Durdević, & Moscoso del Prado Martín, 2009; Moscoso del Prado Martín, Bertram, Häikiö, Schreuder, & Baayen, 2004; Lõo, Järvikivi, & Baayen, 2018; Lõo, Järvikivi, Tomaschek, Tucker, & Baayen, 2018), but also for English (Baayen, Wurm, & Aycock, 2007; Schmidtke, Matsuki, & Kuperman, 2017). For instance, these studies show whole-word frequency effects (Baayen et al., 2007; Schmidtke, Matsuki, & Kuperman, 2017; Lõo et al., 2018), as well as paradigmatic effects (Milin et al., 2009; Moscoso del Prado Martín et al., 2004; Lõo et

al., 2018) in the processing of complex words, which does not align well with the automatic decomposition approach.

In priming, Feldman and colleagues have shown for both English (Feldman, O'Connor, & Moscoso del Prado Martin, 2009) and Serbian (Feldman, Kostić, Gvozdenović, O'Connor, & del Prado Martín, 2012) that semantically transparent pairs show stronger priming than opaque pairs. Järvikivi and Pyykkönen (2011) reported that when morphological family size of the prime was accounted for, priming is smaller for pseudo-complex forms compared to real inflected forms in Finnish. Similarly, in a recent English masked priming study by Lõo and Järvikivi (2019) no priming was found for pseudo-complex words when whole-word frequency of the prime was taken into account in the analysis. Milin et al. (2017) included learning-based measures (Baayen, Milin, Filipovic Durdjevic, Hendrix, & Marelli, 2011) and found comparable priming effects for pseudo-derived words (e.g., *corner*) and orthographic controls (e.g., *brothel*) with more experienced readers showing priming to a lesser extent compared to less experienced readers. Along these same lines, Andrews and Lo (2013) reported that participants with relatively high vocabulary scores showed effects of priming in the transparent condition, but no priming in the opaque condition; whereas participants whose orthography knowledge was better than their vocabulary knowledge also showed priming in the opaque condition. Finally, Medeiros and Duñabeitia (2016) conducted a masked priming lexical decision study with Spanish suffixed words and found priming effects for slow readers, but not for fast readers.

In summary, there is accumulating evidence suggesting that both semantics of the complex words (Feldman et al., 2009; Järvikivi & Pyykkönen, 2011; Lõo & Järvikivi, 2019; Milin et al., 2017) and individual differences of the participants affect morphological decomposition (Schmidtke, Van Dyke, & Kuperman, 2017; Falkauskas & Kuperman, 2015; Medeiros & Duñabeitia, 2016; Andrews & Lo, 2013).

In the present study, we will focus on the affective properties (valence, arousal, danger and usefulness ratings) of complex words. Like simplex words, complex words can also be described along different affective dimensions, for example, from very negative (e.g., *murderer*) to very positive (e.g., *puppy*); from very exciting (e.g., *panics*) to very calming (e.g., *sleeping*); from extremely dangerous (e.g., *lionness*) to not dangerous at all (e.g., *echoing*); and from extremely useful to human survival (e.g., *knives*) to not useful at all (e.g., *scorpions*).

Previous research has shown that these affective properties predict lexical processing costs. For instance, positive, calming, useful and dangerous words have been found to elicit the fastest reaction times in word recognition tasks (Kuperman, Estes, Brysbaert, & Warriner, 2014; Wurm, 2007). Kuperman (2013) reported that compound words that had more positive consituents and were also more positive as a whole were processed faster than negative and neutral compounds.

Until now, affective properties of derived and inflected words have not received much investigation, especially, in the masked priming context (see Forster, 1998 for a discussion of this method). According to the automatic morphemic decomposition view, only affective properties of the stem (e.g, *pup*) and not of the whole (inflected or derived) word (e.g., *puppy*) should influence processing costs

The current study also investigates the effects of individual differences on morphological processing by looking at several self-reported language background and personality measures of participants. The personality component will be more exploratory than the language background measures. Lõo, Toth, Karaca, and Järvikivi (2018) found that personality influenced how participants rated different types of complex words. The arousal scale of the complex words was most prominent for participants who scored high on the neuroticism scale of Big Five personality questionnaire (John & Srivastava, 1999). The present study explores whether personality effects also arise in response times of masked priming lexical decision.

In summary, the goal of the current study is two-fold. First, we will study whether automatic decomposition occurs in a large within-item study design study design when lexcal-distributional and affetive properties of the words are included in the analysis. Second, we will examining individual differences on morphological processing, by exploring participants' self-reported language background and personality measures.

Visual Masked Priming Experiment

Participants

57 native speakers of English (43 female, mean age 21 years, range 18-46) with normal or corrected-to-normal vision participated in the experiment for partial course credit.

Materials

Ninety monomorphemic English words were selected as target stimuli from the Massive Auditory Lexical Database (MALD, Tucker et al., 2018). Each target word (e.g., *pup*) was primed within-item in six conditions. The conditions were the following: identity (e.g., *pup*), inflected (e.g., *pups*), derived (e.g., *puppy*), opaque (e.g., *pupal*), stem-embedded (e.g., *pupil*), and unrelated baseline control condition (e.g., *fencing*).

Additionally, 90 nonwords and 90 real words were added to the item set as fillers. Nonword targets (e.g., *sutt*) followed the phonotactics of English and were also selected from the MALD database. Primes for nonword and real word fillers were always real English words, consisting of the same six condition types with the same proportions as for the real word targets.

Design and procedure

The prime-target pairs were counterbalanced across six lists. Each list contained 360 items. 90 experimental prime-target trials, 90 unrelated prime-target filler trials, and 180 word-prime and nonword trials. In the filler trials, prime and target

pairs mimicked the six conditions in experimental list. Fillers and nonword trials were the same across lists.

The experiment was carried out using the E-Prime experimental software (Psychology Software Tools Inc.) and a SR-BOX response box. All stimuli were presented in black 32-point font Courier New letters on light gray background at the centre of the computer screen.

Each trial began with a fixation cross (+) appearing in the centre of the screen for 1000 ms, immediately followed by a forward mask (##########) for 500 ms. After that, the prime word appeared in lower case letters in the same location for 50ms. The target word appeared in the same location in upper case letters, and remained on the screen until the participant pressed the "yes" or "no" button on the response box. The participants were instructed to decide as accurately and as fast as possible whether the string of letters was an existing word in English or not. Ten practice trials preceded the experimental trials.

Prior to the main task, participants were asked to fill out a language background questionnaire, where they were asked to reflect on their English language skills and reading habits. For instance, they were asked how often they read scholarly or fictional literature; how they estimate their English vocabulary size, and how fast they consider themselves as readers.

They were also asked to fill out a 60-item HEXACO personality inventory questionnaire (Ashton & Lee, 2009), which provided for each participant a separate score on each of the six personality scales: honesty, emotionality, extroversion, agreeableness, conscientiousness, and openness to experience. The whole procedure (questionnaires and lexical decision task) took approximately 60 minutes to complete.

Analysis and Results

Prior to the analysis, practice trials, nonword trials and fillers were removed from the dataset. Trials with response times more than 1600 ms (1.1% of the data) as well as trials with incorrect responses (6.2% of the data) were removed.

Frequencies for the primes and targets were determined using the Corpus of Contemporary American English (COCA, Davies, 2010). Whole-word frequency (i.e., the token frequency of *pups*, *pups* or *puppy*) was used for the analysis. Frequency was log-transformed prior the analysis to reduce the skewness of the distribution.

Affective ratings of valence, arousal, danger and usefulness for each target and prime were collected during a separate rating experiment (see Lõo et al., 2018). In total, 181 native speakers of English rated the experimental items of the current study on an nine-point Likert-scale either on valence, arousal, usefulness or danger scale (1- sad/not exciting/not useful/not dangerous; 9 - happy/exciting/extremely useful/extremely dangerous). Participants in the rating experiment were different from the participants in the current experiment. A rating score for each target and prime word was calculated by taking the average score for each word across all participants.

The statistical analysis was conducted using Generalized Additive Mixed Models (GAMM, Wood, 2006; the R-package *mgcv*). For visualization, we made use of the R-package *itsadug* (van Rij, Baayen, Wieling, & van Rijn, 2016). We opted for GAMM analysis, because it does not assume linearity between the predictor and response variables.

The response variable of interest was the reaction time of masked priming lexical decision in milliseconds. We opted to use raw reaction times because they followed a normal distribution. However, an analysis with the log-transformed reaction times produced the same results. The main predictors were the condition (identity - M, inflected - I, derived - D, pseudo-complex - PC, stem-embedded - SE, baseline - BL), as well as the log-transformed frequency and affective ratings (valence, arousal, danger and usefulness) of the prime and target words. Additionally, we were interested in the effects of individual differences measures, we investigated whether self-reported language knowledge and reading habits, as well as personality had an effect on reaction times.

The output of the final GAMM-model is presented in Table 1. The parametric part shows that participants were significantly faster in identity (t=-4.90, $p<0.00001$), inflected (t=-4.10, $p<0.00001$) and derived (t=-3.43, p=0.006) conditions, whereas the two other conditions (pseudo-complex and stem-embedded condition) were not significant compared to the baseline condition.

Further, participants' openness to new experience and scholarly reading frequency affected reaction times. Reaction times decreased linearly for the participants who scored higher on the openness to experience scale compared to participants who scored lower on the same scale (t=-2.23, p=0.003). In return, reaction times were slower for participants who read more scholarly articles compared to participants who read fewer scholarly articles (t=3.48, p=0.015). There was neither a significant interaction between the condition and the openness score, nor between the condition and the scholarly reading score. Other self-reported language and personality scores were not significant in the final model.

The first three lines of the non-parametric part of the model output show nonlinear interactions between the prime and the target frequency, between the prime and target arousal score as well as between the prime and target usefulness score. These effects are visualized in Figure 1. The yellow color at the bottom left corner of the left panel shows that the reaction times were the slowest when both the prime and target were low-frequency words. However, the interaction between the target and prime frequency seems to disappear when target and prime frequencies increase. This is indicated by the blue color and wider contour lines at the top right corner of the left panel in Figure 1.

The nonlinear interaction between the prime and target arousal score is represented in the middle panel of Figure 1. Reaction times were the fastest when the target word scored high on the arousal scale and the prime word scored low on the arousal scale as indicated by the blue color at the bottom

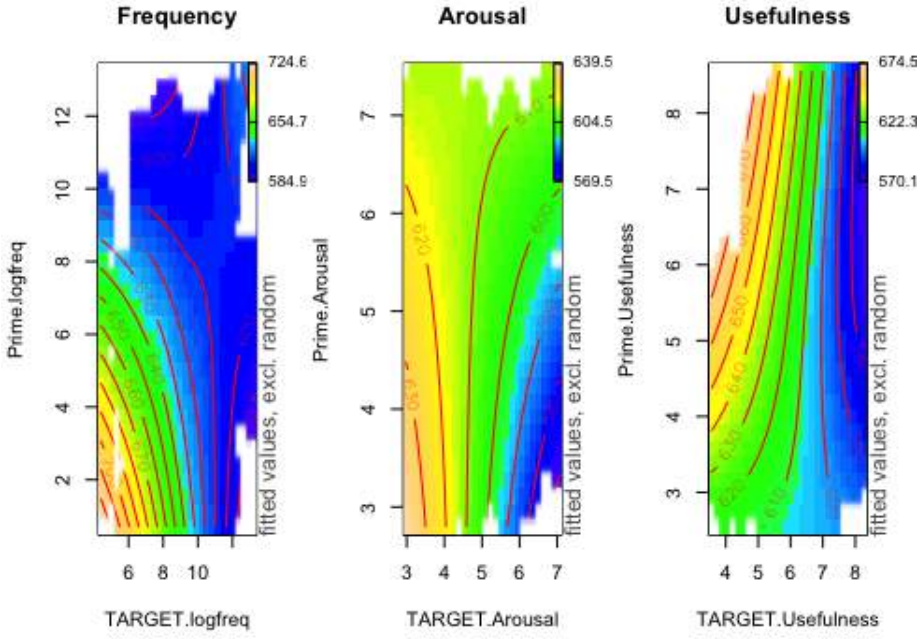

Figure 1: Tensor product smooth for the interaction of prime and target word frequency, arousal and usefulness. Color coding is used to represent model predictions, with yellow indicating slower reaction times, and blue representing faster reaction times

right corner of Figure 1.

Finally, the interaction between the prime and target word usefulness is presented in the right panel of Figure 1. The reaction times were the slowest when the prime was rated as very useful but the target was not, as indicated by the yellow color at the top left corner. Neither the target nor the prime valence and danger scores were significant. Frequency, arousal and usefulness scores did not interact with the condition.

The non-parametric part of the model output also included by-target random intercepts and by-participants random smooths for trial to account for the random variability between the items and participants.

In summary, the GAMM-analysis showed significant priming effects for the identity, derived and inflected conditions, but no priming for the pseudo-complex or stem-embedded conditions. There was a significant interaction between prime and target frequency, arousal and usefulness scores, but this did not interact with the condition. Finally, we found significant effects of participants' openness and scholarly reading, however, these effects did not interact with the condition.

Discussion and Conclusion

The goal of the current study was to investigate English morphological processing using masked priming. Some studies have reported that words like *talker* and *corner* are at least initially processed similarly (Rastle et al., 2004), while others claim that this is not the case, in particular, when various lexical-distributional properties are taken into account (Järvikivi & Pyykkönen, 2011; Lõo & Järvikivi, 2019; Milin et al., 2017), as well as individual differences between participants (Schmidtke, Van Dyke, & Kuperman, 2017; Falkauskas & Kuperman, 2015; Medeiros & Duñabeitia, 2016; Andrews & Lo, 2013).

In line with the latter view, the present study reports priming effects for words with an existing morphological relationship (e.g., *cats*, *puppy*), but no effects of priming for pseudo-complex words (e.g., *corner*). In fact, the processing of pseudo-complex words did not differ at all from either the stem-embedded condition (e.g., *turnip*) or the unrelated baseline condition. This supports findings from another recent English priming study by Lõo and Järvikivi (2019), where there were also no priming effects for pseudo-complex condition, using different materials. Additionally, we showed that the semantics of the complex words plays an important role early on. Like in Lõo and Järvikivi (2019), frequency of the complex word predicted processing costs; however, there were no significant differences between pseudo-complex and truly morphologically complex words in this respect.

Further, we investigated how affective ratings of complex words affect morphological processing. In line with the previous research on compound processing (Kuperman, 2013), we found effects of affective ratings for inflected and derived words. The prime-target ratio of affective ratings influenced the response times in masked priming, further challenging the blind decomposition approach, where the properties of the prime should not have an effect.

Interestingly, out of the four ratings scales (valence, arousal, usefulness and danger), only arousal and useful-

ness target-prime ratios had an effect. Kuperman (2013) reported valence but not arousal effects in compound processing. However, their study used a standard lexical decision task, whereas the current study used masked priming lexical decision, tapping into earlier processing than the standard lexical decision. Arousal and usefulness ratings may be tapping into the internal state of the individual, thus are more subconscious; whereas, valence ratings may require a more conscious thought, and thus get activated later in time than can be captured by a masked priming study.

In general, the effects of affective properties were not that strong in the current study, and there may be different reasons for this. First, in the current study, the derived and inflected primes (e.g., *puppy*, *pups*) have similar meanings to the target (e.g., *pup*), so the affective polarities may have been very similar (for example, the word *puppy* was as happy, exciting, useful and dangerous as the word *pup*). Second, as the design of the current study did not explicitly control for the emotional affectivess of the stimuli, most of the stimuli were neither very positive nor very negative, neither very useful nor very useless, so there may not have been enough variation between the stimuli.

Finally, the current study also focused on the effects of individual differences in morphological processing. Interestingly, they were again the same for truly complex and pseudo-complex words. From the five personality measures (honesty, emotionality, extroversion, conscientiousness, openness to experience), only participants' openness to new experience had an effect on reaction times. More open participants were faster than less open participants. Participants who are more open to experience in general might be also more open to tasks such as a lexical decision task. From the language background measures (self-reported vocabulary knowledge, reading speed, scholarly reading and fictional reading frequency), only scholarly reading had an effect on reaction times. Participants who read more scholarly literature were slower than participants who read less scholarly literature. This is in line with the research showing that more experience with language slows one down in various language tasks (Ramscar, Hendrix, Shaoul, Milin, & Baayen, 2014).

Also this is important to note, however, that both the topic of affective properties and individual differences in morphological processing are relatively new and thus, our findings require further research.

To conclude, the processing of complex words, even in languages with a relative simple morphology, such as English, seems to be much more complex than just a matter of morphemic decomposition. The current study complements this idea by showing that pseudo-complex and morphologically complex words are indeed processed differently. We also showed that both affective properties and individual differences influence English morphological processing; however, the precise nature of these effects requires further research.

Is it easier to segment words from infant- than adult-directed speech? Modeling evidence from an ecological French corpus

Abstract

Infants learn language by exposure to streams of speech produced by their caregivers. Early on, they manage to segment word forms out of this continuous input, which is either directly addressed to them, or directed to other adults, thus overheard. It has been suggested that infant-directed speech is simplified and could facilitate language learning. This study aimed to investigate whether features such as utterance length, segmentation entropy and lexical diversity could account for an advantage in segmentability of infant-directed speech. A large set of word segmentation algorithms was used on an ecologically valid corpus, consisting of 18 sets of recordings gathered from French-learning infants aged 3-48 months. A series of textual analyses confirmed several simplicity features of infant-, compared to adult-directed speech. A small segmentation advantage was also documented, which could not be attributed to any of those corpus features. Some particularities of the data invite further research on more corpora.

Keywords: language acquisition; infant-directed speech; computational modeling; word segmentation; unsupervised learning

Introduction

Infants acquire language early on, building a vocabulary of several hundred word forms by 11 months of life (Ngon et al., 2013). Since most word forms do not appear in isolation (Brent & Siskind, 2001), much previous work studies how infants segment (i.e., pull out) forms from their caregivers' running input. A close look at this input shows that it is not homogeneous, but instead contains some speech addressed to the infants themselves (infant-directed speech or IDS) and some speech overheard by infants which is addressed to others, including adults (adult-directed speech or ADS). These two speech registers differ along many dimensions, including some that may impact word segmentation.

Broadly, IDS has been claimed to present properties that would facilitate language acquisition, with IDS being phonologically, syntactically, and semantically simplified (Soderstrom, 2007). Other characteristics are more relevant to word segmentation. First, IDS may have a higher proportion of single-word phrases (Brent & Siskind, 2001), and phrases might be shorter in length (Newport, Gleitman, & Gleitman, 1977) than in ADS. In shorter phrases, more words would occur at phrase edges, which should improve segmentation: Phrase edges, easily perceptible, are word boundaries provided "for free". Indeed, infants may be more successful at recognizing and segmenting phrase-final words (E. Johnson, Seidl, & Tyler, 2014). Additionally, shorter phrases entail that the set of possible segmentations for each phrase is smaller, lowering segmentation ambiguity. For instance, Fourtassi, Börschinger, Johnson, and Dupoux (2013) showed that ADS might be more ambiguous to segment, when comparing an ADS to an IDS corpus. Second, words may be shorter (Ma, Golinkoff, Houston, & Hirsh-Pasek, 2011), which should mean that word, morphemes, and syllable boundaries coincide more often and there are fewer places to posit or miss positing a boundary. Third, there may be more repetitions, therefore fewer hapaxes (words uttered only once), and overall less lexical diversity (Soderstrom, 2007). Low lexical diversity means fewer target words need to be found. There might be more cues to help segment out frequently repeated words, than words that appear rarely or once. Indeed, one computational modeling study found that artificially reducing phrase length and increasing word repetition in a corpus improved word segmentation with one word segmentation model (Batchelder, 1997). Based on these hypotheses and previous work, we predict that the task of recovering wordforms is easier in IDS than ADS.

Naturally, IDS features may not be the same across infant ages. IDS addressed to very young infants may differ from that addressed to older infants, possibly resembling ADS more as infants get older. For example, IDS features may become less accentuated as the infant grows up; repetitions might decrease, utterance length and lexical diversity increase with age (Henning, Striano, & Lieven, 2005; Soderstrom, 2007). According to the hypotheses explained above, IDS addressed to younger infants should be "easier" to segment than IDS to older infants.

In this paper, we aim to address the question of whether it is easier to segment wordforms from IDS than ADS, using multiple word segmentation models, and taking into account changes with infants' age. In the next section, we review

previous modeling work more thoroughly, before introducing our own approach.

Previous studies

Some studies tested whether infants learn more from IDS than ADS in an experimental situation. However, improvements for IDS compared to ADS could be due to the fact that infants pay more attention when they listen to IDS, and thus learn more from it. This method cannot reveal whether, above and beyond this attentional effect, there are intrinsic *informational* differences that affect segmentability. Fortunately, there is a complementary method to approach this question with a colder eye, which builds on computational models of word segmentation. The input to such word segmentation models is usually speech transcriptions, in order to control for differences such as attention capture and acoustic implementation. Segmentation models used for this method are based on findings by experimental studies that infants might make use of statistical cues. Computational models of infant word segmentation can be grouped into two conceptual classes: lexical and sublexical. Sublexical models segment based on local cues, such as transitional probabilities and phonotactics. Lexical models build a lexicon based on recurrent chunks of speech identified with Bayesian probabilities or by memorizing isolated words.

Little previous modeling work has specifically compared IDS and ADS. Four representative studies are summarized in Table 1. For these four studies, improved segmentation performance was found for IDS than ADS: 15% for Batchelder (2002), 5-8% for Fourtassi et al. (2013), 2-10% for Ludusan, Mazuka, Bernard, Cristia, and Dupoux (2017) and 3-10% for Daland and Pierrehumbert (2011). A recent paper critiqued this previous work as follows (Cristia, Dupoux, Ratner, & Soderstrom, 2018). IDS mainly involved caregivers addressing their infants during predefined tasks (e.g., a play session in the laboratory) or in short visits to the child's home. In the former case, by constraining the context, the structure and lexicon of caregivers might have been limited and adapted to that task. And in both cases, being observed could affect caregivers' behavior, who might produce less spontaneous and more formal speech. Moreover, ADS was mostly addressed to an unfamiliar person (experimenter). These conversations are likely more formal than ADS between caregivers in daily life, and could increase the complexity of the speech. As shown by E. Johnson, Lahey, Ernestus, and Cutler (2013), IDS differs more from ADS to unfamiliar adults, than ADS to familiar adults. This could result in increased qualitative differences between registers and probably overestimated differences in segmentability.

Indeed, Cristia et al. (2018) recently documented a considerably smaller IDS advantage when modeling segmentation on an ecological English IDS and ADS corpus. The corpus consisted of transcriptions from excerpts of day-long recordings; thus infants' linguistic environment was recorded while they were going on with their daily lives, resulting in realistic IDS and ADS. Across a wide range of lexical and sublexical models, the IDS advantage ranged from -2% to 8%, with only 3 models providing evidence of an advantage greater than a measure of error. Interestingly, the difference between registers was further reduced when IDS was matched to ADS in corpus length.

The present study

We contribute to this literature in three main ways. First, we specifically describe IDS-ADS differences using various corpus description tools. We compare the registers in: phrase length, word length, ratio of single word phrases, intrinsic segmentation ambiguity (using segmentation entropy), lexical diversity (using Moving Average Type-Token Ratio – MATTR–, so as to control for corpus size), and ratio of hapaxes. Some, but not all of these features have been separately looked at in previous studies (i.e. Fourtassi et al., 2013 measured segmentation ambiguity and Batchelder, 1997 measured word and phrase length, repetitiveness). This is the first study to systematically investigate a plurality of language features on the same IDS-ADS corpus. We test whether IDS is simpler than ADS, as far as these features are concerned. Moreover, following Batchelder (2002), we further investigate whether variation in these features can actually account for the segmentability of a register.

Second, IDS corpora coming from a wide infant age range have been used by previous research, but IDS addressed to infants of different ages were, most of the times, merged together. One exception is Batchelder (1997), who documented that IDS to younger children (13-18 months) produced more successful results than IDS to older children (22-25 months), whereas ADS results from mothers of younger versus older infants didn't differ. In this paper, we specifically ask whether some IDS features interact with infant age and whether segmentability of IDS might actually be affected by age. For that, we include IDS and ADS from a wide age range, and further investigate possible correlations between features, segmentation scores, and infant age.

Third, we follow Cristia et al. (2018) by analyzing a completely ecological child-centered corpus, based on excerpts of day-long recordings, and which thus contains natural ADS and IDS as the child hears over the course of the day. The results of our study would provide more evidence to the question whether differences in home-recorded IDS and ADS are smaller than those between less controlled IDS-ADS contrasts (see Table 1).

In addition to these three main contributions, we extend the range of languages studied to European French.

Methods

We segmented IDS and ADS of each infant separately. Scripts used for corpus preprocessing, phonologization, and segmentation as well as results and supplementary material are available at `https://osf.io/6vwse/?view_only=0bc4f6c0e23040cbbb92e26d414d4a7a`. Statistical analyses were carried out in R (R Core Team, 2013).

Table 1: Summary of design in previous modeling studies comparing IDS and ADS segmentation. In Language(s), Eng stands for English, Jap for Japanese, Span for Spanish. Under IDS and ADS, we describe the corpora. The specific corpora used were: R= RIKEN; H= Hamasaki; C= Spontaneous Japanese; BR= Bernstein Ratner; B= Buckeye; D= Deuchar & Clark 1992, Marrero; M= Miyata 1995; novel= Moon and the Sixpense; short stories were written by Alejandro Dolina (MacWhinney, 1996). Under model, we note the type of model used: lex for lexical and sublex for sublexical.

Corpus

Sixteen typically developing native French-speaking infants (eight girls, eight boys; ages 3-48 months, M=20, SD=13), whose families were highly educated, were included. Two of the infants were recorded at two different ages. Each child was recorded 10-16 hours per day, three days a week, in their natural environments. The original recordings are available online (Canault, Le Normand, Foudil, Loundon, & Thai-Van, 2016a, 2016b; VanDam et al., 2016). Next, 18 10-min samples, totaling 3 hours per child (1 hour per day), were selected for orthographic transcription by two native French speakers, as detailed in Canault et al. (2016b). The main criteria for selection reported was that a number of activities were sampled, and that there be a high number of productions by the child and the adult. For the present project, the transcriptions of the first day for all infants were corrected by a native French speaker, who made sure that the definition of utterance was stable (and corrected any other errors, such as misattributions or orthographic errors). The coder annotated whether an adult caregiver's utterance was directed to the target child, an adult, or other, using content and context. Utterances addressed to the target child constituted the IDS corpus and those directed to an adult were the ADS corpus.

Pre-processing

Pre-processing was carried out using custom scripts written mainly in bash and in python, available from `https://github.com/georgialoukatou/French_ADS_IDS_segmentation_Lyon`. All extraneous codes (such as punctuation marks or "xxx", the code indicating that what was said could not be understood by the transcriber) were removed, leaving only the orthographic representation of the adults' speech. The corpora were phonologized with the French voice of the espeak TTS system (Duddington, 2012), using the phonemizer wrapper (Bernard, 2018), which further syllabifies according to the Maximum Onset Principle.

Before segmentation, all spaces between words were removed, leaving the input parsed into minimal units. The minimal units were either phones or syllables. Both phonemes and syllables were tested with all models. Utterance boundaries were preserved as such, since they are supposedly salient to infants (Shukla, White, & Aslin, 2011). This constitutes the input to the model. After preprocessing, the 18 infant-directed corpora contained M=487 (SD 350) utterances (range 84 to 1,172 utterances). The 18 adult-directed corpora contained M=238 (SD 230) utterances (range 15 to 780 utterances).

For comparability with previous work, we evaluate the models' performance using lexical token F-scores, measured by comparing the original version of the input (with spaces between words) against the one returned by the model (with spaces in the hypothesized breaks).

Segmentation

Both corpus description and segmentation were carried out using the WordSeg package (Bernard et al., 2018), available from `https://github.com/bootphon/wordseg/`. Due to space limits, the algorithms are only briefly described here. Full technical details can be found in `https://wordseg.readthedocs.io/`. All algorithms are unsupervised, and inspired in infant experimental work.

We used two representatives of the sublexical word segmentation class contains, called DIBS and TP for short. The Diphone Based Segmentation algorithm (DiBS; Daland & Pierrehumbert, 2011) is based on the idea than a phoneme sequence often spanning phrase boundaries would probably span word breaks.

The Transitional Probabilities algorithm family (TP; Saksida, Langus, & Nespor, 2017) is based on the concept that syllable pairs with lower statistical coherence tend to span word breaks. Forward TP (FTP) measures the frequency of occurrence of the syllabic sequence AB given the frequency of occurrence of the syllable A. Backward TP (BTP) measures the frequency of occurrence of the syllabic sequence AB given the frequency of occurrence of the syllable B. The Relative versions (FTPr or BTPr) threshold TPs against that of neighboring sequences. The Absolute versions

Table 2: Paired t-tests measuring feature differences across IDS and ADS. Word length is measured in phonemes. % 1-w phrase stands for ratio of single word phrases. % hapaxes stands for percent of hapaxes. IDS gives the mean values of each feature on the IDS corpus, with standard deviation in parentheses. ADS shows the mean values of each feature on the ADS corpus with standard deviation in parentheses. The window size for MATTR is 10 words. "p" gives the p-value of the t-test.

Feature	IDS	ADS	p
Word length	2.86 (.08)	2.80 (.11)	.071
Phrase length	5.89 (.85)	6.73 (.86)	*
% 1-w phrase	.18 (.06)	.13 (.05)	**
Entropy	.02 (.004)	.03 (.01)	.31
MATTR	.89 (.03)	.93 (.02)	***
% hapaxes	.39 (.22)	.48 (.27)	***

(FTPa or BTPa) instead threshold on the average of all TPs over the sum of different syllable bigrams.

We used two representatives of the lexical class as well: AG and PUDDLE. Adaptor Grammar (AG) uses the Pitman-Yor process, a stochastic process of probability distribution which prefers the reuse of frequently occurring rules versus creating new ones to build a lexicon, then uses that lexicon to parse the input (M. Johnson, Griffiths, & Goldwater, 2007).

Phonotactics from Utterances Determine Distributional Lexical Elements (PUDDLE, Monaghan & Christiansen, 2010) treats each utterance as a lexical item, unless an already stored item is part of this utterance, and the remainders are phonotactically legal. If so, it breaks up the utterance into segments, and the segments would enter the lexicon as new lexical items.

Finally, two baselines were included: Syll=Word treats each syllable as a word and Utt=Word treats each utterance as a word.

Results

We first investigated whether IDS is simpler than ADS in terms of six corpus features that could affect word segmentation, as described in the reasoning above. The results of paired t-tests comparing the registers for each feature are in Table 2, which shows that four out of six features fit our predictions.

We also noticed that IDS size corpus (M=487, SD=350 per child) was significantly larger than the ADS one (M=238, SD=230), based on a t-test with t(17)=2.63, p=0.02. This may mean that these infants were exposed to more IDS than ADS, similar to what Cristia et al. (2018) found for English.

The performance of all segmentation algorithms for both registers is captured in Figure 1. IDS is easier to segment than ADS when points are above the dotted diagonal line. There was a small IDS advantage for most algorithms, although some showed the opposite effect (DiBSs,

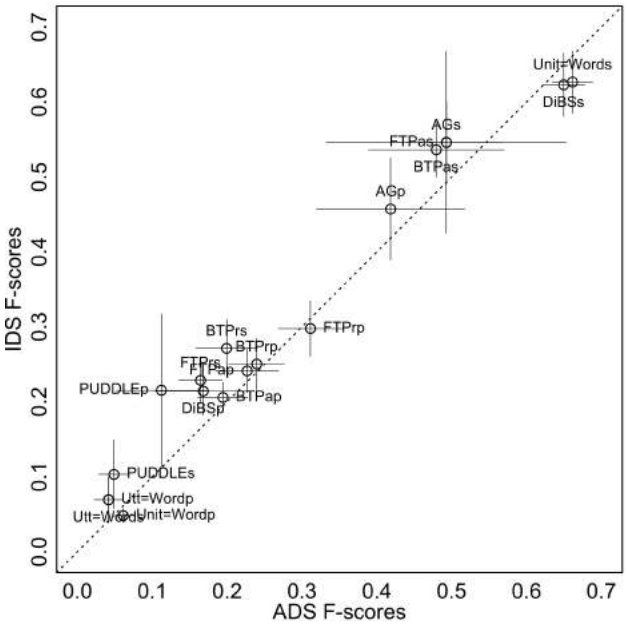

Figure 1: Token F-scores obtained by each algorithm for IDS as function of that for ADS. The final "s" in the model's name means that the basic unit of the corpus was syllables (PUDDLWs, Utt=Words, Unit=Words, DiBSs, FTPas, FTPrs, BTPas, BTPrs, AGs). The final "p" in the model's name means that the basic unit of the corpus was phones (PUDDLWp, Utt=Wordp, Unit=Wordp, DiBSp, FTPap, FTPrp, BTPap, BTPrp, AGp). Error bars show two standard deviations over the 18 corpora.

Unit=Words, Unit=Wordp, FTPrp). We also observe that in many cases the pseudo-confidence intervals cross the diagonal line, suggesting that performance difference is within the range of error. Thus, only FTPrs, BTPrs, Utt=Wordp, PUDDLEp and PUDDLEs showed a clear advantage of IDS. We then tested for overall effects in a linear mixed effect regression model (Bates, Mächler, Bolker, & Walker, 2015) predicting token F-scores from register (IDS or ADS) as a fixed effect, where subject and algorithm (AGs, AGp, DiBSs, DiBSp...) were random effect variables. Register significantly affected token F-scores ($\chi^2(1)=50.87$, $p<.05$, Type II Anova), IDS having a performance advantage of $.03 \pm .004$ (standard error).

Next, we tested whether this performance advantage was due to one of the above-mentioned corpus properties. To see whether performance differences were due to the artifactual difference in corpus length, we also included the number of utterances as a register feature. Thus, 7 new models, each including one of the features as an additional fixed effect, were fit. We then measured the significance of register and features in the new models with a Type II Anova test (Fox & Weisberg, 2011).

If the advantage of IDS was entirely due to one feature, then register would no longer be significant in these addi-

Table 3: Corpus features predict segmentation scores, but do not replace register. β feat stands for the estimated coefficient of that feature; β rgstr for that of register in the new model (which should be compared to 0.03 at the simple model). p features shows whether feature was significant in new model. p rgst shows whether register remained significant in the new model. N. utts stands for number of utterances.

Feature	Feature		Register	
Feature	β	p	β	p
Word length	.02	.48	.03	***
Phrase length	.01	***	.04	***
% 1-w phrase	.06	.29	.03	***
Entropy	-1.58	***	.03	***
MATTR	.5	***	.05	***
% hapaxes	.03	.18	.03	***
N. utts	.00005	***	.02	***

Table 4: Correlation tests (Spearman) of corpus features and infant age for each register. "coef." stands for correlation coefficient.% 1-w phrase stands for ratio of single word phrases. % hapaxes is the ratio of hapaxes.

Feature	IDS coef.	ADS coef.
Word length	.50*	.06
Phrase length	.34	-.56*
% 1-w phrase	-.37	.12
Entropy	-.50*	.70**
TTR	.44	-.37
% hapaxes	.01	.30

tional analyses. Results (in Table 3) showed that phrase length, segmentation entropy, MATTR, and corpus size accounted for variance in the results, but no single feature rendered register effects non-significant.

Next, we investigated whether IDS features change with infant age, with IDS becoming more ADS like as infants age. Spearman correlation tests between properties and infant age for each register separately (Table 4) did not confirm our predictions: Only word length and entropy (neither of which had emerged as register properties on Table 2) correlated with age in IDS; entropy and phrase length did so for ADS. We have no plausible explanation for these effects.

Two infants were recorded twice at different ages, one at 31 and 38 months, the other at 32 and 40 months. Following a recommendation from a reviewer, we inspected these two infants as case studies. An inspection of IDS features demonstrated that phrase length and % of 1-w phrases were the only features having small changes with age, but only the latter would change in the same direction for both infants, increasing by 6% and 1% from the first to the second recording. A few ADS features also changed slightly with age, such as % of 1-w phrases, word length and entropy, but only phrase length changed in the same direction for both infants, decreasing by 1.18 and 1.66 phonemes.

Finally, we created a new model predicting token F-scores register (IDS or ADS) and infant age in months as fixed effects (and model and participant as random effects, as before), and their interaction. Both main effects and the interaction were significant (Age $\chi^2(1)=4.31$, $p<.05$; Register $\chi^2(1)=53.14$, $p<.5$; Age:register $\chi^2(1)=28.81$, $p<.05$). A follow-up analysis separating the registers indicated that ADS scores decreased by $.002 \pm .0005$ (standard error) with age, whereas there was no significant change with age for IDS.

Discussion

In this modeling study, we assessed whether there are informational differences affecting word segmentation between IDS and ADS drawn from the same ecological corpus. First, we investigated whether this naturalistic corpus had IDS-ADS differences in textual features that would make segmentation easier in the former than the latter. We found most features fit our predictions: Phrases were longer, there were more single-word phrases, lexical diversity was lower, and there were fewer hapaxes in IDS than ADS. No significant effect was found for word length and ambiguity. This result contributes to the growing literature documenting IDS features, with the important advantage that current work draws from fully ecological IDS and ADS.

Next, we investigated the segmentability of the corpora using a large set of both lexical and sublexical segmentation models. Although scores varied a great deal across algorithms and some algorithms showed the opposite effect, IDS was overall slightly easier to segment than ADS. The mean difference across registers (CDS minus ADS, in each algorithm separately) was 3%, ranging from –4% to 10%. This effect is smaller than that found in most previous studies, but similar to the one reported by Cristia et al. (2018), who were also drawing from a naturalistic IDS-ADS corpus. This is evidence that previously documented IDS-ADS segmentability differences (as in Table 1) are not representative of what infants actually hear. It is important to note that corpus length across registers was not matched in the present study for practical reasons, but, based on findings by Cristia et al. (2018), we suspect that controling for corpus size would have reduced the IDS advantage even further.

Next, we asked whether some of the above-mentioned textual features uniquely explained segmentability differences across registers. Phrase length, segmentation entropy, and repetitiveness explained significant variance in segmentation scores, above and beyond the effects of register. However, none of the features uniquely explained away the effect of the register, which remained significant in all cases. This means that register effects on segmentability cannot be reduced to any one of these features. Since we only had 18 children's data, we could not fit a model with all 6 features at once for fear of overfitting, but future work with higher power may be able to assess whether these features jointly explain away reg-

ister, or whether there are other textual features that we have not yet considered.

Furthermore, Canault et al. (2016b)'s corpus allowed us to address a question that has been seldom asked, namely IDS-ADS differences across infant ages. Results of correlations between textual features and age, and a regression model on token F-scores did not support our prediction that IDS would become more like ADS as children aged, and thus the IDS-ADS segmentability gap would close. On the contrary, we found that ADS scores dropped with child age. Although further work is needed, we believe this mainly reflects the lower availability of ADS in children's environment as they age. Indeed, replicating a pattern that had been documented in North American English children (Bergelson et al., 2019), we found the number of ADS utterances dropped for older, compared to younger, children.

Before closing, we would like to acknowledge some limitations of this work. Corpus size was overall small (which may lead to inconsistencies in results; Bernard et al., 2018) and, due to the work involved in collecting daylong recordings and annotating fully spontaneous speech, infant sample size was 18 infants. Moreover, data scarcity was correlated with registers and ages: While only 3 of the 18 IDS corpora contained fewer than 100 utterances, 7 did for ADS, and 4 of those belonged to infants older than 31 months. A decrease of ADS quantities with infant age in such day-long recordings has been documented in previous work on North American English (Bergelson et al., 2019), so it may not be an artifact of the current sample selection. Nonetheless, this trend may entail that if we want to control corpus size, we should over-sample ADS at later ages. However, that may not be necessary for our data, where corpus size failed to explain away the register effect, even though it accounted for some variance beyond registers.

Last, speech transcriptions were used for this study, in an attempt to look for intrinsic informational differences across registers. However, some of the most salient features of IDS are speech-related, such as prosody or intonation and acoustic properties, which might also predict ease of segmentation. Although there is a small literature looking at word segmentation from speech, including comparing IDS and ADS (Ludusan, Seidl, Dupoux, & Cristia, 2015), this task remains extremely challenging for computational modelers, with only one open source model (instantiating a single segmentation strategy) exists, which further limits the value of such a line of research.

In sum, we identified several simplicity features more prevalent in IDS than ADS drawn from an ecological French corpus. We further found a small but significant IDS segmentation advantage, contributing to a recurrent question on the learnability properties of IDS. We showed that the IDS segmentation advantage could not be explained away by any one of those simplicity features, and its size changed with infant age in unexpected directions.

Abstract

Humans make plans with remarkable flexibility by leveraging symbolic representations. How are these representations learned? We present a model that starts out with a language of low-level physical constraints and, by observing expert demonstrations, builds up a library of high-level concepts that afford planning and action understanding. We demonstrate its versatility through experiments inspired by developmental psychology literature.

Attentional Capture: Modeling Automatic Mechanisms and Top-Down Control

Abstract

We present a computational model of attentional capture in humans. The model distinguishes between automatic mechanisms that directly determine the focus of visual attention, and deliberate mental actions an individual can perform to influence these mechanisms. The automatic mechanisms select an object as the focus of attention and enhance its location and features, so that nearby or similar objects are likely to be selected in the future. The deliberate actions include engaging with a selected object to further enhance its features, and retrieving a previously selected object from memory. By performing these actions, the model is able to exert limited top-down control over capture, increasing the probability that task-relevant objects will be attended and irrelevant objects will be ignored. To evaluate the model, we conduct a simulation of a recent visual search study, demonstrating that the model can account for three established factors that are known to influence capture.

Keywords: visual attention; visual search; computational modeling

Introduction

What drives attentional capture? That is, when we view a scene, why is our attention drawn to one object, and not to another? This question is important because where we attend determines what information we represent. Whether we are reading a map, driving a car, or shopping at a store, we can perform the task more efficiently if we attend to objects that provide relevant information and ignore task-irrelevant objects.

Much of the debate over attentional capture concerns the role of top-down control (Folk, Remington, & Johnston, 1992; Müller, Reimann, & Krummenacher, 2003; Theeuwes, Reimann, & Mortier, 2006). To what extent can humans deliberately manipulate our own mental states, such that task-relevant objects are more likely to be attended? The evidence suggests that in many cases, task-relevant objects draw attention not because of deliberate control, but because they are similar to objects we have attended recently. For example, if a task involves looking for red objects, the act of finding a red object on previous trials will prime the viewer to find one more easily on future trials (Maljkovic & Nakayama, 1994; Theeuwes et al., 2006). However, in some cases participants appear to be able to strategically tune their attentional systems based on semantic information, such as a word describing the color of the object they should find next (Leonard & Egeth, 2008; Belopolsky & Awh, 2016).

To better understand how top-down goals affect attentional capture, it is helpful to model the specific mechanisms underlying attention. We previously developed a model of multiple-object tracking that relied on two attentional mechanisms: selection and enhancement (Lovett, Bridewell, & Bello, 2017). Selection picks out an item for further processing, and may be thought of as a generalized form of attentional capture, whereas enhancement increases sensitivity to stimuli at a particular location or with particular features. These two mechanisms are closely interwoven: after an object is selected, its location and features are enhanced, such that objects at the same location or with similar visual features are more likely to be selected in the future.

Here, we present a novel computational model that applies the selection and enhancement mechanisms to a visual search task, in which participants must find a blue or orange circle in a field of distractor circles and judge the orientation of a line inside it (Figure 1). Critically for the topic at hand, neither selection nor enhancement is directly controlled in the model. However, other deliberate actions can influence what gets enhanced, thereby biasing the model to select task-relevant objects. In particular, after an object is selected, if the object is task-relevant then the model can `engage` with it. Engagement is the act of maintaining focus on an object while reasoning about its features, for example, judging the orientation of a line inside an attended circle. Engagement leads to greater enhancement of an object's location and features, which supports sustained selection of that object but also causes objects with similar features to be selected in the future.

In the model, engagement also causes the object's representation to be stored in long-term memory, from which it can be retrieved at a later time. Thus, if the model later receives a cue, for example indicating that the next search target will be orange, it can deliberately `retrieve` a representation of a previously selected orange object from memory, allowing that representation to be selected and engaged with, so that orange objects are more likely to be selected.

In the following section, we describe three factors that affect attentional capture, and we argue that our model, which integrates selection and enhancement mechanisms with deliberate mental actions, can explain each factor. We then present the model and describe an evaluation in which it simulates human performance on a search task. We close by considering predictions of the model and directions for future research.

Background

At least three factors govern which objects capture visual attention when viewing a scene: physical salience, selection history, and top-down goals (Awh, Belopolsky, & Theeuwes, 2012). Physical salience increases with the amount of contrast between an object and the rest of the scene, but decreases with the amount of contrast between the other objects in a scene; for example, a red circle will be strongly salient in a field of identical green squares (Duncan & Humphreys, 1989). Salience is determined by both local contrast (between an object and its immediate surroundings) and global contrast (between an object and the other objects throughout the visual scene) (Nothdurft, 1993; Madison, Lleras, & Buetti, 2018).

Whereas salience is a property of the visual stimuli, selection history relates to the viewer's mental state. An object will tend to draw attention if it is visually similar to objects that have been attended in the recent past. In search tasks, this effect often manifests as intertrial priming, where a target is found more easily if its features remain constant from one trial to the next (Maljkovic & Nakayama, 1994). Similarly, a target is found more easily if it is in the same location as a recently attended object (Folk et al., 1992).

Finally, top-down goals involve deliberate control over what object captures attention. This effect is demonstrated when viewers see a cue describing a target, rather than an object similar to the target, and then are able to find the target more readily. A spatially descriptive cue might be an arrow pointing to the region where the target will appear (Posner, 1980), whereas a featurally descriptive cue might be a word describing the target's distinguishing feature (e.g., "red") (Leonard & Egeth, 2008). The ability to use these cues suggests the viewer is making an adjustment that causes objects that match the description to draw attention.

Recently, Belopolsky and Awh (2016) examined the combined contributions of these three factors to attentional capture. They used a search task in which participants viewed six colored circles, found a target circle that could be either blue or orange, and reported whether the line inside the circle was horizontal or vertical (Figure 1). To explore the effect of salience, the colors of the distractor circles were varied: on half the trials, all the distractors were green, resulting in a salient target, whereas on the other half, the distractors were all different colors, resulting in a nonsalient target. To explore the effect of top-down goals, each search trial was preceded by a verbal cue, either the word "blue" or "orange," that predicted the upcoming target's color 80% of the time. Finally, to explore the effect of selection history, performance on repetition trials, where the target's color was the same as the color from the previous trial (e.g., the circle was orange for two trials in a row), was contrasted with performance on non-repetition trials.

Critically, in one study Belopolsky and Awh (2016) presented the search display for only 100 ms, after which the lines within each circle were masked. This brief display time has two major advantages: (1) there is no time to saccade to one of the circles, so eye movements cannot be a factor, and (2) if the first circle attended by the participants is neither blue nor orange, there is no time to look for another circle. Thus, the authors were able to isolate attentional capture from the separate task of assessing whether an attended object meets the search criteria.

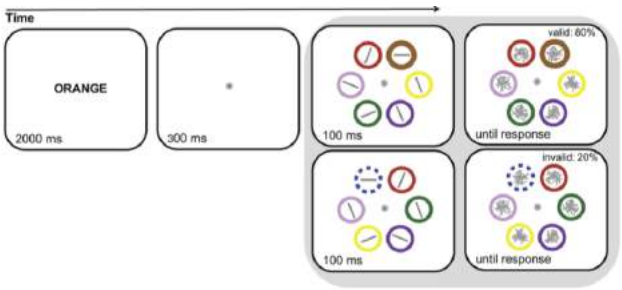

Figure 1: Examples of visual search task with a nonsalient target from Belopolsky and Awh (2016). The top row shows a valid trial with an orange target (appears brownish), whereas the bottom row shows an invalid trial with a blue target. The blue circle is dotted for illustration purposes.

Figure 2 shows the experiment results. Accuracy increased when the target was salient, when the cue was valid (e.g., the cue "orange" preceded an orange circle), or when a target color repeated, indicating that each of the three factors contributed to attentional capture. In addition, there were numerous interactions, notably, cue validity had a greater effect when the target was nonsalient, target repetition had a greater effect when the target was nonsalient, and there was a three-way interaction among the factors. We propose that these interactions are driven by a ceiling effect. As an example, when a target is salient, there is a high likelihood of attending to it during the critical 100 ms, and thus there is little room for additional improvement if the cue is valid.

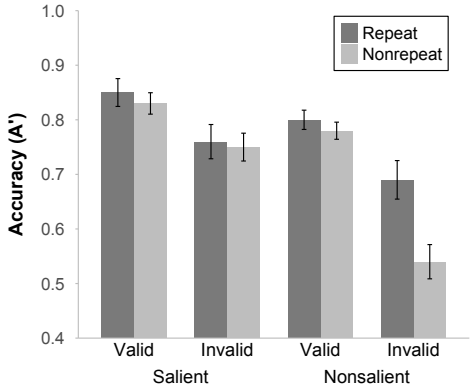

Figure 2: Visual search results from Belopolsky and Awh (2016). Error bars are ± 1 SE.

Selection and Enhancement

Both selection history and top-down goals may result from an interaction between selection and enhancement. After an object is selected, viewers show enhanced sensitivity to other objects in the same location or with the same visual features (Posner, 1980; Egly, Driver, & Rafal, 1994; Bichot, Rossi, & Desimone, 2005). Enhancement manifests as both a greater probability of selecting a stimulus among a field of distractors, and a shorter delay between stimulus onset and selection. Neural evidence suggests enhancement is rooted in modulation of the early visual cortex, for example, after a red object is selected, neurons will respond more strongly to red stimuli throughout the visual field (Somers, Dale, Seiffert, & Tootell, 1999; Saenz, Buracas, & Boynton, 2002).

Applying selection and enhancement to the Belopolsky and Awh (2016) study (discussed previously), the effect of selection history can be readily explained: participants should select an orange circle more quickly if the previous target was also orange because the recent selection would cause the orange color to be enhanced. Explaining top-down goals requires one further step—-after participants view a cue such as the word "orange," they must perform some mental action that produces a representation of an orange object, so that the representation can be selected and the color orange can be enhanced. We propose that participants retrieve a previous example of an orange object from memory. Such a retrieval should be easy, as participants are regularly engaging with orange circles throughout the experiment (note that one alternate hypothesis might be that participants perform mental imagery, imagining an orange circle).

In the next section, we describe a computational model of human performance on the Belopolsky and Awh (2016) search task.

Model

The model is based on three core claims about human attentional processing.

1) Selection picks out a single focus of attention, such as an object in the visual field. Objects are selected based on their *activation strength*, which is a combination of physical salience and spatial/featural enhancement. An object with a higher activation strength is more likely to be selected from among a field of other objects. In addition, an object with a higher activation strength will be selected more quickly after its onset.

2) Selecting an object enables constructing an object representation that can be stored in *visual short-term memory* (VSTM), which is a low-capacity store for representations of recently selected objects (Treisman & Gelade, 1980; Vogel, Woodman, & Luck, 2001). Once an object is represented in VSTM, the viewer can decide to `engage` or `disengage` with the object, depending on whether the object is task relevant. Engagement makes an object's features accessible for further reasoning and supports storing the object's representation in *long-term memory* (LTM), where it will be available for retrieval at a later time. In addition, engagement causes an object's location and features to be enhanced, which helps to maintain focus on the object, while also increasing the probability that nearby or similar objects will be selected. In contrast, disengaging from the object causes its location to be suppressed, so that a different object can be selected.

3) A viewer can `retrieve` an object representation matching a verbal cue (e.g., "orange") from LTM. If this retrieved object representation is selected, then it will be stored back in VSTM, and its features can be enhanced.

Model Framework

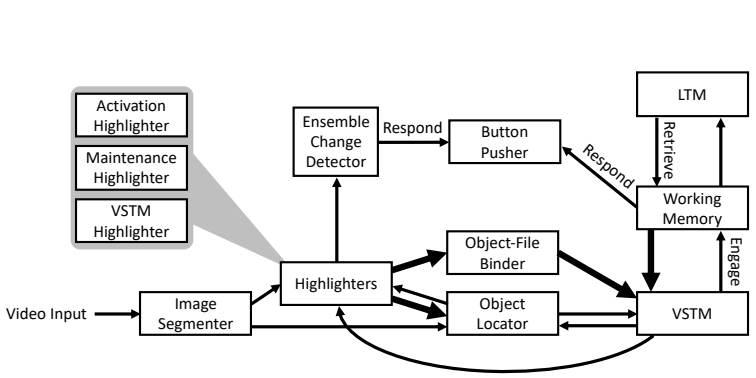
The model is implemented in ARCADIA (Bridewell & Bello, 2016), a computational framework developed to explore the relationships among attention, perception, cognition, and action. ARCADIA models operate over a sequence of cycles. On each cycle, a set of components work in parallel, processing input and generating output. One output item is selected as the focus of attention, and then the next cycle commences, with components receiving as input the output from other components on the previous cycle.

Models built in ARCADIA consist of (1) a set of components; (2) an *attentional strategy*, which sets out the priorities for which component's output will be selected as the focus of attention after each cycle, and (3) optionally, a set of *stimulus-response links*, which indicate that once certain conditions are met, an action should be taken.

Model Runthrough

Figure 3 presents the model's components and illustrates the flow of information. Thin arrows indicate information that flows on every cycle, thick arrows indicate information that flows only when it is selected as the focus of attention, and arrows accompanied by words indicate information that flows only when an action is taken. In the following sections, we shall describe the components and the flow of information in detail, using the search task in Figure 1 as a running example. Note that the model is designed to run on stimuli identical to those shown to humans, with one exception: because the model lacks reading comprehension, the verbal cues "orange" and "blue" are replaced with horizontal and vertical rectangles, respectively. Thus, a horizontal rectangle indicates that the next target will likely be orange.

Figure 3 also provides the model's stimulus-response links, which indicate the conditions under which the model should `engage` with an object, `retrieve` an object representation from memory, or `respond` by pressing a virtual button to end a trial. Whereas many of the model's components perform general-purpose visual processing and have been used in other task models (Bridewell & Bello, 2016; Lovett et al., 2017), the stimulus-response links encode task-specific knowledge about when actions should be performed (e.g., a horizontal rectangle indicates an orange object should be retrieved from memory). These actions provide a means for the model to influence the selection and enhancement mechanisms, and thereby increase the likelihood of task-relevant



Component	Conditions	Action
VSTM	Object is orange, blue, horizontal, or vertical	`Engage` with object
Working Memory	Object is horizontal	`Retrieve` an orange object
Working Memory	Object is vertical	`Retrieve` a blue object
Working Memory	Object is orange or blue	`Respond` "horizontal" or "vertical"
Ensemble Change Detector	Features pooled across the image have changed, and there are multiple objects on screen	`Respond` "guess"

Figure 3: Left: Flow of information between model components. Right: Stimulus-response links for the model.

objects being selected.

Returning to the model's components, processing begins with the Image Segmenter, which takes each frame from an input video and segments it into regions representing possible objects. In the current example, each video begins with a horizontal or vertical rectangle, so the component identifies only one region of interest. Later, when there is a fixation circle surrounded by six larger circles, the component identifies seven regions.

Regions of interest are quickly forgotten unless they are selected as the focus of attention. To this end, components known as *highlighters* suggest particular regions as candidates for attention. In the present model, the Activation Highlighter suggests a region if its combined salience and enhancement (discussed in greater detail later) exceeds a threshold. In contrast, the Maintenance Highlighter suggests the region whose location matches the current focus of attention; this component supports maintaining focus on an object over time. Finally, the VSTM Highlighter suggests a region whose location matches any object represented in VSTM; this component supports returning focus to a recently selected object. Note that the model's attentional strategy gives the highest priority to the Activation Highlighter and the lowest priority to the VSTM Highlighter. This means the model will (1) focus on an object with a sufficiently high activation strength, or if none have a sufficiently high strength, (2) maintain focus on the currently selected object, or if no current object is selected, (3) return focus to a recently selected object.

In the visual search example, when only the fixation circle is visible, it will be selected. When the six outer circles appear around the fixation circle, focus will be maintained on the fixation circle until the activation strength of one of the outer circles exceeds the threshold.

After a region is selected, the Object-File Binder constructs an object representation describing what is found at that region, while at the same time the Object Locator records the region's location and begins tracking the object. The object representation includes the object's physical dimensions and visual features (color, orientation, and brightness). In the current example, the representation contains the necessary information for determining whether a rectangle is vertical or horizontal, determining the color of a circle, or determining whether the line inside a circle is horizontal or vertical.

After an object representation is constructed, the attentional strategy prioritizes selecting it as the focus of attention, so that it can be stored in VSTM (visual short-term memory) which holds representations of the four most recently selected objects. At this point, if the object is task-relevant (a blue or orange target circle, or a vertical or horizontal rectangular cue), the model's stimulus-response links trigger an `engage` action (Figure 3, right side). Engaging with an object causes its representation to move into Working Memory, where it is accessible to other components. In addition, engaging causes the object's location and features to be enhanced (in the present model, the location is enhanced only when the object is visible, and the only feature that can be enhanced is color). For simplicity, if the model does not `engage` with an object, then the model behaves as if it had `disengaged` with the object: the object's location is suppressed, which encourages selection of other objects. Note that all enhancement and suppression effects last only while the object is remembered in VSTM.

In the model, Working Memory functions as a conduit between VSTM and LTM. After a representation is copied from VSTM to Working Memory, it is stored in LTM, which has a greater capacity than VSTM. Later, if the model performs a `retrieve` action, an object representation is copied back into Working Memory, where it can be selected and stored in VSTM. The model's stimulus-response links specify that it should retrieve an orange object after engaging with a horizontal rectangle, or retrieve a blue object after engaging with a vertical rectangle.

In the visual search example, the interactions between VSTM, Working Memory, and LTM give rise to effects of selection history and top-down goals. Suppose two sequential trials each involve an orange circle, and suppose the model successfully selects the orange circle on the first trial. Beginning with this first orange circle, the model will perform the following sequence of selections:

1. Select the first orange circle and generate a response. This ends the first trial.

2. Select the rectangular cue at the beginning of the next trial.

3. Based on the cue, retrieve an object representation from LTM and store it in Working Memory. Select this object representation.

4. Select the fixation circle that precedes the critical 100 ms.

As each of these object or object representations is selected, it will be stored in VSTM. Because VSTM has a capacity for four objects representations, all four will remain in VSTM at the beginning of the second trial's critical 100 ms. Because the circle from the previous trial is in VSTM, its color will be enhanced, resulting in a selection history effect; and because the circle retrieved from LTM is in VSTM, its color will be enhanced, resulting in a top-down goal effect.

Finally, the Button Pusher is passed one of three responses: "vertical" or "horizontal" if the model engages with a target (blue or orange) circle and determines the orientation of its inner line, or a "guess" response if the masks cover the circles before the model engages with a target circle. The appearance of the masks is detected by the Ensemble Change Detector, which responds to large-scale changes to the image.

Overall, the model succeeds at the search task if it selects and engages with the target circle during the 100 ms before the masks appear, enabling it to generate the appropriate response. It fails if either it selects the target circle after the masks appear, in which case the response may be incorrect; or it never selects the target circle, in which case it generates a "guess" response.

Activation Highlighter

The Activation Highlighter integrates salience and enhancement to determine each region's activation strength. Salience is computed via a novel algorithm based on Itti, Koch, and Niebur's (1998) classic computational approach. Operating over the color, orientation, and brightness dimensions, the algorithm computes local contrast throughout the image, and then computes global contrast for each region of interest. A region's salience varies from 0 to 1, where 1 indicates the region strongly stands out on one dimension (e.g., its color is unique, whereas the other regions all have similar colors), or moderately stands out on multiple dimensions.

Spatial enhancement is computed based on whether the region overlaps the location of an object in VSTM. For simplicity, we assign a score of 1 if it overlaps an enhanced object, -1 if it overlaps a suppressed object, and 0 if it does not overlap an object.

Featural enhancement, currently computed only for color, is based on the similarity between colors within a region and colors of objects being enhanced. A region will receive a score of 1 if it perfectly matches the colors of all enhanced objects. Note that in some cases, two different colors may be enhanced—for example, if the previous trial involved a blue circle, but the model just retrieved an orange circle from memory. In these cases, a region will receive a score based on the average of its color match to the two enhanced objects.

To ensure some randomness, Gaussian noise is added to the activation strength, according to the following formula:

$$Gaussian(gaussian\text{-}width) + weight_{sal} * Salience +$$

$$(1 - weight_{sal}) * 0.5(Enhancement_{space} + Enhancement_{features})$$

Finally, the Activation Highlighter computes the average activation strength over the past five cycles and compares this average to an *activation-threshold* to determine whether a region has a sufficiently high score to be selected. Averaging over five cycles achieves the desired effect that objects with more salience or enhancement will be selected more quickly, as it will take fewer cycles after onset for the running average to exceed *activation-threshold*.

Note that there are three free parameters: $weight_{sal}$ the weight given to salience, relative to enhancement; *gaussian-width* the width of the Gaussian noise; and *activation-threshold*. For now, we set $weight_{sal}$ to 0.2 (meaning salience receives one quarter the weight of enhancement), and we shall use the simulation that follows to explore possible noise and threshold values.

Evaluation

To simulate the Belopolsky and Awh (2016) search task, we generated input videos that match the original study's stimuli exactly, with two exceptions: (1) as discussed previously, the verbal cues "orange" and "blue" were replaced with horizontal and vertical rectangles; (2) some portions of each trial were sped up to save processing time, but the critical 100 ms display time went unchanged.

In the original experiment, 24 participants each viewed a large number of practice trials, followed by 600 search trials. For the simulation, five virtual participants each viewed 40 practice trials, followed by 600 search trials. Because the virtual participants were all the same model, and they differed only in the particular trials they viewed, we combined the 3000 (5×600) results and analyzed by item. To reduce variance, "guess" responses were treated as 0.5 correct.

We ran the simulation across a range of *activation-threshold* and *gaussian-width* values. Figure 4 presents the results with a low (0.04) or medium (0.11) threshold, and with no or moderate (0.1) noise. Overall, it appears that a medium threshold and some noise were needed to achieve human-like performance; without these, the model performed at or near ceiling for all salient targets. The rightmost graph in Figure 4 closely matches the human results (Figure 2, note that the units are different), but a qualitative comparison suggests that repetition provides a stronger benefit to the model than to humans. In the model, repetition and valid cues provide similar benefits, but perhaps the benefit from repetition should be weaker because viewers stop engaging with a target circle after a trial ends.

To examine the benefits of target salience, cue validity, and repetition, we conducted an ANOVA for each simulation run. These analyses confirmed that all three factors contributed

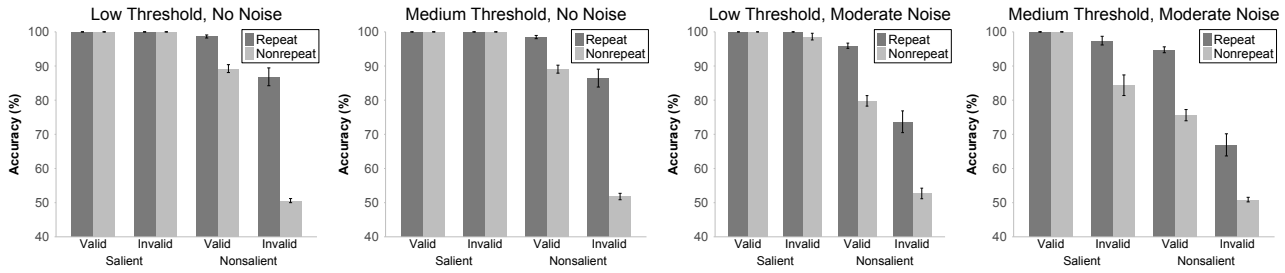


Figure 4: Model simulation results. Error bars are ± 1 SE.

significantly to accuracy (all $ps < .05$), and additionally found that most interactions between factors were significant. As we discussed when considering the human results, we believe these interactions are driven by a ceiling effect—note that performance is at 100% for some conditions.

Conclusion

Our computational model is able to perform a visual search task, while demonstrating how salience, selection history, and top-down goals influence attentional capture. In particular, the acts of `engaging` with task-relevant objects and `retrieving` previously selected objects influence which features become enhanced, thereby causing relevant objects to be selected more easily in the future.

Ultimately, the model suggests that humans possess only limited top-down control over attentional capture. For example, the model predicts that a verbal cue will be effective only when viewers are able to act on it. Suppose that after many trials of the visual search experiment, viewers are presented with a novel verbal cue, such as "red." This cue should provide little benefit because viewers have not been engaging with red circles, and thus red circles are unavailable for retrieval. In contrast, a novel *visual* cue, such as an image of a red circle preceding the search trial, should provide an immediate benefit because selecting the red circle causes its features to be enhanced.

In developing this model, we drew inspiration from previous models of visual search and attentional capture. Notably, most models explain the influence of salience (Itti et al., 1998), top-down goals (Wischnewski, Steil, Kehrer, & Schneider, 2009), or both (Tsotsos, Kotseruba, & Wloka, 2016). We believe our model is unique in explaining the influences of salience, top-down goals, and selection, while making explicit claims about the limits of top-down control.

Moving forward, we plan to evaluate our model and the parameters that have been calibrated on the present task by simulating additional search tasks. These will include conjunctive searches, in which there is benefit to enhancing multiple feature dimensions (color, orientation, curvature, etc) in parallel (Wolfe, 2007). In addition, these will include longer searches in which there is time to move the eyes. Eye movement—which can be simulated in ARCADIA—is another deliberate action that influences selection and enhancement. Thus, viewers can optimize their search performance through strategic control of their looking patterns (Pomplun, Garaas, & Carrasco, 2013). By modeling the actions and strategic decisions that affect attentional capture, we hope to better understand how people can effectively extract important, task-relevant information from the world around them.

Abstract

We report a first effort to model the solution of meaningful four-term visual analogies, by combining a machine-vision model (ResNet50-A) that can classify pixel-level images into object categories, with a cognitive model (BART) that takes semantic representations of words as input and identifies semantic relations instantiated by a word pair. Each model achieves above-chance performance in selecting the best analogical option from a set of four. However, combining the visual and the semantic models increases analogical performance above the level achieved by either model alone. The contribution of vision to reasoning thus may extend beyond simply generating verbal representations from images. These findings provide a proof of concept that a comprehensive model can solve semantically-rich analogies from pixel-level inputs.

Keywords: analogy; relations; learning; machine vision; word embeddings

Introduction

In everyday life, humans continually perceive the world and interpret it in terms of meaningful objects and events. The representations extracted by perception are elaborated into semantic representations that can be communicated by language and further transformed by reasoning processes. The "holy grail" of cognitive science is to develop integrated theories that link perception to language and higher cognition. A natural testbed for developing such integrated theories is the task of reasoning by analogy from meaningful visual inputs. Here we report a first effort to develop a comprehensive model of the solution of visual analogies, by combining a model that can translate pixel-level inputs into verbal captions with a model that can translate semantic vectors for words into coherent patterns of semantic relations.

Figure 1 depicts an example of the analogies on which we focus. This problem is one of a set of 18 developed by Krawzcyk et al. (2008), some of which were adapted from an earlier set created by Goranson (2002), hence dubbed the Goranson Analogy Test (GAT). The upper row presents a pictorial problem in the form *A:B :: C:?*. The task is to select the best analogical completion from among a set of four options shown in the bottom row. For this example, the analogical solution based on matching relations is to choose the pie (wine is made from grapes, as pie is made from pumpkin). The three distractors include one that is semantically related to the *C* term but fails to match the *A:B* relation (witch), one that is visually similar but also fails to match *A:B* (basketball), and one that is simply unrelated (books). Critically, the analogical solution cannot in any obvious way be derived from visual information alone, because the core relation is semantic/functional rather than visual. For example, the fact that wine is made from grapes is not depicted in the visual input; rather, it must be retrieved from semantic memory. Thus, vision is necessary but not sufficient to reliably solve such semantically-rich picture analogies.

The GAT was originally developed as a tool to evaluate the impact of neuropsychological disorders. Krawczyk et al. (2008) found that frontal and temporal patients were impaired to varying degrees, notably showing an elevated tendency to choose the semantic or perceptual distractors. Age-matched controls (approximately age 60) achieved about 98% accuracy even in the presence of similar distractors.

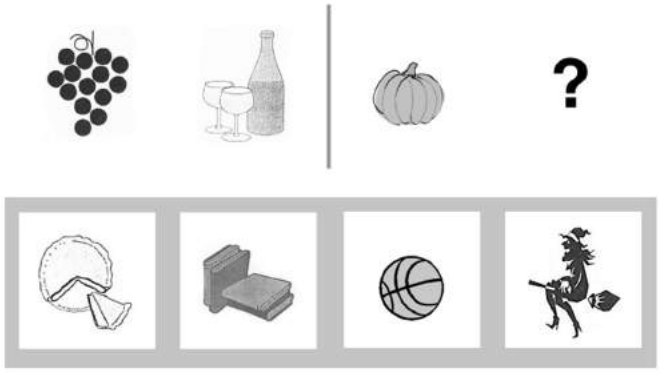

Figure 1. Example of a 4-term pictorial analogy with four alternatives (from Krawzcyk et al., 2008).

Here we focus on the most fundamental question: how can such pictorial analogy problems be solved at all? On the face of it, the process begins with the human visual system operating on pixel-level inputs of the images in the problem to extract a verbal description and/or semantic categorization of the objects. Reasoning processes must use these object descriptions to determine the relation(s) linking paired objects. Based on these relational representations, the reasoner must then assess the degree of relational match between *A:B* and the alternative completions for *C*, finally choosing the option that provides the best match.

Despite decades of progress in developing computational models of visual perception, language processing, and analogical reasoning, no model has tackled the full range of processing required to solve meaningful visual analogies such as the GAT problems. Recent advances in machine vision have led to very significant progress in the recognition of objects from pixel-level representations (Krizhevsky, Sutskever & Hinton, 2012; Semonvan & Zisserman, 2015), including the automatic generation of verbal captions (Farhadi et. al., 2010; Mao et. al., 2016; Krishna et. al., 2016). However, artificial-intelligence (AI) models have been less successful in transforming visual inputs into semantic representations of *relations between objects*. AI models of visual analogy have generally focused on problems that can be solved on the basis of simple visual features, such as color and shape (Reed et. al., 2015; Sadeghi, Zitnick & Farhadi, 2015). In cognitive science, most analogy models have simply assumed high-level representations of complex propositions (usually hand-coded), without dealing with the problem of how these representations could be generated by perceptual processes. Lovett and Forbus (2017) describe a model that applies analogical reasoning to solve Ravens Progressive Matrices problems, which are a form of visual analogies based on transformations of geometrical shapes. However, the inputs provided to the model are high-level perceptual descriptions, rather than a matrix of pixels; and the Ravens test is entirely formal, devoid of any links to semantic knowledge. With important exceptions (e.g., Doumas, Hummel, & Sandhofer, 2008), analogy models have generally set aside the basic problem of how semantic relations could be learned from non-relational inputs.

Here we describe two computational models that together provide an approximate account of the entire process that may underlie solution of GAT problems. One model, ResNet50-A, aims to solve the picture analogies using purely visual information, while also generating verbal captions. The other, BART, aims to solve the same analogies based solely on verbal descriptions of the images. We further show that the analogy assessment derived by ResNet50-A using just visual information not only provides potential verbal inputs to BART, but also adds independent visual information that increases solution accuracy. We will first describe the operation of each of the two models, and then the results obtained by using them both separately and jointly.

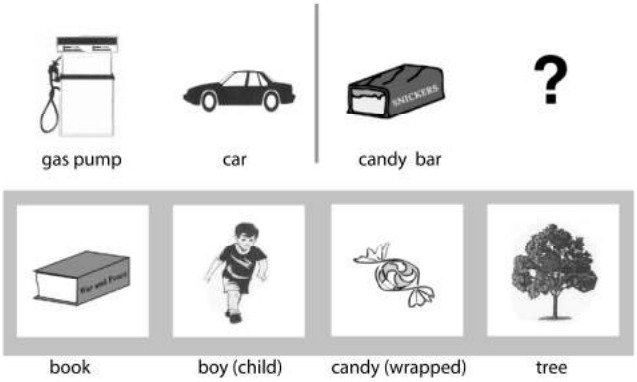

Figure 2. Example of a 4-term pictorial analogy with four alternatives, and corresponding descriptions verbally presented to patients (from Krawzcyk et al., 2008).

GAT Dataset

The GAT dataset includes 18 picture analogies, each consisted of 7 images: the three images in the question, *A*, *B*, and *C*, and the four images for alternative D terms. All images are line drawings or clip art images. Each image was captured in the size of 140x140 pixels. The GAT dataset included a total of 126 images that fall into 118 distinct object categories. A verbal caption describing each image was used by Krawczyk et al. (2008) in their neuropsychological study; these captions were adopted as canonical verbal descriptions of each image for the semantic model, BART. Figure 2 shows a second example, along with approximations of the corresponding verbal descriptions used by Krawczyk et al. (2008). Note that in the neuropsychological study, the accompanying labels were presented orally by the experimenter, rather than in written form.

ResNet: From Pixels to Object Classification

Background

Deep convolutional neural networks (Krizhevsky, Sutskever, & Hinton, 2012; Simonyan & Zisserman, 2015) have led to a series of breakthroughs for a broad range of computer vision tasks. The network depth is of crucial importance. Recent work with deeper networks has exposed a degradation problem: as network depth increases, accuracy reaches a plateau, and then degrades rapidly as network depth increases further. ResNet (He, Zhang, Ren, & Sun, 2016) addresses the degradation problem by introducing a framework termed *deep residual learning*. ResNet fits a residual mapping, realized by a feedforward neural network with identity shortcut connections. Using this method, ResNet can be efficiently trained with as many as 1000 layers. Because of its compelling performance levels, ResNet has quickly emerged as one of the leading architectures for a wide range of tasks in computer vision. Here we adopt ResNet50 (the basic architecture with 50 layers) as a state-of-the-art approach to identifying and captioning the objects in GAT analogies. We then augment the model to create ResNet50-A (where the "A" stands for "Analogy") by adding a decision procedure to generate

potential analogical solutions based solely on visual information in the images.

Training Dataset

The GAT images are line drawings (as are most images used in picture analogy tests that have been developed for psychological research or cognitive assessments). Machine vision models are typically trained on photo-realistic images, and require additional training with line drawings in order to classify them. In order to provide suitable training for ResNet50, we created a database of clip art images that were similar to GAT images, but not identical to them. This dataset, termed the ClipArt dataset, includes the 118 object categories used in the GAT visual analogy problems. To create the ClipArt dataset, we queried Google Image Search using the "Search by image" function, uploading the corresponding GAT image and entering a phrase formed by concatenating the category label and the words "clip art". (For some categories, we visually checked the result and decided to replace "clip art" by "drawing", "sketch", or "cartoon".) We downloaded 200 images for each category and manually removed those that were duplicates or clearly wrong. Each category in the resulting ClipArt dataset was represented by 70-166 images. The images were then processed into gray scale and padded with zero on short edges to fit a 1:1 aspect ratio.

For each category, we randomly selected 50 images for training, and held the rest images for test, resulting in a total of 5900 training images and 5501 test images. Figure 3 juxtaposes a GAT image (left) with a ClipArt image (right) from the same category. To ensure that the model was able to generalize its visual recognition performance, the GAT dataset was only used to guide construction of the ClipArt dataset; the GAT images themselves were not used to train ResNet50.

Training

We implemented ResNet50 using Pytorch on a single TitanX GPU. The training task was image classification by minimizing the cross-entropy loss. The model was pretrained on the ImageNet dataset, and then fine-tuned on our ClipArt dataset for 200 epochs. Batch size was set equal to 120 and learning rate started at 0.01, followed by cosine annealing. For optimization, SGD optimizer was used with momentum = 0.9, weight decay = 0.0001. To prevent overfitting, small random image transformations (e.g., rotation, translation, scaling) were added to the input images. The model achieved a high performance level on the ClipArt test set, achieving 0.883 for top-1 accuracy (i.e., the correct object category label being identified as the first choice of the model), and 0.973 for top-5 accuracy (i.e., the correct object category label being identified as one of the top five choices of the model). When tested on the GAT images for the visual analogy problems, the model achieved 0.833 for top-1 accuracy and 0.984 for top-5 accuracy.

Figure 3. Example images. In each row, the first image is from the GAT dataset, while the remaining images are from the ClipArt dataset. Top row: images with label "electric mixer"; bottom row: images with label "book".

Analogical Inference

We extended ResNet50 to form ResNet50-A by adding a simple computation to derive analogy predictions from the model. We input each GAT image into the neural network and extracted the penultimate feature vector (the vector immediately prior to the output layer). This vector of length 2048 was used as the representation of the image. Mathematically, this transformation can be written as: $\boldsymbol{f} = F(\boldsymbol{I}; \theta)$, where $\boldsymbol{I}$ is the input image, F is the function specified by the neural network and parametrized by θ, and $\boldsymbol{f} \in R^{2048}$ is the resulting feature vector. Thus, for each analogy question, we transfer images $\boldsymbol{I}_A, \boldsymbol{I}_B, \boldsymbol{I}_C, \boldsymbol{I}_{D1}, \boldsymbol{I}_{D2}, \boldsymbol{I}_{D3}, \boldsymbol{I}_{D4}$ into feature vectors $\boldsymbol{f}_A, \boldsymbol{f}_B, \boldsymbol{f}_C, \boldsymbol{f}_{D1}, \boldsymbol{f}_{D2}, \boldsymbol{f}_{D3}, \boldsymbol{f}_{D4}$, respectively.

A decision for an analogy problem in ResNet50-A is derived by selecting the best $D \in \{D_1, D_2, D_3, D_4\}$ such that the relation from *A* to *B* holds for *C* to *D*. To measure how similar the projection from $\boldsymbol{f}_A$ to $\boldsymbol{f}_B$ is to the projection from $\boldsymbol{f}_C$ to $\boldsymbol{f}_D$, we adopted a generic formulation based on cosine distances of the difference vectors. The same approach has been used in the Word2vec model (Zhila et al., 2013). The preferred answer $\widehat{D}$ is defined as the *D* image that generates minimum cosine distance between difference vectors:

$$\widehat{D} = \arg \min_{D \in \{D_1, D_2, D_3, D_4\}} \cos(\boldsymbol{f}_B - \boldsymbol{f}_A, \boldsymbol{f}_D - \boldsymbol{f}_C)$$

Note that this procedure for solving a visual analogy is more sophisticated than simply choosing the $\widehat{D}$ most similar to *C*, since the selection focuses on matching the visual *relation* between the *A:B* and *C:D* image pairs.

For the GAT problems, this purely visual model achieved 44% accuracy in selecting the correct *D* term. Its other choices were distributed across the three distractors (11%, 17% and 28% probabilities of choosing semantic distractors, visual distractors, and unrelated distractors, respectively). Since chance accuracy would be 25%, the purely visual analogy model achieved analogical accuracy well above chance (although well short of the level achieved by neurotypical human adults).

BART: From Verbal Semantics to Relations

The BART model (*Bayesian Analogy with Relational Transformations*) takes as inputs semantic vectors representing word meanings and uses supervised learning to acquire representations of semantic relations. The model was originally applied to learning comparatives (e.g., *larger*, *smarter*; Lu, Chen & Holyoak, 2012), but has recently been generalized to acquire an extremely wide range of semantic relations (e.g., *synonym*, *antonym*, *cause-effect*; Lu, Wu & Holyoak, 2019). For the present project, the inputs to the BART model were word embedding for individual words, each embedding consisting of 300-dimension vectors with continuous-valued features. The word embeddings were obtained by training a deep-learning model, Word2vec (Mikolov et al., 2013; Le & Mikolov, 2014) on a large text corpus (Google News). BART takes as inputs word pairs instantiating a relation, where each pair is represented by the concatenation of the Word2vec vector for each individual word. For example, a vector formed by concatenating the individual vectors for *love* and *hate* would constitute a positive example of the *antonymy* relation. The same word pair might also serve as a negative example of the *category:instance* relation.

Training Dataset

For the present project, we trained BART by combining two datasets of semantic relations. First, the SemEval-2012 Task 2 dataset (Jurgens et al., 2012) was used to teach BART the representations for 79 abstract semantic relations. This dataset is based on a taxonomy of semantic relations and includes 10 general types (e.g., *class inclusion*, *similar*, *contrast*, *cause-purpose*). The dataset includes 3215 word pairs, with 35~48 pairs for each of the 79 relations. The second dataset, developed by Popov, Hristova, and Royce (2017), includes some specific and concrete relations (e.g., the relation *constitution* with examples *brick:house*, *thread:cloth*; the relation *cover* with examples such as *house:roof*; and the relation *boundary* with examples such as *wall:room*). This dataset includes 58 specific relations drawn from ten general categories of relations. Two relations with inadequate numbers of examples were removed. The remaining 56 relations included 12~25 word pairs as examples for each relation.

Training

The BART model consists of a three-stage process to learn a broad range of semantic relations (Lu, Wu & Holyoak, 2019). In its first stage, BART exploits the heuristic that features playing similar functional roles will tend to occupy similar ranks in an ordering of differences between paired words. BART uses the difference ranking operations to generate augmented feature by partially align important features. In the second stage, BART selects a subset of important features. In the third stage, BART adopts Bayesian learning and uses the selected features of word pairs $\mathbf{f}_s$ in training examples to estimate weights distributions $\mathbf{w}$ for representing a particular relation R by applying Bayes rule as:

$$P(\mathbf{w}|\mathbf{f}_s, R) \propto P(R|\mathbf{f}_s, \mathbf{w})P(\mathbf{w}). \quad (1)$$

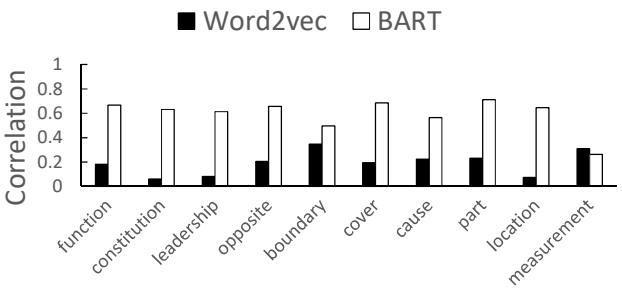

Figure 4. Model predictions of human data for relation typicality in Popov et al. (2017) dataset: Correlations between human generation frequencies and model predictions for 10 relation types for BART (after training with 10 positive examples of each relation) and for the baseline Word2vec model.

After learning, BART calculates the probability of a word pair instantiating a relation. An important aspect of both the Jurgens et al. (2012) and the Popov et al. (2017) norms is that in each set, the word pairs instantiating each relation form a typicality ordering established by human judgments. As reported in Lu et. al. (2019), BART achieved high rank-order correlations between human typicality ratings and predicted probabilities derived from the model for the abstract relations in the Jurgens et al. dataset. Across all 79 individual relations, the model's mean Spearman correlation with the human ordering was .81 (range from .65 to .91). The performance of BART considerably exceeded the mean correlation of .34 achieved using Word2vec itself as a baseline.

For the Popov et al. (2017) dataset, which includes more specific/concrete relations, BART was trained with just 10 word pairs as positive examples of each relation. As shown in Figure 4, BART achieved higher correlations with human typicality as indexed by generation frequencies (mean r = .59) than did the Word2vec model (mean r = .19).

Analogical Inference

To solve 4-term verbal analogy problems, BART forms a distributed representation of the specific relation between each word pair in a problem. BART uses its pool of learned relations to create a more refined representation of the relation(s) between two paired words. The posterior probabilities calculated for all known relations form a relation vector, with each element indicating how likely a word pair instantiates a specific relation. Hence, the result of this operation is to create a distributed representation of the relation(s) between two words, with the original semantic features being projected into a transformed space that can be used to assess relation probabilities.

For analogical reasoning, BART had available 79 relations derived by training on the Jurgens et al. (2012) norms, plus 56 relations derived by training on the Popov et al. (2017) norms.

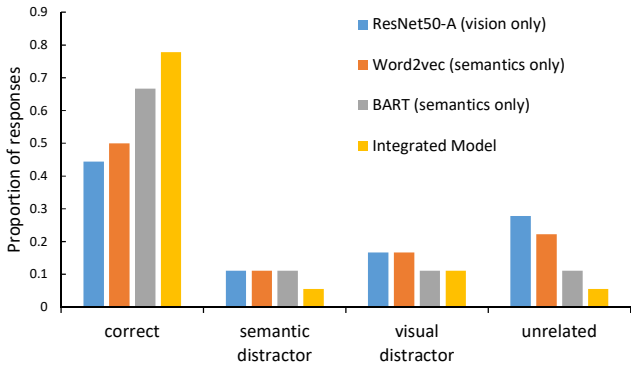

Figure 5. Proportion of responses for GAT problems for which the model's selection was the analogical option (correct), the semantic distractor, the visual distractor, and the unrelated option. Besides ResNet50-A and BART, we also report results obtained using Word2vec, and the integrated model (i.e., ResNet50-A combined with BART).

Of the latter, six relations showed weak correlations with human typicality ratings, indicating BART had failed to learn them adequately from the small number of available examples. Further examinations of the training sets for these six relations revealed that a substantial number of word pairs either included ambiguities or were otherwise questionable as instances of the relation. Accordingly, these six relations were dropped, leaving 50 relations from the Popov et al. set to be included in the relational representations, for a total of 129 learned relations.

Because BART creates relations structured by distinct roles, the model can generate the converse of any learned relation in a rule-based fashion (without additional training). For example, having learned the relation *category:instance*, BART can directly generate the converse relation *instance:category*. By applying converse formation to all trained relations, BART doubled its pool of relations, so that a total set of 258 semantic relations were available to solve GAT analogy problems.

To apply the BART model to GAT problems, the input was the verbal captions for images provided in the study by Krawczyk et al. (2008). Considered as a comprehensive model, this makes the link between ResNet50 and BART only approximate: although ResNet50 achieves high accuracy in generating the target captions, its performance is still less than perfect.

We were also faced with the problem that for many GAT images the optimal caption is a multi-word phrase (e.g., *gas pump*, *woman sewing*). To obtain semantic vectors for phrases that were not included in the Word2vec dictionary, we sometimes substituted one-word near-synonyms for which a vector was available. When that was not feasible, we used a simple averaging method, forming a vector for a phrase by averaging the vectors for its content words (cf. Kintsch, 2001).

For any pair of semantic vectors, BART uses its learned weights to calculate the posterior probability that the pair instantiates each relation in the repertoire of the model. The vector of length 258 formed by these posterior probabilities provides a distributed representation of the specific relation between the two expressions in the pair. Similarly to the procedure we followed to enable ResNet50-A to solve visual analogies, BART's preferred answer $\widehat{D}$ is that which minimizes the cosine distance between the *A:B* relation and the relation formed by *C* paired with each available option.

For the GAT problems, the BART model achieved 67% accuracy in choosing the correct *D* term; other choice probabilities were 11%, 11% and 1% to choose semantic distractors, visual distractors, and unrelated distractors, respectively (see Figure 5). To provide a baseline semantic model, the performance of Word2vec (Mikolov et al., 2013), which does not learn specific semantic relations, can be compared with the performance of BART. The Word2Vec model achieved 50% accuracy in choosing the correct *D* term; other choice probabilities were 11%, 17% and 22% to choose semantic distractors, visual distractors, and unrelated distractors, respectively.

Integration of Visual and Semantic Models

Finally, we examined the performance of an integrated model of solving pictorial analogies, formed by combining the measure of relational similarity obtained from the vision model (ResNet50-A) with the comparable measure obtained from the semantic model (BART). Two free parameters were introduced to create the integrated model.

We first transformed the vectors used by each model to put them on a common scale. The relational similarity measure from the visual model is based on difference vectors of visual features derived from the penultimate layer of ResNet50-A. These difference vectors take values in the range of -8 to 8. In contrast, the BART model forms relation vectors using posterior probabilities within the range [0 1]. To place the two vectors on a similar scale, we introduced a nonlinear transformation with an exponential function for the visual difference features v as $\exp(\alpha v)$ with a scale parameter, set at $\alpha = 2$. Cosine distances based on these transformed visual difference vectors were used to compute relational distance using the visual module:

$$D_v = \cos(\exp(\boldsymbol{\alpha}(\boldsymbol{f}_B - \boldsymbol{f}_A)), \exp(\boldsymbol{\alpha}(\boldsymbol{f}_D - \boldsymbol{f}_C))).$$

The relational similarity measure derived from the semantic module, D_s, was calculated by directly using BART as described in the preceding section. The final relational distance measure was a weighted average of the measures from the visual and semantic modules, $D = \lambda D_v + (1 - \lambda)D_s$, with the weight set as $\lambda = .3$.

Figure 5 presents a summary of the results for solving GAT analogy problems based on the visual-only model (ResNet50-A), two semantic models (Word2Vec and BART), and the integrated model based relational distance measures from both visual (ResNet50-A) and semantic (BART) models. The integrated model achieved the highest accuracy (78%) in solving GAT analogy problems; other choice probabilities were 6%, 11% and 6% to choose semantic distractors, visual distractors, and unrelated distractors, respectively.

We explored the space of parameter values, and found that performance of the integrated model was quite robust. In

general, the basic results were the same for a broad range of parameter values for α, as long as the value of λ was less than .5, so that the final decision was primarily driven by the semantic module, based on BART.

Discussion

The present paper provides a proof-of-concept that vision, language, and reasoning can be integrated to create a comprehensive computational model of how humans or machines might solve meaningful visual analogies. Here our focus has been on a vision module (ResNet50-A) that can generate verbal captions for line drawings, combined with a semantic module (BART) that takes word embeddings based on verbal captions and generates representations of semantic relations. Each model includes a decision procedure for assessing the similarity of relations between objects/words and selecting the best analogical completion from among a set of alternatives. The vision module alone achieves above-chance analogical performance on the GAT problems (picture analogies in *A:B :: C:?* format); the semantic module alone is more successful; and an integration of the two modules (biased to emphasize semantics, but also influenced directly by vision) is yet more successful, achieving 78% accuracy.

Perhaps the most surprising finding from our computational experiments is that the vision module alone was able to achieve above-chance accuracy in selecting the analogical completion, even though the critical relation is semantic/functional. Despite some shortcomings of visual deep learning models (Baker, Lu, Erlikhman & Kellman, 2018), the features in the later layers may capture parallels involving visual context (e.g., the fact that airplanes and eagles both cooccur with sky in many natural images, analogous to the fact that ships and fish both cooccur with water in natural images). Apparently, for some GAT problems, the similarity of the visual difference between the *A:B* pair to that between the *C:D* options is at least weakly correlated with the semantic relations that define the analogical answer. Moreover, the visual module continues to add useful information on top of that provided by the semantic module. Thus, vision may play two important functions in solving picture analogies: generating verbal captions that in turn feed the semantic module, and directly providing visual correlates of semantic relations.

The present project is only a first step toward the "holy grail" of a unified model connecting perception to thinking. The performance of the integrative model falls short of the high accuracy level achieved by healthy human adults not under time pressure (Krawcyzk et al., 2008). A number of incremental improvements are worth pursuing. ResNet50 might benefit from additional training on line drawings. Its accuracy in captioning might also be improved by making use of contextual information (e.g., the presence of a pumpkin as the *C* term in Figure 1 might aid in recognizing the pie). If the captioning accuracy of the visual module could be improved, its output could be directly passed to BART (rather than allowing BART direct access to optimal captions). Furthermore, future investigations need to explore how to combine visual and semantic knowledge to solve generative tasks in analogical reasoning (Chen, Lu & Holyoak, 2017).

Deeper developments would include adopting more sophisticated techniques for translating multi-word captions into semantic vectors, and eventually dealing with structured text descriptions of analogical scenes (Richland, Morrison, & Holyoak, 2006). Perhaps most intriguing is the possibility of creating hybridized visuosemantic representations that would allow perception to meld with meaning.

Abstract

Research has consistently demonstrated that people treat digital technology-based environments such as VR as if they were real. This is consistent with neural reuse and predictive processing theories. Neural circuits that have developed to perform real world actions are reused when performing tasks in computer mediated environments. The current research investigates some of the factors that could support users in leveraging their existing real world representations. A reasonable hypothesis is that users are more likely to emulate existing real world processing if technological artifacts are congruent with their experiential basis. This work investigates the perceived cues of task risks, movement realism and effector realism in performing actions. Effector design is manipulated (gesturing, wand, vs. knife), and participants cut a vegetable in a simulated environment. Participants evoked real world sensory motor contingency when technological artifacts are congruent with their experiential basis.

Keywords: embodied cognition; risk perception; computer mediated learning; danger avoidance; effector; controller

Introduction

Increasingly technological systems have begun to develop new interactive styles that leverage the richness of humans' real world interactions. For example, systems using low cost full body motion tracking, such as Kinect, have been made available. There is also a breakthrough in eye gaze based interactive system such as LC technologies' eye gaze edge tracking. Because of this departure from WIMP interfaces, a significant question arises as to whether and how gestural interactions, or in some cases intention driven touchless interactions, can evoke representations that are similar enough to perceiving and enacting actions in the real world in order to train up responses and habits that would be able to later get deployed in real world practices. If not, what differences might there be?

A myriad of theoretical approaches have been proposed to guide the design of systems that support users embodying themselves in the environment and participating in the interactions meaningfully. One of the central themes of this embodied interactive movement is to encourage the alignment between the representations being constructed for the digital world and the relevant experiential basis, making digital artifacts part of the background in the formation of representations instead of being in the foreground (Dourish, 2001; Hornecker, 2011; Ishii, 2008; Jacob, et al., 2008; Lu, Harter, Kosito & Kotturu, 2014; Slater, 2009). By judiciously re-representing the key elements in physical reality, as well as tapping into visual-perceptual cues, such digital-physical systems create a new interface interaction paradigm that leverages existing embodied proprioceptive abilities and motor skills we all develop and employ in the real world. This movement is consistent with insights from embodied and grounded cognitive science (Kirsh & David, 2013).

Recent views of embodied cognition are exploring the high level neural mechanisms that may be critical to our embodied cognitive abilities. For example, views of cognition as being hierarchical predictive machinery, where higher level layers predict activity of lower layers, and the lower layers send feedback in the form of error signals of the predictions have been proposed (Clark, 2013; Anderson, Richardson, & Chemero, 2012; Barrett & Simmons, 2015). These predicative theories suggest that more abstract concepts and higher level abilities, such as keeping track of goal states, are built up through the testing and refining of predictive mechanisms. The predictions and error signals are fundamentally bidirectional, higher levels generate predictions of the neural patterns of activity of lower layers, and mismatches generate error signals that are propagated back up the hierarchy which can be used to refine the predictive machinery.

This brain as active predictive machine view suggests that the sensory repertoire gathered from past experiences and the current sensory/perceptual inputs constrain the computation of probabilities that underlie neural representations. Such predictive views of embodied cognition are especially relevant to understanding human performance in computer mediated environments. In a computer mediated environment, we use predictive machinery that is evolved and developed to work with other (usually real world) experiences in order to interact with the digital environment (Lu & Harter, 2016).

The reuse and redeployment of neural circuits is expected (according to neural reuse theories) in order for perceptual predictions to be as efficient and accurate as possible in computer mediated environments (Anderson M. L., 2010). There are two mechanisms by which neural circuits are commonly reused, especially in the context of learning to

use a computer mediated environment for some task. In one type of reuse, new types of higher-level prediction abstractions will be created to learn predictions of low-level circuitry that is essentially being used for the purpose it was originally developed for. For example, in order to interpret visual objects being depicted in a virtual reality, they are of course designed to be visually similar to their real world counterparts. Another type of reuse is where low-level circuitry is put to a novel function by existing higher-level abstractions to cope with the differences in an unfamiliar computer mediated experience. For example, we may be experiencing a common task in a simulated environment, such as moving objects around to complete some goal, but our low-level motor actions needed in order to interact with the virtual world use some sort of input effector like a joystick rather than our own hands to perform the task.

In cognition, this predictive machinery results in a tight coupling of what is available in the environment (such as the fidelity of the environment) and the sensory motor contingency that gets triggered in a user. Central to the argument in the current work is the bi-directionality of this coupling. For example, user's movements can modify which aspects of the environment are attended to and reflexively tweak the run-time representations that are used for selecting the next action. However, previous research has been inconclusive to this prediction and the existing research paradigms are not conducive to understanding these bi-directional interactions as they unfold. In existing studies, researchers examined explicit game performance measures and player subjective reports including perceived mental workload, and did not look into real time processing measures (Freeman, et al., 2012; Reinhardt & Hurtienne, 2018). In yet another study, video clips of transitive actions were examined and participants reported the habitual actions were perceived to be easier and more natural to understand (Grandhi, Joue, & Mittelberg, 2011).

In recent work on immersive virtual reality, researchers have demonstrated the current state of the art in terms of providing tracking of handheld effectors in a typical head-mounted display (HMD) virtual reality system (Pandey, Pidlypenskyi, Yang, & Kaeser-Chen, 2018). Tracking the position of the handheld effectors is of course important in theory in order to provide an immersive experience not only of seeing the environment, but of having your body (hands and arms) embodied and perceptible within the environment. This is relevant to our current study, as it shows what may be possible in virtual reality to enable embodying hand movements and interactions. For example, the reported image-based markerless 6 degrees of freedom tracking of handheld effectors demonstrated much more reliable tracking than current virtual reality systems can achieve without additional sensors embedded in the handheld effectors. In fact, though not discussed in this article, it would seem that this method could be applied equally well to tracking the user's hands, even without holding a effector. In the research report, the authors showed that using machine learning and dual visual images, such a system can be trained to track and localize the handheld effectors with very good localization accuracy.

To what extent can users perceive the avatars in extra personal space to be their own bodies? This predictive machinery points to the importance of the visual motor correlations in embodying onto the avatar. For example, an illusory body ownership can be created over an invisible body via visual-motor synchronization (Kondo et al., 2018). While wearing a HMD, participants saw left and right white gloves and socks in front of them, at a distance of 2m, moved along in a virtual room. The visual-motor synchronicity of hands and feet were adequate to create the illusion that the moving virtual gloves and socks were part of participant's own body. This illustrates that humans are more fluid in integrating real and virtual environments than we thought previously. Are there some minimal or necessary conditions where users could blur the boundaries of real and virtual environments and perceive the actions of the avatar to be part of their extended personal space? For example, humans perceive their own mirror reflections to be part of their extra personal space. The question here is the extent to which the visual motor correlations impact users' projecting themselves into the virtual environments and act as if they themselves would be impacted by the consequence of the actions. Given that users are shut off from the real world while using the HMD, there are a number of advantages in examining the integration of real and low-cost simulated environments.

In this research, we look into real time processing measures as we manipulate an effector used by a participant in a simulated environment on a simulated task. We vary the effector to become more congruous with the real world tool they might use to do the same task. In particular, we set up a simple task to cut objects with a knife, and test certain *implicit* task measures as users perform the task but with an empty hand, vs. when holding a wand, vs. when holding a prop knife to interact with the simulated environment. Previous studies did not find realism in effectors resulted in significant differences in performance metrics, and occasionally reported some differences in subjective ratings (Freeman, et al., 2012; Reinhardt & Hurtienne, 2018). We think the explicit performance metrics and subjective evaluations of the user experiences could result from participants' strategic decision making. In the current study, we contrast the significant dimensional differences among effectors and make predictions as to whether there might be implicit differences in participants' behavioral repertoire, which is less likely to be modulated explicitly. We will explore the following hypotheses.

Physicality Hypothesis

Given that the knife and the wand in our study are matched in terms of weight and length, the physical properties of device-based effector vs. open hand are significantly different. Thus the *implicit* task performance in terms of cut

location (i.e., the cut location index) will be expected to be different between device-based effector (knife or wand) vs. open hand gesturing. We do not make predictions in terms of total time on task. It is reasonable to think that it takes longer time to cut when holding an actual physical object. However, if holding a physical object primes an awareness of the risk, then it is possible that the total time on task will be longer.

Risk Perception Hypothesis

Given that the knife is the only effector that could trigger the perception of risk (Aneli, Borghi, & Nicoletti, 2012; Brogni, Caldwell, & Slater, 2011; Liu, Cao, Chen, & Wang, 2017; Zhao, 2017), there would be significant differences in total time on task between the knife condition vs. the non-knife conditions (wand, and open-hand). Also the trajectories people take in moving the effector may differ between these, for example by being less smooth.

Method

The low-cost desktop virtual environments we developed for the experiments reported here aim to emulate a stationary work area, where the avatar puppets the motions of the user's arm in the real world, to allow the user to manipulate objects through the avatar's actions. A typical example we have implemented is a kitchen food preparation area, where the user has control of one arm of the avatar in the virtual space to manipulate knives, bowls, food and other objects. The user can have full control of the arm(s), and in more immersive versions can also control head gaze and direction.

We use the hands-free capability of the Kinect to test different conditions of physical embodiment in a vegetable cutting task, where the user has a (prop) knife versus a wand or a tracked empty hand when controlling an avatar with a virtual knife in the virtual environment. The Kinect device provides position information of the user's hand in real space, which is transmitted to the running Blender program as a set of three position coordinates. We have developed the framework to gather this positioning information reported by the Kinect, and then transmit them to a running Blender simulation. We recorded the effector position in pixels every 10 ms.

Participants

There were 53 undergraduate students recruited from a State University in the United States (Mean age = 24 years), of which 57% were female and 43% were male. In the data reported below, 2 participants' data were trimmed. Participants did not report previous exposure to such a task.

Experimental Design

We used an effector (knife condition, wand condition, vs. open hand condition) between subjects design. The weight and length of the wand were matched with those of the prop knife. Participants were randomly assigned to each of the experimental conditions.

Procedure The height of the monitor was positioned such that the location of the eyes and head of the avatar in the environment was consistent with the location of the human participant's eyes and head in the real world. The food preparation station was positioned right above the waist of a user of average height.

Once participants were successfully calibrated in Kinect, they went through a phase familiarizing themselves with Kinect. For the experimental trial, participants were given the following instructions: (1) they would see a cucumber being cut; (2) kitchen bell tone would signal their turn to make a cut; (3) make the cut where they desire. Participants saw the avatar cut the cucumber, however, they were not told where to cut exactly. As indicated in Figure 1, the length of the cucumber that remained to be cut was not significantly longer than the previous cuts made by the avatar. The idea is that how close the participant cut to the avatar's left hand fingertip would provide an indication of the extent to which participant treated the action as real (i.e., the temporary blurring the boundary of the real and situated environments). In addition, an experimenter indicated the appropriate starting position to facilitate accurate Kinect tracking.

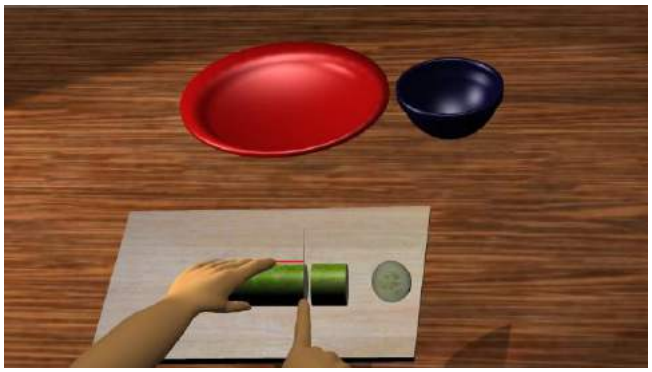

Figure 1. The cut location index is measured in blender pixel units, the distance from the avatars left hand holding the vegetable in the current task, to where the actual cut occurs indicated by the subject's actions in the experiment.

Results

We computed the following measures: (a) the cut location index, which is the distance in pixel coordinates from the participant cut locations to the finger tip of the avatar left hand in the computer mediated environment; and (b) the total task time, which was the total time from when the kitchen bell tone occurred indicating that it was the participant's turn, to when the participant moved the knife in the virtual environment in such a way that it indicated a cut should occur on the vegetable and the action to cut the vegetable was completed. In Figure 1, we depict the cut location index measure (in blender virtual environment pixel units). The measurement indicated in the figure was taken as the actual distance in 3 dimensions from the tip of the avatars fingertip, to the tip of the location where the cucumber cut location began on the vegetable being cut in

the experiment. The higher the value the cut location index is, the less risk there is to being injured.

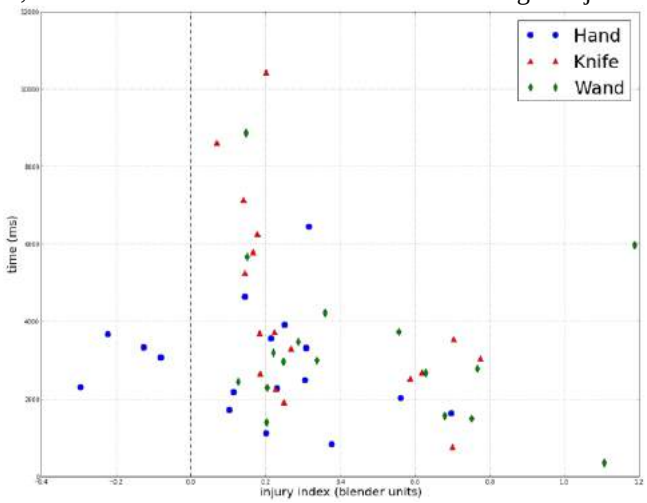

Figure 2. The cut location index scatter plot. Distance (in blender units) of the cut from the avatars hand vs. total task time when cut was made, for the 3 experimental conditions.

In Figure 2, we visualize the results of the cut location index measure together with the time to task measure. In this figure, we indicate the 3 different conditions (open hand, holding a prop knife and wand). Notice that for the knife condition especially subjects take the longest to complete the cut the closer the cut they are attempting to perform is to the avatar's left hand (which might result in potential injury, at a distance of 0.0 or less from the hand). Interestingly as well, all subjects who actually caused an injury to the hand, i.e., cuts that actually went into the avatars finger, were in the most incongruous condition, where the user in reality had an empty hand, but were controlling an avatar wielding a knife in the virtual environment. In general cuts that were more accurate and closer to the hand (without actually injuring the hand) usually took the most amount of time to make.

In Figure 3, we show the average cut location index for participants in each condition, along with 95% confidence intervals. The planned contrast showed that participants cut significantly closer to the fingertip when gesturing open hand than holding an effector, $t(48) = 2.61$, $p = 0.012$. This is consistent with the physicality hypothesis. Also of note, open hand performance on the cut location index showed the closest location index (e.g. cuts that were closest to the finger).

In Figure 4 we summarize the total task time measure. The planned contrast showed that participants used significantly longer time to cut with a knife than the other two non-knife forms, $t(48) = 2.06$, $p = 0.045$. This is consistent with the risk perception hypothesis. So while time to perform the cutting task with knives was significantly slower than the non-knife conditions. Users in the open hand condition might seem to be closest to the avatar's left hand fingertip, but they were significantly more likely to actually cause injuries to the avatar hand in this condition.

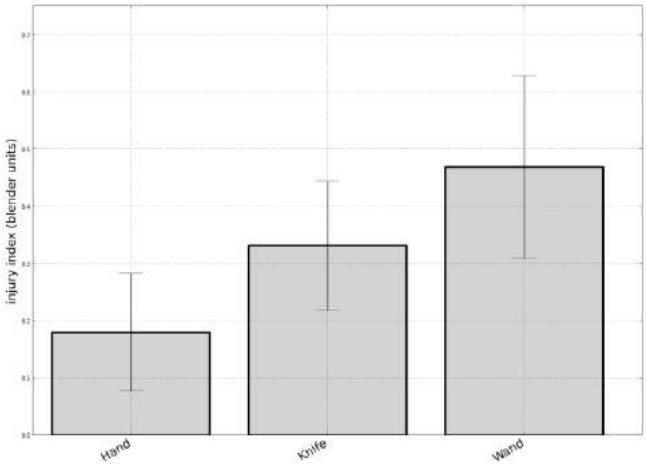

Figure 3. Summary of the cut location index measure. Mean cut locations are shown with whiskers indicating 95% confidence interval limits of the means.

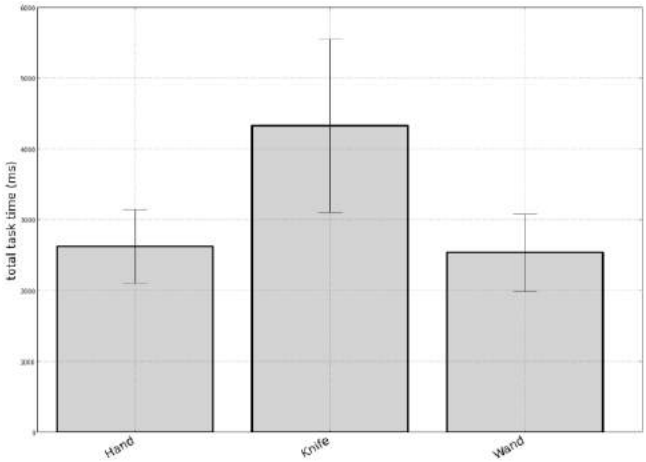

Figure 4. Summary of total task time measure. Figure indicates mean total task time for the three experimental conditions, with 95% confidence interval shown.

Conclusion

The experiment showed that effector congruence in the simulated environment does have some significant effects on task performance. Participants are more likely to treat the task as they would in the real world when the effector they use is the most realistic, and most in line with existing neural circuitry that would typically be employed to accomplish the task. For example, users were much less likely to cause injury to the virtual hand, when they were holding an object in their hand. We interpret this to mean that existing neural circuits and predictive machinery are more likely to be invoked in these more congruous conditions. Thus caution and appropriate location of the virtual knife in space were more likely to be achieved in order not to injure the virtual avatar. The most cautious behavior, in terms of time taken on the task, occurs when

holding a prop knife to manipulate the virtual environment. People using the knife took longer than people using a wand or not holding a prop.

What constitutes better performance when performing common food preparation using a knife? Speed and accuracy, as well as safety are all factors we would identify as important in separating novice level from expert level kitchen workers. Professional chefs are probably able to exceed on all three metrics, cutting quickly and accurately, but rarely if ever causing injury to themselves when using their dangerous tools.

We have done some analysis on the planning and execution of the task as indicated in the motor coordination measures of our participants in this simulated task. For example, in Figure 5 we show an analysis of the smoothness (or its absence of jerkiness) of the actual trajectories of the avatars hands in the virtual environment being controlled by the subjects hand movements through the Kinect effector. We have broken down the trajectories into 5 segments, and used the third time derivative (Hogan, 1984) to measure the smoothness of their trajectories. The whiskers represent 95% confidence intervals of the smoothness measure for each of the 5 trajectory segments. Knife performance differed significantly on this smoothness measure, especially in the middle part of the motion of the virtual knife on the task. These motion analysis measures show how different participants are treating the task when using the more congruent effector.

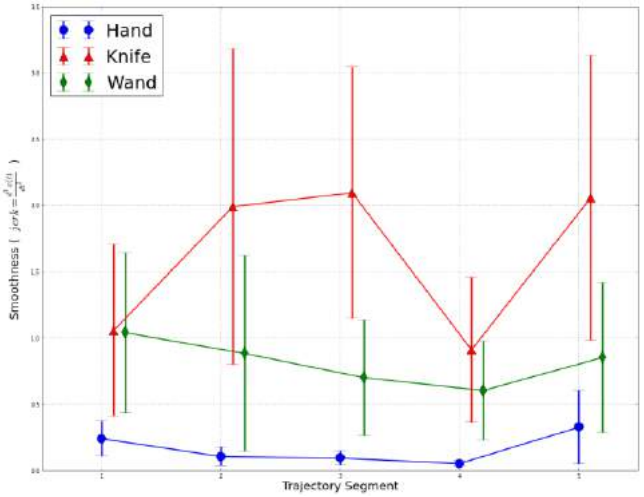

Figure 5. Measure of smoothness of subject's motion of the knife in the virtual environment, broken up into 5 equal length segments. Whiskers indicate 95% confidence interval on the smoothness measure.

Unlike the previous studies, the current results speak to the importance of looking into real time task planning and execution and showcase a paradigm in observing movements in developing embodied design (Fdili Alaoui, et al., 2015). The equivalence on the performance measures does not necessarily speak to the ongoing differences in the users' minds. Let us draw an analogy. When people use a sharp vs a dull knife to prepare food, people would take more time and be more cautious with the sharp knife, but this does not mean people would slice into their finger tips or would not be able to use the full available length of the food being prepared. A simpler view of the effector risk perception hypothesis is that users would produce different vegetable cuts while using different effectors. The implication of this simpler view is that slight differences in effector or other aspects of the environments would lead to significant differences in action outcome. Such a simplified view is in effect inconsistent with the functional redeployment theory of cognition. It is also inconsistent with the finding in virtual reality that people treat the virtual environment as if it were real even though they know it is not real (Bailenson, 2018).

The paradigm developed in the current study shows potential to examine how the bi-directional interactions of changes in simulated environments influence subsequent user actions and vice versa as they unfold in real time (Dawley & Dede, 2014). Through systematic comparison, the current study give insight into what critical ingredients of intuitive touchless interactions should involve (Chattopadhyay & Debaleena, 2015; Gillies & Marco, 2016). When the congruency between the effector in the virtual environments and the tool used in the real world tasks supports the low-level visual motor contingency, users are more likely to incorporate the extra personal space into their behavioral repertoire.

Predictive views of embodied cognition that take into account how neural circuits are likely to be reused when experiencing a simulated environment are a rich conceptual framework to better understand how to improve immersion and learning outcomes when training in simulated environments. This theory could address a number of thorny issues. For example, why environments with minimal realism can still trigger the experience of immersion and why often environments with varying degrees of realism do not get rated differently when it comes to the subjective reports of user interaction experience. A system that provides less support to align with real world sensory motor contingencies, the more perceptual prediction errors will be generated along the way and the more hierarchical adjustments will have to be made to compensate for errors. This would lead to the greater probability of errors on the task and less satisfaction as reflected in the subjective reports of user experience.

Abstract

We propose a cognitively plausible method for representing and querying spatial relationships in a neural architecture. This technique employs a fractional binding operator that captures continuous spatial information in spatial semantic pointers (SSPs). We propose a model that takes an image with several objects, parses the image into an SSP memory representation, and answers queries about the objects. We demonstrate that our model allows us to not only store and extract objects and their spatial information, but also perform queries based on location and in relation to other objects. We show that we can query images with 2, 3, and 4 objects with relative spatial locations. We also show that the model qualitatively reproduces Kosslyn's famous map experiment.

Keywords: Semantic Pointer Architecture; spatial representation; spatial memory; spatial relations; fractional binding; continuous spaces; cognitively plausible representation

Introduction

Capturing spatial reasoning has been a long-standing and difficult challenge when using artificial neural network models (Haldekar et al., 2017). Nevertheless, spatial cognition has long been studied in cognitive science (Kosslyn, 1980). Often, such research has led to proposals in which mental representations of space are continuous (Kosslyn, 1984). These representations are thus manipulated like physical images: shifting them, scanning over them, extracting spatial relations from them – effectively treating mental representations of images somewhat like physical maps. While there have been vigorous debates on the empirical adequacy of such proposals (Pylyshyn, 1973), here we explore the practicalities of implementing mental manipulations of this variety in compact and efficient representations that lend themselves to implementation in neural networks.

We approach this problem by using an architecture that deploys fractional binding to construct spatial semantic pointers (SSPs). We demonstrate that our binding architecture allows us to not only store and extract objects and their locations, but also perform mental queries to find objects based on location and in relation to other objects. It is, in particular, the ability to query such representations regarding spatial relations that we believe makes this a promising architecture for capturing many human mental image manipulation behaviors. The ability to perform such queries relies on the fact that these representations are continuous, as proposed by Kosslyn and others. The specific goal of this paper is to describe and simulate a cognitively plausible architecture that captures core qualitative features of spatial reasoning.

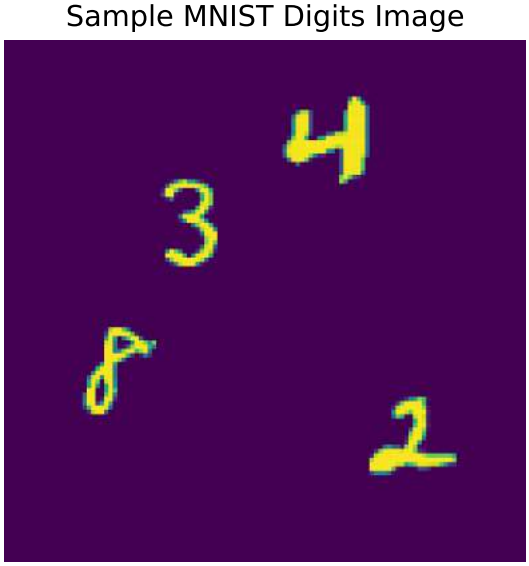

Figure 1: MNIST digits placed randomly in a 120x120 space. Given a query of: "8" and "up and right", the correct response is either: "3" or "4".

We begin by specifying our experimental design, which focuses on asking relational questions about a represented image. We then describe the spatial representation we use, discuss its properties, and note its natural affinity for implementation in spiking neural networks. After this we describe how regions are represented to allow for spatial relation queries. Then, we describe each of the elements of our architecture, as well as how they are integrated in the final system. We subsequently present results showing the accuracy of assessing spatial relations in a spatial working memory task. We also use this same representation to reproduce the main feature of Kosslyn's famous map experiment: reaction time scaling linearly with spatial distance. Finally, we discuss our findings and identify future work.

Experimental design

Our first experiment adopts a task similar to that proposed by Weiss et al. (2016). Specifically, we construct a set of example images to perform queries on by selecting batches of digits from the MNIST database and placing them at random locations on a 120x120 image. We choose between 2 and 4

digits to include in a given image. We then generate queries automatically by randomly selecting a target digit and computing its relative direction from another randomly selected query digit. For this experiment, we limited the query direction to 4 possible quadrants: up and left, up and right, down and left, down and right. Given the query digit and direction, we expect the response to be one of the target digits (if there are multiple such digits, then either one is marked correct). For instance, in Figure 1 we show an example randomly generated image, for which we might query "What is up and to the right of the 8?" A response of either "3" or "4" would be marked correct.

For this experiment, we normalized the coordinates of the digits in the 120×120 pixel image to a continuous 10x10 space, specifically the intervals $x \in [-5,5]$ and $y \in [-5,5]$, before encoding them in a memory through our model visual system. Given our chosen representation, this range was found to provide a good trade-off between accuracy and precision.

We also performed a second experiment, similar to the visual-spatial map experiment by Kosslyn et al. (1978). Kosslyn's map experiment recorded the time that it takes for a subject to scan from one location to another in memory, and demonstrated that closer objects are typically reached faster. For our experiment, we used a memory of several digits placed randomly, and scanned from a queried starting object to the queried ending object.

Methods

Spatial representation

We employ the method for spatial representation proposed by Komer et al. (2019). This method generalizes the notion of binding that is employed by several vector symbolic architectures (VSAs) to continuous spaces. The method defines a "spatial semantic pointer" (SSP) to be the result of a fractional binding. The particular binding used is the circular convolution operator proposed by Plate (1995), which is essentially element-wise multiplication of vectors in Fourier space. The natural extension of this is then element-wise exponentiation in Fourier space. Supposing B is a fixed d-dimensional vector (i.e., semantic pointer), fractional binding is defined by expressing the binding in the complex domain:

$$B^k = \mathcal{F}^{-1}\left\{\mathcal{F}\{B\}^k\right\}, \quad k \in \mathbb{R}, \tag{1}$$

where $\mathcal{F}\{\cdot\}$ is the Fourier transform, and $\mathcal{F}\{B\}^k$ is an element-wise exponentiation of a complex vector—analogous to exponentiation using fractional powers (e.g., $b^{2.5}$)—permitting k to be real. This representation can thus map from a continuous space, $\mathbb{R}$, to a high-dimensional vector space, $\mathbb{R}^d$. Because the high-dimensional space of semantic pointers can support construction of cognitive structures, various kinds of syntactic inference, and so on (Eliasmith, 2013), this proposed representation provides a novel link between such cognitive operations and continuous spaces.

To explore this link, in this work we use a generalization of the representation to multiple dimensions (Komer et al., 2019). We can represent points in $\mathbb{R}^n$ by repeating equation 1, n times, using a different semantic pointer for each represented dimension (i.e., for each axis), and then binding all of the resulting vectors together. For $n = 2$ (i.e., for a 2-D spatial map), the SSP that represents the point (x,y) is defined as the vector resulting from the function:

$$S(x,y) = X^x \circledast Y^y, \tag{2}$$

where X and Y are fixed semantic pointers, x and y are reals, and we are using fractional binding as defined by equation 1.

In this work we explore querying spatial relations between multiple objects in memory – for instance, asking "What is below and left of the 3?" To specify the spatial query, we represent the region of space being queried (e.g., below and left) as another SSP. The SSP that represents a continuous region (e.g., a solid rectangle), specified by some infinite set of points R, is defined as:

$$S(R) = \int_{(x,y)\in R} X^x \circledast Y^y \, dx\, dy. \tag{3}$$

To move this region to be relative to a given starting point, we exploit the shift property of SSPs. In particular,

$$B^{k_1} \circledast B^{k_2} = B^{k_1+k_2}, \quad k_1, k_2 \in \mathbb{R}. \tag{4}$$

This means that to shift any SSP, we only need to convolve the spatial representation of a region or objects with the SSP representing the coordinates of the shift direction. For example, we can shift a region representing a direction, (e.g., "up and right") to the location of an object to generate a region representing a query (e.g., the "8" in the previous example).

Conversely, we can also leverage this property to shift the entire spatial memory relative to the origin. This gives rise to a notion of movement through the space and an egocentric interpretation of the space rather than the previous allocentric interpretation. Thus this method of semantic pointer supports both egocentric and allocentric coding of space.

To represent a single object occupying some location, we bind its tag (OBJ) with the SSP from equation 2:

$$M = OBJ \circledast S(x,y). \tag{5}$$

In general, to represent a set of m labelled objects together in the same memory, we can use superposition:

$$M = \sum_{i=1}^{m} OBJ_i \circledast S(x_i, y_i), \tag{6}$$

with a distinct semantic pointer OBJ_i tagging each object.

Furthermore, rather than placing objects at singular points in memory, it may be more intuitive to bind objects to regions in memory. This can be done similarly:

$$M = \sum_{i=1}^{m} OBJ_i \circledast S(R_i), \tag{7}$$

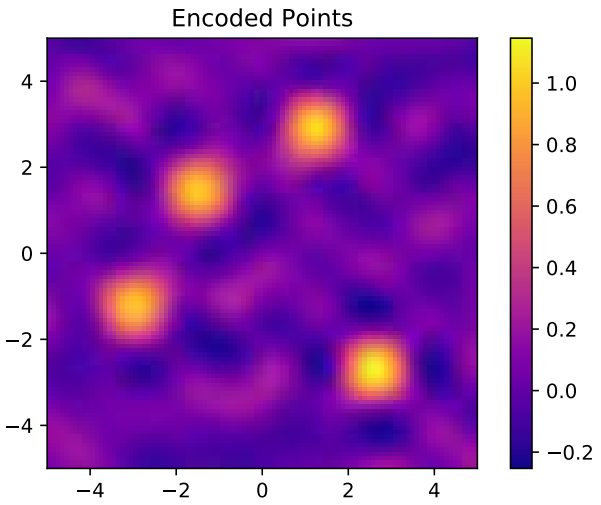

Figure 2: Heatmap of the four locations from Figure 1, represented by a single spatial semantic pointer (equation 6).

with R_i representing the region that a particular object occupies. This representation allows us to represent notions of size and shape in memory as well.

Given a representation like that in equation 6 or 7, we can query it in a number of ways. For example, to determine what object(s) are within some region R, we can compute:

$$M \circledast S(R)^{-1}, \tag{8}$$

where $(\cdot)^{-1}$ corresponds to the approximate inverse vector used to unbind using circular convolution. By the properties of binding and superposition, the resulting vector will have the highest cosine similarity (i.e., dot product) with the object(s) within R.

While only part of our architecture is currently implemented in a neural network (see below), all of the operations, except fractional binding, needed for the architecture have previously been implemented in spiking neural network models (Eliasmith, 2013). The fractional binding itself is implemented in spiking neurons by Komer et al. (2019). These implementations use the methods of the Neural Engineering Framework (Eliasmith & Anderson, 2003).

Using the spatial representation

In this section we briefly demonstrate the use of equations 3, 4, and 6. All of the SSP representations in the model are 512-dimensional. We begin by encoding multiple objects into the memory, as per equation 6, is demonstrated in Figure 2. Here we can see an example of the four objects from Figure 1 being encoded into the represented space. While we are showing a decoding of this representation mapped into the continuous space, the full representation is a single 512-dimensional vector. The number of objects in memory does not change the size of the representing vector, although there are effective limits on capacity (Komer et al., 2019). We also tested a region based system by binding every digit to the square region occupied by the digit rather than just a single point.

To query such a representation, we can construct a region vector. A region vector, as defined by equation 3, is also a 512-dimensional SSP, but it represents an entire region instead of a specific point. Region vectors can be used just like a regular location vector. We can bind objects to it, add it to a memory, and we can also use it to extract objects that are located within a region. Furthermore, as regions are integrals over pointers raised to coordinate exponents, binding a region to a point vector shifts the exponents in the integral by the coordinates of the point (see equation 4), which in turn shifts the entire region represented by the integral (see Figure 3-Top) in the direction of the point relative to the origin. In our experiment, this allows us to pre-compute four regions at the origin and then use binding to shift them to generate any specific query vector (see Figure 3-Bottom). Notably, when region vectors are used to query memories encoding objects at those locations, there is no need to extract the coordinates of the objects being searched over; all computations are performed within the space of our SSPs, without multiple encoding and decoding steps.

Model architecture

In this section we briefly describe each of the components in our model that perform the tasks described in the experimental design section. We also describe the integration of the components and overall flow of information through the model.

Image generation

The images processed by the system are generated by using batches of 28x28 pixel images from the MNIST database and placing them randomly on a 120x120 image (see Figure 1). Because queries are limited to the 4 diagonal directions, we ensured the digits are not too close in the vertical or horizontal direction. We also ensured the digits do not overlap. We generated sets of 5,000 samples for images containing each of 2, 3, and 4 digits.

MNIST Network

In order to generate the SSP representation from the experiment images, we use a straightforward convolutional deep neural network as a perceptual module. It consists of two 3-by-3 convolution layers with 32 and 64 filters respectively. These were followed by a 128 unit fully connected dense layer and a 10 unit fully-connected dense layer for classification. This network was trained on the MNIST dataset achieving 99% validation accuracy.

Since our work focuses on representing spatial relationships rather than classifying multi-digit MNIST images, we use the actual coordinates of the digits to generate a saccade-like cropping of the full image to 28x28 sub-images before providing them to the convolutional network. The identified images are then mapped to random 512-dimensional semantic pointers, which are bound to SSP encoded locations, and

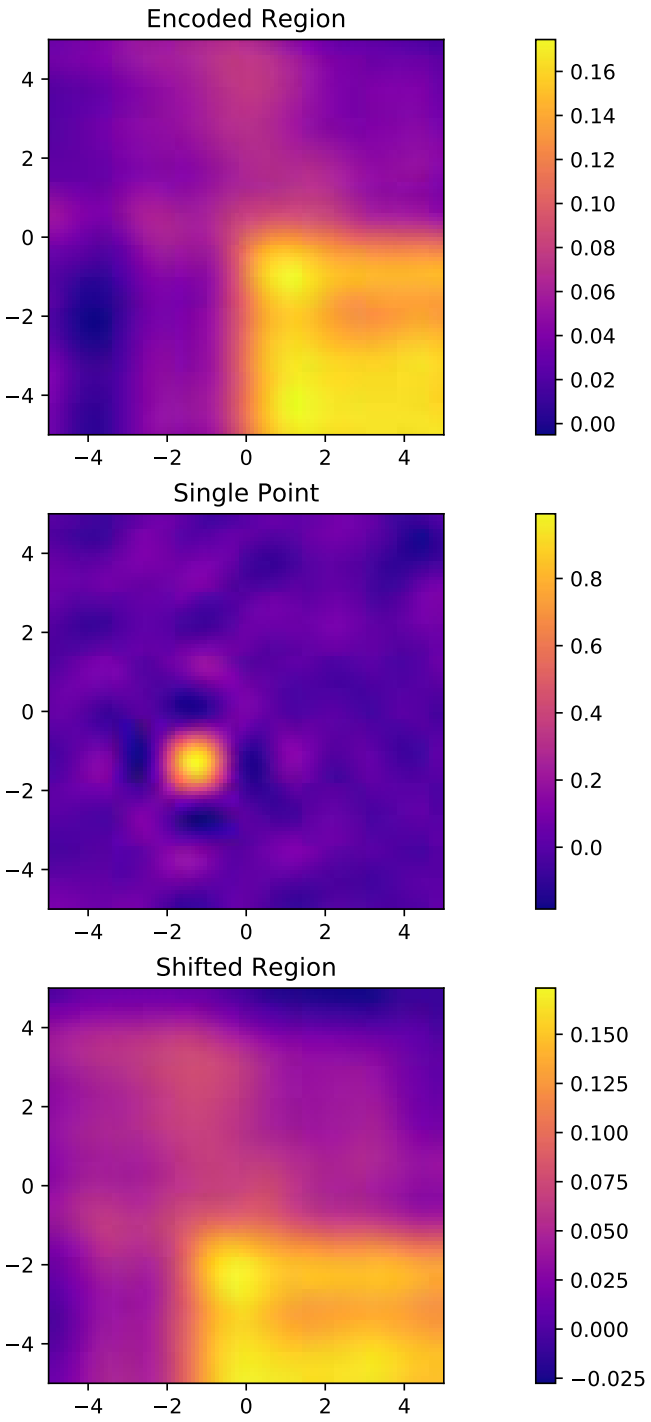

Figure 3: Demonstration of shifting the region representation for a "down and right" query (top panel), to a point encoded as an SSP (middle panel), resulting in a region vector for querying "down and right" with respect to the point (bottom panel).

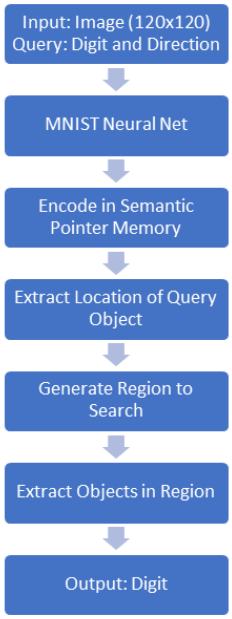

Figure 4: Flowchart of entire process

summed across all objects. This process results in a memory representation in the 512-dimensional space, which is subsequently queried using a region representation as described above.

Cleanup memory

When using SSP representations, as with any compressed VSA, the extracted location vector of an object includes noise. When there are multiple objects in the memory, the amount of noise grows. As a result, VSAs of this sort typically include a cleanup memory that maps a noisy vector onto the nearest known vector in the space. In the case of a continuous space, to extract the (x, y) location of the query digit, we generate the known vectors by sampling the continuous space on a 100x100 grid. This grid covers the two $[-5, 5]$ axes of the image. To implement the memory, we perform a simple dot product similarity check between the extracted noisy vector and the set of known vectors to find the closest matching vector within the resolution of our grid. Dot products are easily computed in parallel, making this a quick and effective way to reduce noise and improve performance. This kind of memory can be efficiently implemented in spiking neurons (Stewart et al., 2011).

Full system

Before running an experiment, we set up the model by randomly selecting two 512-dimensional unitary semantic pointers to use as axis vectors (i.e., X and Y in 2). We also create a vocabulary of ten 512-dimensional semantic pointers, one for each digit. We then pre-compute 10x10 region vectors for each query, as well as a 100x100 resolution cleanup memory.

We then feed an image into the model architecture, the full pipeline of which is depicted in Figure 4. The image is clas-

sifed by the MNIST network, and an object memory is created by summing the SSP representations for each digit in the image, as described above. Extraction of the location of the query object (i.e., the object mentioned in the query) proceeds by performing an inverse convolution on the memory with the query object to find its location, and the cleanup memory is used to reduce noise on the found location. Generating the region to search is accomplished by convolving the identifed location of the query object with the region vector corresponding to the query direction to find the region where the target object might be. Extracting objects in the region occurs by performing an inverse convolution between the shifted region and the original memory. Finally, the similarity between the results of this query and each object in the vocabulary is calculated as a dot product. The object with the highest similarity determines the model's response to the query.

Scanning System

The scanning system involves similar steps. We reuse the axis vectors as well as the pre-computed cleanup memory tables from the previous system. The map image is converted to a memory vector as above. Given a starting and ending object, the locations are extracted by performing inverse convolution with the objects in question on the memory. These locations are cleaned with the cleanup memory and used to determine the direction vector of the scanning using SSPs:

$$V = (X^{x_5} \circledast Y^{y_5}) \circledast (X^{x_2} \circledast Y^{y_2})^{-1} \tag{9}$$

where x_5 is the x position of the "5", and so on. We then normalize this vector, shrinking it to a 0.05 unit step, and repeatedly apply it to the starting vector ($V_{t+1} = V_t \circledast V$ where $V_0 = X^{x_5} \circledast Y^{y_5}$).

To scan the memory, we started at the starting location from above, and extracted the objects in that location with inverse convolution. The scan location is then updated by convolution with the step vector generated above, shifting the location towards the target object, and the above steps are repeated. A dot product similarity comparison is used at each step to determine what objects were extracted or "seen" by the scan. A 0.8 similarity threshold is used to determine when the target object has been reached.

Results

Relational Query Experiment

For the query experiment, we ran 5,000 randomly generated experiments for each of 2, 3, and 4 digit images. For the experiment, we tested the accuracy of the output by simply marking the response as correct if the model response matched an object in the queried region.

Table 1 shows the results from the experiment involving identifying a target digit given an image, a query object, and a query. Correctness is calculated by comparing the output to all digits in the correct direction. Baseline performance is the probability of answering a query correctly by randomly selecting one of the remaining digits in the image. This is calculated by dividing the average number of correct answers in each image by one less than the total number of digits in the image. Naturally for the 2 digit case, there is only one possible answer other than the digit used to query so the probability would be 100%. The baseline probability is very high due to the broadness of our query.

	2 Digits	3 Digits	4 Digits
Point Representation Accuracy	92.18	84.40	72.90
Region Representation Accuracy	95.98	87.22	81.24
Baseline probability	100.00	71.76	62.60

Table 1: Experimental results for spatial relation queries.

The results from the 2 object query indicate that using a region vector decreases accuracy compared to a simple location query. A location query with two objects in memory (e.g., what is at location (x,y)) has 100% accuracy (results not shown). In this experiment, the 2 digit case is similar to a location query, but for a region. The drop in accuracy is likely because as the region representation becomes larger, a single vector is being used to represent the effective superposition (integral) of many vectors (all those defining the region). This result suggests that region size will determine decoding accuracy, a hypothesis to test in future work.

The 3 and 4 digit experiments showed that extracting object information from an object-location memory improved performance by about 13% and 10% for point based memory and 15% and 19% for region based memory compared to the baseline guessing probability. Representing object locations as regions in memory rather than singular points provided dramatic improvements in accuracy, particularly in the 4 digit case. This is likely due to the fact that a query region is more similar to a square within the region than a single point, leading to higher accuracy extractions with inverse convolution. This suggests that more specific queries involving smaller or tighter regions would yield higher accuracy as their shapes would more closely resemble the regions the objects are bound to compared to the large query regions used in our experiment. Comparing the differences in accuracy for queries of different shapes and sizes is a topic for future study.

The decrease in accuracy as number of digits in the image increases is expected, as a higher number of digits adds difficulty in selecting the correct output since the memory encodes all of the digits. It is a standard property of VSAs for decodability to decrease as a function of the number of objects represented in a structure. While we have not determined the maximum capacity of the proposed representation, being able to store and reasonably accurately recall the relations between four numbers is consistent with standard estimates of working memory capacity at 4 items (Buschman et al., 2011).

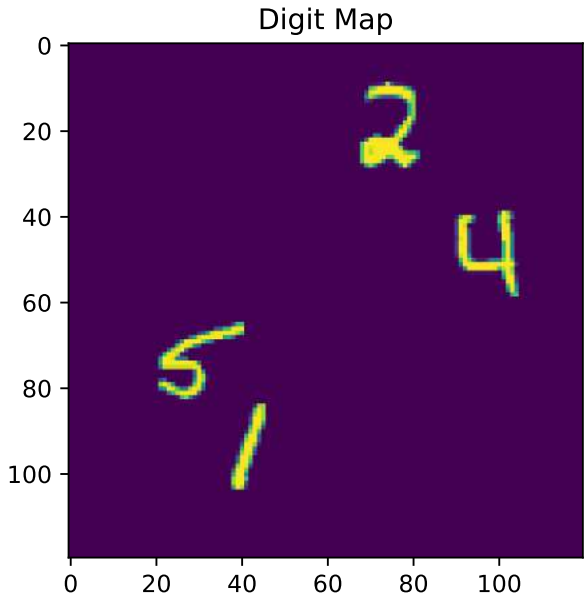

Figure 5: Digits placed randomly in a 120x120 space to represent a map of objects. The memory is scanned from "5" to "1" and "5" to "2".

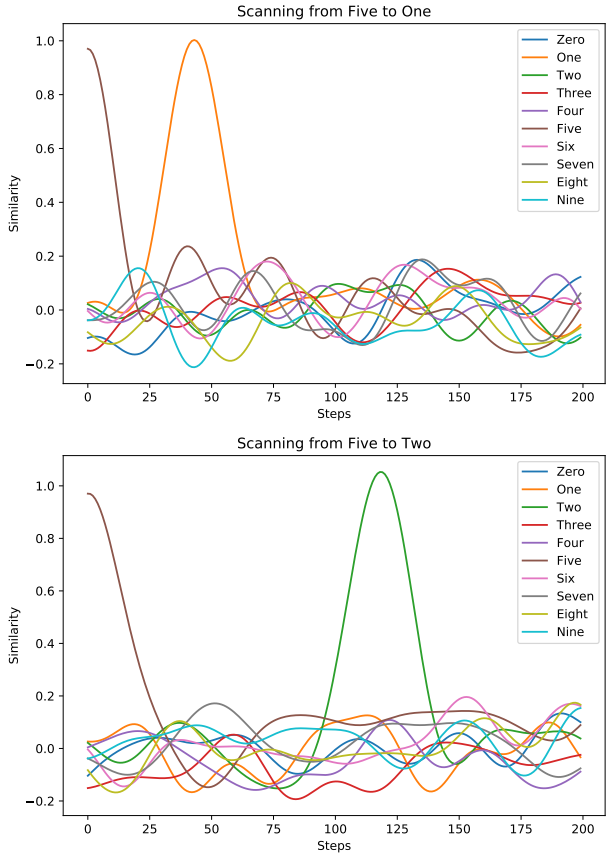

Figure 6: Similarity outputs over time for scanning from the "5" to "1" (top) or "5" to "2" (bottom).

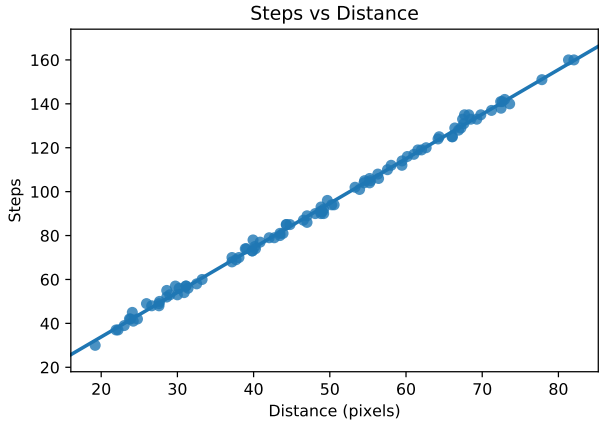

Figure 7: Plot of steps to reach target object vs the distance between starting and target objects over 100 trials (Pearson's $R > 0.99$, p-value $< 10^{-6}$).

Image Scanning

An image is generated with the same method as in the first experiment to represent a map of objects, with each digit representing an arbitrary object in the map (Figure 5). For the experiment shown in Figure 6 we chose the object "5" as the starting location and the two objects "1" and "2" to be the near and far target objects respectively. From the two plots, we can see a peak at the 0 mark for the starting object "5" which falls away, and a peak at the target object, "1" and "2", when the scan reaches it.

This experiment was repeated 100 times, with the number of steps required to reach a similarity threshold of at least 0.8 recorded for each trial (Figure 7).

Kosslyn et al. (1978) showed that human spatial memory is represented in a metric space by demonstrating that further objects take longer to scan to in memory, with time linearly related to distance. This experiment shows that the qualitative cognitive behaviour demonstrated by Kosslyn's map scanning experiment is naturally captured by our SSP memory representation.

Discussion

Our proposed architecture is able to receive an image of multiple objects and generate an SSP representation. Subsequently given a spatial relation query the model can successfully answer with reasonably high accuracy. This provides evidence that the SSP representation can be used to encode continuous spaces in a kind of mental map using representations easily implementable in neural networks. In short, our results show that such representations can be used to reproduce qualitative cognitive behavior relying on spatial manipulation of information encoded in this manner.

A critical next step is to compare human performance on this same task with the proposed model. Preliminary results suggest that accuracy can be manipulated by appropriately choosing the base vectors (i.e., X and Y), and manipulating

the dimensionality of the vector space being used. The range of these parameters that match human performance remains to be determined.

There are many possibilities for extending this model. Our particular focus was on two kinds of spatial relation query. However, the direction queries could be generalized to be in any direction (e.g., specifying a vector direction and generating a cone region in that direction). As well, other manipulations, such as spatial rotations, shifts, and so on, can be performed without decoding the SSP. There are a wide variety of psychological results that can provide points of comparison for such manipulations.

Furthermore, the representation itself could be made more complex. For instance, introducing the color of the object (encodable as another 3D continuous space for RGB values), or additional features is natural in this framework. We expect additional information encoded in the memory will adversely affect performance, as seen in human memory tasks.

Finally, the full model can be implemented in a spiking neural network to determine if the proposed representations are robust to biologically plausible implementation. While we expect that this will be successful, given past work that has implemented each of the components, it remains to be seen what effect such implementation has on the accuracy of responding to spatial queries.

Conclusions

We have demonstrated that spatial semantic pointers (SSPs) using fractional binding provide a viable method of representing spatial relationships in a simple model supporting two kinds of visual spatial reasoning. This method lends itself well to implementation in neural networks, and is consistent with cognitive work suggesting that internal representations used in mental imagery represent continuous mental spaces. We believe this is one of few available suggestions for how complex object representations (i.e., high-dimensional feature vectors for digits) can be encoded in a continuous space, and manipulated to answer questions about relations in that space.

Acknowledgments

We would like to thank Terry Stewart for his early work exploring SSPs and personal discussions, and Jan Gosmann for his work on the mathematics of fractional binding for semantic pointers. Statistical learning creates implicit subadditive predictions

Abstract

The cognitive system readily learns when multiple cues jointly predict a specific outcome. What is less known is how the mind generates predictions when only a single cue is present. In four experiments, participants were first exposed to two objects followed by a circle with a specific size or a specific numeric value. Afterwards, participants viewed a single object and estimated the associated size or value. Finally, participants recalled the size or value that followed the initial two objects. We found that the estimated size associated with the single object was significantly smaller than 100% but significantly larger than 50% of the recalled size associated with the two objects. No participants were consciously aware of the associations. The results reveal a new consequence of statistical learning on automatic inferences: When multiple objects were previously associated with an outcome, the single object is implicitly expected to predict a subadditive outcome.

Keywords: Implicit learning; support theory; subadditive inferences; regularities; predictions

Introduction

A remarkable capacity of the cognitive system is to extract the relationships among objects in the environment. Statistical learning is one mechanism that detects the statistical relationships between individual objects in terms of co-occurrences over space or time (Fiser & Aslin, 2001; Saffran, Aslin, & Newport, 1996). In contrast to other forms of associative learning, statistical learning occurs incidentally, without conscious intent or explicit awareness, and thus observers are often not explicitly aware of object co-occurrences (Turk Browne, Jungé, & Scholl, 2005; Turk-Browne, Scholl, Chun & Johnson, 2009).

The ability to extract statistical regularities from the environment has a series of cognitive consequences. For example, statistical learning encodes the co-occurring objects more efficiently in working memory (Brady, Konkle, & Alvarez, 2009; Zhao & Yu, 2016), draws attention spontaneously and persistently to the co-occurring objects (Yu & Zhao, 2015; Zhao, Al-Aidroos, & Turk-Browne, 2013; Zhao & Luo, 2017), forms new transitive inferences based on prior associations (Luo & Zhao, 2018), enhances memory representation of individual objects (Kim, Lewis-Peacock, Norman, & Turk-Browne, 2014; Otsuka & Saiki, 2016), and induces false memories of co-occurring objects (Luo & Zhao, 2017).

Past research on statistical learning has predominately focused on associations between individual objects that co-occur in space or time (e.g., A appears next to or before B). Moreover, most studies in associative learning focused on how the relationship between the cue and the outcome is learned, how learning modulates subsequent processes, and how predictive cues are selectively prioritized (e.g., Mackintosh, 1975; Le Pelley et al., 2016).

In the daily visual environment, multiple objects sometimes co-occur to jointly predict a specific outcome. For example, two co-authors often publish a paper together, or two co-founders start a company. What is less known is how the mind generates predictions when only a single cue is present, after learning that two cues were previously jointly associated with an outcome. For example, when author A and author B have been publishing high-quality papers together, what's the automatic inference when you see a paper by only author A?

Here we examine three possible hypotheses: (1) the complete inheritance hypothesis that suggests that the single cue predicts 100% of the outcome previously associated with the two cues, (2) the proportional inheritance hypothesis that suggests that the single cue predicts 50% of the outcome, and (3) the subadditive hypothesis that suggests that the single cue predicts more than 50% but less than 100% of the outcome previously associated with the two cues. The subadditive hypothesis is consistent with support theory (Tversky & Koehler, 1994), that suggests that when people unpack an event (e.g., the probability of death due to natural causes) into disjoint components (e.g., the probability of death due to heart attack, cancer, or other natural causes), they tend to increase the evidentiary support for the event. In other words, people tend to provide a higher probability of death due to natural causes when they are asked to estimate the probability of death due to each component of natural causes separately, compare to reporting the probability of death due to natural causes as one category.

To test these hypotheses, we conducted a series of four experiments to examine how the mind makes predictions when a single cue is present after learning that multiple cues previously jointly predicted an outcome.

Experiment 1

In this experiment, participants were first exposed to two cues (e.g., red and blue squares) that were immediately followed by an outcome (e.g., a circle with a specific size). We examined how they generated predictions of the outcome when only a single cue was present (e.g., a red square).

Participants

A total of 42 undergraduates (31 female; mean age=19.6 years, SD=1.5) from University of British Columbia (UBC) participated in the experiment for course credit. Participants reported normal or corrected-to-normal visual acuity and provided informed consent. The protocol was approved by the UBC Behavioral Research Ethics Board.

Stimuli

The stimuli consisted of eight squares in eight distinct colors (color name = R/G/B values: red = 255/0/0; green = 0/255/0; blue = 0/0/255; yellow = 255/255/0; magenta = 255/0/255; cyan = 0/255/255; orange = 255/158/0; brown = 103/29/0). Each square subtended 2.7° of visual angle. The colored squares were randomly assigned into four pairs for each participant and remained constant throughout the experiment. Each color pair was randomly associated with a gray circle (R/G/B = 128/128/128) with a specific diameter. The circle diameter subtended 3.0° (or 100 pixels), 6.0° (or 200 pixels), 9.0° (or 300 pixels), or 12.0° (or 400 pixels) of visual angle (Fig.1a). Thus, each color pair was associated with a circle of a specific size.

Apparatus

Participants in all experiments were seated 50cm from a computer monitor (refresh rate = 60 Hz). Stimuli were presented using MATLAB and PsychophysicsToolbox (http://psychtoolbox.org).

Procedure

The experiment consisted of three phases: exposure phase, inference phase, and recall phase. During exposure, two colored squares (e.g., red and blue squares) appeared in a horizontal configuration at the center of the screen for 500ms, followed by a 500ms inter-stimulus interval (ISI), and then the circle with a rotated T in the middle appeared at the center of the screen for 500ms in each trial (Fig.1b). Each color-size pair was repeated 80 times to form a single continuous temporal sequence of color-size pairs in a pseudorandom order with a constraint where no single color-size pair could repeat back-to-back. In total, there were 320 trials. Participants performed a cover task where they judged as quickly and accurately as possible whether the rotated T in the circle was pointing to the left or right (by pressing the "1" or "0" key for left or right, respectively). The cover task was irrelevant to learning the color-size pairs, in order to conceal the true purpose of the study. This also ensured that statistical learning of the color-size pairs was incidental. Participants were not told anything about the color-size pairs.

After exposure, participants performed an inference phase (Fig.1c). In each trial, participants viewed a single color square for 500ms followed by a 3000ms blank screen. Afterwards, a probe circle with a diameter subtending 0.6° (or 20 pixels) was presented on the screen. Participants were asked to estimate the size of the circle that was associated with the color square by adjusting the size of the probe circle using their mouse. The diameter of the adjustable circle was restricted to a range from 20 pixels to 420 pixels. The adjustable circle remained on the screen until the "a" key was pressed to register participant's estimate. Each member of a color pair was tested four times, resulting in 32 trials in total (the order of the trials was randomized).

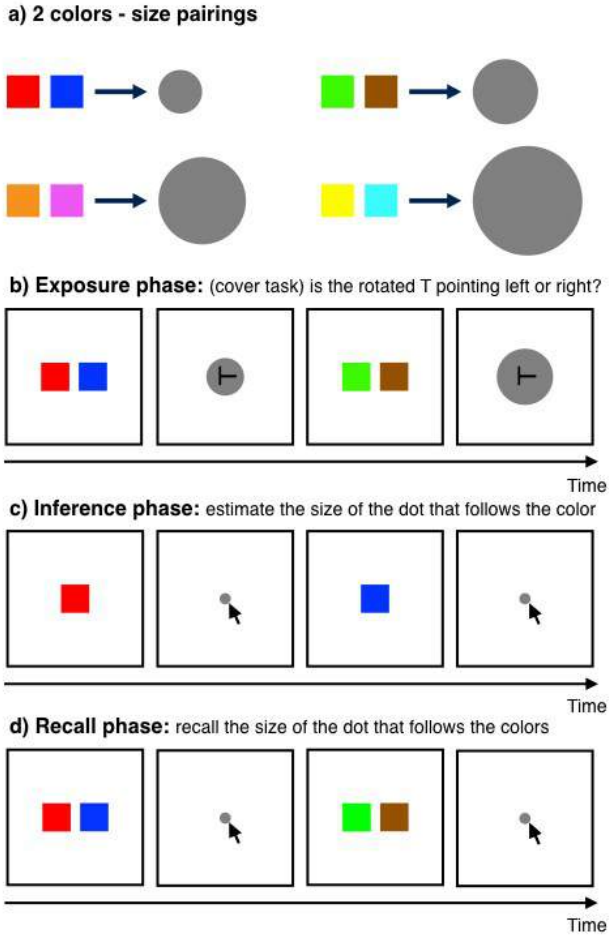

Figure 1. Experiment 1 paradigm. (a) Four color-size pairs were presented (e.g., red and blue squares followed by a circle with a diameter of 100 pixels). (b) Exposure phase using a cover task to expose the color-size pairs to participants. (c) Inference phase where participants estimated the size of the circle was associated with the color. (d) Recall phase where participants recalled the size of the circle that followed the two color squares.

To examine whether participants had successfully learned the color-size pairs (i.e., the association between the two color squares and the size of the circle), participants completed a size recall task following the inference phase (Fig.1d). In each trial, participants viewed the original color pair (e.g., red and blue squares) that they viewed during exposure for 500ms followed by a 3000ms blank screen. Afterwards, a probe circle with a diameter subtending 0.6° (or 20 pixels) was presented on the screen. Participants were asked to recall the size of the circle that was associated with the original two colors during exposure by adjusting the size of the probe using their mouse. The diameter of the

adjustable circle was restricted to a range from 20 pixels to 420 pixels. The adjustable circle remained on the screen until the "a" key was pressed to register participant's estimate. Each color pair was tested four times, producing 16 trials in total (the order of the trials was randomized).

A debriefing session was conducted at the end of the experiment, where participants were asked if they had noticed any pairings of squares and circles that appeared one after another. For those who responded yes, we further asked them to write in sentences which type of circle followed which colors.

Results and Discussion

We first analyzed whether the inferred circle size associated with one single object in the pair (e.g., red square) was different from the inferred circle size associated with the other member of the pair (e.g., blue square) to rule out any spatial positioning bias. We found that the inferred circle size associated with one object was not different from the inferred circle size associated with the other member in the pair for all four types of circle diameter (p's>.19). Thus, we combined the inferred size of either member in the pair.

We also found that in the recall phase, participants overestimated the size of the small circle (mean recalled circle diameter of a circle diameter of 100 pixels was 176.1, SD=84.5), and they underestimated the size of the large circle (mean recalled circle diameter of a circle diameter of 400 pixels was 225.8, SD=100.6). Given these recall biases, we compared the inferred size with the recalled size, not with the objective size in the following analyses.

The purpose of this experiment was to examine how the mind predicts the outcome given a single predictor, after learning that two predictors were associated with a specific outcome. We compared the inferred size associated with the single object during inference phase to the recalled size associated with the two objects to test the complete inheritance hypothesis. We also compared the inferred size associated with the single object during inference phase to the 50% of the recalled size to test the proportional inheritance hypothesis (Fig.2a).

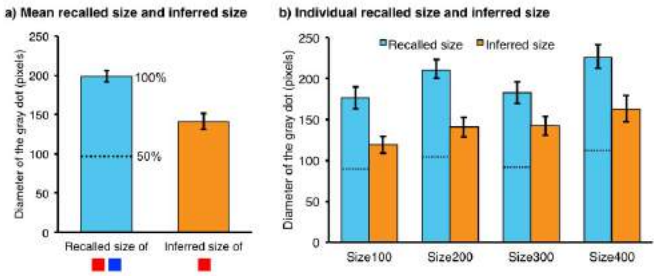

Figure 2. Experiment 1 results. (a) The mean recalled size of the circle associated with two objects and the mean inferred size of the circle associated with a single object. (b) The recalled size of the circle associated with two objects and the inferred size of the circle associated with a single object for each color-size pairing (error bars reflect ±1 SEM; dashed line represents 50% of the recalled size).

We found that the inferred size associated with the single object (mean inferred diameter=141.1, SD=63.6) was significantly smaller than the recalled size associated with the two objects (mean recalled diameter=198.6, SD=46.8) [$t(41)$=6.90, p<.001, d=1.03], but significantly larger than 50% of the recalled size [$t(41)$=5.01, p<.001, d=0.87] (corrected for multiple comparisons). Additionally, the same results were consistently found for each color-size pairing (Fig.2b). The results support the subadditive hypothesis. During debriefing, three participants reported noticing the color-size pairs, but none could correctly report which circle size followed which specific color pair. This suggests that participants had no explicit awareness of the color-size pairs.

These findings suggest that people implicitly predict a subadditive outcome from a single predictor after learning that two predictors previously jointly predicted a specific outcome.

Experiment 2

This experiment aimed to replicate and extend the findings in Experiment 1 by increasing the number of predictors from two to three.

Participants

A new group of 40 undergraduates (34 female, mean age=19.7 years, SD=2.2) from UBC participated in the experiment for course credit.

Stimuli

The stimuli were identical to those in Experiment 1, except that we added a black color (R/G/B=0/0/0) to the color set. There were nine color squares in total, randomly assigned into three triplets for each participant. Each triplet was randomly associated to a gray circle with a specific diameter. The circle diameter subtended 3.0° (or 100 pixels), 7.5° (or 250 pixels), or 12.0° (or 400 pixels) of visual angle (Fig.3a).

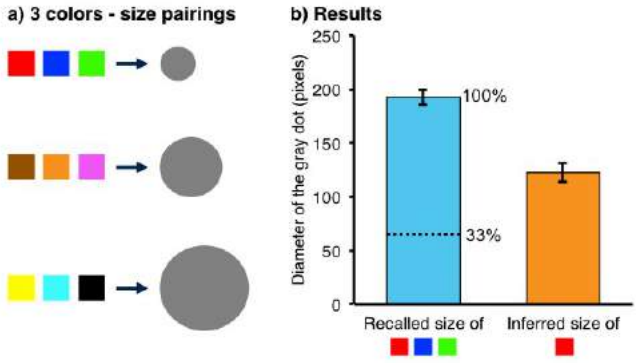

Figure 3. Experiment 2. (a) Three color-size pairs (e.g., red, blue, and green squares–circle with a diameter of 100 pixels). (b) The mean recalled size of the circle associated with three objects and the mean inferred size of the circle associated with a single object (error bars reflect ±1 SEM; dashed line represents 33% of the recalled size).

Procedure

The procedure was identical to that in Experiment 1, except that the three color squares were followed by a circle of a given size in the exposure phase, and participants recalled the circle size associated with the three squares in the recall phase.

Results and Discussion

In a one-way repeated-measures ANOVA, we found no difference between the inferred circle size associated with each object in the triplet for all three types of circle size (p's>.55). Thus, we combined the inferred size of each member in the triplet. We also found that participants overestimated the size of the small circle (mean recalled circle diameter of a circle diameter of 100 pixels was 188.4, SD=78.1) and underestimated the size of the larger circle (mean recalled circle diameter of a circle diameter of 400 pixels was 197.3, SD=94.8). Given these biases, we compared the inferred size with the recalled size, not with the objective size in the following analyses.

We found that the inferred size associated with the single object (mean diameter=124.2, SD=59.5) was significantly smaller than the recalled size associated with the three objects (mean diameter=198.3, SD=53.1) [$t(41)=7.87$, $p<.001$, $d=1.31$], but significantly larger than 33% of the recalled size [$t(41)=6.90$, $p<.001$, $d=1.32$] (corrected for multiple comparisons; Fig.3b). The results again support the subadditive hypothesis.

During debriefing, two participants reported noticing the color-size pairs, but none could correctly report which circle size followed the specific color triplet. This suggests that participants had no explicit awareness of the color-size pairs.

These findings successfully replicated the findings in Experiment 1, showing that people implicitly predict a subadditive outcome from a single predictor after learning that three predictors previously jointly predicted a specific outcome.

Experiment 3

Experiment 3 aimed to generalize the findings to other types of outcomes from circle sizes to numeric values. Specifically, after learning that two objects (e.g., red and blue squares) were associated with a specific numeric value, we examined how people made predictions of value from a single predictor (e.g., red square).

Participants

A new group of 45 undergraduates (41 female, mean age=20.38 years, SD=2.8) from UBC participated in the experiment for course credit.

Stimuli

The stimuli were identical to those in Experiment 1, except that each color pair was associated with a specific three-digit number. There were four three-digit numbers: 150, 400, 650, and 900. Each number was associated with a color pair (Fig.4a).

Procedure

As in Experiment 1, there were three phases (exposure, inference, and recognition). The exposure phase was identical to Experiment 1, except that in the cover task, participants viewed a three-digit number above the rotated T in the circle (Fig.4b). Since that a specific number may be easier to learn than the size of a circle, we reduced the number of repetitions for each color-number pair to 40 times, resulting in 160 trials in total (the order of trials was randomized).

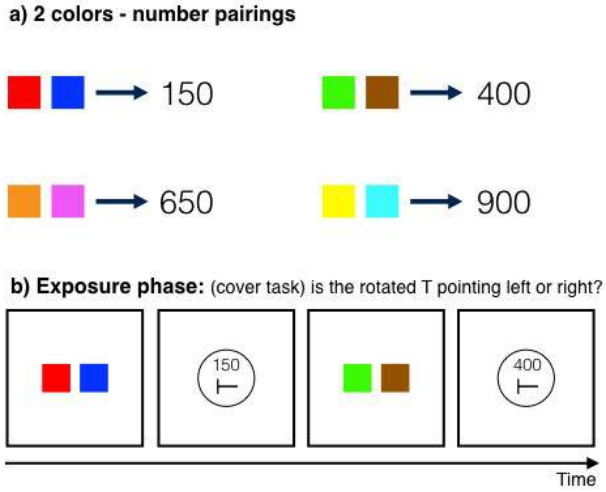

Figure 4. Experiment 3 paradigm. (a) Four color-number pairs (e.g., red and blue squares-150). (b) Exposure phase using a cover task to expose the color-number pairs to participants.

In the inference phase, participants viewed a single colored square and were asked to estimate the number that was associated with the color square by typing a number on the keyboard. The estimated number was restricted to a range from 0 to 1050. Participants had the option to delete and revise their estimated number until the "a" key was pressed to register their estimate.

In the recognition phase, participants viewed a pair of color squares that was presented in exposure and were asked to recall the number that was associated with the color pair by typing the number on the keyboard. The recalled number was restricted to a range from 0 to 1050. Participants had the option to delete and revise their recalled number until the "a" key was pressed to register their estimate. A debriefing session was conducted at the end as before.

Results and Discussion

We found that the inferred number associated with a single object was not different from the inferred number associated with the other member in the pair (p's>.32). Thus, we combined the inferred number of each member in the pair. We also found that participants overestimated the small number (mean recalled number of 150 was 489.7,

SD=227.3) and underestimated the large number (mean recalled number of 900 was 557.0, SD=251.7). Given these biases, we compared the inferred number with the recalled number, not with the objective number in the following analyses.

We found that the inferred number associated with the single object (mean inferred number=476.5, SD=150.8) was marginally smaller than the recalled number associated with the two objects (mean recalled number=513.2, SD=97.3) [$t(44)=1.79$, $p=.08$, $d=0.29$], but significantly larger than 50% of the recalled number [$t(44)=10.86$, $p<.001$, $d=1.96$] (corrected for multiple comparisons; Fig.5). The results again support the subadditive hypothesis.

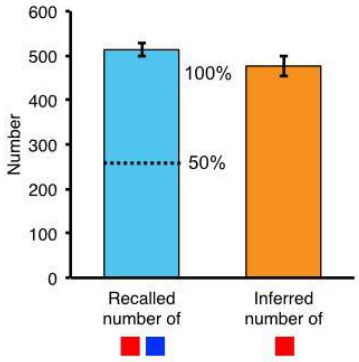

Figure 5. Experiment 3 results. The mean recalled number associated with two objects and the mean inferred number associated with a single object (error bars reflect ±1 SEM; dashed line represents 50% of the recalled number).

During debriefing, two participants reported noticing the color-number pairs, but none could correctly report which number followed which specific colors. This suggests that participants had no explicit awareness of the color-number pairs.

These findings again replicated the findings in Experiment 1, showing that people implicitly predict a subadditive outcome from a single predictor after learning that two predictors previously jointly predicted a specific outcome.

Experiment 4

This experiment aimed to extend the findings in Experiment 3 by increasing the number of predictors from two to three.

Participants

A new group of 33 undergraduates (28 female, mean age=20.2 years, SD=1.7) from UBC participated in the experiment for course credit.

Stimuli and Procedure

The stimuli and the procedure were identical to Experiment 3, except that there were three color triplets and each triplet was associated with 150, 525, or 900 (Fig.6a).

Results and Discussion

In a one-way repeated-measures ANOVA, we found no difference between the inferred number associated with each object in the triplet for all three types of numbers (p's>.35). Thus, we combined the inferred number of each member in the triplet. We also found that participants overestimated the small number (mean recalled number of 150 was 485.7, SD=267.0) and underestimated the large number (mean recalled number of 900 was 592.7, SD=246.8). Given these biases, we compared the inferred number with the recalled number, not with the objective number in the following analyses.

We found that the inferred number associated with the single object (mean inferred number=401.1, SD=180.3) was significantly smaller than the recalled number associated with the three objects (mean recalled number=501.3, SD=106.8), [$t(32)=3.03$, $p=.005$, $d=0.68$], but significantly larger than 33% of the recalled number [$t(32)=7.61$, $p<.001$, $d=1.80$] (corrected for multiple comparisons; Fig.6b). The results again support the subadditive hypothesis.

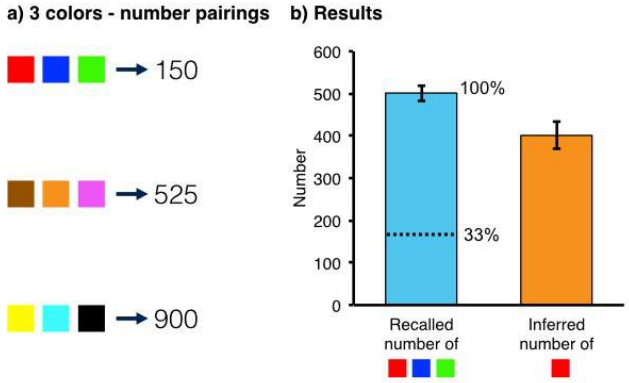

Figure 6. Experiment 4. (a) Three color-number triplets (e.g., red, blue, and green squares-150). (b) The mean recalled number associated with three objects and the mean inferred number associated with a single object (error bars reflect ±1 SEM; dashed line represents 33% of the recalled number).

During debriefing, one participant reported noticing the color-number pairs, but the participant could not correctly report which number followed which specific colors. This suggests that participants had no explicit awareness of the color-number pairs.

These findings replicated the findings in Experiment 3, showing that people implicitly predict a subadditive outcome from a single predictor after learning that three predictors previously jointly predicted a specific outcome.

General Discussion

The goal of this study was to examine how the mind automatically generates prediction when only a single cue is present, after learning that multiple cues were previously jointly associated with an outcome. We found that after learning that two co-occurring objects (e.g., red and blue squares) predicted a specific circle size, participants inferred the circle size associated with a single color (e.g., red

square) to be smaller than the original circle size associated with the color pair, but larger than 50% of the circle size associated with the color pair (Experiment 1). We further extended the number of predictors from two to three. After learning that three co-occurring objects predicted a specific circle size, participants inferred the circle size associated with a single color to be smaller than the circle size associated with the color triplet, but larger than 33% of the circle size associated with the color triplet (Experiment 2). We further replicated and extended the experiment from circle sizes to numeric values as outcomes for two predictors (Experiment 3) and three predictors (Experiment 4). Importantly, no participant was consciously aware of the association between the predictors and the outcome across all experiments, suggesting that the inference of the size or number associated with one single predictor was largely implicit. The current findings also suggest when people predict an outcome relying on a single cue from a set of cues, they do not inherently generate the prediction based on the outcome associated with the complete set of cues, nor do they proportionally inherit the outcome based on the number of cues. Instead, they make predictions in a subadditive manner, which is consistent with support theory (Tversky & Koehler, 1994).

One rationale behind support theory is that unpacking an event to its individual component may evoke other relevant elements that might have been missed. When participants were asked to infer the size associated with each individual color in the pair or triplet, they might have to think more extensively for each color, compared to recalling the outcome associated with the color pair or triplet. A second rationale behind support theory is that explicitly referring to an individual component of an event would increase its salience. When participants were asked to infer the size associated with a single color, their attention was drawn to the single color which may increase the weight of the single color in their prediction of the outcome.

Alternatively, previous studies have suggested that seeing one object in a pair may activate the unitized representation of the pair (e.g., Alvarez & Oliva, 2008). The co-occurring objects (e.g., red and blue squares) may be grouped in the mind during learning. When participants were asked to predict the outcome relying on a single object (e.g., a red square), the object may trigger the representation of the group but not fully activate the representation of the group. Therefore, participants may predict an outcome above 50% but less than 100% of the original outcome.

Another possible explanation is that participants could add the size predicted by each colored square in a sublinear fashion, creating a subadditive sum. A new experiment is needed to test this hypothesis to tease apart whether the subadditivity is driven by the sublinear representation of each size or the sublinear summation of the two sizes. Specifically, participants are first exposed to one unique color predicting a unique size during the exposure phase (e.g., a red square predicting a circle with a certain diameter, and a blue square predicting a circle with a certain diameter). In the inference phase, participants see a red square with a blue square presented side by side simultaneously, and they will be asked to infer the circle size associated with the two squares. In the recall phase, participants simply recall the original size of the circle associated with the red square and the blue square. If the inferred size is equal to the sum of the two recalled sizes, then this would suggest that participants use an additive approach to predict the outcome. If the inferred size is smaller than the sum of the two recalled sizes but larger than each recalled size, then this would suggest that participants use a subadditive approach.

In summary, we found a new consequence of statistical learning on automatic inferences: When multiple objects jointly predict a specific outcome, the presence of a single object implicitly triggers a subadditive prediction.

Abstract

Sequential testimonies where more or less reliable sources argue about an issue are central to public debates. Often, the majority of sources may argue that a hypothesis is true while a minority dissenter may claim the opposite (e.g. scientists and lobbyists in the climate change debate).

In this paper, we show that people are sensitive to source reliability as well as the structural relationship between the sources. Participants follow Bayesian predictions for revising belief in the hypothesis *and* the reliability of the competing sources given majority consent, minority dissent, and shared reliability between sources. Shared reliability and dissent is a key issue for public debate and belief revision. The paper provides novel insight into the workings of these aspects.

Keywords: Source reliability; Shared reliability; Source dependency; Bayesian modelling; Belief revision

Introduction

Information is crucial to revising or maintaining beliefs, to making decisions in an uncertain world, and to compare and contrast support for competing hypotheses. While we can certainly acquire information through personal experience (e.g. witnessing congested traffic may change the route we travel to work, participating in a public demonstration may give an impression of the degree of support for a particular cause, etc.), most of the information we get in our everyday lives comes via other people. Meteorologists provide us with necessary weather information for planning the day, news readers give us an overview of relevant events that happen within our respective countries and abroad, and friends, family members, and co-workers provide invaluable information on a range of issues that help us appreciate their lives, consider information we have not been privy to before talking to that person, or information that is necessary for doing our respective jobs.

Appeals to authority have traditionally been regarded as a reasoning fallacy – this is due to the fact that perceived authority should not add credence to the conditional link between the evidence and a hypothesis. That is, whether or not a piece of information increases the likelihood of a hypothesis is, in principle, independent from the source that conveys the piece of information. Classically, this has led some people to be sceptical of appeals to authority.

The notion that appeals to authority should be distrusted in principle reverberates in theories of argumentation and reasoning. For example, two prominent models of persuasion, the Elaboration Likelihood-Model (Petty & Cacioppo, 1984) and the Heuristic-Systematic Model (Chaiken & Maheswaran, 1994), classify appeals to authority as a shallow and weak cue. In this view, people should disregard the characteristics of the source as they are given greater incentive to interrogate and elaborate on the evidence and its relation to the hypothesis. In other words, as the incentive to understand the link between evidence and claim increases, the nature of the source should matter less and less.

While it is it true in principle that the messenger neither adds nor subtracts to the link between evidence and claim, overlooking the epistemic impact of perceived source reliability neglects a crucial communicative and reasoning function. In a world where sources can lie and make up evidence, their reliability becomes crucially linked with the strength of the argument. Additionally, in a highly uncertain world, some information requires deep expertise to process (e.g. climate data may be accessible to a general population, but requires considerable expertise to adequately model and understand). Given the capacity to misinform and generate mistaken causal models due to a lack of expertise, the reliability of the speaker is an important element for people to update and revise their beliefs in the world.

In line with this perspective, the impact of the perceived reliability of a source is shown to be crucial for reasoning and decision-making. Treating the reliability of a source as a shallow cue, the literature on persuasion has shown the impact of appeals to authority (Petty & Cacioppo, 1984; Tormala & Clarkson, 2007), the developmental literature suggests children seek out credible figures to guide their perception of the world (Harris & Corriveau, 2011), and appeals to authority have been shown to impact legal

reasoning (Lagnado et al., 2013). Further, it increases adherence with persuasion strategies (Cialdini, 2007), and perceived reliability is able to predict whether or not people believe an unknown policy is good, given recommendations from different political sources (Madsen, 2016).

The paper explores three aspects of perceived reliability. First, it replicates a Bayesian model of the impact of sequential reports from more or less reliable sources. This replication shows people update their beliefs in a hypothesis given reports from sources *as well as* updating the perceived reliability of the sources themselves. Second, it replicates recent findings that shared reliability (e.g. sources sharing a common background) impacts the degree of belief in a hypothesis and the perceived reliability of sources, in line with Bayesian predictions. This explores aspects of source dependency. Finally, we extend this work by presenting novel findings on the impact of minority dissenters on belief in a hypothesis and the perception of reliability among sources, given the introduction of shared reliability. Minority dissent and shared reliability are crucial aspects of information transmission (see see Whalen et al., 2013 for dependency and Perfors et al., 2018 for minority dissent), as they appear a number of domains – indeed, most debates are characterised by sources that disagree. For example, in climate change both are apparent and important factors of public debate.

A Bayesian approach to source reliability

Whilst some have argued reliance on the reliability of others to revise subjective beliefs about the world is a shallow persuasive cue (Petty & Cacioppo, 1984; Chaiken & Maheswaran, 1994), others have argued reliance is rationally justified and a necessary component of belief revision (see Bovens & Hartmann, 2003; Hahn et al., 2009).

The latter applies a Bayesian perspective to reliability. Bayesian reasoning uses subjective, probabilistic degrees of belief in propositions where Bayes' theorem integrates prior beliefs with the likelihood ratio to estimate the posterior degree of belief (Howson & Urbach, 1996). Bayes is an alternative to logicist approaches to reasoning (Oaksford & Chater, 1991) and has been applied to argumentation theory (Hahn & Oaksford, 2006; 2007), which has found Bayesian reasoning can account human information integration in practical reasoning (see Oaksford & Chater, 2007).

The Bayesian approach suggests that people's subjective perceptions of the reliability of the speaker normatively should yield different information integration. For example, if the messenger has no expertise, the information may be regarded as pure noise (as it is equally likely to be true or false). In this case, the recipient should not revise her beliefs one way or another. Comparatively, if low trustworthiness entails simple misinformation, the recipient may increase her belief in the opposite direction given positive reports from a distrusted source. Due to the Bayesian nature of the above models, the reliability function of reports relies on conditional probabilities (see e.g. Madsen, 2016 where participants revise their beliefs negatively in a proposed policy given positive reports from subjectively distrusted politicians).

More formally, the model integrates two components to account for overall reliability: perceived trustworthiness and perceived expertise (Hahn et al., 2009)[1]. In this framework, expertise refers to the *capacity* to provide accurate information about the topic in question. This is highly domain-dependent. For example, an astrophysicist may be able to calculate the mass of a distant celestial body, but may not be able to give a valid economic forecast. While expertise refers to capacity, trust refers to the *intention* of providing true and accurate information to the best of ones ability. For example, the astrophysicist may omit data points that contradict personally held theories or beliefs. The model components are orthogonal, as a person can be highly expert in some domain while at the same time be entirely untrustworthy – or vice versa. The orthogonal assumption is theoretically grounded (Bovens & Hartmann, 2003) and empirically supported (Harris et al., 2015)

Formally, Bayes' theorem is used to integrate reliability where the posterior degree of belief in the hypothesis (H) given the representation (Rep) yields:

$$P(H|Rep) = \frac{P(H)x\,P(Rep|H)}{P(H)x\,P(Rep|H) + P(\neg H)x\,P(Rep|\neg H)}$$ [2]

The formalisation predicts how people should integrate uncertain information from more or less reliable sources. Model predictions have enjoyed a good fit with behavioural data (Harris et al., 2015; Madsen, 2016). Overall, the findings suggest people are sensitive to the reliability of the individual speaker and integrate the information from the speaker in a normatively rational manner.

Shared reliability: corroboration and negation

The empirical work underpinning the Bayesian source reliability model suggests that people do modulate information integration given perceived speaker reliability. The influence of reliability on belief revision means that the perceived source reliability *itself* is important in the belief revision process.

If the recipient believes the source is credible, she should revise her beliefs more positively if the source provides positive reports for a hypothesis. As a consequence, if the perceived source reliability changes, Bayesian (normative) models entail that the effect of this source should change for future reports and the impact of the already observed report. That is, if a speaker is revealed to be less than credible, audiences should be more likely to disregard any reports from that source in the future. Changes to the perceived

[1] The operationalization of reliability as an amalgamation of perceived expertise and trustworthiness is remarkably close to findings in social psychology where reliability is defined as an amalgamation of traits related to *warmth* and *competence* (Fiske et al., 2007; Cuddy et al., 2011).

[2] P(Rep|H) = P(Rep|H, Exp, T) * P(Exp) * P(T) + P(Rep|H, ¬Exp, T) * P(¬Exp) * P(T) + P(Rep|H, ¬Exp, ¬T) * P(¬Exp) * P(¬T) + P(Rep|H, Exp, ¬T) * P(Exp) * P(¬T); mutatis mutandis for P(Rep|¬H)

reliability of sources can conceivably happen for a number of reasons – for example if the source corroborates a highly unlikely hypothesis.

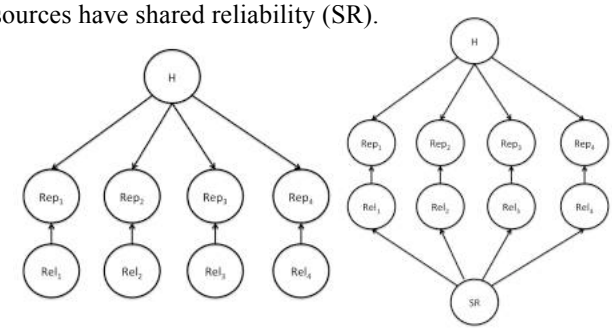
Further, reports are seldom made in isolation. Frequently, people will see multiple reports for a given issue. These sources, perceived as more or less credible by the recipient in question, may argue for or against a hypothesis. For example, in climate change debates, pundits, experts, and members of the media frequently make predictions about a particular hypothesis or issue. Considering flood risks in coastal areas, many experts tend to warn that weather will become more extreme and floods more prominent (e.g. in Miami). However, minority dissenters may argue that floods will not change over time. Here, we have multiple sources (e.g. scientists) that corroborate and support a hypothesis (rising floods) and a dissenter (e.g. a senator) who negates the hypothesis.

People's prior belief in the hypothesis, their perceived reliability for each source, and their perception of the dependency of sources (e.g. shared reliability versus independent sources) should normatively influence their belief in the hypothesis and perceived reliability, given positive or negative reports from the sources. The paper explores whether this is the case empirically.

In order to approach these questions, we use Bovens and Hartmann (2003) foundational and Bayesian perspective on modeling source reliability. Aside from suggesting people should revise their belief in the reliability of the source and in the hypothesis given sequential reports, their models show that *the structure* of the perceived relationship of sources influence the degree to which their reports should these beliefs given multiple testimonies.

Figure 1a-b illustrates different structural relationships between independent sources with independently perceived reliability ($Rel_{1\text{-}4}$) who provide a report ($Rep_{1\text{-}4}$) concerning a hypothesis (H). 'Independent sources' refer to situations where the sources can be considered entirely independent of one another (Fig. 1a). For example, climate scientists may run studies independently of each other and report their findings with no knowledge of the findings of other scientists (here, the strength of the report will in part depend on each reports personal reliability).

Comparatively, if sources share a common background (e.g. the scientists may have been trained at the same school to use a specific model to explore climate phenomena), they become partially dependent (Fig. 1b). In this case, the sources have shared reliability (SR).



(1a) *(1b)*

Fig. 1a-b: independent sources and sources with shared reliability

Shared reliability constrains the informativeness of a source, as their reliabilities are influenced by the common-cause (e.g. attending a good or bad school). That is, the common background can weaken the impact of the reports provided by these sources. More intuitively, in finding out that sources share a compromising background (e.g. have all attended a fraudulent school), then the individual reliabilities of those sources are compromised, and in turn the strength of their support. Bovens and Hartmann (2003) provide a formal way to calculate "…how the posterior probability of the reliability of the nt^h witness increases as more and more witness reports from in" (p. 79):

$$P^{*(n)}(REL_n) = P(REL_n|REP_1, \ldots, REP_n) = \frac{h[us(s+a\bar{s})^{n-1} + \bar{u}t(t+a\bar{t})^{n-1}]}{h[u(s+a\bar{s})^n + \bar{u}(t+a\bar{t})^n] + \bar{h}[u(s+a\bar{s})^n + \bar{u}(t+a\bar{t})^n]}$$

where u is the probability of the shared background being reliable, P(SR) – that is, how reliable the source is seen to be prior to any information about shared reliability, s is the conditional probability: $1 > P(Rel_i|SR)$ – that is, the likelihood that source i is reliable *given* the shared reliability. The conditional probability $> P(Rel_i|SR) > 0$ is represented by t, whilst a is a randomization parameter (that is, the degree of noise), and h is the prior probability of the hypothesis (that is, degree of belief in the hypothesis prior to any reports).[3]

In sum, the equation shows that the posterior degree of reliability of the n^{th} witness (or source) depends on the randomization parameter (a) and prior probability of the hypothesis (h). For example, if $a = .9$ and $h = .3$, initial witness reliability falls from .5 to .25 (see p. 80), but increases as additional positive reports confirm the initial report.[4]

Recently, Madsen et al. (2018) tested this intuition. That is, whether people update their beliefs in the reliability of the source and the belief in the hypotheses when they experience sequential corroborative testimonies. In their study, all reports *corroborated* the hypotheses (that is, all sources provided positive reports for the hypothesis). However, as mentioned, many (if not most) debates are between sources that disagree about a particular issue. For this reason, it is imperative to understand the function of (minority) dissenters.

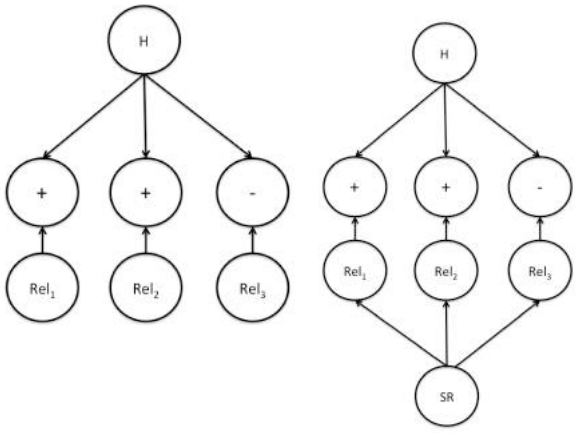
Madsen et al. find support for the model of corroborating sources, as P(Rel) decreased given a corroborative report of an unlikely hypothesis, but subsequently increased as more corroborative reports were given. Further, when participants learned sources attended the same school, they adjusted their posterior degree of belief negatively for the hypothesis *and* source reliability. The effect was stronger if experts'

[3] C.3 (pp. 136-137) and C.4 (pp. 137-138) in Bovens and Hartmann (2003) provide the full derivation for $P^{*(n-1)}(REL_n) = P(REL_n|REL_1, \ldots, REL_{n-1})$ and $P^{*(n)}(REL_n) = P(REL_n|REP_1, \ldots, REP_n)$ respectively

[4] The current study does not elicit a randomization parameter

school was bad compared with sharing a school described as 'excellent'. Finally, their study suggests people revise posterior degree of belief in the reliability of sources retrospectively. That is, as $sources_{2\text{-}3}$ provided reports, the reliability of $source_1$ was adjusted to be in line with perceived reliability of the n^{th} source.

This paper extends this work by exploring three facets of source dependency and reliability. First, a source may corroborate or negate a report for a given hypothesis. We test how participants update their beliefs in the hypothesis and the reliability of each source given corroborative reports from $sources_{1\text{-}2}$ and a negative report from $source_3$ (denoted by '+' and '-' respectively in the Fig. 2a and b).



(2a) *(2b)*

Fig. 2a-b: Negation from independent sources and sources with shared reliability

Second, we explore how dependency impacts perception of the hypothesis and reliability when the 3rd source dissents and negates the reports of $sources_{1\text{-}2}$. Here, we use the same a shared reliability structure (Fig. 2b).

We use the experimental design of Madsen et al. (2018), altering it to explore the following:

Given reports from the 3rd dissenting source, we expect decreases in reliability for all sources and a decrease in belief in the hypothesis. This is due to the fact that dissent adds additional uncertainty to the hypothesis (the initial sources may be wrong) and onto the sources themselves (either the 3rd source or the initial sources may have been mistaken/providing bad information). For the likely scenario we expect a significant drop in reliability for the 3rd source in particular, as this source goes against a very likely hypothesis *and* two corroborating reports. In addition, in accordance with Madsen et al (2018), P(Rel) should *decrease* when source 1 reports an unlikely hypothesis, but subsequently recover, as source 2, still perceived to be independent, corroborates the unlikely prediction.

Method

Material and procedure: To replicate Madsen et al. (2018) and enable direct comparisons, we use their method and materials. To test model predictions, we use low and high probability scenarios. In the low probability scenario, participants were asked to evaluate the likelihood of a crash in the stock market with the following description:

> *"Imagine you are watching a news programme about the economy. Specifically, the programme considers whether or not the UK stock market will crash (i.e. fall by more than 30%) within the next 6 months. Historically, the likelihood of a crash occurring within a 6-month window is 5%.*
>
> *In your opinion, how likely is the UK stock market to crash within the next 6 months?"*

Having read this, participants provided prior estimates for their beliefs in the hypothesis on a scale from 0-1 (0: I am completely certain the stock market will NOT crash within the next 6 months; 1: I am completely certain the stock market will crash within the next 6 months). To elicit the reliability of sources, we defined reliability:

> *"Reliability can be defined as having access to relevant information about a topic, and a willingness to say what you believe to be the true state of the world.*
>
> *How reliable are economists in predicting the market crashes?"*

Having read this, participants provided their belief in the source reliability from 0-1 (0: economists are completely unreliable; 1: economists are completely reliable). Reports from sources were provided as interviews with experts on the subject. For example:

> *"Now, imagine that an economist, Robert, is being interviewed about the economy. Robert states the following: "I am completely certain the stock market will crash within the next 6 months."*
>
> *Given Robert's report, how likely is the UK stock market to crash within the next 6 months?"*

Participants then gave subjective estimates of their beliefs in the hypothesis and in each source hitherto presented. Sources were presented sequentially. To test the effect of negation, $sources_{1\text{-}2}$ always corroborated the hypothesis and $source_3$ always negated the hypothesis. This implemented a minority dissenter. The dissent only functions in light of the initial corroborations. As such, the dissenter had to be at the end of the scenario. Further, placing the dissenter towards the end allowed for replication of corroborative $reports_{1\text{-}2}$, as participants had not yet been exposed to dissent.

Finally, having seen the three sequential reports, the participants were told the sources were partially dependent (i.e. shared a background), which was manipulated between-subjects as either high or low quality (SR Condition). An example of the high quality SR Condition statement for the low likelihood scenario:

> *"It turns out, all the interviewed economists studied at the same school and subscribe to the same economic theories. Their school has a very good reputation for excellent teaching and accurate approaches to economy.*
>
> *Given the fact that they all studied at the same school and follow the same economic theories, how likely is the UK stock market to crash within the next 6 months?"*

After each report and the SR condition, P(H) and $P(Rel_{1\text{-}n})$ were measured. Participants read both scenarios in a

counterbalanced order, with the SR Condition manipulated independently for each scenario.[5].

Participants: 100 participants (71 female, μ_{age} = 34.51, σ = 11.49) were recruited from the online recruitment source Prolific Academic. All had to be aged 18+ and native English speakers from either the UK or the USA. All participants had to have a prior completion rate of 95%. Median completion time was 5.56 min (σ = 2.11) and participants were paid £0.8 (resulting in an effective fair hourly wage of £8.63/hour for participation).

Results

All inferential statistics reported below were Bayesian[6], and were conducted used the JASP statistical software (JASP Team, 2018). The probability manipulations were successful in generating high and low estimates for the two scenarios: The market crash scenario was rated as unlikely (μ = .337, σ = .243) and the salmon growth scenario was rated as likely (μ = .806, σ = .116). In both scenarios, sources were rated higher ($P(Rel_{Economist})$: μ = .638, σ = .156; $P(Rel_{Biologist})$: μ = .731, σ = .128). Importantly, though, both sources were rated positively, which allows for the testing of whether positive reports of unlikely hypotheses influence reliability estimates negatively.

Following predictions from Bovens and Hartmann (2003), we expect positive reports of an unlikely hypothesis to lead to an initial decrease in estimates of reliability. To test this, we use repeated measures ANOVA ($P(Rel) - P(Rel_1|Rep_1)$). We observe a negative revision of reliability of source 1 given a positive report of an unlikely hypothesis (N = 100), BF_{10} = 179636.1 (in the current design, the source predicts the stock market will crash within a 6-month period). However, as participants learn another source also provides a positive report ($P(Rel_1|Rep_1) - P(Rel_1|Rep_2)$), they revise their belief in the initial source and revise reliability in a positive direction (N = 100), BF_{10} = 798759.1.

When a third source then contradicts ($P(Rel_1|Rep_2) - P(Rel_1|Rep_3)$), the reliability of the original reporter is then reduced once again (N = 100), BF_{10} = 352673.82 We further note strong evidence for a null difference in the estimated reliabilities across the three sources (N = 100), BF_{10} = 0.127, despite the presence of a contradicting minority, suggesting that all sources are penalized given the dissent among them.

In addition, participants *increase* their belief in the likelihood of the hypothesis, whilst they simultaneously *decrease* their belief in the reliability of the reporting source ($P(H)$ to $P(H|Rep_1)$; N = 100), $BF_{10} = 5.958 * 10^7$. That is, the introduction of a dissenting minority source on belief in the likelihood of the hypothesis ($P(H|Rep_2) - P(H|Rep_3)$) leads to a significant decrease (N = 100), BF_{10} = 281255.7.

We next turn the high likelihood scenario (biologists predicting salmon growth). To test whether participants neither increase or decrease the reliability of sources that provide positive statements for highly likely hypotheses (hypothesis 2), we conducted a repeated measures ANOVA ($P(Rel)$ to $P(Rel_1|Rep_1)$), finding no significant change (N = 100), BF_{10} = 0.401. We do however note the introduction of a contradicting source ($P(Rel_1|Rep_2) - P(Rel_1|Rep_3)$) leads to a significant decrease in reliability of the first source (N = 100), BF_{10} = 12458.36. Critically, given this introduction, and separating these results from those of the unlikely scenario, there was a substantial difference in the estimated reliability of the dissenter (μ = .489, σ = .207), and the first two (corroborating) reporters (Source 1: μ = .707, σ = .16; Source 2: μ = .717, σ = .156; N = 100), $BF_{10} > 1 * 10^{10}$. This suggests that - while introducing uncertainty to the reliability of the corroborating sources - providing dissenting reports about a hypothesis with a high prior belief and two corroborating reports can significantly damage perceived reliability. That is, if a minority dissents against prevailing wisdom *and* goes against other witnesses, she may suffer a loss of reliability.

We further note that as in the unlikely scenario, the introduction of a report from dissenting minority source on belief in the likelihood of the hypothesis ($P(H|Rep_2) - P(H|Rep_3)$) leads to a significant decrease (N = 100), $BF_{10} = 5.561 * 10^6$. The main results are shown in Fig. 3.

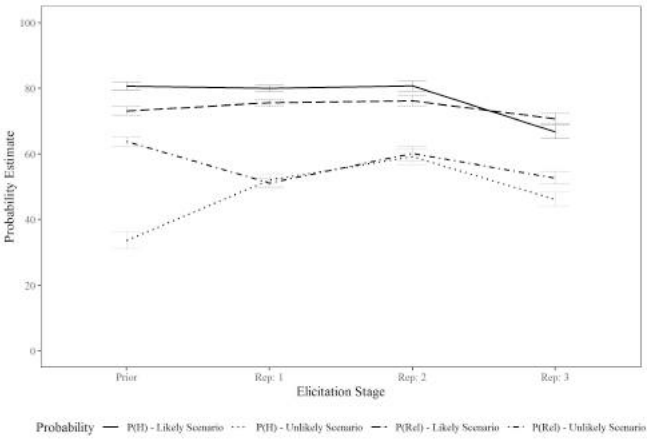


Fig. 3: P(Rel) and $P(H)$ given $reports_{1\text{-}3}$

Results of shared reliability

To test whether the impact of introducing a shared reliability among sources (hypothesis 3), we compare posterior degrees of belief in the hypothesis and the reliability of the sources.

A repeated measures ANOVA was conducted on belief in the hypothesis (P(H)) for the introduction of the shared reliability information (i.e. $P(H|Rep_3)$ to P(H|SR)), with the inclusion of the shared reliability condition (high/low-quality) as a between-subjects condition.

For the unlikely scenario, belief in the hypothesis (economic crash), was affected by the introduction of a

[5] The high likelihood scenario was identical to the above, but considered predictions that the Norwegian salmon population would grow over the next 5-year period.

[6] All analyses assume an uninformed prior.

shared reliability (main effect of introduction), $BF_{Inclusion}$[7] = 110.1, and if shared reliability was high or low quality (low < high), $BF_{Inclusion}$ = 272.1, demonstrating a successful manipulation check. Importantly, the significant interaction of shared reliability condition, and its introduction, $BF_{Inclusion}$ = 550.8, revealed belief in the hypothesis decreased when the shared reliability was low-quality but increased when the shared reliability was of high quality. Consequently, the model with all the above terms included was the best fit, BF_M[8] = 550.81, and significant overall, BF_{10} = 486.26.

We observe the same effects for revision of reliability estimates. The main effect of an introduction of a shared reliability, $BF_{Inclusion}$ = 4.798 * 10^9, and main effect of shared reliability condition (low-quality < high-quality), $BF_{Inclusion}$ = 1.583 * 10^8, are best described by the significant interaction of the two, $BF_{Inclusion}$ = 4.421 * 10^8, where high quality shared reliability leads to a minor increase in estimated reliability, whilst low quality shared reliability leads to a substantial decrease. Once again, the model with all the above terms included was the best fit, BF_M= 4.421 * 10^8, and significant overall, BF_{10} = 1.552 * 10^{10}.

The above analyses were then repeated for the likely scenario, where, against predictions, the belief in the hypothesis (salmon growth) was found to be unaffected by the introduction of a shared reliability, $BF_{Inclusion}$ = 1.227, or its quality, $BF_{Inclusion}$ = 0.194. However, the introduction of shared reliability was found to decrease estimations of source reliability, $BF_{Inclusion}$ = 1.116 * 10^{10}, and whether a shared reliability was high or low-quality led to higher or lower reliability estimates (respectively), $BF_{Inclusion}$ = 5.082 * 10^7, once more passing the manipulation check. Critically, reductions in reliability (given the introduction of a shared reliability among sources), is found to be localized to when the introduced shared reliability is of low-quality (right-hand facet, Fig. 4), $BF_{Inclusion}$ = 8.252 * 10^7. Finally, the model with the above terms included was the best fit, BF_M = 8.252 * 10^7, and significant overall, BF_{10} = 6.162 * 10^{10}. The main results are shown in Fig. 4.

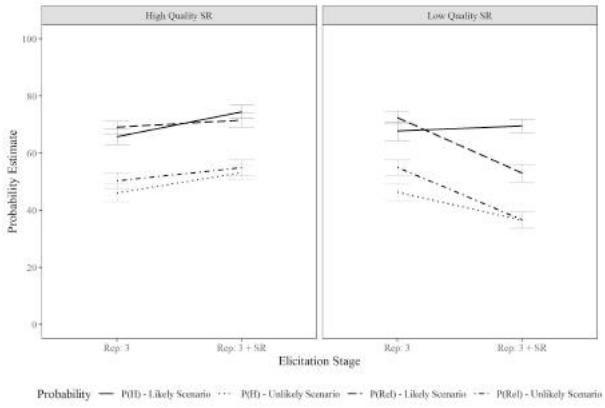

Fig. 4: P(Rel) and P(H) given shared reliability

Discussion and concluding remarks

Despite the prevalence of dissent in public debates, the role of minority dissenters has not been adequately explored or modelled. This is a crucial function if to understand the functional impact of dissent in debates such as climate change or political predictions.

The paper tests how people revise beliefs in the reliability of sources and a hypothesis given sequential reports. The two initial reports support the hypothesis while the 3rd report rejects it. First, P(Rel) initially decreases when the source provides a positive report for an unlikely hypothesis, but rebounds when the 2nd source corroborates the initial report. Additionally, P(H) increases for the same reports while P(Rel) does not change for predicting the *likely* hypothesis while P(H) increases slightly. This replicates findings from Madsen et al (2018) and follows Bayesian predictions.

Second, the negation of the hypothesis yielded novel results. In both scenarios, negation decreased P(Rel) for all sources, presumably as it introduces noise and uncertainty. P(H) decreases when the 3rd source rejects the hypothesis for the unlikely scenario, but does not decrease for the likely scenario. This suggests that while participants revise their belief in an unlikely hypothesis (a market crash within six months), they decrease their belief in the hypothesis when dissent is voiced against this idea. Comparatively, P(H) does not decrease with dissent in the likely scenario. Rather, P(Rel) for $source_3$ decreases significantly given rejection of the likely hypothesis. P(Rel) also decreases for $sources_{1\text{-}2}$ given dissent in the likely case, but not to the same extent as is suffered by the dissenter.

Finally, shared reliability appears to work asymmetrically for consenters and dissenters. If the school enjoys a good reputation, perceived reliability increases for consenters, but less so for dissenters. If the shared reliability is perceived as high quality, people's degree of belief in the hypothesis additionally increases. However, for both perceived source reliability and the hypothesis, we see a decrease when the shared reliability is of poor quality.

In all, the study suggests people are sensitive to source reliability as well as the structural relationship between the sources. Belief revisions generally follow Hahn et al. (2009) such that positive reports from very credible sources lend credence to the hypothesis. Additionally, participants update perceived source reliability in accordance with predictions, as supporting unlikely hypotheses is initially detrimental, but sequentially rebounds given corroboration. Finally, perceived partial dependence is crucial, as shared reliability moderates perceptions of the hypothesis and the reliability of all sources involved. In all, the study provides additional support for a Bayesian approach to source reliability.

Abstract

Misinformation, and its impact on society, has become an increasingly topical field of study of late. A body of literature exists that suggests misinformation can retain an influence over beliefs despite subsequent retraction, known as the Continued Influence Effect (CIE). Researchers have argued this to be irrational. However, we show using a Bayesian formalism why this argument is overly assumptive, pointing to (previously overlooked) considerations of reliability of, and dependence between, misinforming and retracting sources. We demonstrate that lay reasoners intuitively endorse assumptions that demarcate CIE as a rational process, based on the fact misinformation *precedes* its retraction. Moreover, despite using established CIE materials, we further upturn the applecart by finding participants show CIE, and appropriately penalize the reliabilities of contradicting sources.

Keywords: Continued Influence Effect; Negation; Reliability; Dependency; Reasoning

Introduction

Misinformation can have a lasting effect on beliefs that people entertain and on the inferences they can make about events[1]. Poor information, whether spread deliberatively or mistakenly, can have serious and widespread repercussions for society. For example, despite being corrected repeatedly, some people belief that there is a causal link between the measles mumps and rubella (MMR) vaccination and autism.

This belief persists in some communities despite scientific evidence refuting the myth (Horne et al., 2015). Decreased acceptance of the MMR vaccination has contributed to a 7% drop in vaccination rates in the UK and a 1.7-fold increase in refusal to vaccinate in the US (Smith et al., 2008), and consequently, an increase in a vaccine-preventable disease.

The harmful effects of misinformation and ineffectiveness of attempts to correct mistaken beliefs have become a great concern for contemporary society (Gordon, Brooks, Quadflieg, Ecker, & Lewandowsky, 2017; Lewandowsky, Ecker, Seifert, Schwarz, & Cook, 2012), and has recently become a weighty issue for governments, media organizations, and citizens (see Lewandowsky et al., 2017). Problematically, though, studies show that belief in erroneous information can persist even after it has been unambiguously corrected (Lewandowsky et al., 2012)
Regardless of how information is corrected, research shows that it often fails to abolish the effects of misinformation (see Lewandowsky et al., 2012 for review). The so-called *Continued Influence Effect* (CIE) of misinformation refers to the consistent finding that information initially presented as true continues to influence beliefs and reasoning despite clear and credible corrections (Ecker et al., 2011a, 2011b; Johnson & Seifert, 1994; Rich & Zaragoza, 2016).

In the paper, we explore two aspects of CIE. First, no normative account of how people should "optimally" process corrections to misinformation has been provided to date. CIE studies typically report the observed phenomenon in a variety of contexts and settings. To explore the effect systematically, we provide a Bayesian Network model to test whether CIE is truly irrational or if the phenomenon can be explained rationally. Second, past research shows the importance of dependency (Madsen et al., 2018). That is, whether a source is truly independent from another source, or if they are somehow related. This influences the impact of the report on the hypothesis *and* perceived reliability. In accordance with these studies, we manipulate the source of debunking such that the initial source debunks its own statement or a different source debunks the statement.

[1] We define information as any piece of information or evidence that is initially thought to be true, but which later turns out to be erroneous, but which can be corrected. Going beyond the current study, the intention behind the dissemination of misinformation is crucial (e.g. the difference between an honest mistake and a malevolent lie – both of which may provide poor information).

Exploring CIE through a formal reasoning model yields interesting results. First, we find a rational explanation for CIE. We show that belief in the hypothesis remains above prior level, but instead the reliability (in the second reporter case) is penalized. Second, perceived dependence influences the effect. Given a Bayesian network, CIE is irrational only insofar that the sources are entirely *independent* of each other. Comparatively, when considering reports temporally and dependent, CIE is entirely *rational*. Correcting is often done by a source that is, in some way, linked with the initial source of misinformation (e.g. a reporter working at the same network). This highlights a significant conceptual limitation to the way in which CIE is framed classically.
Finally, we can demonstrate irrationality in a manner that is backwards to what is typically reported in CIE studies. In CIE studies, people should not stick with original beliefs given correction, but do so any way. We show cases where there are reasonable grounds for why people should stick with their original beliefs, but do not.

The continued influence effect

Continued influence studies examine corrections to misinformation using variants of a laboratory paradigm first developed by Wilkes and Leatherbarrow (1988; but also see Johnson & Seifert, 1994). There are two leading cognitive explanations for CIE (Gordon et al., 2018; Lewandowsky et al., 2012):

First, ***the selective retrieval account*** argues that CIE occurs when correct and incorrect information are stored in memory simultaneously, and misinformation is activated but inadequately blocked (Ecker et al., 2011a). Second, ***the model updating account*** argues that people continually construct a mental event model as new information becomes available. Correcting information without providing a credible alternative (e.g. a competing causal explanation) leaves people with a gap in their mental model. On this view, people prefer a coherent but incorrect model to a correct but incomplete one and thus maintain the invalidated information (Ecker et al. 2010; Johnson & Seifert, 1994).

A typical CIE task involves a series of sequentially presented statements describing an unfolding event, similar to a breaking news report. Misinformation that allows inferences to be drawn about the outcome of the event is presented early in the sequence, but retracted later. Participants' event comprehension is assessed, typically to show that misinformation continues to influence people's inferential reasoning even though they clearly understand and remember that the information was corrected (Johnson & Seifert, 1994). The effect persists even when given prior warnings about the persistence of misinformation (Ecker et al., 2010). The fact that retractions are often ineffective at 'removing' misinformation from people's understanding of events emphasizes the need to identify and model factors that contribute to the *Continued Influence Effect*.

Sustained reliance on misinformation given a retraction is often depicted as a bias – or systematic deviation from a normative standard – and therefore irrational (e.g. Lewandowsky et al., 2012). This perspective assumes two things; first, that the optimal solution is always to disregard initially prior information in favour of new information, and second that the 'true' value of the retraction is known.

Source reliability

Establishing a source's reliability is critical when deciding whether to rely on the information conveyed to us by other people, and may drive the CIE. Reliability can be separated into issues of: i) observational sensitivity, ii) objectivity, and iii) veracity (Schum, 1994). For example, jurors must establish whether a witness' testimony is truthful and accurate in order to reach a verdict, and voters must similarly place their confidence in the statements of politicians when deciding who to vote for.

While appeals to authority and reliance on testimonies traditionally have been seen as fallacoius (ad verecundiam) or as a shallow cue, Bayesian models have integrated reliability within a normative theory of reasoning (Bovens & Hartmann, 2003; Hahn et al,. 2009; Harris et al., 2015).

People use a range of cues to evaluate a source's reliability. For example, in the legal domain witnesses may contradict themselves or be contradicted by others, which may reassess the credibility (see Connor Desai et al., 2016). Moderating perceived source reliability is an sensible act if new information, additional contradictory or corroborative reports, or insight into whether or not the sources are related to each other is made known. In addition to new infomraiton, source dependecy moderates perceived reliability (Bovens & Hartmann, 2003; Madsen et al., 2018).

Contradiction is particularly relevant to CIE studies where the misinformation and its retraction are typically issued by the same source. A source who announces that they previously gave incorrect information may appear less reliable than one who does not. Consistent with this, one CIE study found that distrust in the source of the retraction was a primary reason for disbelieving the retraction (Guillory & Geraci, 2010; 2013). Indeed, Lewandowsky et al., (2012) argue that source reliability (high and low) may facilitate 'tagging' of correct and incorrect information and facilitate retrieval of information when this information is made salient.

Thus, perceived reliability moderates the degree to which people are willing to integrate reports from more or less reliable sources. If a highly reliable source provides report about an issue, the recepient should *normatively* revise her belief in the suggested direction. Second, reports from independent sources are more diagnostic than reports that stem from sources who share a common background. In order to model reliability estimates, belief in the hypothess, and to develop a formal model of CIE, we adopt a Bayesian approach.

A Bayesian approach to source reliability

As mentioned, CIE studies do not provide a normative account of how people should process retractions to misinformation. The lack of formalism is crucial as there

may be situations where continued reliance on misinformation is rational given the lack of information and inherent uncertainty of the situation. In such situations, people may use cues like reliability to assess the validity of misinformation and its retraction, and decide how much to incorporate these pieces of information into their beliefs.

Bayes' theorem gives a normative belief revision model. It integrates people's subjective prior degrees of belief with the likelihood ratio to estimate the posterior degree of belief. It has been applied to conditional reasoning (Oaksford & Chater, 2007), argumentation (Hahn & Oaksford, 2006; 2007), and other areas of cognition (Chater et al., 2010).

To explore CIE formally, we use a Bayesian Network (BN) framework (Pearl, 2000). BNs use graph structures to represent the probabilistic relationships between hypotheses and evidence (including reliability), using conditional probabilities to represent the strength of relations, and show what inferences are rationally permitted from a given model given available information. This is an ideal method for examining whether CIE is rational in some circumstances, as it provides the means to test causal models of scenarios – including their models of the reliability of the sources providing information – and compare inferences to a normative standard (Fenton et al, 2013).

Congruency of information with the misinformation and the reliability of sources providing the misinformation or the retraction are potential moderators of the CIE. BNs provide a formal model to test responses against model predictions and test foundational assumptions of the CIE.

Comparing judgments to Bayesian predictions test if there are situations in which retaining belief in misinformation after a retraction is rational. Formally modelling the causal relations between information included in a scenario would make it possible to test participants' causal models of scenarios. This provides an understanding of the cognitive mechanisms involved in the CIE.

Method

Participants: 101 participants were recruited from Prolific Academic (71 females, age = 31.57±9.6). Participants were paid £1.50 (~$1.97) and took 14 minutes (on average) to complete the experiment.

Stimuli, Design & Procedure: To replicate CIE studies, we used stimuli adapted from past research (Johnson & Seifert, 1994; Gordon et al., 2017, see Table 1 for an example of stimulus material).

Table 1: Example of news report and comprehension probes

Sentence	Control	Retraction (Same Source)	Retraction (Different Source)
Example News Report			
Sentence 1	*A motorcyclist died yesterday after being knocked off his bike by a car.*		
Sentence 2	***Officer Jones reported that the driver of the car had been travelling over the speed limit.***	***Officer Jones reported that the driver of the car was intoxicated.***	***Officer Jones reported that the driver of the car was intoxicated.***
Sentence 3	The accident happened on the A7 north of Carlisle.		
Sentence 4	The motorcyclist was 30 years old and had two children.		
Sentence 5	***Officer Jones revealed that the car driver was not intoxicated.***	***Officer Jones revealed that the car driver was not intoxicated.***	***Officer Smith revealed that the car driver was not intoxicated***
Sentence 6	The driver of the car was also injured in the incident.		
Example Comprehension Probes			
Question 1	Drink-driving charges should be brought against the driver of the car		
Question 2	The driver should be forced to complete a drink-driving awareness course		
Question 3	A breathalyser would have returned a positive result		

It was a between-subjects study with the effect of retracting information was assessed between groups (Control, Retraction – Same Source, Retraction – Different Source). Participants were randomly assigned to a condition.

Sentence 2 differed between control and retraction conditions for each event. In retraction conditions, sentence 2 contained (mis)information. In the control condition, it contained circumstantial information to provide a baseline for the comprehension test. The key sentence (sentence 5) was identical in all conditions. Given exposure to sentence 2, sentence 5 did or did not correct previous information. For source conditions, the source of the (mis)information (sentence 2) and retraction (sentence 5) were either the same (same source) or different (different source).

In all, we tested four scenarios. Presentation order of the scenarios was randomized across participants. The scenarios used were selected from a set of eight pilot reports (N = 70)

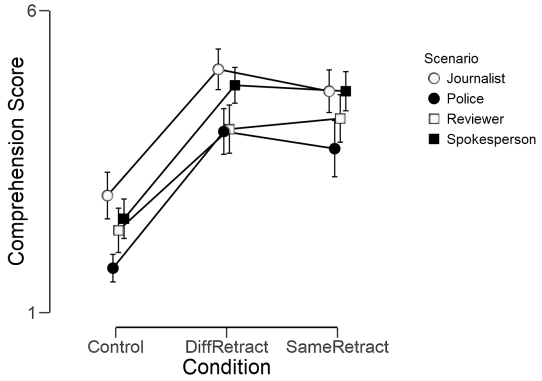

Figure 1. Mean comprehension scores, split by scenario (line) and condition (horizontal axis). Error bars reflect 95% CI.

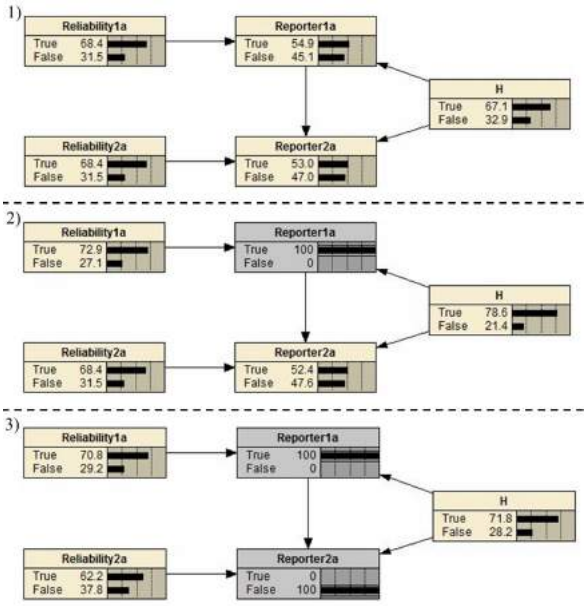

Figure 2a. Group BN model for the retraction different condition, police officer scenario. 1) Baseline (no observation) stage, 2) Single positive (first) report stage (i.e. control condition), and 3) Final (retraction) state given a second, separate reporter.

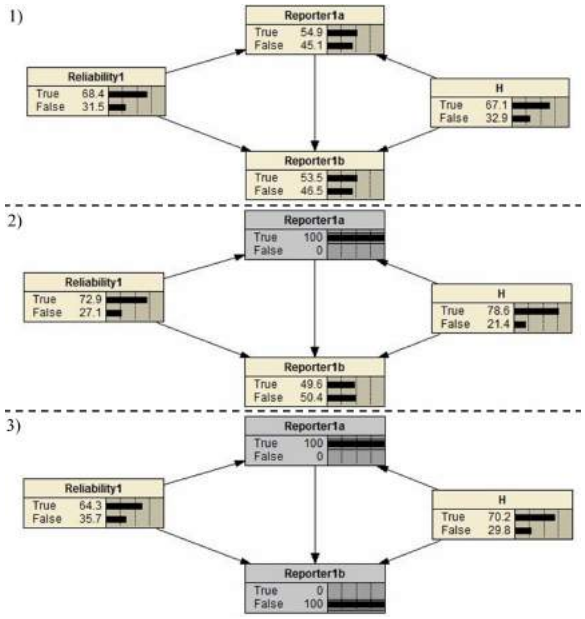

Figure 2b. Group BN model for the retraction same condition, police officer scenario. 1) Baseline (no observation) stage, 2) Single positive (first) report stage (i.e. control condition), and 3) Final (retraction) state given a second, report from the same reporter.

where scenarios with the largest 'continued influence effect' of misinformation were chosen for the actual study.

Prior to reading any scenario, participants provided prior estimates for their beliefs in the reliability of the sources of misinformation that would appear in the subsequent reports and whether they would provide reliable reports. This was measured on a scale of 0 (Extremely unlikely) to 100 (Extremely likely).

Further, to parameterise the model, participants provided six conditional probability estimates per report (24 in total). They rated their belief that the source of report 1 would make an erroneous statement in reporting about an event, if they were or were not reliable on the same scale as used for prior beliefs. Questions about the second reporter differed between the same and different source conditions. Eliciting conditional probabilities allowed for parameter-free models.

Continued reliance of misinformation was measured by a set of comprehension probes that followed each scenario (see Table 1). Participants rated each probe on a 7-point scale from 'strongly disagree' to 'strongly agree'. In line with previous CIE methods, probes referred to the critical information (sentence 5). Higher endorsement of comprehension probes measured the degree to which the misinformation presented in sentence 2 had been incorporated into a participants' understanding of the report.

After rating the probes participants provided their belief posterior probability on a similar scale used for prior beliefs. For example, in the scenario in Table 1, participants were asked: 1) Given everything you know so far about the incident in question, how likely do you think it is that the accident occurred because the driver was intoxicated/travelling over the speed limit? 2) Given everything you know so far about the incident in question, how likely to do you think it is that the police officer is reliable in their reporting? Participants who received a retraction from a different source as the misinformation provided an additional estimate for the reliability of the second reporter.

Results

Bayesian analyses were done with JASP statistical software (JASP Team, 2018) and assumed an uninformed prior.

Comprehension Scores

A Bayesian repeated measures ANOVA was used to determine the effect of condition and scenario type on mean comprehension scores. Strong evidence was found for the main effect of condition, $BF_{Inclusion} = 1.917 * 10^{12}$, and scenario, $BF_{Inclusion} = 5.44 * 10^{9}$, but no interaction, $BF_{Inclusion} = 0.122$. The model including just main effects was the strongest fit, $BF_M = 131.26$, and significant overall, $BF_{10} = 2.105 * 10^{22}$. As illustrated in Fig. 1 below, scenarios differed in comprehension scores from one another, and there was a differential influence of condition.

Critically, the effect of condition indicated significantly higher endorsement of comprehension probes following the presentation and retraction of misinformation compared to when no misinformation was presented at all. This indicates that, a CIE was observed across all scenarios, such that a retraction was insufficient to bring endorsement ratings back to baseline.

Bayesian Model Fits

Using the conditional probabilities and priors elicited from participants, group means on these estimates were used to parameterize 2 group-condition models for each scenario. Although the conditional probabilities and priors for each first reporter and reliability node were fitted based on all participants, two important exceptions are noted. First, conditional probabilities for the second reporter were based solely on estimates from the condition of relevance (i.e. only estimates from the retraction different condition were used to parameterize the entailed different second reporter in that condition). Secondly, prior probabilities for each hypothesis were reverse-engineered (via Bayes Theorem) using the posteriors provided by control condition. More precisely, taking the control condition BN model, the posterior for the hypothesis was fitted, given the single positive report. Retracting the observation could reveal the approximate prior (absent observations) for that hypothesis. This "prior" was fitted into the models for the two retraction conditions.

Figs 2a and 2b show example condition models for the Police officer scenario, fitted from participant data according to the protocol outlined above. Several important trends are noticeable:

Firstly, as expected, given a single positive reporter (stage 2), belief in the hypothesis (H) increases, and the predicted likelihood of corroboration from the second report increases. However, when the second, contradicting report is observed (stage 3), the belief in the hypothesis (H) does *not* return to prior (stage 1) levels. Instead, the reliability of sources decreases given the contradiction, this decrease is strongest in the second reporter (different condition), but is also substantial when the same reporter contradicts themselves (Fig. 2b, stage 2 to stage 3).

Critically, the reason for this effect (retention of belief in H, but reduction in perceived reliability) is due to the capturing of the temporal dependence from first to second report. Put another way, the models capture the intuition that a second report is aware of the first report (whether internally in the case of the same reporter condition, or via general narrative in the different reporter condition). The manner and strength of this influence is then captured by the elicited conditional probabilities from participants.

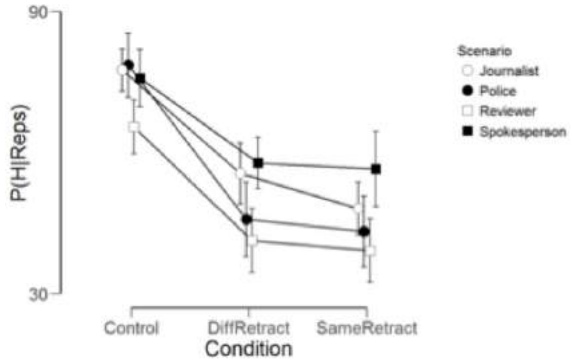

Figure 4. Posterior estimates of belief in the hypothesis (H), given all reports, split by scenario (line) and condition (horizontal axis). Error bars reflect 95% CI

Participant Estimates

Returning to participant data, we again use Bayesian repeated measures ANOVA to examine whether probability estimates correspond to the BN model predictions (and thus map onto a continued influence effect), or corroborate the comprehension score measures (and indicate an absence of CIE – against fitted normative prescription).

Hypothesis. Turning first to posterior estimates of belief in the hypothesis, we find main effects of condition, $BF_{Inclusion} = 3.328 * 10^9$, and scenario, $BF_{Inclusion} = 41812.52$, but no interaction, $BF_{Inclusion} = 0.467$. The model consisting of the main effects along was the strongest fit, $BF_M = 34.27$, and significant overall, $BF_{10} = 2.247 * 10^{14}$. As Fig. 4 illustrates, these effects corroborate comprehension scores, wherein the effect of condition is driven by a reduction in belief in the hypothesis from control to retraction conditions. Crucially, this shows that participants generally deviate from the *prescribed* CIE effect entailed by the BN models, decreasing belief in the hypothesis below the control condition (and prior), given the retraction.

Reliability. Turning next to estimates of reliability, we add to the repeated measures ANOVA analysis a within-subject factor of prior to posterior. Here we find significant main effects of condition (control > retraction different and same), $BF_{Inclusion} > 1.00 * 10^{20}$, scenario, $BF_{Inclusion} = 124.44$, and prior-posterior (posterior < prior), $BF_{Inclusion} > 1.00 * 10^{20}$. Figs 5a-5c illustrate the significant interaction of condition and prior-posterior, $BF_{Inclusion} > 1.00 * 10^{20}$, wherein reliability estimates increased in the control condition (Fig. 5a; where no contradiction occurs, and in line with the increase observed in Fig. 3a and 3b, stage 2), but decreased in both retraction conditions (Fig. 5b and 5c; also in line with model predictions illustrated in Fig. 3a and 3b, stage 3). Lastly, a significant interaction of scenario and prior-posterior was also observed, $BF_{Inclusion} = 75.92$, wherein the spokesperson scenario entailed smaller changes from prior to posterior than the 3 remaining scenarios. The model including the above significant terms yielded the strongest fit, $BF_M = 484.97$, and was significant overall, $BF_{10} = 1.559 * 10^{28}$.

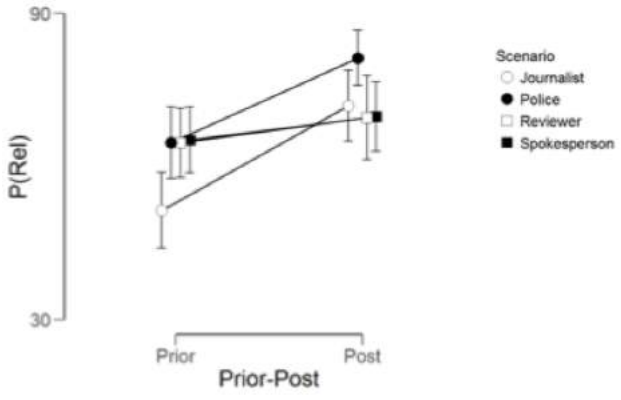

Figure 5a. Control condition reliability estimates for reporters from prior to posterior (reports observed), split by scenario (lines). Error bars reflect 95% CI.

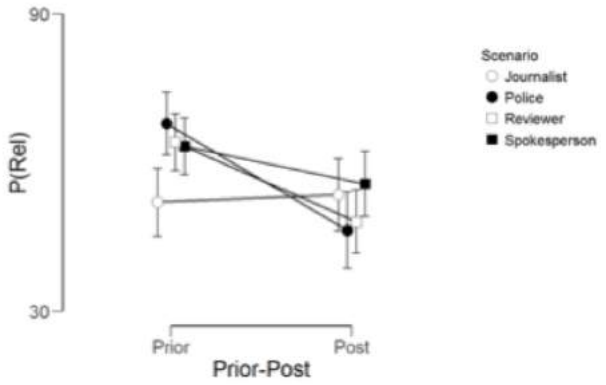

Figure 5b. Retraction different condition reliability estimates for reporters from prior to posterior (reports observed), split by scenario (lines). Error bars reflect 95% CI.

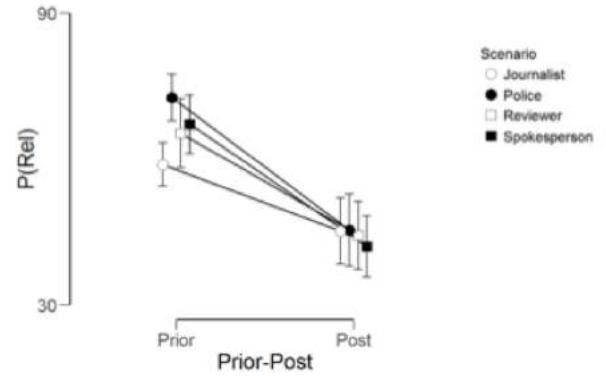

Figure 5c. Retraction same condition reliability estimates for reporters from prior to posterior (reports observed), split by scenario (lines). Error bars reflect 95% CI.

Finally, we note that the retraction condition showed no significant difference in posterior reliability estimates between the two different (first and second) reporters, $BF_{10} = 0.135$, contrary to model predictions (wherein the second reporter should be more substantially penalized).

Discussion and concluding remarks

Previous CIE studies have consistently found that misinformation continues to be influence beyond a clear and credible retraction (e.g. Ecker et al., 2010; 2011a; 2011b; Johnson & Seifert, 1994; Rich & Zaragoza, 2016). Continued reliance on misinformation after a retraction has been depicted as a bias and therefore irrational (Lewandowsky et al., 2012). However, there is an argument that people should exhibit CIE if source reliability judgments are incorporated into how beliefs about misinformation are updated following a retraction.

This paper's aim was to formally model CIE, using a Bayesian Network framework, to capture the temporal dependency between misinformation and its retraction, and the impact this may have on source reliability. We compared participants' judgments to Bayesian predictions to establish whether retaining belief in misinformation (hypothesis) after a retraction is, in fact, sometimes rational.

Participants rated their belief in the hypothesis, and the reliability of sources, when there was no retraction of misinformation, when the retraction was offered by the same source as the misinformation, or by a different source than the misinformation, for a series of news reports.

Behavioural measures showed the standard CIE across all scenarios. Comprehension of the news reports was measured to establish whether misinformation had been incorporated into participant's understanding of the report despite having been retracted. A classic CIE was observed whereby misinformation continued to influence news report comprehension despite being retracted. The effect was observed whether the retraction was offered by the same or a different source to the misinformation.

We also find a rational explanation for CIE. Qualitatively we show that belief in the hypothesis remains above prior level, but instead the reliability of the second reporter (i.e. the retraction) is penalised. Participant's posterior estimates also decreased below their priors, and against what their model predicts. This finding is contrary to the typical account of CIE that people continue to rely on retracted misinformation even though they should. Instead, suggesting that people should continue to rely on misinformation but do not!

Focusing on the condition in which misinformation and retraction come from the same source, participants decrease their estimate for the reporter after they have contradicted themselves, in line with model predictions. In the different source condition, participants decrease their estimates in the reliability of the first reporter (which is incorrect according to the model), and increase reliability estimates of the second reporter (which is correct according to the model). Interestingly, the second reporter was considered more reliable than the first in the police officer and reviewer scenarios (against model predictions), but less reliable than the first in the journalist and spokesperson scenarios (in line with model predictions).

Taking together, we show that participants *should in fact* exhibit a CIE effect (according to fitted Bayesian Network models), and although we find this effect in with standard behavioural measures, we do not observe this with novel probability estimate (P(H) measures. Yet, we do find appropriate penalization in reliability estimates given a contradiction among reports – something hitherto unnoticed in CIE studies, but predicted by our formalism.

To conclude, this research provides a formal account of CIE using the BN framework, and shows that continued reliance on misinformation is in some circumstances rational. This approach captures the qualitative inferences participants make about the reliability of sources of who provide contradictory information. These findings also suggest that perceived reliability moderates the degree to which people are willing to integrate reports from more or less reliable sources.

Abstract

This study experimentally investigated the effect of suggestions from a physically present robot on human creative generation. In the experiments, we used a creative task in which the participants were required to draw creatures living on a planet other than the Earth, and a physically present robot, which provided suggestions for creative drawing to the participants with speech sounds and physical movements. First, the results of the pilot experiment confirmed that drawing creativity was enhanced for the participants supported by a robot; however, they were unlikely to refer to the suggestions. Based on the results, two hypotheses were developed: the suggestions from a robot offered a variety of different perspectives and facilitated metacognition (Hypothesis 1), and the suggestions worked as distractions and suppressed fixated perspectives (Hypothesis 2). The experiment was conducted to investigate these hypotheses. As a result, Hypothesis 1 was supported. The results were discussed based on previous studies.

Keywords: Robot; Human-robot interaction; Creativity; Creative generation; Metacognition; Collaboration.

Introduction

Creative generation and collaboration

Creative generation is performed in various situations, such as engineers thinking of new information tools, novelists thinking of new stories, and chefs thinking of new recipes. Guilford (1979) showed that creative generation involved two types of thinking processes: divergent and convergent thinking. Divergent thinking is the process of generating multiple possible ideas. By contrast, convergent thinking is the process of examining the generated ideas to determine the best. The ideas would be refined by alternately repeating these two thinking processes. Also, Finke, Ward, and Smith (1992) developed the geneplore model of creative generation in which there are generative and exploratory phases. In the generative phase, abstract representations of ideas called preinventive forms are created. Following the generative phase, in the exploratory phase, the generated ideas are interpreted in a meaningful ways for specific purposes. The ideas become sophisticated as these two phases are repeated one after the other.

The scope of creative generation can be limited because people generate ideas based on existing representations of prior knowledge (Ward, 1994). Therefore, representational change, or re-representation, in divergent thinking or the generative phase is crucially important. It occurs when a representation described from a certain perspective is reinterpreted from a different perspective (Ward, Smith, & Finke, 1999).

In the field of cognitive science, many previous studies have shown that collaborative activities provide opportunities for people to develop new perspectives. For example, people reinterpret and deepen their knowledge by providing explanations about their knowledge and asking reflective questions to each other (Miyake, 1986). Also, in a collaborative problem solving situation, people develop abstract representation of the solution by alternately taking the roles of a task-doer, who externalizes their own ideas, and a task-monitor, who objectively reflects the others' ideas (Shirouzu, Miyake, & Masukawa, 2002). Moreover, people can acquire an integrated perspective of multiple viewpoints by taking a perspective from others that is incompatible with their own perspective (Hayashi, 2018). These previous studies show that it is important to interact with others to facilitate metacognition and form new perspectives that cannot be achieved alone.

Human-robot interaction

The development of technology has brought the prevalence of robots that support human physical and cognitive activities (e.g. Ros, Baroni, & Demiris, 2014; Saerbeck, Schut, Bartneck, & Janse, 2010). However, there are not many studies that experimentally investigated how robotic support influences human cognitive activities during human-robot interaction.

Leyzberg, Spaulding, Toneva, and Scassellati (2012) experimentally investigated how advice from a robot influenced human problem-solving performance with a nonogram puzzle. Their study compared the effects of advice from a physically present robot, a robot displayed on a screen, and only auditory sound. As a result, the participants supported by the physically present robot solved the puzzle faster than the participants supported by the displayed robot and auditory sound after receiving advice multiple times.

Moreover, a physically present robot gave better impressions to people than a virtually displayed robot or animated character. In particular, people felt the robot was more likable, helpful, enjoyable, trustworthy, creditable, and informative (Kidd & Breazeal, 2004; Powers, Kiesler, Fussell, & Torrey, 2007). Also, people became more compliant with a physically present robot than to a robot displayed on a screen (Bainbridge, Hart, Kim, & Scassellati, 2011). These effects were considered to occur because of the robot's physical presence (Powers et al., 2007). On the other hand, it was more difficult for people to recall suggestions from a physically present robot than suggestions from a robot displayed on a screen. Since people tended to allocate their attention to the presence of the robot, they were considered to allocate less attention to the contents of the suggestions and had diffi-

culty recalling the suggestions (Powers et al., 2007). These previous studies showed that suggestions from a physically present robot provided different effects on people from those provided from a robot or animated character displayed on a screen and those in text or auditory sound.

Purpose of this study

The number of studies related to human-robot interaction has been increasing. However, there are still few studies that investigated human cognitive activities supported by a physically present robot. In particular, not much is known about how a robot could support human creativity. The focus of this study was on human creative generation and how suggestions from a robot influenced creativity.

Pilot experiment

The pilot experiment was conducted to confirm the effect of the suggestions from a physically present robot on creative generation and develop experimental hypotheses about the features of the suggestions.

Experimental task

The task used in the pilot experiment was a creative task used by Ward (1994). The participants were required to draw creatures living on a planet other than the Earth.

The participants draw creatures on a canvas displayed on a computer screen (Figure 1a) with a digital pen. The canvas was created with HTML5 Canvas and JavaScript. The participants could choose one of two colors, black and white, to draw a line by physically tapping one of the square boxes on the display. Also, they could change the line width and the level of the transparency by tapping and moving the slider bars before drawing the line. The software provided a redo button to redo drawing a line, a delete button to delete all the drawn lines on the canvas, and a submit button to save a drawn creature as a picture file and to delete the creature from the canvas.

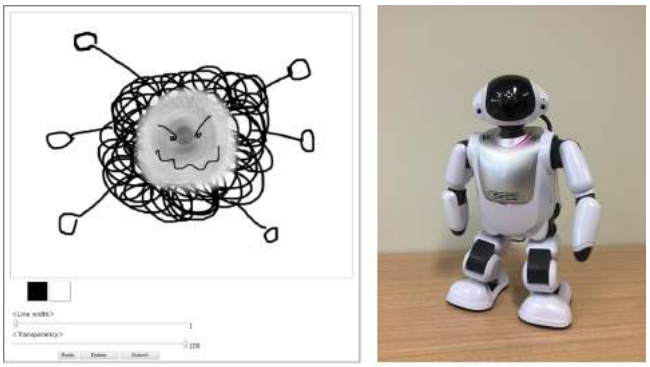
Method

Participants Thirty university students participated in the pilot experiment as volunteers.

Experimental design The experiment had a one-factor between participants design. The factor was the type of suggestions (no-, text-, and robot-suggestions).

In the robot-suggestion condition, the robot, Palmi by DMM.com LLC, was used (Figure 1b). The robot gave suggestions for creative drawing to the participants with speech sounds and the physical movements of moving the arms, legs, or head according to entered commands. Also, the no-suggestion condition was set up as a control condition in which the participants performed the task without suggestions.

Moreover, the text-suggestion condition was set up in which the participants were given the same suggestions as in the robot-suggestion condition. However, the suggestions were displayed in letters in the lower right corner of the display. Because text information allows people to carefully consider the meaning compared to auditory information (Blasio & Milani, 2008), the suggestions in text were presumed to be actively referenced and thus enhanced the creativity of the drawing.



(a) Canvas (b) Robot

Figure 1: (a) A canvas displayed on a computer screen and (b) the robot used in the experiments.

Suggestions For the robot- and text-suggestion conditions, 20 suggestions were created to encourage the participants to use metacognition and consider their ideas from a variety of different perspectives in divergent thinking or the generative phase. Some of the suggestions are shown in Table 1.

Procedure Ten participants were randomly assigned to each condition. First, the experimental task was explained to the participants. After the participants received the explanation of the drawing operations, they practiced drawing pictures for five minutes. Following the practice, in the robot-suggestion condition, the participants were told that the robot in front of them would give them suggestions for creative drawings during the task. Also, in the text-suggestion condition, the participants were told that the suggestions for creative drawings would be displayed on the screen during the task. After the explanation and instructions, the participants performed the task for 20 minutes. All participants were instructed to draw as many creative creatures as possible.

In the text- and robot-suggestion conditions, 10 suggestions were randomly selected from the 20 suggestions for each participant and given in randomized order every two minutes from the beginning of the task. The participants in these conditions were instructed to refer to the given suggestions as necessary.

After the task was finished under the robot- and the text-suggestion conditions, the participants rated to what degree the suggestions were referred to in order to draw creative creatures with a 5-point scale (1: not referred at all - 5: extremely referred).

Results

First, the average number of drawn creatures in each condition was 2.40 for robot-suggestion, 2.60 for no-suggestion, and 2.80 for text-suggestion conditions. A one-way analysis of variance (ANOVA) showed no significant differences in the number of drawn creatures between the three conditions ($F(2,27) = 0.53, p = .60$). The result showed that the participants drew creatures to the same extent in the three conditions.

Second, the creativity of the creatures was rated on originality using a 10-point scale (1: not original at all - 10: extremely original). Three independent raters who knew nothing about the experiment were trained and then rated the originality of all creatures in randomized order. The rated scores between the three raters were judged consistent ($\alpha = .69$).

Based on the originality scores for each drawn creature in the three conditions, a one-way ANOVA was performed (Figure 2). As a result, there was a significant main effect ($F(2,27) = 14.50, p < .001$). A multiple comparison test with Ryan's method revealed that the score was significantly higher in the robot- and text-suggestion conditions than in the no-suggestion condition ($t(48) = 3.68, p < .001$; $t(52) = 3.46, p < .001$). However, there was no significant difference between the robot- and text-suggestion conditions ($t(50) = 0.36, p = .72$).

Moreover, a t-test was performed to compare the reference ratings between the robot- and text-suggestion conditions (Figure 3). As a result, the rating was significantly lower in the robot-suggestion condition than in the text-suggestion condition ($t(18) = 3.82, p < .001$).

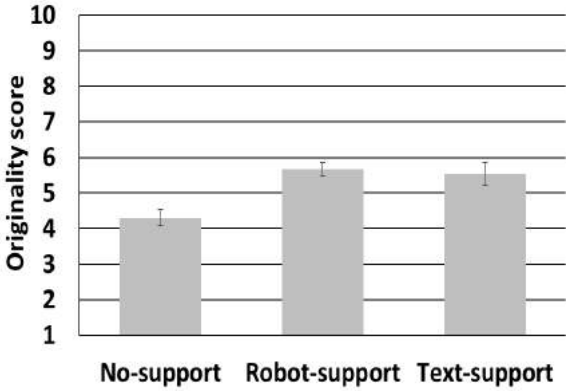


Figure 2: Average originality score in each condition in the pilot experiment. The error bars indicate the standard error.

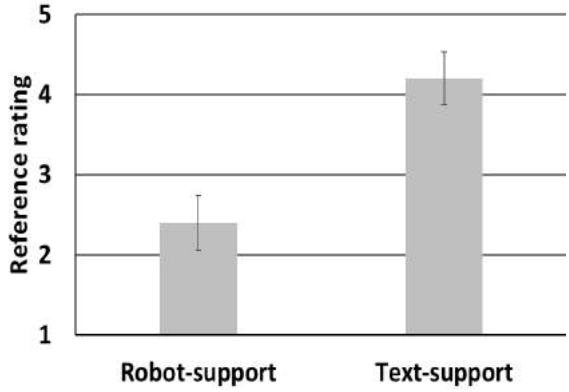

Figure 3: Average reference rating in each condition in the pilot experiment. The error bars indicate the standard error.

Discussion

First, the results confirmed that the suggestions from a robot enhanced the creativity of drawings. Second, the participants referred to the suggestions less frequently when given from the robot than when displayed in text. In addition, the suggestions in text were actively referred to and enhanced the creativity as predicted.

Although the participants were unlikely to refer to the suggestions from the robot over all, only some of the suggestions might be referred to and encouraged the participants to use metacognition and generate ideas from a variety of different perspectives. However, there is another possibility that the suggestions from the robot enhanced the creativity of drawings by causing irrelevant distractions.

Because the suggestions from the robot were less likely to be referred to, the suggestions might have tended to distract the participants from focusing on the task. In creative generation, irrelevant distractions can be beneficial in suppressing fixated perspectives and focusing on irrelevant information (Amer, Campbell, & Hasher, 2016; Dijksterhuis & Meurs, 2006). Therefore, the suggestions from the robot were assumed to work as irrelevant distractions and supported the participants in suppressing fixated perspectives and ideas. As a result, they might generate ideas from new perspectives and enhance the creativity of drawings.

In the following experiment, we conducted an experiment to investigate the features of the suggestions from a robot with considerations of facilitating metacognition and causing distractions.

Experiment

Method

Participants Sixty-seven university students participated in this experiment for course credit.

Experimental design The experiment had a one-factor between participants design. The factor was the frequency of the suggestions (high and low). The frequency of the suggestions was manipulated by the number of suggestions provided during the task. In the high-frequency condition, 12 suggestions were given every two minutes for 24 minutes. Conversely, in the low-frequency condition, six suggestions were given every four minutes for 24 minutes.

Suggestions and distractions In this experiment, two different situations were set up: the no-distraction and distraction situations. In the no-distraction situation, all suggestions provided during the task were related to drawing creative

creatures (Table 1). They were selected from the suggestions used in the pilot experiment. Contrarily, the distraction situation was set up to provide apparent distractions, suggestions completely unrelated to drawing creative creatures, in order to enhance the effect of distractions (Table 2). In the distraction situation, half of the suggestions were selected from the list in Table 1, and the other half were selected from the list in Table 2. If the suggestions had prevented the participants from focusing on the task and enhanced creativity, the effect of distractions would have appeared prominently in the distraction situation.

Table 1: A list of suggestions

	Suggestions related to drawing creative creatures
1	Let's think about the shape of the creature.
2	Let's think about what kind of features the creature would have.
3	What kind of environment does the creature live in?
4	Let's think about what the creative creature would be.
5	Let's think about the movement of the creature.
6	Let's reconsider the idea.
7	Let's think about incidents that occur outside of Earth.
8	Let's think in a different way.
9	How about combining different ideas?
10	Let's think in different perspectives.
11	Let's think about something that could be referred to.
12	What kind of features would the creature have?

Table 2: A list of distractions

	Distractions
1	Look up to the ceiling and count 10 seconds as accurately as possible.
2	Close your eyes and count 10 seconds as accurately as possible.
3	Raise your feet and count 10 seconds as accurately as possible.
4	Let's do a mental calculation. What is eight plus six minus seven? (Silence for 3 seconds) The answer is seven.
5	Let's do a mental calculation. What is four plus nine minus five? (Silence for 3 seconds) The answer is eight.
6	Let's do a mental calculation. What is seven plus five minus nine? (Silence for 3 seconds) The answer is three.

Procedure The participants were randomly assigned to each condition in each situation. As a result, 16 participants were assigned to the low-frequency condition in the distraction situation and 17 participants were assigned to the other conditions. All the participants performed the task with the robot.

The task and the procedure were the same as in the pilot experiment. However, in this experiment, although the task display was the same as in the pilot experiment, an iPad by Apple Inc. was used to draw the creatures. Also, each task took 24 minutes. The suggestions or distractions were randomly chosen for each participant and given in randomized order.

After the task was finished, in addition to the reference rating, the participants in the distraction situation rated to what degree the suggestions and distractions were followed with a 5-point scale (1: not followed at all - 5: extremely followed).

Hypothesis

In this experiment, the following two hypotheses were examined in each of the no-distraction and distraction situations.

Hypothesis 1: The suggestions from a robot enhance creativity by facilitating metacognition.

Hypothesis 2: The suggestions from a robot enhance creativity by causing irrelevant distractions.

If Hypothesis 1 were confirmed, the participants would refer to the suggestions and generate creative ideas from the perspectives of the suggestions. There would be more opportunities for the participants to achieve helpful suggestions in the high-frequency condition than in the low-frequency condition. Therefore, in the both no-distraction and distraction situations, the participants in the high-frequency condition would refer to the suggestions more frequently and draw more creative creatures than those in the low-frequency condition.

Contrarily, if Hypothesis 2 were confirmed, the suggestions would distract the participants and enhance creativity; therefore, the suggestions would be unlikely to be referred to in order to draw creative creatures. There would be more opportunities for the participants to be distracted in the high-frequency condition than in the low-frequency condition. Thus, in the both no-distraction and distraction situations, the participants in the high-frequency condition would draw more creative creatures than those in the low-frequency condition; however, they would refer to the suggestions as frequently as those in the low-frequency condition.

Results

The average number of drawn creatures in the no-distraction situation was 9.29 for the high-frequency and 10.41 for the low-frequency condition. Also, the average number in the distraction situation was 6.94 for the high-frequency and 8.56 for the low-frequency condition. The results of t-tests showed that there was neither significant difference in the number of drawn creatures between the two conditions in the no-distraction situation ($t(32) = 0.98, p = .33$) nor in the distraction situation ($t(31) = 2.18, p = .05$). These results showed that the participants drew creatures to the same extent in the two conditions in each situation.

Also, the result of a t-test showed that there was no significant difference in the rating, what degree the suggestions and distractions were followed, between the high-frequency ($M = 4.05$) and low-frequency ($M = 3.88$) conditions in the distraction situation ($t(31) = 0.49, p = .63$). The result showed that the participants followed the suggestions and distractions to the same extent in the two conditions in the distraction situation.

For the analysis of the hypotheses, first, the originality of the creatures was rated in the same way as the pilot experiment. Three independent raters different from those in the

pilot experiment were trained and then rated all creatures in randomized order. The rated scores between the three raters were judged consistent ($\alpha = .72$).

Next, the average originality score of each participant was calculated in each condition, and a t-test was performed on the score in each situation (Figure 4). The results revealed that in the no-distraction situation, the score was significantly higher in the high-frequency condition than those in the low-frequency condition ($t(32) = 3.62, p < .001$). In contrast, in the distraction situation, there was no significant difference between the two conditions ($t(31) = 0.07, p = .94$).

Moreover, a t-test was performed to compare the reference ratings between the two conditions in each situation (Figure 5). The results indicated that in the no-distraction situation, the rating was significantly higher in the high-frequency condition than in the low-frequency condition ($t(32) = 2.51, p < .05$). On the other hand, in the distraction situation, there was no significant difference between the two conditions ($t(31) = 0.09, p = .93$).

The results in the no-distraction situation supported Hypothesis 1. However, the results in the distraction situation did not support neither Hypothesis 1 nor 2.

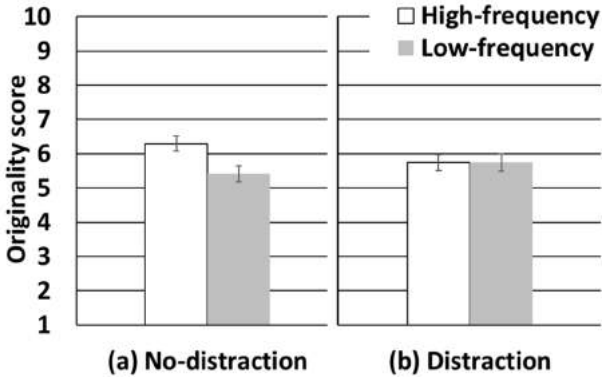

Figure 4: Average originality score of each condition in (a) no-distraction and (b) distraction situations. The error bars indicate the standard error.

Discussion

In the no-distraction situation, the participants in the high-frequency condition referred to the suggestions more frequently and created more original creatures than those in the low-frequency condition. This result supported Hypothesis 1, that is, the suggestions from the robot enhanced creativity by offering a variety of different perspectives to generate ideas and facilitate metacognition.

However, the effect of facilitating metacognition was not found in the distraction situation. This might be because the number of the suggestions related to drawing creative creatures was too small in the high-frequency condition, and therefore, there were not enough opportunities to facilitate metacognition. Also, the effect of causing distractions was not found in the distraction situation. Baird et al. (2012)

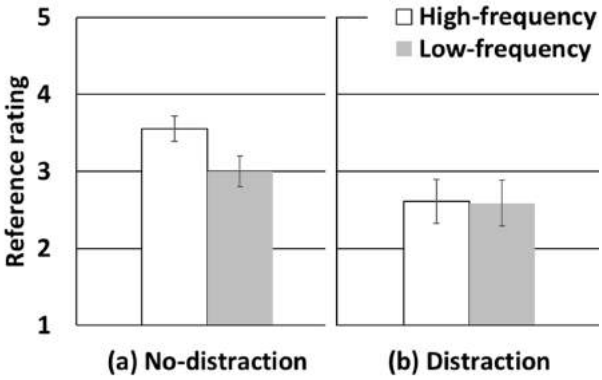

Figure 5: Average reference rating of each condition in (a) no-distraction and (b) distraction situations. The error bars indicate the standard error.

showed that distractions which require light cognitive load enhance creative generation. In their experiment, the participants who performed the undemanding preceding task, which required cognitive load light enough to elicit mind wandering, enhanced creativity in the following creative task, the unusual uses task, more than those who performed the demanding preceding task, which required more cognitive load. The distractions provided in this study might be too demanding for the participants to enhance creativity.

General discussion

Robots have been developed for a variety of applications. However, there have only been a few studies that investigated how a physically present robot could support human cognitive activities. This study focused on creative generation to investigate how suggestions from a robot would influence human creative generation. The results of the experiment revealed that the suggestions from a robot enhanced creative generation by offering a variety of different perspectives.

In human-human collaboration, representational change occurs when people reflect their own and the other's ideas or knowledge by asking, explaining, or externalizing (e.g. Miyake, 1986). The robot used in this study was not interactive; however, representational change might be caused by the suggestions in the same manner as in the previous studies of human-human collaboration. In particular, the participants were considered to refer to some of the suggestions from the robot and reflect their own ideas according to the suggestions.

Moreover, Okada and Ishibashi (2017) showed that in a creative drawing situation, new perspectives in drawing were acquired by copying and viewing other's unfamiliar artworks, and the creativity of drawings increased. However, in their experiment, a human verbal suggestion, which recommended creating original and creative drawings in different styles, did not enhance the creativity of drawings. In contrast to the previous study, in this study, the suggestions from a robot with speech sounds enhanced the creativity of drawings. Since the robot provided multiple different types of suggestions during

the task, at least some of them were assumed to encourage the participants to consider their ideas from the viewpoints of the suggestions.

Furthermore, in the pilot experiment of this study, although the suggestions from the robot enhanced creativity, they were less referred to than suggestions in text form. In contrast, Leyzberg et al. (2012) showed that the advice from a physically present robot enhanced human problem solving performance and indicated a possibility that people might perceive the authority or social standing of a physically present robot and take their advice seriously.

This difference was assumed to happen because of the difference in the interactivity of the robots. In the previous study, the robot provided the advice according to the time required to solve the problem. On the other hand, in this study, the robot provided the suggestions without consideration of the participants. Thus, the participants in this study might not have perceived the sociality or interactivity of the robot to take the suggestions seriously as in the previous study. Another possibility related to the type of task was also considered. In the previous study, a well-defined problem, nonogram puzzle, was used as the task. Because there were clear solving strategies, the relevant advice about the strategies could be provided to participants. In contrast, in this study, an ill-defined problem, creative drawing, was used as the task. Since there were several possible and different perspectives to take for the creative drawings, there was a possibility that many of the suggestions from the robot did not match their ideas and likely were ignored during the task.

Finally, in this study, the suggestions from a robot were made to facilitate metacognition. However, the enhanced creativity observed in this study needs to be ensured as the result of facilitated metacognition. The results in this study could not deny the possibility that the suggestions facilitated other types of cognitive processes involved in creative generation and enhanced creativity. Therefore, in our future study, we will investigate how each suggestion from a robot influences cognitive process and creativity.

Abstract

Despite the *lack of invariance problem* (the many-to-many mapping between acoustics and percepts), we experience *phonetic constancy* and typically perceive what a speaker intends. Models of human speech recognition have side-stepped this problem, working with abstract, idealized inputs and deferring the challenge of working with real speech. In contrast, automatic speech recognition powered by *deep learning* networks have allowed robust, real-world speech recognition. However, the complexities of deep learning architectures and training regimens make it difficult to use them to provide direct insights into mechanisms that may support human speech recognition. We developed a simple network that borrows one element from automatic speech recognition (*long short-term memory* nodes, which provide dynamic memory for short and long spans). This allows the network to learn to map real speech from multiple talkers to semantic targets with high accuracy. Internal representations emerge that resemble phonetically-organized responses in human superior temporal gyrus, suggesting that the model develops a distributed phonological code despite no explicit training on phonetic or phonemic targets. The ability to work with real speech is a major advance for cognitive models of human speech recognition.

Keywords: spoken word recognition; computational models; neural networks; deep learning

Introduction

Human speech recognition (HSR) poses some of the greatest unsolved scientific challenges in the cognitive and neural sciences. Despite a many-to-many mapping between acoustic patterns and percepts (for now, let us assume percepts are phonemes, i.e., consonants and vowels), listeners experience *phonetic constancy*: we hear what the speaker intends even though the same acoustic pattern can cue different phonemes depending on context, and different patterns can cue the same phoneme. This challenge is the *lack of invariance problem*.

Many factors complicate the acoustic-perceptual mapping: (a) coarticulation (temporal and articulatory overlap of phonemes in series; Liberman et al., 1967), (b) lack of robust boundaries between phonemes or words (Cole & Jakimik, 1980), and (c) shifts in the mapping due to variation in speaking rate (Miller & Baer, 1983), talker characteristics (Joos, 1948; Peterson & Barney, 1952), phonetic context (Liberman et al., 1967), coarticulation (Liberman et al., 1952), and novelty of message content (Fowler & Hosum, 1987). Similar problems are found in other perceptual domains (e.g., visual objects must be recognized despite variation in size, rotation, and illumination; DiCarlo & Cox, 2007). However, the temporal and transient nature of speech compounds the challenge.

Deep vs. minimal networks for speech recognition

One might suppose that the lack of invariance problem has been solved in contemporary automatic speech recognition (ASR) systems, such as those used daily by billions of smartphone users. The deep-learning neural network models underlying the best ASR (Hinton et al., 2012) provide robust

real-world application but little guidance for theories of HSR. Deep nets for ASR require many complex and richly connected layers, as well as complex, carefully engineered training regimens.

That said, researchers interested in HSR have developed less complex deep networks with the aim of illuminating possible mechanisms supporting audition and HSR. Nagamine et al. (2015), for example, examined hidden units of a 5-layer network trained explicitly on phoneme recognition and observed responses strikingly similar to phonetically-structured responses in human superior temporal gyrus (Mesgarani et al., 2014). Kell et al. (2018) used a deep network to achieve human-like accuracy on two unusual tasks: (1) recognizing the word at the *center* of a two second sample of speech and (2) musical genre identification. Their network had many layers and required complex training. The first 7 layers were shared for speech and music, but then it branched into specialized speech and music pathways (with 5 additional layers). The model surpassed standard spectrotemporal filter models of auditory cortex in predicting human cortical responses to natural sounds (measured with fMRI. Kell et al. suggested that deep networks might provide the only computational approach able to achieve human-like performance for natural stimuli.

We optimistically disagree. Our aim is to develop maximally simple (minimal) models of HSR. Theoretical progress will be difficult if our models approach the complexity of their biological target (the neural basis for HSR). At the same time, we aim to grapple with details that have been left out of deep learning models of auditory perception. First, several models have achieved high accuracy by side-stepping the temporal nature of speech (e.g., by treating an utterance or sound as a static image, with time as one axis) rather than as a time series. Furthermore, such models have not addressed the kinds of human data of greatest interest to psycholinguists who study human spoken word recognition, such as the time course of lexical activation and competition (Allopenna et al., 1998).

Simpler shallow computational models have been applied to grappled with over-time inputs and time course of lexical competition, but with two different limitations: (1) they do not use real speech as input (instead using, for example, |abstract distributed phonetic features over time (TRACE: McClelland & Elman, 1986) or human diphone confusion probabilities (Shortlist B: Norris & McQueen, 2008); (2) they tend not to address learning. Models developed since the mid 1980s have either adopted these simplifications in order to address the time course of spoken word recognition with large vocabularies, or have strived for greater realism but in small-inventory models (e.g., Grossberg et al., 1997), or have attempted to incorporate ASR approaches into cognitive models of spoken word recognition (e.g., Scharenborg, 2010; Scharenborg et al., 2005). Such approaches have led to genuine insights, but the models tend to have low accuracy, limited empirical coverage, or both.

Minimal models from long short-term memory nodes
Our aim is to develop a *minimal* cognitive model of HSR that could *learn to map over-time speech to semantics, without explicit phonetic training,* that remains simple enough to generate hypotheses for mechanisms that could support HSR. However, current network-based cognitive models of HSR do not appear adequate for processing real speech.

Thus, we examined a variety of network architectures and elements used in network models used for ASR. We found that a two-layer recurrent network provides the needed power for our goal domain if its hidden units are *long short-term memory* (LSTM) nodes (Hochreiter & Schmidhuber, 1997). LSTM nodes add 3 internal gates and a memory cell that allow nodes to develop sensitivity to information over long time scales, mitigating the *vanishing gradient problem* (Hochreiter et al., 2001). In the following sections, we describe a new neural network model of HSR, EARSHOT (*Emulation of Auditory Recognition of Speech by Humans Over Time*), that we believe approaches the minimal complexity required to map real speech to semantics.

Methods

Network structure and parameters

The EARSHOT network is schematized in Fig. 1. Its 256 input units are fully connected to 512 LSTM hidden units. The hidden layer is fully recurrent (i.e., every unit has a connection to every other unit). A *tanh* activation function is applied to hidden outputs. The hidden units are fully connected to 300 output units. High accuracy on our task (described below) required ~500 hidden units (performance is not improved by increasing to 750 or 1000 hidden nodes).

Materials

We pseudo-randomly selected 1000 words from a list of uninflected English words, with the constraints that (a) word length varied from 1-8 phonemes (mean = 5.5) and (b) every phoneme had to occur in at least 10 words. We created speech files for each of the 1000 words pronounced by 10 talkers in the Apple text-to-speech application, *say* (5 females [Agnes, Kathy, Princess, Vicki, Victoria] and 5 males [Alex, Bruce, Fred, Junior, Ralph]). Mean duration was 659 ms (range: 289-1121 ms). We also created 360 consonant-vowel (CV) and VC syllables for testing purposes (using 15 vowels and 24 consonants). Sound files were converted to spectrographic representations with 256 channels in 10 ms steps with sampling rate of 8000 hz.

We created random sparse vectors for each word as a proxy for semantic representations. Vectors had 300 elements, with 10 "on" (set to 1, others set to 0). This common simplification is considered acceptable given the largely arbitrary mapping from form to menaing (e.g., Lazlo & Plaut, 2012).

Training method

We trained 10 instantiations of EARSHOT. For each model, a different one of the 10 talkers was excluded from training (reserved to test generalization to a novel talker). We excluded 100 different randomly selected words from each trained-on talker (reserved to test generalization to unseen

items from trained-on talkers). So for each model, the training set was 8100 input-output patterns, with all 10,000 pairs included for testing.

Each training epoch included one presentation of each of the 8100 training items in random order with no pause or other indication of word boundaries. The target pattern was the semantic vector for the current word, and it was compared to the output at each time step. To enhance learning, we used *minibatch gradient descent*, *Noam decay*, and *Adam optimizing* (Vaswani et al., 2017). Full details are available in a longer preprint (Magnuson et al., 2018). Connections were trained using backpropagation through time (Werbos, 1988). Training accuracy largely plateaued by 8000 epochs. We then resumed training with formerly excluded talkers included. The logic was that when humans encounter new talkers, we presumably learn to adapt to them by learning any idiosyncratic aspects of their acoustics-to-percepts mapping (e.g., by using lexical hypotheses to guide learning). In simple tests of generalization, the model cannot learn. We continued training for another 2000 epochs (8001-10,000).

Testing method Every 1000 epochs, models were tested with all 10,000 words (including excluded words and talkers). Successful recognition was operationalized as the output vector's cosine similarity to the target exceed any other item's cosine similarity to the output by at least 0.05 for at least 100 ms, and subsequently, no item could exceed the target's cosine similarity to the output before word offset.

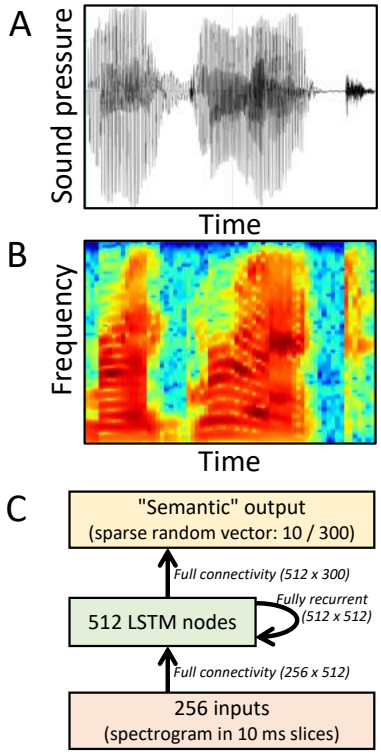

Figure 1. Model input and structure. (A) Audio files are converted to spectrograms **(B),** with 256 channels (rows) in 10 ms steps (columns). Color indicates amplitude (blue-red indicates low-high). **(C)**. The model is a standard recurrent network, except "long short-term memory" nodes are used in the hidden layer, allowing it to become sensitive to multiple temporal grains.

Replicability We trained all 10 models 3 times; only minor variations were observed between iterations. We present results from the first run of each model in this report.

Hardware and software Simulations were conducted on a Windows 10 workstation with an i7-6700k CPU, 64-gb of RAM, and a Titan-X (12-gb) graphics card. Simulations were implemented using Python 3.6 and TensorFlow 1.7. Each model required approximately 10 hours for training.

Alternative architectures In developing EARSHOT, we explored dozens of combinations of candidate architectures and model elements. We limited networks to 2 layers of forward connections (inputs→hidden→outputs). We varied 3 aspects of models: number of hidden units (typically from 100 to 1000 nodes before rejecting a model if accuracy plateaued below 90%), hidden unit type (standard integrative nodes vs. LSTMs), and degree of recurrence (full recurrence, as in the model reported here, vs. single-step recurrence, as in simple recurrent networks; Elman, 1990). For inputs, we explored spectrograms at various resolutions, Mel Frequency Cepstral Coefficients (MFCCs), and cochleagrams. Most combinations failed to achieve high accuracy. Aside from the model reported here, the only combinations that achieved greater than 90% accuracy was an MFCC-based model that failed to show human-like time course despite high accuracy. Note that this does not mean that only a single set of parameters worked; the model described above begins achieving high accuracy with more than 256 LSTM hidden units, and *maximal* accuracy with ~500 or more LSTM nodes.

Results

Accuracy and time course

We present key model behavior results in Fig. 2. Mean accuracy on training items was quite high (88%) after 8000 epochs. Accuracy was 67% for excluded words from trained-on talkers but only 33% for excluded talkers, with a very wide range (4% to 78%). When training resumed with all talkers and items included, performance improved rapidly (to 89% and 86% for excluded words and talkers, respectively, 93% for previously trained-on items).

Next, we consider the challenge of simulating the time course of HSR (Allopenna et al., 1998). This is a central behavioral target in psycholinguistics but has not been addressed in deep learning models of speech (Kell et al., 2018; Nagamine et al., 2015). Our minimal model exhibits the correct qualitative pattern for phonological competition (Fig. 2B) and makes predictions similar to the gold-standard of HSR, TRACE (Fig. 2C; McClelland & Elman, 1986). This similarity might suggest that any model that can map speech inputs to word-form outputs (as in TRACE) or semantic outputs (EARSHOT) would exhibit this human-like time course. However, this is not the case. As we noted above, an MFCC-based model was able to achieve high accuracy, but could not simulate the patterns seen in Figs. 2B and 2C.

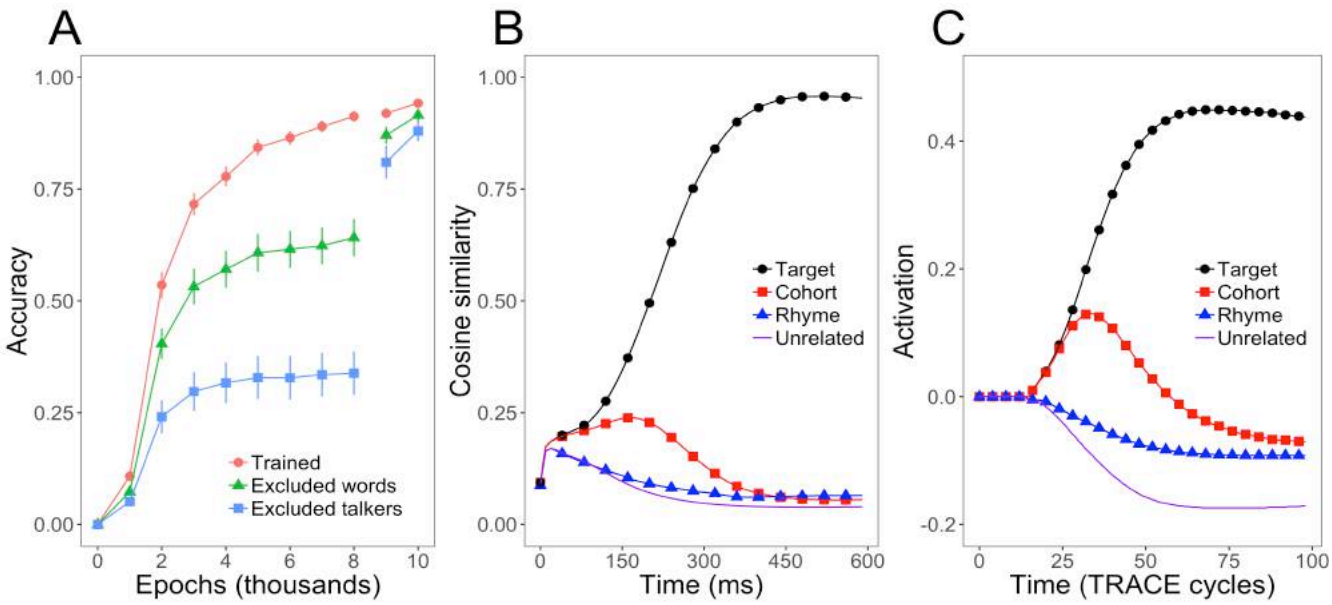

Figure 2. Model performance. (A) Accuracy by epoch averaged over 10 models. When training resumed with all items included (epochs 8001-10,000), high performance was achieved quickly for all talkers. **(B)** Competition time course (correct trials), for 2 criterial competitor types. For a target (e.g., CAT), "Cohort" represents mean cosine similarity for words overlapping in the first 2 phonemes (CAN, CASTLE). "Rhyme" words rhyme with the target (BAT, SAT). "Unrelated" is the average for all words phonologically dissimilar from the target. This pattern closely follows human performance (Allopenna et al., 1998). **(C)** For comparison, we conducted simulations with the TRACE model, with its standard 212-word lexicon, 14-phoneme inventory, and idealized "pseudo-spectral" inputs. Crucially, EARSHOT displays the same rank ordering and similar timing for competitor types as the gold-standard TRACE model.

Unpacking the model

How can we determine how the model works, and how can its mechanisms guide theories of HSR (both cognitive and neural)? To address this, we borrowed an approach that Mesgarani et al. (2014) developed for decoding human electrocorticography data. We presented the model with all possible CV and VC vowels, and examined the responses of every hidden unit over time. For every hidden unit paired with every phoneme, we calculated a *Phonetic Sensitivity Index* (PSI). For example, for unit 239, we would note its mean activation in response to /b/ from the onset of /b/ to 100 ms later. We then subtract unit 239's response to each other phoneme in turn from its response to /b/. When the difference is > 0.3, the PSI for {239, /b/} would be incremented. We repeat this for all 39 phonemes. The maximum PSI for a unit-phoneme pair would be 38 (indicating a unit that responded more strongly to that phoneme than to any other).

We calculated the PSI for all unit-phoneme pairs. Then, we subjected the resulting unit-by-phoneme matrix to hierarchical clustering (Fig. 3). This allows us to ask whether phonetic structure emerges as the model learns to map speech to semantics, even though no explicit information about phonetic features or phonemes is given in training.

About 50% of hidden units exhibited structured responses in the SI time window (20% of electrodes examined by Mesgarani et al. [2014] met their inclusion criteria). The hierarchically clustered PSI solution bears remarkable resemblance to that derived from electrodes in human superior temporal gyrus, with selective responses for phonetically similar phonemes.

The PSI analysis reveals an internal phonetic code that emerges over training. However, hidden units have more complex dynamics than are revealed by the PSIs. Profiles include strong responses at phoneme onset, but also delayed and sustained responses (see Magnuson et al., 2018). In future work, we will explore how the full combination of response profiles support EARSHOT's robust performance. It is also possible that the variety of response profiles observed in the model could be the basis for hypotheses regarding candidate response profiles that might occur in human cortical recordings.

Discussion

Decades after the *lack of invariance problem* – the absence of invariant cues to speech sounds (e.g., Joos, 1948; Liberman et al., 1952; Peterson & Barney, 1952) – was first described, speech science offers limited explanations for human phonetic constancy. A significant obstacle is that computational models of HSR have side-stepped the problem of working directly on the speech signal. Instead, models have focused on the challenges inherent in spoken word recognition beyond initial encoding, using simplified inputs such as gradient phonetic features (McClelland & Elman, 1986), phonemes (Hannagan et al., 2013; You & Magnuson, 2018), or human phoneme confusion probabilities (Norris & McQueen, 2008) instead of real speech. Ironically, simplifying assumptions can *complicate* theoretical challenges (Magnuson, 2008) by masking constraints (in this

case, e.g., prosodic cues to phoneme identity or word length).

Simplifying assumptions about input were motivated by complexity concerns. As McClelland and Elman (1986) argued, models aimed at guiding psychological theory must prioritize psychological over computational adequacy, favoring simplicity and understandability over full, end-to-end modeling. A comprehensive and robust model that is itself too complex to understand offers little guidance to HSR theories.

In developing EARSHOT, our aim was to maximally conserve psychological adequacy (i.e., simplicity) in a model that takes real speech as input. Borrowing one tool from ASR – long short-term memory (LSTM) nodes (Hochreiter & Schmidhuber, 1997) – allowed a *shallow* recurrent network to *learn* to map from *speech* to pseudo-semantics while exhibiting human-like dynamics of lexical activation and competition (similar to TRACE; Fig. 2). Generalization (on items from trained-on talkers that were not included in training, as well as talkers wholly excluded from training) was fairly low and quite variable. On the one hand, this represents a major advance, since there simply are no other *cognitive* models of HSR that operate on real speech. This is the first time such a simple model has been applied to problems entailed by doing so (talker variability, etc.). On the other hand, relatively low and variable generalization may reflect the degree to which the model *memorizes* training patterns. In ongoing work, we are exploring the use of more variable inputs, but ultimately, we must move to using open-ended training items produced by natural talkers.

Another contrast with other models of HSR is that EARSHOT is a learning model. Although we have thus far used an unnatural training regimen, EARSHOT allows the exploration of more naturalistic learning.

Admittedly, *how* the model succeeds in learning to map speech to semantics is not yet completely clear. By importing techniques from human electrocorticography (Mesgarani et al., 2014), we were able to track responses of hidden units to specific phonemes (Fig. 3) and observe the model's emergent sensitivity to phonetic structure. It develops this sensitivity without any explicit training or information about phonetic features or phonemes. Deeper understanding will require more complex analyses of not just hidden units, but also output units and weight layers.

However, the preliminary similarity of EARSHOT's hidden unit responses to responses in human superior temporal cortex (Mesgarani et al., 2014) suggests that our approach has potential for new means of developing cognitive models that are potentially linkable to the neural substrates supporting HSR. Speculatively, we would propose that response profiles observed in hidden units in a model like

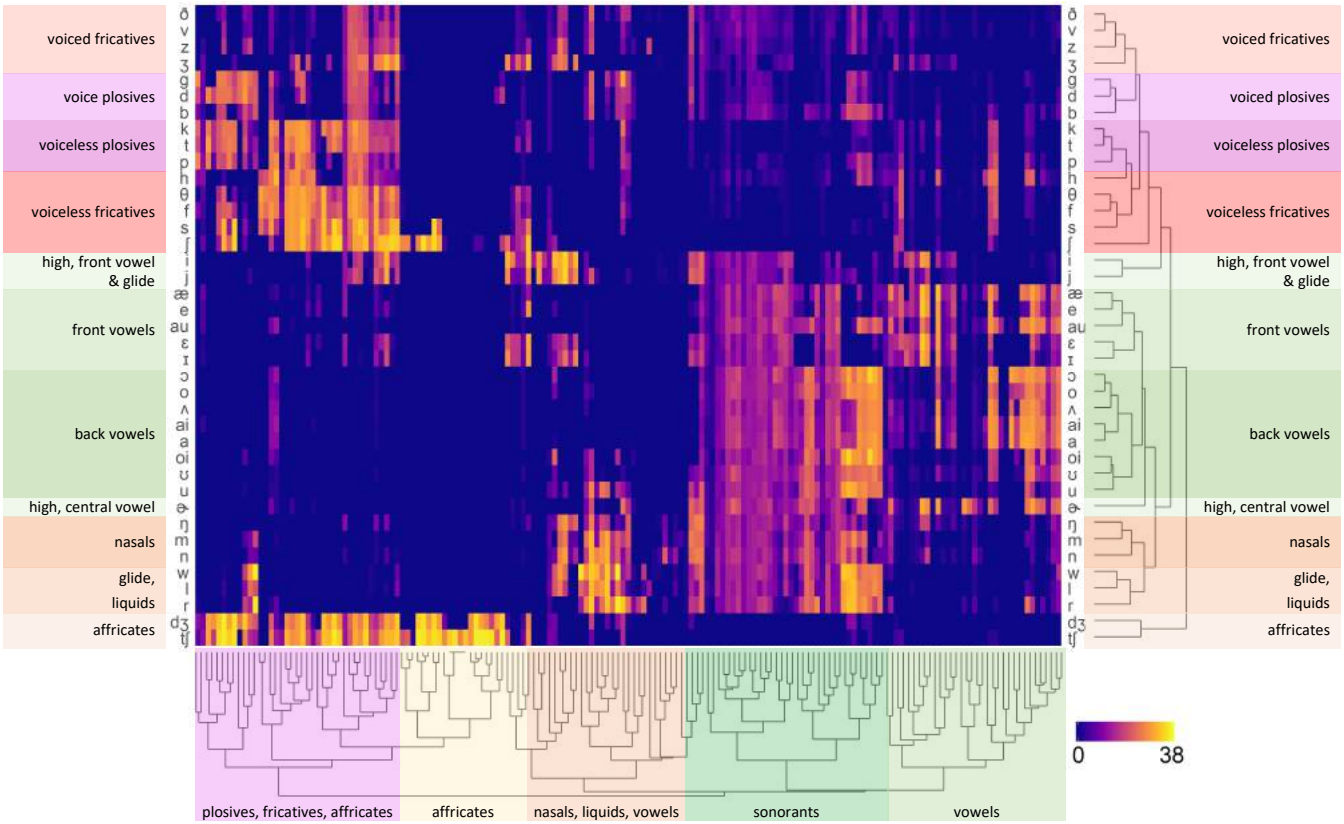

Fig. 3. Phonetic sensitivity revealed by hierarchical clustering. *Phonetic Sensitivity Index (PSI)* based on hidden unit (x-axis) responses in the presence of specific phonemes. For every hidden unit-phoneme pair, PSI was incremented for every phoneme to which the hidden unit responded substantially *more weakly* (yellow indicates high selectivity, with maximum PSI of 38, given 39 phonemes). 246 HUs showing selective responses are included. We used hierarchical clustering to sort both axes, revealing substantial structure in hidden unit responses.

EARSHOT could provide hypotheses for human cortical responses.

In conclusion, EARSHOT may provide a first step towards a comprehensive solution to the overarching challenge for theories and models of HSR – the *lack-of-invariance problem.* Simulations on previously out-of-reach topics (talker and rate variability, etc.) can be conducted with the *same materials* presented to human listeners. Our aim in this brief report is to provide a snapshot of the basic properties of EARSHOT. In a longer subsequent report, we will describe our ongoing work to more fully assess the capabilities of the model.

Abstract

Emergence of collective cooperation in an inherently selfish society is a paradox that has preoccupied biologists, sociologists, and cognitive scientists alike for centuries. We propose a computational model and demonstrate through simulations how collective cooperation can emerge from selfish interests: the goal of improving each individual's own rewards. We also demonstrate how the same selfish interests lead to the dynamic emergence of a network of interconnected agents. Our model includes two simple mechanisms: Selfish-Trust (ST) and Selfish-Connection (SC). ST involves the possibility of relying on others in a society of agents when it is beneficial to the individual, and SC involves the possibility of connecting to other agents when those agents help improve the individual's own benefit. Our simulation results suggest that collective cooperation can emerge from ST and a complex dynamic network can emerge from ST and SC. The simulated data demonstrate an important property of many living organisms: patterns of temporal complexity, which are essential to transfer information among agents of any society of living beings.

Keywords: Altruism Paradox, Emergence of Cooperation, Selfishness, Trust, Networks, Artificial Intelligence

Introduction

For Charles Darwin (Darwin, 1871) altruism remained a paradox: the act of sacrificing an individual's own benefit for the benefit of the collective community of living organisms was regarded as a contradiction to evolutionary theories. The dilemma of emergence of cooperative behavior in situations in which there is a large incentive to defect for the individual benefit has been widely studied in sociology and cognitive sciences. The Prisoner's dilemma (PD) has been a leading metaphor for the study of the evolution of cooperative behavior in populations of selfish in which selfishness is more rewarded in the short-term (M. Nowak & Sigmund, 1993; Gonzalez, Ben-Asher, Martin, & Dutt, 2015).

The PD, dates back to the early development of Game Theory (Rapoport & Chammah, 1965), and it is a common abstraction of the essential elements of many naturalistic situations involving cooperative behavior. It is generally represented with a payoff matrix that provides payoffs according to the actions of two players (see Table 1). When both players cooperate, each of them gains the payoff $\prod(t) = R$, and when both players defect, each of them gains $\prod(t) = P$. If the player i defects and player j cooperates, player i gains the payoff $\prod(t) = T$ and player j gains the payoff $\prod(t) = S$ and vice versa. The constraints on the values of the payoffs in the PD are $T > R > P > S$ and $S + T < 2R$. The temptation to defect is established by setting the condition $T > R$.

		Player j: C	Player j: D
Player i	C	(R,R)	(S,T)
	D	(T,S)	(P,P)

Table 1: The general payoffs of PD game. The first value of each pair is the payoff of agent i and the second value is the payoff of the agent j.

The dilemma is that, while the longer-term best mutual action is to cooperate, in the short-term each individual would prefer to defect because it indicates a higher reward to the individual. Assuming that the other player also searches for its own individual maximum reward, the pair will end up in a $D-D$ situation with the minimum payoff for the two players $2P$.

How do individuals realize that cooperation is mutually beneficial in the long-term? this question has been addressed by many researchers, at various levels of inquiry, involving pairs of agents (Gonzalez et al., 2015; Moisan, ten Brincke, Murphy, & Gonzalez, 2018) as well as larger social networks (M. Nowak & Sigmund, 1993). Research suggests that, at the pair level, people dynamically adjust their actions according to their observations of others' actions and outcomes; at the network level, research suggests that the emergence of cooperation may be explained from *network reciprocity*, where individuals play with those agents with whom they are already connected in a network structure. The demonstration of how social networks and structured populations with explicit connections foster cooperation was introduced by Nowak and May (1992). Alternative models based on Network reciprocity assume agents in a network play the PD with the agents with whom they have specific interconnections. Agents act by copying the strategy of the richest neighbor, basing their decisions on the observation of the others' payoffs. Thus, network reciprocity depends on the existence of a network structure (an already predefined set of connections among agents) and on the awareness of the behavior and pay-

offs of interconnected agents. Network reciprocity assumes that the evolution of cooperation is a function of the difference between the payoffs of the interacting agents.

Thus, past research assumes that the emergence of collective cooperation requires the observation of others' actions and/or outcomes and the existence of predefined connections among agents. Indeed, empirical work suggests that the emergence of cooperation depends on the level of information available to each agent (Martin, Gonzalez, Juvina, & Lebiere, 2014); and the less information about other agents exist, the more difficult, and perhaps the longer it takes, for cooperation to emerge (Martin et al., 2014; Rapoport & Chammah, 1965). However, other experiments suggest that humans do not consider others' payoffs when making their decisions, and that a network structure does not influence the final cooperative outcome (Fischbacher, Gächter, & Fehr, 2001). Indeed, in many aspects of life, we influence others through our choices and others' choices affect us, but we are not necessarily aware of the exact actions and rewards received by others affecting us. For example, when a member of society avoids air travel in order to reduce the individual's carbon footprint, he or she might not be able to observe whether others are reducing their air travel too, yet rely on decisions others make, influencing the community as a whole. It is thus, difficult to explain how behaviors can be self-perpetuating even when the source of influence is unknown (Martin et al., 2014).

In this research, we aim at advancing our understanding of the emergence of collective cooperation in the absence of explicit knowledge of others' actions and outcomes, and in the absence of an explicit predefined network structure that connects agents in a society. We introduce an algorithm (*Living Thing*, LT) to demonstrate that collective cooperation can emerge and survive between agents, out of selfishness (i.e., the individual's need to act on their own personal benefit), and in the absence of others' information (i.e., without a need to any predefined network). We aim at developing hypotheses that can help resolve social dilemmas that exist in the real world. For example, if we understand how collective cooperation emerges only from the decisions of each individual, we could propose solutions that reduce the dilemmas in social problems such as littering in public places or the lack of contributions to a reduction of CO_2 in the atmosphere (Martin et al., 2014).

A LT agent will act according to the reinforcement of its own past actions (Reinforcement Learning, RL), but it will rely on two mechanisms that may overwrite the agent's RL actions: Selfish-Trust (ST) and Selfish-Connection (SC). ST is a decision to follow or rely on other agent's decision expecting that it will improve the own agent's reward with respect to the agent's own previous payoff. ST is expected to turn the initially defector agents to agents that cooperate most of the time. SC is a mechanism that helps agents learn who to play with: agents increase the propensity of playing with the same other agent if the payoff received after playing with that other agent is higher than the agent's own previous payoff.

Past models of network formation rely on a concept of preferential attachment (PA) (Barabási & Albert, 1999), which uses rules according to which an agent would have a higher chance of linking with other agents that already have many links (i.e., high reputation nodes). In contrast, LT demonstrates that such propensities to connect to other agents emerge dynamically, according to the experienced benefits that the other agent brings to the individual's own benefit (SC).

We carry an analysis of the emergence of cooperation from these mechanisms. The simulation results hint at how to explain emergent collective cooperation from individual selfish interests. An important hypothesis emerging from this work is that cooperation can emerge and survive out of the selfishness of agents even when there are no specific awareness of outcomes of other agents, and that a network structure can emerge dynamically from the connections guided by self individual interests.

Living Thing (LT) Algorithm

Figure 1 shows one-time cycle of the LT algorithm from the perspective of one of the agents, agent i, but every step is executed for agent j simultaneously. In Step 1, a pair of randomly selected agents i and j "agree" to play. Only one pair of agents is selected at each time cycle. The following are general notations in the algorithm: V_i is the decision of the agent to Cooperate (C) or Defect (D); r represents a random number in the interval [0 1] which should be generated whenever it is called in the algorithm; Δ is a positive number that represents an increase in three possible cumulative tendencies: to play C or D, to trust the paired agent or not, or to play again with a previous agent. These cumulative tendencies increase by Δ when the benefit of the agent i changes with respect to its previous benefit and if there is no change then we set $\Delta = 0$ which means no change happens in the system. Δ, in general, can be a function of the difference between two past payoffs of the agent and it can be different for different cumulative tendencies, but it does not change the general results presented later (the form of sensitivity to payoffs is important when two systems interact with each other which is out of scope of this paper).

The following steps are executed in each time t of the algorithm:

Pairing Agents (1)

Agent i and agent j get picked randomly. Agent i at time t has the propensity $P_{ij}(t) = M_{ij}(t)/\sum_k M_{ik}(t)$ to play with agent j. $0 < P_{ij}(t) < 1$. $M_{ij}(t)$ is cumulative tendency for agent i to pick agent j to play at time t. This cumulative tendency changes at step 7 according to the last two payoffs received by agent i.

At the same time, agent j has a propensity $P_{ji}(t) = M_{ji}(t)/\sum_k M_{jk}(t)$ to play with agent i. $0 < P_{ji}(t) < 1$. Two agents i and j pair-up if two random numbers, $0 < r_1 < 1$ and $0 < r_2 < 1$, satisfy inequalities $r_1 < P_{ij}(t)$ and $r_2 < P_{ji}(t)$.

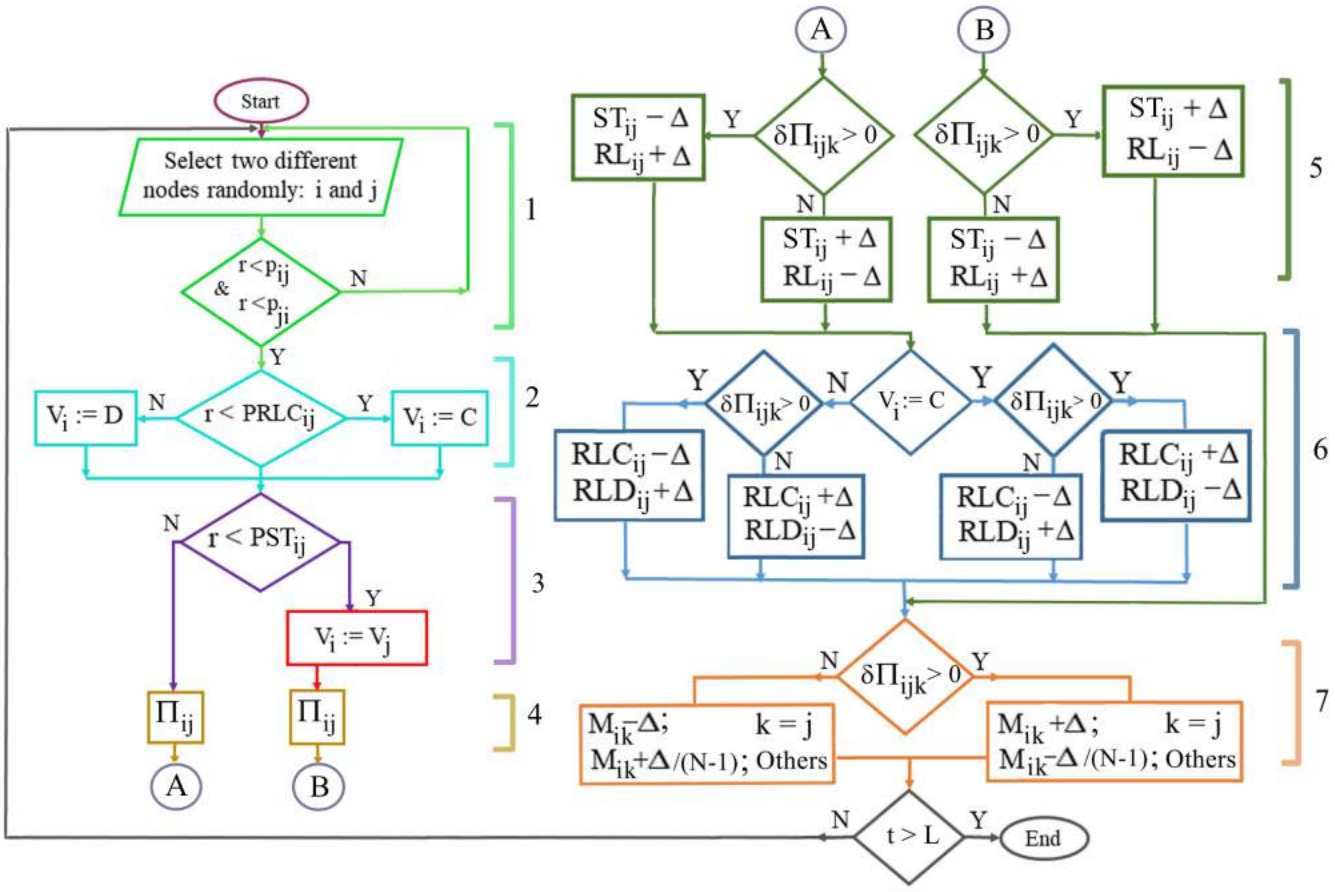

Figure 1: Flowchart of the LT algorithm. "Y" and "N" letters represent "Yes" and "No", respectively.

Otherwise another two agents are randomly selected in each time t.

Reinforcement Learning (RL) (2)

Agent i initially selects an action by reinforcement learning (RL): This agent has the propensity $PRLC_{ij}(t) = RLC_{ij}(t)/(RLC_{ij}(t)+RLD_{ij}(t))$ to pick C and has the propensity $PRLD_{ij}(t) = RLD_{ij}(t)/(RLC_{ij}(t)+RLD_{ij}(t))$ to pick D as it's next potential decision.

$RLC_{ij}(t)$ and $RLD_{ij}(t)$ are cumulative tendencies for agent i playing with agent j, at time t, for choice C or D, respectively. These cumulative tendencies change at step 6 based on the last two payoffs of agent i.

To select the action, a random number r gets picked and if $r < PRLC_{ij}(t)$ then it's next decision will be C otherwise will be D. The same process applies for agent j.

Selfish-Trust (ST) (3)

Instead of executing the decision determined by RL in Step 2, agent i has a chance to trust the decision made by agent j made using RL in Step 2, and with whom agent i is paired with. The propensity that agent i relies on the decision of agent j is: $PST_{ij}(t) = ST_{ij}(t)/(ST_{ij}(t)+RL_{ij}(t))$. $ST_{ij}(t)$ and $RL_{ij}(t)$ are cumulative tendencies for agent i to execute its choice based on ST from agent j, at time t, or to execute its choice based on RL respectively. These cumulative tendencies update in step 5 based on the last two payoffs of agent i. Again, if a random number r is less than $PST_{ij}(t)$ then ST happens.

Evaluating Own Payoffs (4)

At time t agent i after executing its C or D action while playing the PD game with agent j, receives the payoff $\prod_{ij}(t)$. The last two payoffs of the agent i are used to determine the changes in its accumulative tendencies: $\delta\prod_{ijk}(t) = \prod_{ij}(t) - \prod_{ik}(t-1)$, where agent (k) is the agent that played with agent i in trial $t-1$. In the flowchart we showed this quantity as $\delta\prod$.

Update of cumulative tendency of ST or RL (5)

If agent i used ST and after playing with agent j its payoff is higher than its previous payoff, $\delta\prod_{ijk}(t) > 0$, then the accumulative tendencies ST_{ij} and RL_{ij} , for the next time agent i and j, change to $ST_{ij}+\Delta$ and $RL_{ij}-\Delta$. The same happens for agent j.

Similarly, if agent i used RL and after playing with agent j its payoff is higher than its previous payoff, $\delta\prod_{ijk}(t) > 0$, then the accumulative tendencies RL_{ij} and ST_{ij}, for the next

		Player j	
		C	D
Player i	C	$(1,1)$	$(0,1.9)$
	D	$(1.9,0)$	$(0,0)$

Table 2: The payoffs of PD game used in the simulations. The first value of each pair is the payoff of agent i and the second value is the payoff of its pair, agent j.

time agent i and j pair up, change to $RL_{ij}+\Delta$ and $ST_{ij}-\Delta$. The same happens for agent j.

Update of cumulative tendency to choose C or D (6)

Step 6 is only active if the agent decided to use RL is step 3. If agent i played with agent j and received a payoff higher than its previous payoff, $\delta\prod_{ijk}(t)>0$, and this happened because agent i played C, then the accumulative tendencies RLC_{ij} and RLD_{ij}, for the next time agent i and j pair up, change to $RLC_{ij}+\Delta$ and $RLD_{ij}+\Delta$. If the increase happened because agent i played D, then the accumulative tendencies RLD_{ij} and RLC_{ij} , for the next time agent i and j pair up, change to $RLD_{ij}+\Delta$ and $RLC_{ij}-\Delta$. The same happens for agent j.

Selfish-Connection (SC) (7)

In this step the cumulative tendency to play with a specific agent changes. If agent i, after playing with agent j, receives higher benefit with respect to its previous payoff, $\delta\prod_{ijk}(t)>0$, then the cumulative tendency of pairing with agent j, M_{ij}, increases to $M_{ij}+\Delta$ and for the rest of the cumulative tendencies decreases to $M_{il}-\Delta/(N-1), l\neq j$. If $\delta\prod_{ijk}(t)<0$, then the cumulative tendency of pairing with agent j, M_{ij}, decreases to $M_{ij}-\Delta$ and for the rest of the cumulative tendencies increases to $M_{il}+\Delta/(N-1), l\neq j$. The same happens for agent j.

Simulation Methods

We studied a system with $N=100$ agents. Initially all the agents are defectors, have payoff of zero, have more chance to stay as defector; $RLC_{ij}(0)=1$, $RLD_{ij}(0)=99$, have more chance to use RL over ST; $ST_{ij}(0)=1$, $RL_{ij}(0)=99$, and have equal chance to pair up with other agents; $M_{ij}(0)=100$. We set $\Delta=10$. Δ is the property of the system and shows the sensitivity of the agent to the feedback from its two last payoffs. Smaller Δ decreases the rate of reaching to cooperation but doesn't change the dynamical properties of the system. The payoffs matrix used has the values shown in Table 2 as suggested by Gintis (2009): $R=1$, $P=0$ and $S=0$. So, the maximal possible value of T is 2. We selected the value $T=1.9$, which gives a very strong incentive to defect.

Results

Emergence of Cooperation from ST

Here we show that simple mechanism of ST can lead agents who play PD game (which has a high tendency to defect) toward cooperation. Figure 2 shows the proportion of cooperation in simulations that rely only on the RL mechanism (blue curve) compared to the emergence of cooperation when the simulations rely on the additional ST mechanism.

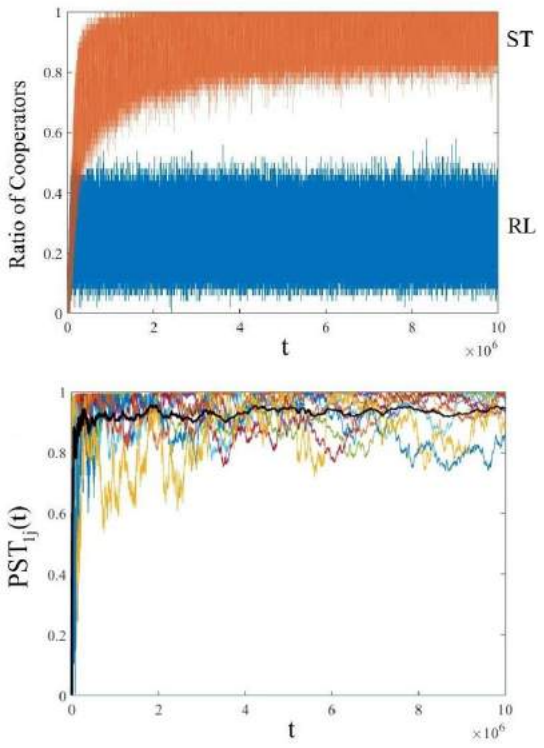

Figure 2: Top panel: the orange curve is the ratio of Cooperators vs. time for $N=100$ agents, randomly paired up to play PD game and used ST (steps 7 in LT algorithm inactive) for updates of the strategy and cumulative tendencies. The blue curve is the ratio of cooperators for $N=100$ agents, randomly paired up to play PD game and just used RL for the decision making process (steps 3 and 7 in LT algorithm inactive). Bottom panel: emergence and evolution of the probability of trust of unit 1 the other 9 agents in a system with 10 agents, used ST to update their strategies and cumulative tendencies. The thicker, black curve in this figure is the average of all the nine probabilities of trust

The blue curve in the top panel of Figure 2 shows the time evolution of the ratio of cooperators when RL is the only mechanism that agents use to update their strategy (steps 3 and 7 are inactive).

The orange curve in the top panel of Figure 2 shows the emergence of cooperation between agents when at any trial two of them (out of 100) paired up randomly and used ST (steps 7 in LT algorithm inactive) to update their strategy (C or D) and their cumulative tendencies. The system reached its dynamic equilibrium after about 2×10^6 and sustained around the average ratio of cooperation of 0.9.

This shows the effect of ST on improving the level of cooperation compared to only RL. In the absence of ST the ratio of cooperators fluctuates around 0.3 which means the majority of agents are defectors.

The nine curves in the bottom panel of Figure 2 are the chances that one of the agents might trust others in a system with 10 agents. The thicker, black curve is the average of the STs between agent 1 and the other nine agents. The chances of ST increased and sustained to about 0.9. This means that the agent learns that ST has benefit for it (and for the whole society). The payoff of the individual is not shown here because it is proportional to the level of cooperation: more cooperation results in more payoff for individual agent and for the emerged group. In conclusion, cooperation emerges and survives because ST lets the strategies to spread between the agents, if it benefits them individually.

Emergence of Complexity over time

The analysis of the fluctuations of a time series gives us a measure for the complexity of the system. We define the events in the time series as the times the time series crosses its mean value. The distribution of the time intervals between the two consecutive events is of interest (Figure 3).

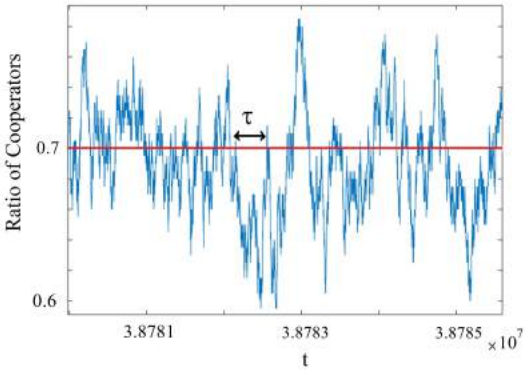

Figure 3: Demonstration of defining events in a time series. The blue curve is a zoomed in part of the Ratio of Cooperators' time series (as an example) and the horizontal red line is its mean value. Whenever the time series crosses the mean value is defined as an event. The distribution of the time intervals between two consecutive events gives a measure for the complexity of the system (complexity index μ).

We collect all the time intervals between two consecutive events (τ's) and evaluate the probability density function (PDF) $\psi(\tau)$. If the resulting distribution is Poisson then the dynamic of the system is random and obeys ordinary statistics. But, if the PDF is a power law; $\psi(\tau) \propto 1/\tau^{\mu}$, then the dynamics falls in the category of the complex systems, for example, the dynamics of the brain. The parameter μ, the slope of the Inverse power law in a log-log plot, is a measure for the complexity of the time series: when $\mu > 3$ then the system is ordinary while for $1 < \mu < 3$ there is Ergodicity Breaking and the system does not obey ordinary statistics.

Temporal criticality is crucial for transfer of information between two intelligence systems (Aquino, Bologna, West, & Grigolini, 2011). To measure the complexity index μ of the time series of the ratio of cooperators on the four cases of emergence of cooperation (top panels in Figure 2 and Figure 6), we studied their fluctuations in the asymptotic regime ($t > 5 \times 10^6$) around their mean value.

Figure 4 shows that the time series of the ratio of cooperators for both cases where agents used ST or just used RL, time series of top panel in Figure 2, have inverse power law PDF with the same complexity index of $\mu = 1.3$ (which falls in the interval $1 < \mu < 3$). The difference is that the linear part of the distribution for the first case, where ST exists, is extended toward larger τ's which means the system is more complex respect to the latter case.

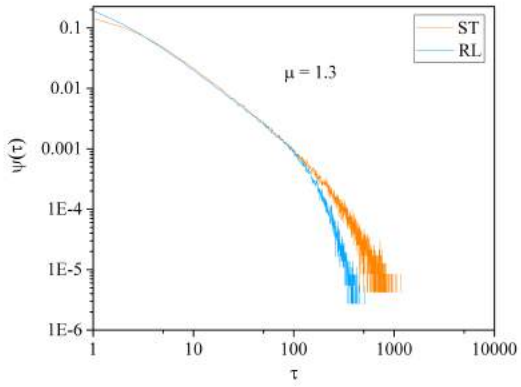

Figure 4: The PDF of the time intervals between the two consecutive events of the time series of Figure 2 (in log-log scale).

Figure 5 shows the PDFs of the time series of the ratio of cooperators for the cases where agents are using ST SC (LT) or RL SC for their evolution, top panel in Figure 6. Both cases have an inverse power law PDF. The PDF of the first case where ST and SC are both active shows very extended linear part with complexity index of $\mu = 1.73$. This complexity is similar to that of the time series of the living things (Allegrini, Paradisi, Menicucci, & Gemignani, 2010).

On the other hand, the complexity of the second case is similar to the system where agents were using just RL (blue curve of Figure 5). This means that SC could increase the complexity of the system where ST was already in action.

Emergence of connections with other agents

In this section we add another level of learning to ST by letting the agent to find the agents which playing with them increases its payoff respect to its previous payoff (all sections of the LT algorithm active). The aim is to show that a dynamic complex network emerges naturally and from the ST and SC mechanisms of the LT model.

The blue curve in the top panel of Figure 6 is the ratio of cooperators when SC is added to RL (section 3 of the LT algorithm inactive). The blue curves in the top panels of Figure 2 and Figure 6 are very similar, which means that adding

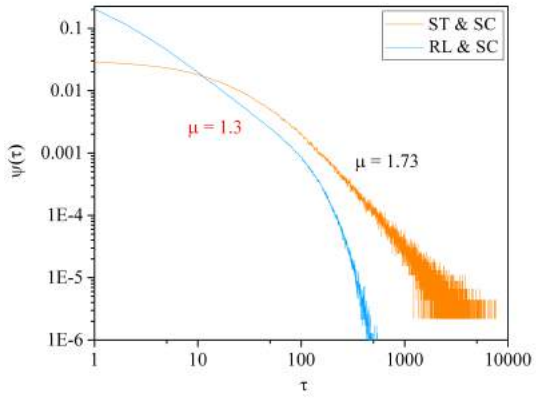

Figure 5: The PDF of the time intervals between the two consecutive events of the time series of Figure 6 (in log-log scale).

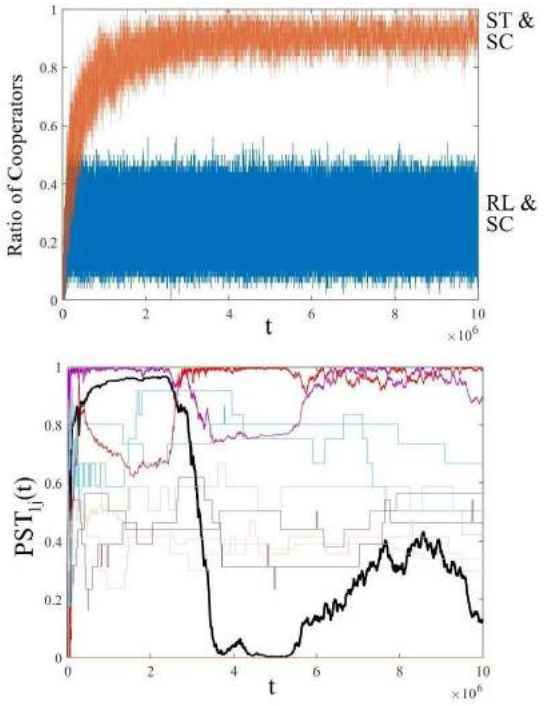

Figure 6: Top panel: orange curve: the ratio of Cooperators vs. time for $N = 100$ agents which in addition to ST they use SC to pick their partner to play PD game (all sections of the LT algorithm active). The Blue curve is the ratio of cooperators, paired using SC, but updated their strategies only with RL (section 3 of the LT algorithm inactive). Bottom panel: emergence and evolution of trust of unit 1 the other 9 agents in a system with 10 agents using the LT algorithm (ST SC) to update their strategies and cumulative tendencies. The thicker, black curve in this figure is the chance of agent 1 to play with the agent which is most trusting (the purple curve close to 1).

the ability to the agents to select their partner is not favoring cooperation when ST is inactive. The reason is that only when ST is active the level of cooperation between the agents increases and because of mutual benefit, which is stable, an agent can rank the links by changing the chance of playing with other agents based on the increase on its last two payoffs.

To illustrate this, we plot the chances of an agent (called agent 1) to trust the other 9 agents using LT algorithm in the bottom panel of Figure 6. This figure shows that the agent trusts some of the agents more than others, most of the time, and only from time to time it trusts other agents. But later on, the agent starts to trust some agents most of the time. The thicker, black curve in this figure is the chance that the agent (1) connects to the agent corresponding to the purple curve. The similarities between the red and purple curves show that the agent 1 learns to connect with the agent which it is most trusting, most of the time. The preferential connections here are dynamic and are based on the perception of the benefit that an agent receives from the other agents. This process creates connections among agents that are dynamic. Some connections become stronger and others become weaker according to the SC mechanism.

Figure 7 demonstrates the chance of a random agent (represented by a dot in the center) pairing with the other 99 agents at two different times: $t = 10^2$ (top panel) and 10^6 (bottom panel). The thickness of the lines represents the chance of the pairings. At $t = 10^2$, we observe an almost uniform distribution of the probability of the connections of an agent to the others (top panel); but later, the agent learned to prefer to connect to some partners more than to others (bottom panel).

Figure 8 shows the probability density function of the pairings for all the agents in Figure 7 (bottom panel). This distribution, plotted in a log-log scale, shows an inverse power law $\propto 1/P^{\beta}$ with complexity index of $\beta = 1.3$, rather than having a Poisson distribution, showing that the emerged network is complex.

Discussion and Implications of Results

The novelty of the LT algorithm is the demonstration of how collective behavior can emerge from Selfish Trust and how a network can emerge from Selfish connections; in the absence of an explicit a-priory network structure, and in the absence of explicit awareness of others' outcomes. LT uses ST that adapts to increase or decrease the chance that agent i will trust the strategy of agent j, if that strategy is beneficial or detrimental for agent i itself. LT also uses SC that adapts to increase or decrease the chance of agent i to connect to agent j, if agent j has contributed or not to the own benefit of agent i. This means that selfishness of agent i is used as the main learning incentive: If the payoff of the agent i increased with respect to its previous payoff then it will increase the likelihood of repeating its last action. This control of the dynamics is internal and emergent according to the self-interest of the

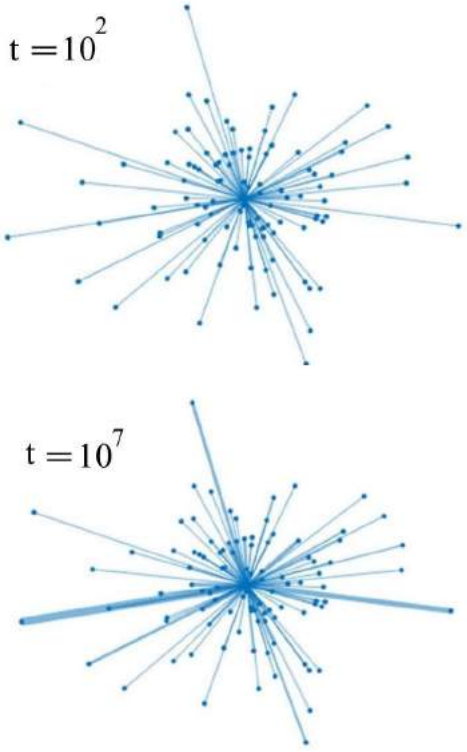

Figure 7: Each dot represents an agent. The dot in the center shows the agent of interest and the other 99 dots are connected to it with lines. The thickness of each line is proportional to the chance of the corresponding agents to pair up at time $t = 10^2$ (top figure) and $t = 10^7$ (bottom figure).

agents, leading the system to self-organization. The role of ST is to spread the strategies between the agents, if it is increasing the payoff of individuals with respect to their previous one. Adding SC to ST lets each agent learn which agents to connect to, in order to increase its own payoff with respect to its last one. SC can improve the complexity of the system by forming a dynamic network of chances of pairings, which results in an inverse power law PDF with complexity index of $\beta = 1.3$. The self-organized system evolved by LT host events with inverse power law PDF of the interval between the consecutive events with complexity index $\mu = 1.73 < 3$. This is the main property of dynamic complex systems which makes them able to transfer information and match to another.

The contrasting roles of shape in human vision and convolutional neural networks

Abstract

Convolutional neural networks (CNNs) were inspired by human vision and, in some settings, achieve a performance comparable to human object recognition. This has lead to the speculation that both systems use similar mechanisms to perform recognition. In this study, we conducted a series of simulations that indicate that there is a fundamental difference between human vision and vanilla CNNs: while object recognition in humans relies on analysing shape, these CNNs do not have such a *shape-bias*. We teased apart the type of features selected by the model by modifying the CIFAR-10 dataset so that, in addition to containing objects with shape, the images concurrently contained non-shape features, such as a noise-like mask. When trained on these modified set of images, the model did not show any bias towards selecting shapes as features. Instead it relied on whichever feature allowed it to perform the best prediction – even when this feature was a noise-like mask or a single predictive pixel amongst 50176 pixels.

Introduction

Object recognition in humans is largely a function of analyzing shape (Biederman, 1987; Hummel, 2013). A wealth of data from psychological experiments show that shape plays a privileged role in object recognition compared to other diagnostic features such as size, colour, luminance or texture. For example, Biederman and Ju (1988) showed that error rates and reaction times are virtually identical in a recognition task when full coloured photographs of objects are replaced by their line drawings even when colour was a diagnostic feature. This indicates that shape-based representations mediate recognition. Similarly, Mapelli and Behrmann (1997) found that, for patients with an object recognition deficit (visual agnosia), surface colour played minimal role in aiding object recognition unless the shape of the object was ambiguous, indicating that shape is instrumental to recognition, whereas surface characteristics such as colour and texture play only a secondary role. More recently, Baker and Kellman (2018) have shown that participants extract shape information automatically from arrays of dot patterns within the first 100ms of stimulus onset, even for tasks where extracting this information may be detrimental to performance on a task. Experiments from developmental psychology show that this privileged status of shape starts early in life and becomes stronger with age. For example, Landau, Smith, and Jones (1988) found that 2-3-year-old children as well as adults weight shape more heavily than size or texture when generalising the name of a learnt object to novel instances. They also found that the weight placed on shape increases in strength and generality from early childhood to adulthood.

By contrast, it is unclear whether shape plays a privileged role in how convolutional neural networks (CNNs) categorise objects. It is often claimed that CNNs learn representations of objects that are similar to the representations that monkeys and humans use when identifying objects (Rajalingham et al., 2018), and that CNNs largely rely on learning shape representations in order to categorise objects (Kubilius, Bracci, & de Beeck, 2016; Jozwik, Kriegeskorte, Storrs, & Mur, 2017). On the other hand, there are a growing number of studies that show that CNNs often categorise images on the basis on non-shape attributes of images. This is demonstrated by the existence of adversarial images that are confidently classified as a familiar category despite the lack of any shape information in the input (Nguyen, Yosinski, & Clune, 2015), adversarial images that contain the correct shape but altered colours that are confidently misclassified (e.g., categorizing an image of an airplane as a dog when only the colour of the plane has been manipulated), and large reductions in performance when trained coloured images are converted to greyscale (Geirhos et al., 2017) or the colours are inverted (Hosseini, Xiao, Jaiswal, & Poovendran, 2017). In addition, there are demonstrations that CNNs can easily learn to categorise random patterns of pixels that have no shape (Zhang, Bengio, Hardt, Recht, & Vinyals, 2016). All of these findings suggest that shape may not play a privileged role in how some well-known and high-performance CNNs perform object categorisation.

However, some recent studies have argued that convolutional neural networks can show a shape-bias. Ritter, Barrett, Santoro, and Botvinick (2017) took an Inception model, a high-performance CNN (Szegedy, Vanhoucke, Ioffe, Shlens, & Wojna, 2016), and presented novel objects to the model that had been pre-trained to recognise the categories from ImageNet dataset. They found that the representations in hidden layers were more similar for two (novel) objects that overlapped in shape than for two objects that overlapped in colour. They interpret this proximity in hidden layer representations between objects of same shape as a shape-bias. In another study, Feinman and Lake (2018) trained a CNN on a controlled dataset containing synthetic images that differed on three dimensions: shape, colour and texture. They found that when this dataset was constructed in such a manner that the

(a) Salt-and-pepper noise (b) Additive noise (c) Single diagnostic pixel

Figure 1: Hidden in plane sight. Images taken from CIFAR-10 dataset and scaled up to 224x224 pixels. (a) Image is converted to greyscale and we add a salt-and-pepper noise-like mask to each training image; (b) Image is converted to greyscale and we add uniform additive noise mask to each training image; (c) A single diagnostic pixel is inserted in the image (dotted red circle is inserted here to illustrate the location of the pixel).

category name correlated with shape more than colour or texture, the network had a higher propensity for classifying novel objects based on shape rather than colour or texture. In other words, the network learns to reflect the feature bias of the training set; when the biased feature is a shape, the network shows shape-bias.

Both these studies assume that shape-bias is a property of the environment itself. Feinman and Lake (2018) explicitly make shape more diagnostic than any other feature in the dataset, while Ritter et al. (2017) assume that this is implicitly the case. However, it is not not clear that shape is necessarily the most diagnostic feature in the environment of biological systems and it is also unclear whether deep neural networks would develop an inductive bias for shape when this is not the most diagnostic feature. Our goal in this study was to test the stronger claim that CNNs show a shape-bias even when there is no such bias in the dataset. Within the psychological literature it is still unsettled whether our visual system identifies objects on the basis of shape because we learn through experience that shape is the most reliable cue to object identification or because there are innate inductive biases that make shape a privileged cue from the beginning (for discussion see Elman, 2008; Xu, Dewar, & Perfors, 2009).

It is certainly possible that CNNs have an inductive bias to rely on shape given that the depth of the architecture and pooling operations enables them to combine features of the stimuli in a hierarchical manner where lower layers represent high-frequency features while higher layers represent more abstract features, such as the shape, which are invariant to local changes of input (Bengio, Courville, & Vincent, 2013). If shape emerges due to this hierarchical composition of features, it is possible that it is preferred to other features (such as colour or texture) that do not lend themselves to such a hierarchical composition. Henceforth we use the term shape-bias to refer to the hypothesis that the visual system has an innate inductive bias to rely on shape cues to identify objects rather than the view that the visual system learns to identify objects on the basis of whatever visual cues are most strongly associated with object category.

Here we systematically explore the impact of non-shape features in the categorisation performance of convolutional neural networks on CIFAR-10 images. We introduced non-shape features to images by adding informative noise-like masks to the training set. We tried several types of masks and an extreme version where the non-shape feature consisted of just a single pixel with a location correlated to the image category (see Figure 1). We show that vanilla CNNs, that perform object classification on CIFAR-10 to near human level, nevertheless learn and depend on non-shape features that are highly diagnostic of object categories and often fails to learn anything about shape under these conditions. These results did not depend on the type of network architecture used, the learning algorithm or regularisation method indicating that this was a property of a broad class of CNNs rather than the particular setup chosen by us. This highlights that, even though they mimic the hierarchical architectural and learning processes of biological vision, the vanilla architectures and algorithms for learning in CNNs simply pick up whatever statistical structure is most relevant to learning the training set, with shape playing no special role. To dispel any confusions at the outset, we would like to emphasise that this does *not* imply that CNNs do not encode shape information under any circumstance, but that shape does not seem to be weighted more than other diagnostic features, even when these features are noise-like masks or the luminance of a single pixel.

Experiments

We modified the CIFAR-10 dataset (which contains 10 classes with 6000 images per class, see `https://www.cs.toronto.edu/~kriz/cifar.html`) so that each image contained not only features that pertain to the shape (e.g. object outlines) but also features without any shape information. As non-shape features we used noise-like masks that were combined with the original image. Two different types

of masks were used: the *salt-and-pepper noise mask* turned a certain proportion of image pixels to either black or white, while a *additive uniform noise mask* added a value sampled from a uniform distribution to each pixel of an image. We also tested an extreme form of the salt-and-pepper noise mask where only one pixel was turned to a particular colour. In this case the location and colour of the pixel were different for different categories but correlated for images within a category. Masks were independently sampled for each category but were either fixed for all images in a category (in which case the mask predicted the category) or sampled from a distribution with category-dependent parameters (in which case these parameters predicted the category). So these modified images concurrently contained features that were related to shape and features without shape information.

We trained the model on these modified sets of images and tested it under three conditions. During the 'Same' condition, the test set was modified in exactly the same manner – i.e., either images in each category were generated by using the same mask as that for the training images of that category (when the mask was fixed) or they were generated by using the same parameters as the parameters used to generate noise masks for training images of that category (when the mask was variable). In contrast, during the 'Diff' condition, the noise masks (or their parameters) for each category were swapped with another category. So, for example, a noise mask that was used in the 'DOG' category during training was inserted into images in the 'CAT' category during testing. The premise here was that if the model based it's decisions on shape-related features, then it would ignore the noise mask and the performance during 'Same' and 'Diff' condition should be similar. On the other hand, if the model relied on properties of the (non-shape) mask, then it's performance would be worse in the 'Diff' condition compared to the 'Same' condition. Finally, we used a third, 'NoPix', condition to estimate the extent to which the network relied on features of the noise mask. In this condition, we presented the network with a version of the image without any mask, with the premise that the difference between the performance in 'Same' and 'NoPix' condition should quantify the relative extent to which the network relied on shape-based and non-shape features. We ran all of the simulations using the well-known VGG-16 network (Simonyan & Zisserman, 2014) and checked that our main results replicate for a deeper network, ResNet-101 (He, Zhang, Ren, & Sun, 2016). To give the model the best chance to recognise shape-based features, all simulations were carried out on CNNs that had previously been trained on ImageNet categories and replaced only the fully-connected layers to perform the new classification task. We then turned the learning rate to a small value and trained these networks on the new classification task.

Methods

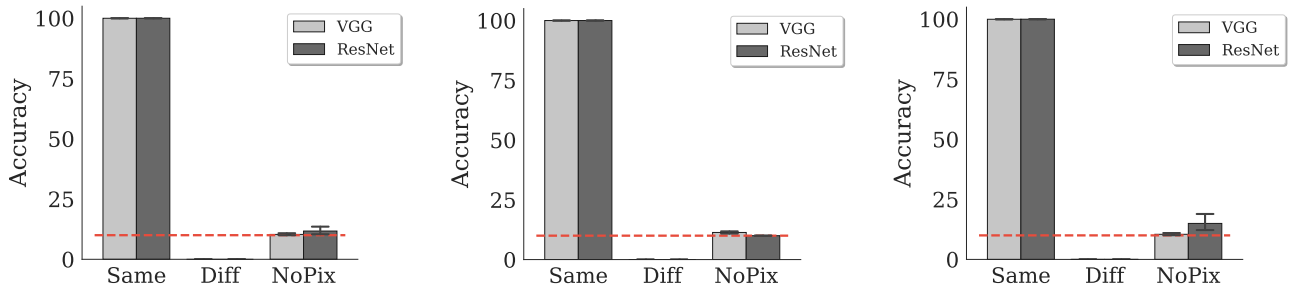
We used a method similar to Geirhos et al. (2017) to transform images from the CIFAR-10 dataset. All transformations were performed using the Pillow fork of the Python Imaging Library (`https://pillow.readthedocs.io`). Each 32x32 pixel image was rescaled to 224x224 pixels using the `PIL.Image.LANCZOS` method. For the single-pixel mask, we used 3-channel RGB images while for the salt-and-pepper and additive noise mask, we transformed images to greyscale. When images were transformed to greyscale, their contrast was adjusted to 80% by scaling the value of each pixel using the formula: $0.8 \times v + \frac{1-0.8}{2} \times 128$, where v was the original value of the pixel in the range $[0, 255]$.

The salt-and-pepper mask was created by taking the transformed greyscale image and setting each pixel to either black or white with a probability p. When the mask was fixed for a category (Experiment 1–3 below), all images had the exact same set of pixels that were turned either black or white and the p was set to 0.05. When the mask varied from image to image within a category (Experiment 4 below), the pixels were sampled independently for each image and the probability p was fixed for each category but varied between categories in the range $[0.03, 0.06]$.

The additive uniform noise mask was created by taking the transformed greyscale image and adding a value sampled from the uniform distribution $[-w, w]$ to this image, where $2w$ was the width of the uniform distribution and was set to 8. When the noise mask was fixed, this sampling was done only once per category and the same mask was added to each image. When the mask was variable, it was sampled independently for each image from a distribution $[\mu - w, \mu + w]$, where μ was the mean that depended on the category and varied in the range $[-50, 50]$.

The single pixel mask was created by choosing a random location, (x, y), (sampled from a uniform distribution on the interval $[0, 224]$) on the image and changing the colour of the pixel to a value c (sampled from a uniform distribution on the interval $[0, 255]$). When the mask was fixed for each category, (x, y, c) remained constant for all images in a category, but varied between categories. When the mask was variable, each of x, y and c were sampled independently for each image from a Gaussian distribution with a constant variance and a mean that depended on the category of the image. If any value in a sampled set of (x, y, c) values fell out of their respective range, that value was re-sampled.

Simulations were carried out using either a 16-layer VGG network (Simonyan & Zisserman, 2014) or 101-layer ResNet network provided by the `torchvision` package of `Pytorch`. These networks were either trained from the scratch on the modified dataset or were first pre-trained on ImageNet and then trained on the modified dataset. When the networks were pre-trained, we replaced the fully-connected layers of the VGG/Resnet pre-trained model with three/one fully-connected layer(s) with 10 units (for 10 categories) on the output layer. Since the results remain qualitatively the same, we report the results for the networks pre-trained on ImageNet. We tried a number of different optimization algorithms, including RMSProp, SGD and Adam (Kingma & Ba, 2014). Results again remained qualitatively the same. We



(a) Salt-and-pepper noise (b) Additive noise (c) Single diagnostic pixel

Figure 2: Accuracy on test images under the three types of noise-like masks shown in Figure 1. 'Same': the noise-like mask has same properties for test and training images of each category; 'Diff': the properties of the mask during test are swapped with another category from training; 'NoPix': No mask is inserted. The dashed (red) line indicates chance performance and error bars show 95% confidence interval. Light and dark gray bars show accuracies on `VGG-16` and `ResNet-101`.

started with a learning rate of $1e-3$ when training the network from scratch and used a learning rate of $1e-5$ when fine-tuning a pre-trained network. In all cases, we used cross-entropy as the loss function. The input to both types of networks was a 3-channel RGB image. For greyscale images, all three channels were set to the same value.

Experiment 1

In the first experiment, all images in a category had the exact same noise mask. For salt-and-pepper mask, this meant that noise masks were sampled independently for each category, but the same set of pixels in each image were modified for all images in a category. Similarly, for the additive uniform noise mask, the same mask was added to each image in a category. For the single pixel noise, the location and colour of the added pixel were independently sampled for each category, but kept constant for all images in a category.

The results of the first experiment are shown in Figure 2. We obtain the same pattern of results for all three cases: when noise mask in the test images matches the noise mask in training images, the model classifies images nearly perfectly; when noise masks are swapped, the accuracy drops to zero; when the mask is completely removed, the categorisation accuracy is at chance. Furthermore, we get the same pattern of results on both VGG and ResNet networks and irrespective of the type of regularisation used (we tried several well-known regularisation methods including *Batch Normalization*, *Weight Decay* or *Dropout*). These results clearly indicate that the model learns to completely rely on features of the noise-like mask, rather than any shape-related information present in the images. Even in the extreme case, where only one pixel amongst 50176 was diagnostic of the category, the model prefers to classify based on this feature over other shape-related features present in each image.

Experiment 2 & 3

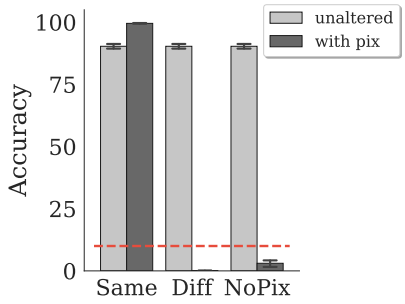
One possible reason why humans prefer to rely on shape-related features to categorise objects while CNNs do not is that humans are guided by past experience and bring this past knowledge to new categorisation tasks. So when a human sees an object with superimposed noise, they generalise from past experience and look for shape-based information, paying less attention to non-shape related features such as the noise-like mask in above images. We conducted two further experiments to test whether networks similarly generalise from concurrent and past experience.

In Experiment 2, we divided the training set into two subsets. The first subset ('with pix') contained three randomly chosen categories from CIFAR-10 and, like above, contained a category-correlated pixel in all images of these categories. The second subset ('unaltered') contained the remaining seven categories from CIFAR-10 and was left unaltered – i.e. we did not add the category-correlated pixel to images of this subset. We trained a VGG-16 network on all ten categories at the same time. We were interested in finding out whether the network generalised from one subset to another and started using the features used to categorise images in the 'unaltered' subset to images of the 'with pix' subset. All other details of the experiment remain same as Experiment 1.

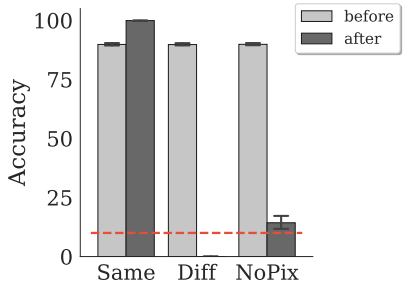
The results from this experiment are shown in Figure 3a. The model learnt to predict the images in the 'unaltered' subset with nearly 90% accuracy. However the performance on the 'with pix' subset still completely depended on the location and colour of the added pixel: accuracy was nearly 100% when test images contained the pixel in the same location, but dropped below chance when this pixel was removed. Thus, the network did not seem to generalise the features (concurrently) learnt in the 'unaltered' categories to the categories containing the diagnostic pixel.

In Experiment 3 we tested what happens when the network is first trained on images that did not contain such a pixel (a 'before' phase) followed by a second ('after') phase in which such a pixel was inserted in the training set. In the first phase, a we trained a VGG-16 network on an unaltered CIFAR-10 training set. Once the network had learnt this task, we trained it on the modified set of images in a second phase, introduc-

ing a predictive pixel in each category. So all that changes between the 'before' and 'after' phases is the insertion of a single category-correlated pixel to each image.



(a) Generalising between subsets



(b) Generalising from one time to another

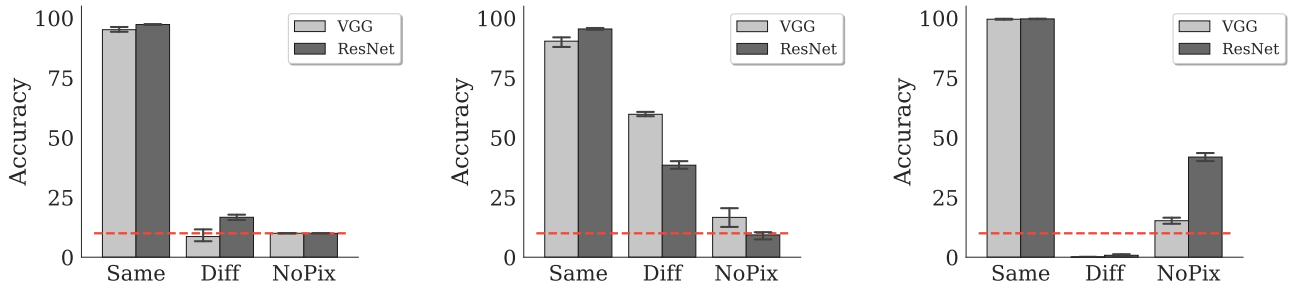
Figure 3: Lack of generalisation. Accuracy under Same, Diff and NoPix conditions for (a) two subsets: an 'unaltered' subset where no noise-like mask was inserted in training images and a 'with pix' subset where a single diagnostic pixel was inserted, and (b) for two phases: a 'before' phase, where a pre-trained VGG network was trained on images without any noise masks and tested on the three conditions, and an 'after' phase, where the model from before phase was then trained on images with a single diagnostic pixel.

We observed that (Figure 3b), instead of relying on past experience with these images, the model learnt to completely rely on the predictive pixel to perform categorisation – accuracy dropped from nearly 100% to 0% between 'Same' and 'Diff' conditions. Crucially, the model completely forgot about how to perform categorisation when the predictive pixel was removed – accuracy was close to chance in the 'NoPix' condition during the 'after' phase. Thus learning about the diagnostic feature seemed to be accompanied by unlearning previously learnt representations. This, catastrophic forgetting, is a well-known problem in neural networks (McCloskey & Cohen, 1989) and contrasts with how humans transfer their knowledge from one task to another. Some recent solutions to catastrophic learning in neural networks have been suggested, such as Elastic Weight Consolidation (Kirkpatrick et al., 2017) and it remains to be seen whether this can overcome some of these problems.

Experiment 4

The non-shape features used in the experiments above have all been completely invariant from one image to another within a category. It can be argued that these features are selected by the model over other shape-based features because they provide a very strong predictive signal. It is possible that if these features contained larger variance, the model would be more likely to rely on shape-based features while performing categorisation. In the next experiment, we introduced variability in the non-shape features by sampling the noise-like mask independently from a distribution for each training and test image within a category. In order to make these noise-like masks diagnostic of an image's category, a parameter of this distribution correlated with an image's category. For the salt-and-pepper noise, this meant that the probability, p, of changing a pixel to black or white was different for each category. Thus, the parameter, p, became diagnostic of the category. However, the masks now varied from image to image and were independently sampled with the (category-dependent) probability, p. Similarly, for the additive uniform noise, masks could vary from one image to other within a category but the mean of the distribution depended on each category (see Methods above for details). For the single diagnostic pixel, the inserted pixel could vary in location and colour from one image to the other, but were generated from a Gaussian distribution with a mean determined by the category of the image and a fixed standard deviation. We ran these simulations on both VGG-16 and Resnet-101 and aside from the way in which the dataset was generated, all other details remain same as Experiment 1.

The results of introducing a variable noise mask are shown in Figure 4. Introducing variability in the location and colour of the single diagnostic pixel brought very little change to the VGG model's behaviour (compare Figure 4c with Figure 2c). Performance in the NoPix condition was somewhat better for ResNet, however the pattern of result remained the same – performance dropped substantially from the Same to NoPix condition. Similarly, introducing variability in the salt-and-pepper masks lead to only a minor change in behaviour of the model, with accuracy in 'Diff' condition dropping to chance, rather than 0%. The most intriguing change in behaviour occurred when variability was introduced to the additive uniform noise mask (Figure 4b). While the VGG and ResNet networks differed quantitatively in these results, the pattern of results remained the same: when the noise mask was completely removed (NoPix condition) the model performed *worse* than when the images contained a noise mask from a different category (Diff condition). In other words, removing the mask makes the image less informative for the model, not only compared to images with the correct category-correlated (Same) mask, but also compared to images with the incorrect (Diff) mask – the model seems to rely on the presence of the noise-like mask to make an inference.



(a) Salt-and-pepper noise (b) Additive noise (c) Single diagnostic pixel

Figure 4: Accuracy on test images when the noise mask varies between images of a category. Training images contain (a) salt-and-pepper noise, or (b) additive uniform noise, or (c) just one diagnostic pixel. The dashed (red) line indicates chance performance. See Figure 2 for a description of the 'Same', 'Diff' and 'NoPix' conditions.

Related Work

Su, Vargas, and Kouichi (2017) demonstrated that CNNs trained on CIFAR-10 and ImageNet can be fooled by introducing a single adversarial pixel, with error rates of 68% and 41%, respectively. Unlike our approach the model was trained with uncorrupted images and the authors systematically searched for an adversarial pixel that lead to any sort of error (so-called non-targeted attack). So, in contrast to our goal, the goal of their study was not to explore whether CNNs systematically learn non-spatial information. However, the findings are in line with ours – the CNNs trained by them do not seem to be categorising based on shape. Rather, it must be that there was, by chance, some pixel value that was highly correlated with a given output category and the model picked up on this idiosyncratic correspondence. As a consequence, when this pixel was added to another category the model was fooled.

Two recent studies – Geirhos et al. (2018) and Baker, Lu, Erlikhman, and Kellman (2018) – manipulate the texture and shape of images independently and show that CNNs trained on ImageNet are biased towards picking up texture compared to shape. These results are again in line with our results and show that CNNs will make inferences on whichever feature is most predictive in the training set. Indeed, when Geirhos et al. (2018) make the texture less diagnostic of category, the model seems to use non-texture features for performing classification. Our findings go beyond past work by highlighting the extent to which CNNs categorize objects on the basis of non-shape features even when it is given concurrent or prior training without such non-shape features. Indeed, a single diagnostic pixel can override all the shape information present in the training images.

Conclusions

In a series of simulations we found that some high-performance convolutional networks trained to categorise CIFAR-10 images that included noise-like masks diagnostic of the output categories often learned to categorise on the basis of these masks rather than features present within the CIFAR-10 images themselves. Indeed, the models often entirely relied on the masks, and performed at floor when the noise was removed from the images. This clearly highlights that, when a shape-bias is not present within the training dataset itself, these models do not show a shape-bias due to their own architectural or algorithmic properties.

In our experiments, we specifically engineered our dataset to contain invariant non-shape features. One might object that large datasets like ImageNet and CIFAR-10 don't contain such features so that the models trained on these datasets end up relying on shape to perform categorisation. But it is well-known that popular datasets contain various biases due to conditions under which the images were captured as well as the different motivations for construction of the datasets (Torralba & Efros, 2011). So biases like the one we engineered may well be present in these datasets and networks trained on these datasets may be picking on these features. This, in turn, implies that these networks may be relying on entirely different set of features and representations to perform classification than human beings or other animals.

If CNNs do indeed rely too heavily on non-shape features present within datasets, it could also be the source of various idiosyncratic behaviours such as being confounded by fooling images (Nguyen et al., 2015) or being overly sensitive to colour (Hosseini et al., 2017), noise (Geirhos et al., 2017) or even single pixels in images (Su et al., 2017). The alternative hypothesis that the human visual system learns to categorize objects on whatever statistical regularities are strongest in the input cannot be ruled out on the basis of our findings, but it would predict that humans would show a similar pattern of result to these models, such as picking up on single pixels or noise-like masks to categorise stimuli. In addition, this view also needs to explain why human beings are not susceptible to adversarial attacks such as the non-shape fooling images in the same manner as vanilla CNNs. We are currently carrying modelling and behavioural work to provide further insights into the computational benefits of inducing a shape-bias to CNNs and how these modified CNNs relate to human vision.

How Many Dimensions of Mind Perception Really Are There?

Bertram F. Malle
Brown University

Abstract

Previous research suggests that people's folk conception of the mind is organized along a few fundamental dimensions; but studies disagree on the exact number of those dimensions. With an expanded item pool of mental capacities, variations of question probes, and numerous judged agents, four studies provide consistent evidence for three dimensions of perceived mind: *Affect (A), Moral and Mental Regulation (M)*, and *Reality Interaction (R)*. The dimensions are not simply bundles of semantically related features but capture psychological functions of the mind—to engage with its own processes, with other minds, and with the social and physical world. Under some conditions, two of the three dimensions further divide: *A* divides into negative and positive (social) affect, and *M* divides into moral cognition and social cognition. We offer a 20-item instrument to measure people's 3- and 5-dimensional representations of human and other minds.

Keywords: anthropomorphism; social cognition; theory of mind; morality; principal component analysis; robots.

Introduction

A significant question for cognitive science is how humans conceptualize agents and their minds. Research in cognitive development has taught us that features such as self-propelled motion, contingent response, and eyes convince infants that they are interacting with a special category of thing: what we call agents (Johnson, 2000; Premack, 1990). Once infants identify agents, they follow their gaze, imitate them, make inferences about their goals, and eventually ascribe complex mental states to them. Over the childhood years, children develop ever more differentiated conceptions of mental states, such that, for example, a goal concept divides into desires and intentions, emotion concepts of good and bad differentiate into a staggering number of different affective terms, and moral dispositions of *mean* and *nice* turn into sophisticated assessments of moral character. In short, we know that humans grow up to have deep-seated expectations about other humans' mental, social, and moral capacities (Hamlin, 2013; Malle, 2005; Tomasello, 2003). But do people treat these capacities as just one long list? Or is there an underlying conceptual organization to uncover? Only empirical studies can answer this question.

Dimensions of Mind

Despite humans' rich representations of mental capacities, previous work indeed suggests that there are fundamental dimensions by which humans organize these capacities. But research diverges on the number of those dimensions.

D'Andrade (1987) considered six categories of mental states: perception, belief, emotions, desires, intentions, and self-control. Interviews suggested that people indeed make distinctions among these classes, but no methods were applied to assess whether the researcher-imposed category number actually captured people's own conceptual structure. Haslam et al. (2008) rearranged d'Andrade's categories, combining intentions and self-control but separating primary from secondary emotions. Through multi-dimensional scaling, they were able to reduce these categories into a two-dimensional space: perception vs. all other categories; thoughts and intentions vs. desires and emotions.

Gray, Gray, and Wegner (2007) offered the simple and elegant proposal that humans distinguish mental states along two dimensions: Experience and Agency. The empirical evidence for this two-dimensional structure was a principal component analysis (PCA) of 18 mental capacities, which people evaluated in 13 different agents. This proposal had seminal impact in research on dehumanization, moral judgment, objectification, and human-robot interaction.

The interpretation of what makes up the two-dimensional space of Experience and Agency is, however, not entirely clear. Even though each dimension in Gray et al.'s study had several items that loaded high on its dimension and low on the other dimension, there were numerous items that loaded high on both dimensions, showing barely distinguishable loadings (see Table 1). Moreover, although the highest-loading Experience items are quite coherent, incorporating physiology and affect, the highest-loading Agency items are more heterogeneous, including planning and self-control as agentic capacities but also emotion recognition, memory, and morality, which are less obviously agentic.

Table 1: Loading matrix for PCA of 18 mental capacities by Gray, Gray, and Wegner (2007).

	Experience	Agency	*Difference*
Hunger	0.98	0.15	*0.83*
Fear	0.93	0.31	*0.62*
Pain	0.89	0.42	*0.48*
Pleasure	0.85	0.51	*0.34*
Rage	0.78	0.59	*0.20*
Desire	0.76	0.64	*0.12*
Joy	0.68	0.61	*0.07*
Personality	0.72	0.68	*0.04*
Consciousness	0.71	0.69	*0.03*
Pride	0.71	0.69	*0.03*
Embarrassment	0.70	0.65	*0.05*
Thought	0.68	0.73	*0.05*
Communication	0.66	0.74	*0.08*
Planning	0.55	0.82	*0.27*
Emotion recognition	0.54	0.83	*0.29*
Morality	0.36	0.93	*0.57*
Memory	0.33	0.91	*0.58*
Self-control	0.18	0.97	*0.79*

Note: Clearly and highly loading items on each dimension are color-marked. Items in the middle show almost no difference in their loadings on the two dimensions.

Replications by Takahashi, Ban, and Asada (2016) and Weisman, Dweck, and Markman (2017) confirmed the Experience dimension with its familiar marker items but continued to find several middling items (in particular, personality, consciousness, pride, and embarrassment) as well as considerable heterogeneity on the Agency dimension.

Other studies suggest that people may conceptualize the mind in three rather than two dimensions. Kozak, Marsh, & Wegner (2006) applied a PCA to 10 items similar to those in Gray et al. (2007) and identified three dimensions, labeled Emotion (feelings, pain, emotion, pleasure; hence similar to Experience), Intention (doing things on purpose, planning, goals; hence similar to Agency), and Cognition (conscious, memory, thought). Using a larger item pool of 40 mental capacities, Weisman et al. (2017) found three major dimensions, which they labeled Body (related to Experience), Heart (primarily covering emotions), and Mind (perceptions, cognition). Thus, Agency did not emerge in this structure.

The Present Investigation

How do people represent and conceptualize capacities of the mind, and what number of fundamental dimensions underlie this representation? To answer this question, we need a comprehensive item pool. As noted by several authors (Haslam et al., 2008; Weisman et al., 2017), the original 18 capacities used by Gray et al. had limitations (e.g., perception items were missing, some categories were represented by single items). Only an expanded item pool and replications across different pools can reveal the dimensions of mind perception. Across four studies, we therefore analyzed varied item pools that represent capacities of perception, cognition, emotion, agentic control, learning, communication, and social-cognitive and social-moral capacities, all represented by multiple items. For consistency, one constraint was to include items about which one could explicitly ask, "Is the agent capable of X?" This question disfavors highly specific states (e.g., feeling disrespected) and abstract words such as "personality." Across studies we experimented with different items and formulations in order to gain confidence in the clusters of capacities that best represent the dimensions of mind perception. In analogy to cognitive theories of concepts, we conceive of such dimensions as bundles of capacities typically represented together; if similar dimensions of mind reappear across variations in items and samples, we can be more confident in the underlying dimension in question.

The conceptual structure of mental capacities is difficult to study when asking participants to indicate how much of each capacity human adults have, as the ratings will tend to be at ceiling. Following other authors, we increased judgment variance by including nonhuman agents, which arguably lack some of the capacities. Particularly useful targets are robot agents, as the reality of their minds is a wide open question. Robots are like a projection screen for people's general conceptions of mind, so these conceptions may emerge particularly well when people judge robots' minds.

In the present project, we thus investigated how many dimensions may be fundamental in people's representations of various agents' minds. We report on a first study in detail to lay out our methodological approach and major results, then summarize the results of three additional studies that varied the pool of capacities and tested different question probes and judged agents. We then report on a final study that relied on an integrated item pool derived from multiple previous data sets so as to represent the full conceptual range of people's perceptions of mind. Based on these results, we offer a parsimonious multi-dimensional measurement scale of mental capacities applicable to humans and other agents.

For instructions, item formulations, and detailed results tables, please see the Supplementary Materials (SM), which can be found at http://bit.ly/SA_MindCapacities.

Study 1

Methods

To generate a broad item pool we took Gray et al.'s item pool as a starting point and classified them into four rough groups: physiological (hunger, pain), affective (joy, pride, desire, pleasure, rage, fear, emotion recognition), cognitive (remember, planning, thinking), and agentic (self-control, communicate). Taking Sytsma and Machery (2010), Haslam et al., (2008), and d'Andrade (1987) as inspiration, we added two items to the agentic group (choosing freely, imitating others) and two to the physiological group (sleep, thirst) to make them four each. We retained six of the affective items (reformulating emotion recognition into empathy); decomposed "thinking" into more concrete cognitive capacities (believing, knowing, deliberating, reasoning) to make the total of cognitive items six as well. We added four perceptual items (perceive, see or hear, taste or smell, vividly imagine) and differentiated morality into four items (moral obligations, having values, deserving praise or blame, deserving punishment). We omitted the two most abstract items of personality and consciousness, as well as embarrassment, all of which were undifferentiated in Gray et al. (see Table 1).

Participants were 160 undergraduate students from a private university in the Northeast United States; no demographic information was collected. In a one-page survey, each participant rated one of 16 agents (e.g., human adult, robot, rabbit, chimpanzee, similar to Gray et al.'s agents, but also group agents, such as a city council and a large company). Twelve participants were excluded, two how provided illegible ratings, ten who had a rating range of 0 or 1 on the 8-point scale, leaving 148 participants for analysis. Fewer than 1% of individual item ratings were mising and were replaced by their respective sample means.

On the top of the survey page, the agent was introduced, and each statement repeated the agent description (e.g., "The most advanced robot in 2050 can feel joy," "…can have values," "can perceive things.") The 28 statements were listed in random order with rating scales next to each statement. The column header for the ratings contained the question, "Is this true?", and the anchors for the ratings scales were "Definitely NOT true" (0) and "Definitely true" (7).

We used Principal Component Analysis (PCA) to analyze the correlation matrix resulting from the 148 (participants) × 28 (capacities) raw data, ignoring agent type, which served as a source of meaningful judgment variability. One challenge of PCA is that multiple criteria are available to decide how many components one should extract. Common heuristics include Kaiser's (1960) rule ("K1"; retain components with eigenvalue $\lambda > 1$) and Cattell' (1966) scree test (on the scree plot, draw a linear fit line from the smallest components upward and retain those that lie above the line). However, with larger variable sets, K1 extracts too many factors, and the scree test can suffer from ambiguity. Zwick and Velicer (1986) compared these and more sophisticated criteria and concluded that Parallel Analysis (PA) represents the best approach. This procedure (Buja & Eyuboglu, 1992) recognizes that even for a population of perfectly uncorrelated variables, any sample from it will contain correlations among variables that a PCA would pick up and turn into spurious components with $\lambda > 1$. By assessing hundreds of random permutations of the actual data matrix, PA estimates what number and size of spurious components one can expect if the original data were in reality uncorrelated (i.e., all λs = 1). The recommendation is then to retain those components from the actual PCA whose eigenvalues are at or above the corresponding spurious ones.

Results

The K1 and scree criteria suggested 4 components, but the fourth was very weak, $\lambda = 1.04$. PA suggested 3 components. The three-component solution accounted for 67.3% of the total variance and was interpretable after rotation (see Table 2). The first component had 25.1% explained variance (EV) and grouped 11 items with loadings $l \geq .60$, both social-moral capacities (shame, values, obligations, praise) and cognitive control capacities (believing, deliberating, choosing). We label this component *Moral and Mental Regulation* (*M*). The second component (22.7% EV) grouped 8 physiological and affective items together (e.g., hunger, pain, taste, anger, joy); we label this component *Affect* (*A*). The third component (15.6% EV) grouped perceptual, cognitive, and some interaction items (perceive, remember, know, communicate), which we label *Reality Interaction* (*R*).

To illustrate in a heuristic way how much a loading matrix approximates *simple structure* (D'Agostino & Russell, 2014) we counted items with "errand loadings"—defined as $l > .316$ (i.e., > 10% of variance) on components that are not the item's primary component (where it loads most highly). Of all possible 84 loadings, 15 (18%) were errand in this way. To examine the possibility of component correlations we applied oblique rotation to all 28 items, which reduced errand loadings to 11% (which is expected for oblique rotations). This solution showed small correlations between *A* and *M* ($r = .21$) and between *A* and *R* ($r = .18$) and a more notable one between *M* and *R* ($r = .42$). Thus, Agency from Gray et al.'s (2007) two-dimensional model broke into two dimensions that may, however, not be entirely independent.

Discussion

Study 1 recovered the Experience dimension from previous studies (here, labeled *Affect*), but by expanding the item pool to represent domains of perception, cognition, and morality we uncovered a third dimension of mind perception. Specifically, the Agency dimension (arguably multi-faceted to begin with) broke into two distinct dimensions. The original Gray et al. items of morality, empathy, and planning became part of a *Moral and Mental Regulation* dimension, whereas items of perception, cognition, and communication constituted a *Reality Interaction* dimension. These two dimensions can be treated as orthogonal, but in an oblique rotation they show a cleaner simple structure with a nontrivial correlation.

Importantly, the items that define each dimension hang together not simply due to semantic similarity (e.g., moral and mental regulation are semantically distinct). The items constitute their components in psychologically meaningful ways. For example, *R* refers to a progression of information processing from perceiving to knowing to remembering to communicating. Likewise, *M*'s cognitive facet forms a sequential process: we believe things, then deliberate, then choose and plan; and *M*'s moral facet refers to empathy, obligations, and values as action regulation and also includes responses to one's moral (or immoral) behavior in the form of pride or shame on the inside, praise or blame from the outside. Thus, moral and mental regulation occurs in a dynamic mental and social context and is the culmination of a complex and nuanced picture of the social-moral mind.

Table 2. Loading matrix of PCA on 28 items in Study 1.

	Moral & Mental Regulation	Affect	Reality Interaction
can feel shame or pride	0.79	0.35	0.20
can have values	0.76	0.10	0.26
may deserve praise or blame	0.76	0.18	0.04
may deserve punishment	0.74	0.12	-0.06
has moral obligations	0.71	0.02	0.28
can have empathy for others	0.68	0.23	0.21
can believe certain things	0.64	0.22	0.37
can deliberate	0.64	-0.01	0.49
can vividly imagine things	0.63	0.39	0.30
can plan for the future	0.63	-0.19	0.41
can choose freely	0.61	0.29	0.31
can feel thirsty	0.12	0.91	-0.04
can be in physical pain	0.09	0.88	-0.01
has a need for sleep	0.08	0.86	0.01
can feel hunger	0.08	0.82	0.05
can taste or smell things	-0.07	0.80	0.32
can experience pleasure	0.34	0.75	0.18
can be angry	0.45	0.64	0.08
can feel joy	0.46	0.62	0.18
can see or hear things	-0.08	0.60	0.59
can want certain things	0.42	0.51	0.28
can communicate with others	0.10	0.30	0.73
can remember things	0.11	0.09	0.67
can perceive things	0.37	0.12	0.66
can reason logically	0.50	-0.18	0.64
can know certain things	0.52	-0.02	0.63
can exercise self-control	0.35	0.20	0.61
can imitate others	0.46	0.03	0.47

Study 2

Encouraged by the effects of enlarging the item pool of mental capacities we further expanded the pool by rewriting several items for clarity and adding 30 new ones, for a total of 54, to represent (with several items each) physiology, affect, moral competence, social cognition, thinking and cognitive control, perception, learning, and communication. We thus allowed for the possibility of components from Study 1 breaking apart even further (thus pointing to more dimensions) or else clustering reliably around the same three dimensions, despite new item content.

We probed mental capacity ascriptions to an average adult, a two-year-old child, a cat, and a home care robot. Any given participant made judgments for only one agent. Of 459 participants recruited online via Amazon Mechanical Turk, 17 provided fewer than a quarter of ratings and 27 had a rating range of 0 or 1 (on an 8-point scale), leaving 415 participants for analysis. Of these, 45.3% identified as female, 53.5% as male. They ranged in age from 18 to 74 (M = 35.5, SD = 11.8), and 52% of them had completed a bachelor's degree or higher. In the principal component analysis (PCA), the K1 and scree criteria suggested five components, but PA suggested three. We considered a 4-component solution, but the fourth component accounted for less than 5% of the variance and had only three items with l > .50 and almost as high cross-loadings on other components. The 3-component solution (see Table SM3) explained 65.2% of the variance.

Table 3. Loading matrix of Orthogonal PCA on 38 selected items in Study 1

	Affect	Moral & Mental Regulation	Reality Interaction
Being hungry	0.91	-0.17	0.11
Feeling pain	0.91	-0.16	0.10
Feeling pleasure	0.91	-0.04	0.14
Feeling panic	0.90	-0.02	0.16
Feeling happy	0.90	-0.01	0.12
Having emotions	0.88	0.06	0.13
Getting angry	0.88	-0.02	0.19
Loving specific people	0.87	0.00	0.21
Having intense urges	0.86	0.00	0.17
Smelling and tasting things	0.83	-0.11	0.25
Having desires	0.83	0.09	0.18
Feeling stress	0.82	0.13	0.10
Disliking people	0.80	0.09	0.23
Feeling gratitude	0.72	0.39	0.04
Feeling compassion	0.72	0.38	-0.06
Vividly imagining things	0.65	0.33	0.11
Feeling sexual arousal	0.63	0.28	-0.03
Providing reasons for their actions	-0.18	0.87	0.04
Planning for the future	-0.02	0.86	0.09
Upholding moral values	0.25	0.85	-0.07
Understanding a person's goals	0.13	0.85	-0.03
Explaining their decisions to others	-0.22	0.84	0.03
Setting goals	-0.05	0.83	0.05
Praising moral actions	0.18	0.81	-0.07
Disapproving of immoral actions	0.29	0.79	-0.07
Reasoning logically	-0.21	0.78	0.24
Understanding others' minds	0.26	0.77	-0.03
Taking a person's visual point of view	0.02	0.74	0.02
Inferring what a person is thinking	0.12	0.74	0.09
Deliberating before acting	0.03	0.73	0.30
Exercising self-control	0.17	0.72	0.08
Following norms	0.11	0.70	0.10
Communicating verbally	-0.20	0.64	0.26
Moving on their own	0.20	0.07	0.78
Seeing and hearing the world around them	0.31	-0.03	0.74
Learning by imitation	0.12	0.27	0.63
Communicating nonverbally	0.31	0.18	0.63
Feeling temperature, touch, etc.	0.49	-0.01	0.62

The first component had 21 strongly loading items ($l \geq .60$), dominated by affective states (pain, hunger, stress), emotions (angry, compassion, gratitude), and social relations (loving people, relationships). We see here again the *Affect* dimension from Study 1, supplemented by social facets. The second component had 17 strongly loading items, capturing moral capacities (e.g., upholding values, praising moral actions), social cognition (e.g., understanding others' minds, their goals, and thinking), and cognitive control (e.g., setting goals, providing reasons for one's actions). We see here the *Moral and Mental Regulation* dimension, with enhanced social-cognitive facets. The third component included 7 strongly loading items, featuring seeing, learning, moving, and communicating, confirming the *Reality Interaction* dimensions of Study 1. The remaining items loaded more weakly or on multiple components, producing the bulk of the 15% errand loadings. Removing weaker and cross-loading items led to a set of 38 items that had only 2% errand loadings, yielding a clean three-dimensional structure (see Table 3). Oblique rotation on all items also reduced errand loadings (12%) and showed modest correlations (the highest between M and R at .30). Removing 12 weak items reduced errand loadings to 6% and the M*R correlation to .26 (see Table SM4).

In sum, we replicated a three-dimensional structure of mind perception. The previously labeled Experience factor is well represented by the *Affect* dimension, which includes social emotions and relations. The previously labeled *Agency* dimension again separated into one of *Social-Moral and Mental Regulation* and the dynamic dimension of *Reality Interaction* (perception, learning, to action).

Studies 3a and 3b

Now we report on two samples that we collected in continuation of a related project in which we focused on mental capacities people *would like to* see in robots, thus a slightly different question from the one in Studies 1 and 2. However, these studies had a considerable impact on our last stage of item selection and so we describe them briefly.

Though the rating means may differ between inferred capacities of various agents and desired capacities of robots in particular, the dimensional structure should still be similar. We presented participants in Study 3a (N = 100) with 60 mental capacity items largely the same as in Study 2, and participants in Study 3b (N = 99) with a selection of 41 items. The two samples were recruited online from Amazon Mechanical Turk and had highly similar demographics as those in Study 2. We invited people to indicate which capacities they would want or not want in "the most advanced home robot" they could imagine, defined as an autonomous robot that takes care of older adults or children and does household chores.

In Study 3a, K1 and scree criteria suggested 6 to 13 components, but PA suggested 3 to 4, so we examined both solutions. Each one yielded R (perception, cognition, learning) and A (but solely negative affective states). In the 4-component solution, the third and fourth component both

contained social emotions, relations, and hints of morality, and it was difficult to find a distinction between the two components. Indeed, in the 3-component solution the two combined into a dimension similar to *M* (but populated more with positive social emotions and relations than we saw in Studies 1 and 2), and errand loadings decreased from 14% to 11%. Oblique rotation reduced errand loadings to 6%, with the highest correlation between *M* and *R* at $r = .39$. Overall, the three-dimensional structure from Studies 1 and 2 was replicated even when probing people's desired capacities for robots. However, *A* became negative and *M* took on positive social emotions that had loaded on *A* in Studies 1 and 2. We will return to this trend in Study 4.

For Study 3b, we reduced the number of items to 41, omitting eight items with very low loadings in Study 3a, five that were semantically redundant with other items in the set, and two that plainly do not apply to robots (physiology, hunger). Four items were omitted due to a clerical error. K1 and scree criteria suggested 5 to 8 components, but PA suggested only 2 to 3. The 2-component solution dispersed familiar *M* items across both other item sets, making the solution difficult to interpret, even from an Experience-Agency perspective (see Table SM6). The 3-component solution showed three strong components after rotation (15.3% to 23.1% EV), replicating *A* (solely negative affective states), *M* (social emotions, relations, and moral capacities), *R* (perception, decision making, communication, and some stray social cognition), with 20% errand loadings. Oblique rotation improved the errand rate to 10%, with *M* and *R* correlating at .48, and at .40 after removal of very weak items.

Taken together, the two studies on desired mental capacities of robots largely supported a three-dimensional structure of mind perception. However, Study 3a raised the possibility of a split of *Affect* into a positive and negative facet, which we decided to explore further in Study 4. However, the primary purpose of Study 4 is explained next.

Integrative Item Selection

After we completed this first set of studies, Weisman et al. (2017) published a series of studies that suggested three dimensions of mind comparable to our three, thus providing further confidence in a three-dimensional model of mind perception. However, their components (to which we will refer as W1 to W3) differed somewhat from ours in item composition and in the authors' interpretation. W1 was labeled "Body," highlighting its physiological items, but almost half of its high-loading items refer to basic emotions (calm, angry, fear, safe). W2 was labeled "Heart," also highlighting emotion items (embarrassed, pride, love), but these emotions are social, and other items in this component also hinted at moral capacities (telling right from wrong, guilt) and cognitive control (thoughts, intentions, self-restraint), casting doubt on the labeling of "Heart." W3 was nonspecifically labeled "Mind," but it encompassed perception, memory, reason, and communication.

Aside from interpretational ambiguities, some of the discrepancies between Weisman et al.'s and our three-dimensional model can be explained by item selection, so to address this possibility, we collated the 62 items used at least twice across Gray et al., Weisman et al., Malle and Thapa Magar (2017), and our data reported so far. We tracked each item's loadings within the corresponding components across data sets. This correspondence was straightforward for our three components and Weisman et al.'s. (*A* ~ W1, *M* ~ W2, *R* ~ W3). Gray et al.'s first component clearly corresponds to *A* and all but one of the other reused items fit under *M*. We reanalyzed the data from Malle and Thapa Magar (2017) with the same criteria as we had applied in the present studies and found better support for a three-dimensional structure (rather than the originally reported four-dimensional structure), and the three dimensions were very similar to the present *A-M-R* structure. (See the resulting compilation matrix in Table SM8.)

We identified candidate items by using two inclusion heuristics: (a) A *differential loading* index was the averaged loading in a given component minus the averaged loadings on the other two components; we aimed for this difference to be at least .30. (b) An item's *number of replications* on the same component with a loading $l > .50$; we aimed for two or more such replications. We also used two exclusion heuristics: (c) content was already covered by another item; (d) item had substantial loadings on two components. We made specific attempts to retain enough items in the content domains of agency, perception, social emotions, and social cognition. The resulting item pool included 12 items targeting *A* (physiology, basic emotions and motivation), 20 targeting *M* (perhaps the most diverse dimension with social emotions, moral competence, social cognition, and cognitive control), and 10 targeting *R* (perception, learning, communication, action).

Study 4

In light of possible differences between the dimensional structure of inferred and desired capacities, which had arisen in Studies 3a and 3b, we asked one group of participants to *infer* the capacities of either an average adult, a two-year-old child, or one of two kinds of robots—a home robot or a military robot; and we asked a second group to indicate the capacities they *would like* a home or military robot to have. Of 495 participants recruited from Amazon Mechanical Turk, 11 entered no ratings, 2 entered fewer than half, and 19 had a rating range of 1 or 0 on an 8-point scale, leaving an N of 463, again with very similar demographics as those in Study 2.

We applied PCA to each question condition separately. In the inferred capacity group ($N = 304$), K1 and scree suggested three to four components, while parallel analysis suggested three, which were easily interpretable as the *A-M-R* structure (71.1% EV, 19% errand loadings). After removing only four items with $l < .60$, errand loadings decreased to 10% (73.1% EV). An oblique rotation yielded virtually not change, with *M* and *R* showing a small correlation of .32.

In the desired-capacity condition ($N = 159$), K1 suggested eight components, the scree plot suggested six and especially showed a fourth and fifth component distinctly separating

from the lower ones. Parallel analysis suggested three, but this solution (EV = 51.7%) was not interpretable as it intermixed items that in other studies consistently loaded in the familiar *A, M,* and *R* dimensions. When allowing a fourth component, the Affect items split into a negative set (e.g., anger, stress, pain) and a positive set (e.g., happy, gratitude, friendships), the moral items formed their own component, but *M* and *R* items remained intermixed. When allowing a fifth component, finally, rotation produced five evenly strong components (EVs = 10.6% to 13.2%), with *M* and *R* cleanly separating and errand loadings down to 11% (Table SM10). Under oblique rotation, correlations were moderate, with the highest between the social and moral component at .37.

Instrument development

The final step was to create a measurement instrument of people's perceptions of mind that accommodates both inferred and desired capacities and is also suitable for other applications. We aimed for five subscales representing the components of the desired-capacity set whereby the items of the negative and positive-social affect subscales would combine into an overall Affect scale and the items of the moral and social-cognitive subscales would combine into an overall Social-Moral scale, thus representing the three-dimensional structure of inferred capacities. Of the 42 items in the two analyses (inferred, desired) of Study 4, we removed 10 that had $l < .50$ or strong cross-loadings in at least one analysis, and 2 items that fell under distinct components in the two analyses. Then we selected the four highest-loading items in each of the five components, yielding a 20-item measure with sufficient internal consistency on each of the five subscales (see Fig. 1), and errand loadings of 5-7%. With only two items more than Gray et al. used, we can now measure three to five dimensions of mind perception.

	Desired Capacities		*Inferred Capacities*	
Feeling happy	0.84	**Positive Social Affect**	0.96	**Affect**
Loving specific people	0.80		0.91	
Feeling pleasure	0.79	*16.2% EV*	0.94	*36.7% EV*
Experiencing gratitude	0.77	α = 0.88	0.80	α = 0.98
Feeling pain	0.86	**Negative Affect**	0.97	
Feeling stress	0.81		0.87	
Experiencing fear	0.78	*15.3% EV*	0.94	
Feeling tired	0.77	α = 0.86	0.95	
Disapproving of immoral actions	0.80	**Moral Cognition**	0.83	**Moral & Social Cognition**
Telling right from wrong	0.77		0.73	
Upholding moral values	0.76	*13.5% EV*	0.84	
Praising moral actions	0.66	α = 0.84	0.81	*29.4% EV*
Inferring a person's thinking	0.78	**Social Cognition**	0.80	α = 0.94
Planning for the future	0.75		0.82	
Understanding others' minds	0.67	*12.6% EV*	0.84	
Setting goals	0.61	0.78	0.83	
Communicating verbally	0.81	**Reality Interaction**	0.67	**Reality Interaction**
Seeing and hearing the world	0.70		0.68	
Learning from instruction	0.69	*12.5% EV*	0.72	*11.2% EV*
Moving on their own	0.68	α = 0.79	0.76	α = 0.71

Figure 1: Individual item loadings from PCAs on desired mental capacities of robots (5 components, left) and inferred capacities of humans or robots (3 components, right).

General Discussion

What are the dimensions of mind? Our results suggest that people's ascriptions of mental capacities follow at least three major axes. A three-dimensional structure is consistent with previous work (Kozak et al., 2006; Weisman et al., 2017), but the specific dimensions we identified, and successfully replicated over five different samples, offer new insights into their psychological meaning and interrelationships.

First, each dimension shows multiple facets that previously have been overlooked. Dimension *A* unites aspects of physiological and positive as well as negative emotional capacities that are largely unintentional. *M* encompasses aspects of both moral cognition and social cognition, which itself includes the simulation of one's own mind (e.g., planning) and others' minds (e.g., inferring their thoughts); its appropriate label may thus be *Moral & Social Cognition.* These processes are largely under the agent's intentional control and enable understanding and regulation of one's own and others' behavior, thus carving out a specific meaning of agency. *R* illustrates the dynamic transition from perception and cognition through learning to communication and action—a second more specific meaning of agency.

It is noteworthy that none of the dimensions are made up simply of bundles of semantically related words. The use of PCA in personality psychology has sometimes been criticized as merely recovering dictionary relations between trait adjectives (e.g., Extraversion = outgoing, sociable, gregarious, friendly, etc; *cf*. D'Andrade, 2017). The items that are clustering together in the *A-M-R* structure are only midly semantically related, but more so they point to fundamental psychological functions of the mind—to engage with its own processes, with other minds, and with the social and physical environment.

We also found that, under some conditions, two of the three dimensions bifurcate: *A* divides into negative and positive-social affect; *M* divides into moral cognition and social cognition. We have so far identified only instance in which a full five-dimensional structure emerges: when people consider the desired capacities of a robot. Other instances may emerge as a function of one's attitude toward the agent (e.g., friend or foe), or the functional role of the capacity ascriptions (e.g., for interaction vs. evaluation).

Finally, we have offered a short, reliable measure of the three- to five-dimensional structure of mind perception, thus opening the door to many new investigations. These include developmental and cross-cultural studies of mind perception, as well as studies into how mind perceptions change over time—such as when interacting with a robot. The scale also invites a more refined assessment of anthropomorphism, sometimes cast as a relatively indiscriminate human tendency that may, in reality, be more selective. Finally, questions of dehumanization can be posed anew, as denying "mind" is unlikely to occur in a simple on/off way (Rai, Valdesolo, & Graham, 2017); rather, its impact on social and moral behavior may be differentiated depending on what aspect of mind—out of three to five—is denied.

Abstract

Studies have claimed that blind people's spatial representations are different from sighted people, and blind people display superior auditory processing. Due to the nature of auditory and haptic information, it has been proposed that blind people have spatial representations that are more sequential than sighted people. Even the temporary loss of sight—such as through blindfolding—can affect spatial representations, but not much research has been done on this topic. We compared blindfolded and sighted people's linguistic spatial expressions and non-linguistic localization accuracy to test how blindfolding affects the representation of path in auditory motion events. We found that blindfolded people were as good as sighted people when localizing simple sounds, but they outperformed sighted people when localizing auditory motion events. Blindfolded people's path related speech also included more sequential, and less holistic elements. Our results indicate that even temporary loss of sight influences spatial representations of auditory motion events.

Keywords: blindfolding; localization; pointing; auditory motion events; spatial language

Introduction

Information provided by visual, auditory, and haptic systems work together to enhance detection, localization, and identification of objects and events in the world. Compared to auditory and haptic input, vision has the advantage of providing simultaneous, precise, and detailed information about features of objects and events that take place in close and distant space (e.g., Eimer, 2004; Thinus-Blanc & Gaunet, 1997).

Considering the qualitative differences between inputs from sensory modalities, it is interesting to ask how blindness influences conceptualization of space, and how this is reflected in the spatial language of blind individuals. Numerous studies have reported enhanced auditory spatial skills in blindness (e.g., Lessard, Paré, Lepore & Lassonde, 1998; Röder et al., 1999; Voss et al., 2004), and the spatial language of blind individuals has been shown to be conceptually different when it is based on haptic input (Iverson, 1999; Iverson & Goldin-Meadow, 1997). The present study is the first to focus on how information acquired from the auditory modality alone affects spatial event conceptualization as expressed in both language and pointing gestures in blindfolded and sighted people.

It is claimed that blind individuals can compensate for their lack of vision through better auditory processing. Consistent with this, some studies suggest the blind even outperform their blindfolded counterparts in low-level auditory spatial tasks, such as estimating distance based on echo cues and localizing direction of a sound in the horizontal plane (e.g., Després, Candas & Dufour, 2005; Dufour, Després & Candas, 2005; Lessard et al., 1998; Röder et al., 1999; Voss et al., 2004). It is possible that blindfolding creates a temporary disadvantage for sighted individuals' spatial mapping of sounds. Only a single study compared sound localization skills of blindfolded and sighted individuals (Tabry, Zatorre, & Voss, 2013). Tabry et al. presented simple sounds on the horizontal and vertical planes and measured accuracy of pointing by hand or head laser pointer. Tabry et al. found that the absence of visual feedback decreases localization accuracy mostly for head-pointing and sounds on the vertical plane.

Other studies measuring navigation and spatial updating skills have claimed that blind individuals have impaired performance when required to process multiple pieces of information or simultaneous information, such as creating representations of large-scale environments, or inferring new spatial relations that are not directly experienced (finding the shortest way from A to B, when only experiencing A to C and B to C) (e.g., Coluccia, Mammarella & Cornoldi, 2009; Pasqualotto & Newell, 2007, Rieser, Guth & Hill, 1982; Thinus-Blanc & Gaunet, 1997). This may be because blind individuals have to rely on sensory information that is perceptually represented sequentially, thereby making it

more difficult to build holistic spatial representations of path information.

Language studies investigating speech and gesture in route description tasks have also found evidence that blind peoples' conceptualization of space has an underlying sequential representation of path for large-scale layouts; but that they can build holistic representations for small-scale layouts (Iverson, 1999; Iverson & Goldin-Meadow, 1997). Iverson and Goldin-Meadow (1997) examined sighted, blindfolded, and blind children's speech and co-speech gesture production in a task where participants had to give directions for familiar locations in their school. The results showed that blind children's speech was more segmented, with several landmark points on the path described, whereas sighted and blindfolded children linguistically represented the area in a global manner. Iverson and Goldin-Meadow did not report any difference between sighted and blindfolded children's speech but this is not surprising given the fact that blindfolded children also initially saw the scene before the description task and so, their initial encoding of the school space was based on visual input.

As a follow-up Iverson (1999) examined sighted, blindfolded, and blind children's route descriptions for small-scale scenes constructed from Lego blocks. Even though both blind and blindfolded children explored the Lego scenes haptically, while sighted children explored the Lego scenes visually, all children gave similar path expressions (in terms of landmark use). Iverson claimed that the Lego scenes could be encoded similarly by touching and seeing because the amount of available spatial information was equivalent for both modalities, which allowed blind children to build more holistic representations for small-scale scenes.

The Present Study

We investigated the effect of blindfolding on localization and verbal descriptions of auditory motion events. Having both linguistic and non-linguistic tasks performed by the same participants helps us understand whether possible differences between groups come from the processes required for linguistic packaging, or are grounded in more fundamental spatial representations, independent of the demands of speech production.

As shown by Tabry et al. (2013), blindfolding can influence sighted people's spatial mapping of sounds. To investigate this possibility further, we measured localization ability in two non-linguistic tasks for simple beep sounds and also for the first time in more complex auditory motion events. In both tasks, participants were asked to trace the path of the movement as accurately as they could by tracing a line with their finger or hand. Tabry et al. (2013) used simple sounds similar to our beep sounds, and only one condition in their study—hand pointing on the horizontal plane—was relevant to the task in the current study. In this condition, Tabry et al. did not report a difference between the blindfolded and the sighted group in the degrees of deviation from target location. Based on Tabry et al.'s findings, we expected no difference between blindfolded and sighted participants in the localization task with beep sounds. We also examined whether these findings for simple beep sounds generalize to localization of complex auditory events. It may be the case that as the stimulus becomes more complex, there is more opportunity to see differences between sighted and blindfolded individuals.

In speech we aimed to explore path representations by measuring different manners of encoding. As we know from the blindness literature (e.g., Iverson & Goldin-Meadow, 1997; Thinus-Blanc & Gaunet, 1997), sequential representations typically encode consecutive landmarks in relation to path, but spatial relations between distant objects are not encoded explicitly. To address the distinction between sequential and holistic path representations, we coded whether speech included information about source, goal, orientation, and path verbs. Source and goal elements in speech represent sequential information because those encode discrete units of information—such as which landmark is a starting point of movement—without explicitly encoding its spatial relation to other elements. We take orientation and path verbs in speech to represent spatial relations because these encode information about direction (e.g., from left to right) and trajectory of movement (e.g., approaching). Thus, it can be argued that mentions of orientation and path verb show more holistic representation of the space. We conducted the current study in Turkish as source and goal elements are optional when describing a motion event. Therefore, Turkish enables us to compare differences in the event descriptions.

If having visual cues at encoding—such as seeing the source of a sound—enables people to build a more holistic representations of space, even temporary absence of sight may affect spatial representations and make them more akin to the representations created by the blind, i.e., make them more sequential. As such, it may be expected that, compared to sighted people, blindfolded people's event descriptions would include more sequential path information, such as more mentions of the source, but less holistic path information that encodes trajectory of motion and the relation between two different locations—such as figure and source.

Method

Participants

Twelve sighted (M = 22.27 years, SD = 2.10, 7 female) and 12 blindfolded (M = 21.83 years, SD = 2.21, 7 female) Turkish adult speakers participated in the experiment in exchange for extra credit in an introductory psychology course. The sample size was based on previous studies comparing sighted and blindfolded participants (Iverson 1999; Iverson & Goldin-Meadow, 1997; Tabry et al., 2013). Participants all had normal or corrected-to-normal vision and provided written informed consent.

Auditory Stimuli

We filmed and simultaneously recorded the sound of locomotion and non-locomotion events. Locomotion events served as the critical experimental items in the study, whereas non-locomotion events served as filler items. For the locomotion events, an actress moved in distinct manners (walk, run, and limp) with respect to a landmark object (door or elevator) along a specific path (to, from, into, and out of). Each manner was combined with each path, creating 12 different items. The sound recorder was placed next to the landmark objects, so the path direction in the events was either approaching (for *to* and *into* paths) or away from (for *from* and *out of* paths) listeners. In addition, the path azimuth was edited using Soundtrack Pro audio editing software to increase the variety of possible path motion. Five movement angles were created in a semicircular space ranging from 90° left to 90° right with 45° intervals, thus from the right to the left these are: 0° (right), 45° (right-sided), 90° (front), 135° (left-sided), and 180° (left) motions (see Figure 1). We created all 12 events with the 5 movement angles, resulting in 60 events in total. All locomotion events were exported as 5.1 surround sound.

For the non-locomotion events, the same actress performed different actions with objects (e.g., drinking water, eating chips), and the video and sound were recorded across from her. We did not examine these items further. There were 77 experimental trials in total, including 60 locomotion events and 17 non-locomotion events. Locomotion events lasted 9s (SD: 1.9) and non-locomotion events 8s (SD: 2.2) on average.

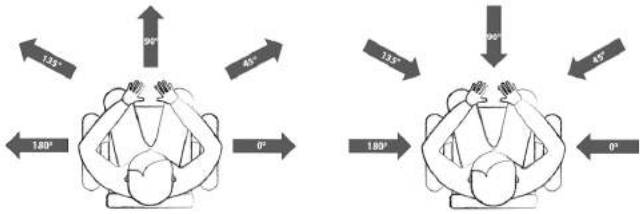

Figure 1: Path direction and angles for "from" and "out of" events (left) and "to" and "into" events (right).

In addition to the locomotion and non-locomotion events, we prepared 60 audio-clips consisting of beeps. These sounds were intended to assess people's accuracy in localizing simple dynamic stimuli, in contrast to the more complex, naturalistic locomotion events. To make a beep clip, a 1s beep sound was compounded with a 1s silence lasting 9s in total. The direction of sound movement in each clip was manipulated as described for the locomotion events (see Figure 1).

Procedure

Each participant was tested in a quiet room on Bogazici University campus in Istanbul, Turkey. The procedure of the experiment was the same for both groups, except that blindfolded participants' eyes were covered before they entered the room, and the experimenter helped them to be seated. In the room, five speakers were placed 1.34 m far from the participant's head and approximately 95 cm high from the ground in a 5+1 surround system configuration. Front left and right speakers were placed 30° off center, and rear left and right speakers were 110° off center. Participants sat in the middle of the speakers. The experimenter stayed in the room during the experiment to initiate the tasks and advance the trials on a laptop using Presentation Software.

There were two sorts of tasks:

(1) Event Description Task Participants listened to audio-clips of the events. Before the experiment started, there were 2 practice trials consisting of one locomotion and one non-locomotion event. In each trial, an event was presented aurally and participants were asked to describe what happened. They were told that another participant would watch their descriptions and listen to the same sounds to try and match the sound clips.

(2) Localization Task with Events vs. Beeps Participants listened to the audio-clips of 60 locomotion events and 60 audio-clips consisting of beep sounds in two separate tasks for each stimulus type. There were 4 practice trials in each task. After each audio-clip, they were asked to trace the path of the movement in the semicircular frontal space as accurately as they could by tracing a line with their finger or hand. They were instructed not to describe the audio stimuli, but only trace the paths.

Participants first performed the event description task. During this task, participants' speech was recorded with two video cameras. One camera was placed across from the participant and the other recorded the top view of the participants' frontal space so as to capture arm and hand movements. Following the event description task, participants performed either the localization task with audio events or the localization task with beeps. The order of these two tasks was counterbalanced across participants. Finally, participants were asked to fill out a demographic questionnaire on a laptop. The total duration of the experiment was around 75 minutes.

Coding

Descriptions for the motion events were transcribed and coded by a native Turkish speaker. First, the event descriptions were split into clauses. Clauses were coded as relevant or irrelevant to the target events. Second, each relevant clause for each event was coded, according to the type of information it contained: (1) the use of sequential elements—(a) source (starting point of movement), and (b) goal (the end point of the movement); and (2) holistic elements—(a) orientation (direction), and (2) path verb (trajectory of motion). An example description below encodes information about the source, the orientation, and the path verb of the movement as:

(1)

Asansör-den	***sağ-a***	***doğru***	***uzak-laş-(ı)yor.***
elevator-ABL	right-DAT	towards	away-VERB-PRS.3SG
(source)	(orientation)		(path verb)

'(someone) moves away from the elevator towards the right.'
(VERB = verbal suffix)

For the localization tasks, direction and angle localization were coded by an assistant. There were 2 possible directions (approaching or going away) and 5 possible angles (from 90° left to 90° right with 45° intervals). Twenty percent of the coding was checked by the first author of the study. Interrater agreement was at least 0.80 (95% CI: 0.69, 0.91) using Kappa for both tasks.

Results

For all analyses reported in the paper, we used mixed effects regression models. All models were generated using the lme4 package (Bates, Mächler, Bolker, & Walker, 2015) in R (R Core Team, 2018). We begin by presenting the data for the simplest task—the localization task with beeps—before moving to the data of the localization task with events and the event description task.

Localization Task with Events vs. Beeps

First we investigated whether sighted and blindfolded participants differed in how they localized motion using simple beep sounds. We ran two separate glmer models to test the effects of blindfolding on binary values (correct, incorrect) for: (1) angle and (2) direction accuracy. Since localization of direction and angle was simultaneously performed by participants, we also included the accuracy of the other variable as a predictor in the models. That is, the model for direction accuracy included angle accuracy as a predictor in addition to the group factor (sighted or blindfolded). The optimal random effects structure included random intercepts of participant and item. Model 1 for angle accuracy showed that blindfolded participants did not differ in localizing the angle of beep sounds from sighted participants, and that participants became significantly more successful as direction accuracy increased (see Table 1 and Figure 2). Similarly, Model 2 for direction accuracy showed that blindfolded participants did not differ in localizing direction of beep sounds from sighted participants, and that participants became significantly more successful as angle accuracy increased (see Table 1 and Figure 2). These results showed that blindfolding did not affect localization ability when the sounds were simple, dynamic beeps, and all participants succeeded in localizing the direction of beep sounds—in fact, they were at ceiling levels.

Table 1: Accuracy models for angle and direction localization of the beep sounds.

	Estimate	Std.Error	z-value	*p*-value
Model 1 for Angle				
(Intercept)	-0.5671	0.5265	-1.077	0.2814
Group	-0.0545	0.2937	-0.186	0.8527
Dir. Acc.	1.6281	0.4317	3.771	<0.001***
Model 2 for Direction

Group	-0.8279	0.6735	-1.229	0.2190
Ang. Acc.	1.4246	0.4509	3.160	0.0016**

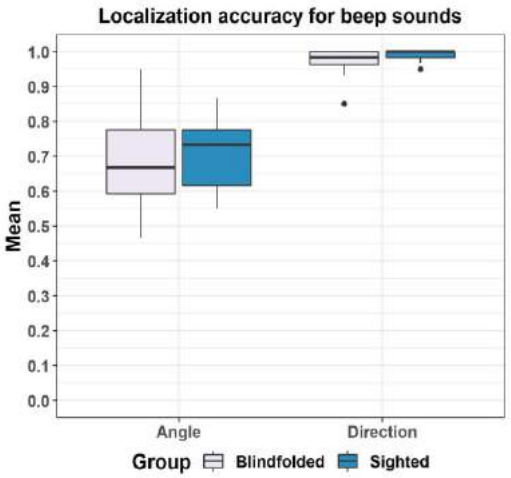

Figure 2: Localization accuracy for beep sounds.

For the locomotion events, we again ran two separate glmer models to test the effects of blindfolding on binary values for (1) angle and (2) direction accuracy. Model 3 for angle accuracy showed that blindfolded participants performed better in localizing angle of locomotion events than sighted participants, and that participants became significantly more successful as direction accuracy increased (see Table 2 and Figure 3). Similarly, Model 4 for direction accuracy showed that blindfolded participants performed better in localizing direction of locomotion events than sighted participants, and that participants became significantly more successful as angle accuracy increased (see Table 2 and Figure 3). As with the beep sounds, all participants were almost at ceiling for identifying the direction of motion. Unlike for beeps, blindfolded participants were better able to identify the angle and direction of auditory events when sounds were meaningful, locomotion events.

Table 2: Accuracy models for angle and direction localization of the locomotion events.

	Estimate	Std.Error	z-value	*p*-value
Model 3 for Angle				
(Intercept)	-0.1714	0.3603	-0.476	0.6344
Group	0.5814	0.3047	1.908	0.0564 .

Group	1.5285	0.5390	2.836	0.0046**
Ang. Acc.	0.7153	0.3261	2.194	0.0283*

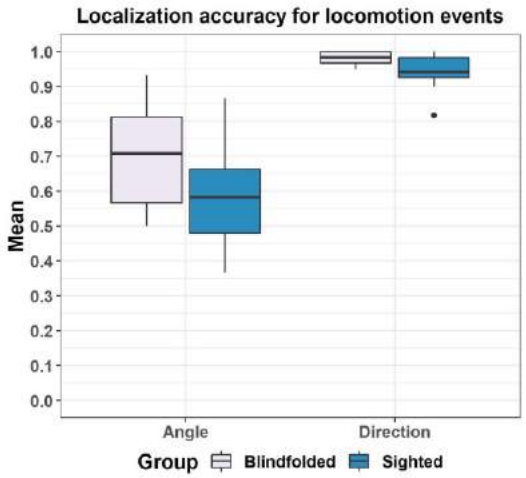

Figure 3: Localization accuracy for locomotion events.

Event Description Task

Finally, to investigate whether sighted and blindfolded participants differed in how they described the path of events, we calculated the ratio of sequential (source and goal) and holistic path descriptions (orientation and path verb) per relevant clause. To do this, total counts of sequential and holistic path descriptions were divided by the number of relevant clauses for each trial. So, we had a 2-level variable for the type of linguistic expression (sequential vs. holistic) and a 2-level variable for the group (blindfolded vs. sighted) as predictors.

We ran an lmer model to test the effects of blindfolding and type of linguistic expression using ratio of mention per clause as input. The optimal random effects structure included random intercepts of participant and event. The results showed that there was a significant effect of type of linguistic expression, with all participants mentioning more holistic than sequential descriptions ($p < .001$). This difference was not surprising because of the fact that one of the holistic elements included verbs. Due to its typology, Turkish usually expresses path of motion in the verb (Talmy, 1985). There was no effect of blindfolding in how often participants mentioned all path elements in their descriptions ($p = .272$). Crucially, the interaction between group and type of linguistic expression was significant ($p <.001$; see Table 3 for model summary and Figure 4). Blindfolded participants gave more sequential but less holistic descriptions in their speech compared to sighted participants.

Table 3: Models for ratio of sequential and holistic path descriptions in the events.

	Estimate	Std.Error	t-value	*p*-value
(Intercept)	0.3187	0.0854	3.730	<0.001***

Group	0.1319	0.1175	1.123	0.272
E.Type:Gr	-0.2038	0.0471	-4.307	<0.001***

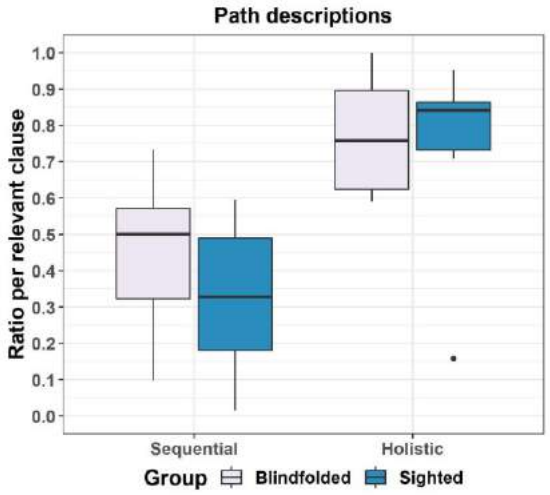

Figure 4: Ratio of sequential and holistic path descriptions per relevant clauses in the events.

Discussion

In the present study, we examined the effect of blindfolding on localization and verbal descriptions of auditory motion events. In the localization task with beeps, we showed that blindfolded participants performed as well as sighted participants when localizing simple sounds. Our results are in line with Tabry et al. (2013). Similar to our localization task with beeps, Tabry et al. tested hand-pointing accuracy for simple sounds on the horizontal plane, and reported no effect of blindfolding in the deviation from target. This does not necessarily imply there are never differences in localization in response to blindfolding. Tabry et al. (2013) did find differences in other paradigms, such as head-pointing and localizing simple sounds on the vertical plane. Based on the results of our localization task, and Tabry et al.'s similar paradigm, we can conclude that blindfolded and sighted people behave similarly in the spatial mapping of simple sounds when orienting their hands toward a specific location on the horizontal plane.

In contrast to the simple auditory tones, blindfolded participants outperformed sighted participants when localizing more complex auditory locomotion events. Earlier studies investigating sound localization abilities in blindness have only ever used simple sounds as stimuli. Our result

suggests that having no visual feedback creates an advantage in localization when mapping complex sounds onto an event space. One possible explanation for this advantage could be that closing the eyes increases auditory attention and thereby leads to better performance when localizing complex sounds. Since participants are already near ceiling for simple sounds, there is no room to see this improvement in that condition. A recent study by Wöstmann, Schmitt, and Obleser (2019) found that while attending to one of two spoken streams, even in a darkened room, closing eyes modulated attention, and increased alpha power for the attended stream. Wöstmann et al. suggested that closing eyes might decrease the dominance of vision, and thus enhance attention to nonvisual input. Although they did not report behavioral enhancement with closed eyes, their participants performed the tasks in a darkened room where there was no distracting visual input. In our study, to the contrary, sighted participants could see the location of the audio-speakers, which could possibly distract them while listening to sounds and/or localizing them in space. Thus, it is possible that our paradigm is more suitable to detect a possible beneficial behavioral effect of closing eyes. Furthermore, one could hypothesize that blind people might perform even better due to their better ability to process auditory information than both blindfolded and sighted people. Future studies could examine this possibility.

We did not find an effect of blindfolding on how often participants mentioned path in their descriptions regardless of the type of linguistic expression. However, we did find that blindfolded participants gave more sequential, and less holistic descriptions for the path of auditory motion events, compared to sighted participants. This is in line with the claim that blindness leads to sequential representations and segmented speech due to the more sequential nature of the sensory information that the resulting spatial representations depend on (e.g., Iverson & Goldin-Meadow, 1997). Iverson (1999) and Iverson and Goldin-Meadow (1997) showed that landmarks on a described route were used to segment the path into several pieces. We also found that blindfolded participants in our data used more landmark information encoded as source and goal in their descriptions. Thus, our results suggest that even temporary loss of sight changes how people talk about events by possibly hindering the building of a holistic representation of space.

Conclusion

We are the first to investigate the effect of the temporary loss of sight on localization and verbal descriptions of auditory motion events. We showed that temporary loss of sight leads to more sequential and less holistic path descriptions, and better localization of auditory events as measured by pointing. These effects suggest that even the temporary loss of sight might change the sort of spatial representations people build in response to complex auditory events.

Insulating Distributional Semantic Models from Catastrophic Interference

Willa M. Mannering and Michael N. Jones
Indiana University, Bloomington
[wmanneri] [jonesmn]@indiana.edu

Abstract

Predictive neural networks, such as word2vec, have seen impressive recent popularity as an architecture to learn distributional semantics in the fields of machine learning and cognitive science. They are particularly popular because they learn continuously, making them more space efficient and cognitively plausible than classic models of semantic memory. However, a major weakness of this architecture is *catastrophic interference* (CI): The sudden and complete loss of previously learned associations when encoding new ones. CI is an issue with backpropagation; when learning sequential data, the error signal dramatically modifies the connection weights between nodes—causing rapid forgetting of previously learned information. CI is a huge problem for predictive semantic models of word meaning, because multiple word senses interfere with each other. Here, we evaluate a recently proposed solution to CI from neuroscience, elastic weight consolidation, as well as a Hebbian learning architecture from the memory literature that does not produce an error signal. Both solutions are evaluated on an artificial and natural language task in their ability to insulate a previously learned sense of a word when learning a new one.

Keywords: distributional semantic models; catastrophic interference; word2vec; random vector accumulation; elastic weight consolidation

Introduction

Distributional models of semantic memory (DSMs; e.g., Landauer & Dumais, 1997) attempt to explain how humans learn the meaning of words through statistical inference. All DSMs are based on the distributional hypothesis of language (Harris, 1970), often summarized as learning a word's meaning "by the company it keeps" (Firth, 1957). Classic DSMs use counts of co-occurrence between words in a corpus to construct semantic representations. Recently, with the development of predictive DSMs and improvements in overall computing power, the fields of cognitive science and machine learning have seen an increase in popularity of error-driven DSMs within connectionist architectures. Predictive DSMs use the backpropagation of an error signal through the network to predict context and are particularly popular because they learn continuously—making them more space efficient and more cognitively plausible than earlier DSMs.

However, a major weakness of predictive DSMs is *catastrophic interference* (CI): The sudden and complete loss of previously learned associations when encoding new ones (French, 1999). When a predictive neural network is exposed to sequential data, the introduction of completely new information causes the error signal to be very large, effectively "shocking" the model and causing it to overcorrect the weights to accommodate the new information. The problem of CI is a major issue not only for functional reasons but for implications of cognitive plausibility as well.

The standard predictive network currently discussed in the literature is Mikolov et al.'s (2013) word2vec model. Word2vec is a feedforward neural network with input and output layers that contain one node per word in the vocabulary, and a hidden layer of approximately 300 nodes. The word2vec architecture has two possible model directions. The context may be used to predict the word—which is referred to as the Continuous Bag of Words (CBOW) model—or, the word may be used to predict the context—which is referred to as the skipgram model. We will use skipgram in this paper because it maps conceptually onto most connectionist models and has been shown to perform better with smaller training corpora than the CBOW model.

Dachapally and Jones (2018) recently investigated the impact of CI on the internal representations produced by predictive DSMs when applied to sequentially learned word senses. Because of its current popularity, they used Mikolov et al.'s (2013) word2vec model to evaluate the effects of CI on the model's final semantic representations. In their study, Dachapally and Jones used homonyms to measure the effects of CI. Take for example a homonym like *bank,* with its two distinct meanings: river-bank and financial-bank. The word *bank* should have its final representation positioned equidistant to its two meanings in semantic space. Because of CI, however, if the financial sense was learned first, followed by the river sense, the final representation of *bank* would be positioned proximal to river-bank words, and the financial sense would be forgotten. This study was the first evaluation of CI in a predictive semantic model. Now that we know CI affects semantic representations produced by predictive DSMs, we can begin to propose and evaluate possible solutions for CI.

The goal of the current paper is to expand on Dachapally and Jones' (2018) work by implementing and comparing two possible solutions to CI from the cognitive and neural sciences. The first candidate solution is *elastic weight consolidation* (Kirkpatrick et al., 2017) which has been impressively successful on machine learning tasks and can be considered a "vaccination" for predictive DSMs that would prevent the effects of CI. The second candidate solution is a different architecture, *random vector accumulation* (Jones, Willits, & Dennis, 2015), which can be considered naturally "immune" to the effects of CI by way of its learning mechanism.

The goal of elastic weight consolidation (EWC) is to allow a predictive neural network to learn two sequential tasks, Task A and then Task B, without incurring CI. To do this, Kirkpatrick et al. (2017) introduced a method to constrain the

parameters of a neural network after learning Task A so that the network can subsequently learn Task B without forgetting Task A. The new loss function they introduce is a quadratic penalty that differentially constrains parameters in the neural network depending on how important each parameter is to completing Task A. To determine which weights in the network are important for Task A they calculate the Fisher Information for each parameter—a mathematical method to measure the amount of information a variable carries about a parameter. The resulting loss function that gets minimized in elastic weight consolidation is:

$$\mathcal{L}(\theta) = \mathcal{L}_{\mathcal{B}}(\theta) + \sum_i \frac{\lambda}{2} F_i \left(\theta_i - \theta^*_{A,i}\right)^2 \qquad (1)$$

where $\mathcal{L}_{\mathcal{B}}(\theta)$ is the loss for Task B, λ controls how important Task B is compared to Task A, F is the Fisher Information calculated for each parameter, and θ represents the parameters in the network. Kirkpatrick et al. (2017) showed that EWC was able to insulate against CI when training a predictive neural network on the MNIST (LeCun et al., 1998) data set, a free data set of handwritten images. While EWC has been tested several times on categorization tasks, this paper will present the first implementation for use with distributional semantic models.

EWC has potential as a "vaccine" for predictive DSMs, that is, networks may be insulated from CI without having to implement new architectures. There is reason to suspect that EWC may have limited effectiveness when translated to the field of semantic modeling. EWC calculates the relevance of each model parameter to Task A based on the actual class of the training data. However, in the case of semantic modeling, we are not necessarily interested in the final predicted class of the training data but in the internal representations created by models as they learn. It is one goal of this paper to determine how EWC affects the internal representations of predictive DSMs.

The second candidate solution to CI that we evaluate is a different architecture: random vector accumulation (RVA; Jones et al., 2015). RVA is an alternate architecture that should theoretically be "immune" to CI by nature of the learning mechanism. RVA is the theoretical mechanism that is core to semantic models such as BEAGLE (Jones & Mewhort, 2007). Unlike predictive DSMs, which are affected by CI due to the error signal produced during learning, RVA models should be immune to CI because they utilize principles of associative learning and do not rely on an error signal to learn. These models learn via a simple Hebbian co-occurrence learning mechanism. The most basic RVAs first begin by initializing two random vectors from an arbitrary distribution and of arbitrary dimensionality for each word encountered in a corpus. One vector is unique to each word in the vocabulary, the environment vector, and the other is a summation of all context words, the memory vector. The update function for the memory vector of each word in the vocabulary is described in Equation 2:

$$m_i = e_{i-1} + e_{i+1} \qquad (2)$$

where m_i is the memory vector for an arbitrary word in a corpus, e_{i-1} is the unique environment vector for the context word before *i,* and e_{i+1} is the unique environment vector for the context vector after *i.* So, the memory vector for word *i* stores the context vectors for every other word that appears in context with word *i.*

Similar to Dachapally and Jones' (2018) study, this paper will use homonyms to measure the bias in semantic space created by CI. For each model, EWC and RVA, two conditions will be tested and compared to the performance of the original word2vec model in both an artificial and natural language. In the first condition, a target homonym will have two equally frequent senses with distinct meanings. Ideally, the target homonym should be equidistant from both of its two senses in semantic space. In the second condition, a target homonym will have two senses, one which is dominant (occurs more frequently) and one which is subordinate. In this case, the target homonym should be closer in semantic space to the dominant sense. Dachapally and Jones (2018) found that in both the artificial and natural language when word2vec was trained sequentially on equally balanced word senses, the target word was closer in semantic space to whichever sense had been trained most recently—forgetting the first sense of the word. The same effect was found when a target homonym had a dominant and subordinate sense; CI caused the target word to be more similar to the subordinate sense if the subordinate sense was trained most recently. Importantly, recency overpowered frequency, and the subordinate sense of the word became dominant if it was the most recently learned. To determine the effects of CI on a neural network equipped with EWC and on RVAs, a similar experimental structure will be used.

Experiment 1: Effects of CI on EWC and RVAs in an Artificial Language

Dachapally and Jones (2018) used a simple artificial language in which there is a single homonym, *bass,* that has two distinct meanings—*bass*[fish] and *bass*[guitar]. A corpus was created from this simple language by sampling word pairs from the following Markov grammar:

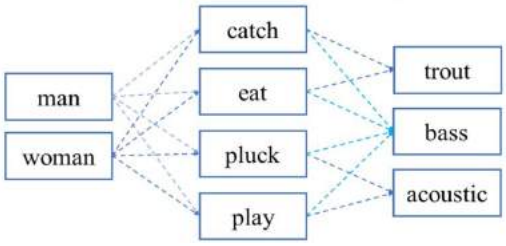

Figure 1. The artificial language used to test. Bass is the target homonym, and its position in semantic space relative to the two sense-pure synonyms (acoustic/bass) is evaluated.

In the first condition, a corpus of 8,000 sentences was generated from this grammar ("man catch bass", "woman play bass"). Each sense of the word *bass* was equally

frequent; the fish-sense made up half of the total sentences and the guitar-sense made up the other half. To measure the similarity of *bass* to its fish-sense and *bass* to its guitar-sense, the cosine similarity between the vector representation for *bass* and its two sense-pure synonyms *trout* and *acoustic* were calculated, respectively.

In the second condition, a corpus of 5,332 sentences was generated from the grammar—one sense of *bass* was dominant and the other subordinate. The dominant sense made up 4,000 of the total sentences and the subordinate sense made up 1,332. Thus, the subordinate sense was 1/3 as frequent as the dominant sense. Similar to the first condition, to determine the bias created in semantic space by CI, the similarity of *bass* to the dominant sense and *bass* to the subordinate sense was measured using the cosine similarity of the vector representations produced by each model.

The word2vec models used in this paper are both implemented using TensorFlow. Additionally, it is important to note that the implementation of the word2vec model in this experiment is different than both Mikolov et al.'s (2013) model and the model that was originally used in Dachapally & Jones' (2018) experiment. The full word2vec model as implemented by Mikolov et al. necessarily includes negative sampling and subsampling of the training data. Negative sampling is the practice of including negative information in the training data and subsampling is a method that results in less frequent words being sampled more often than frequent words. The model used by Dachapally & Jones used a different loss function called noise contrastive estimation which is common in the language modeling community because it is able to handle large input sizes. The model used in this experiment was purposely changed in order to be the most similar to the models previously used to implement EWC. This model uses cross entropy loss and does not use negative sampling or subsampling which may be responsible for the differences seen in the results of this paper.

Results

Figure 2 shows the cosine similarity of the vectors produced by word2vec, EWC, and the RVA in the case where sense 1 and sense 2 of *bass* are equally frequent. The pattern produced by word2vec is consistent with the findings in Dachapally and Jones' (2018) original experiment. When the model was trained in random order, the *bass-sense1* and *bass-sense2* similarities produced were approximately equal. When trained in sequential order, the sense which was sampled most recently ended up having a higher similarity to *bass*. The same procedure was repeated using EWC and the RVA. After exploring various parameter settings of both, we found that implementing EWC had virtually no effect on the results of the first experiment and that vector similarities produced by the RVA model were unaffected by CI.

Figure 3 shows the cosine similarity of the vectors produced by word2vec, EWC, and the RVA in the case where one sense is dominant and the other is subordinate. The pattern produced by word2vec is once again consistent with Dachapally and Jones' (2018) findings. When trained in random order, the dominant sense is more similar to *bass* than the subordinate sense. When trained in sequential order, the effects of CI reverse the frequency effects; when the subordinate sense of *bass* is trained last it becomes more similar to bass than the dominant sense. When the same procedure was performed using EWC and the RVA, we saw similar results to the first condition. The addition of EWC did not change the performance of word2vec and the RVA model was once again unaffected by CI.

EWC adds one additional parameter to the word2vec model, λ, which controls the importance of Task A compared

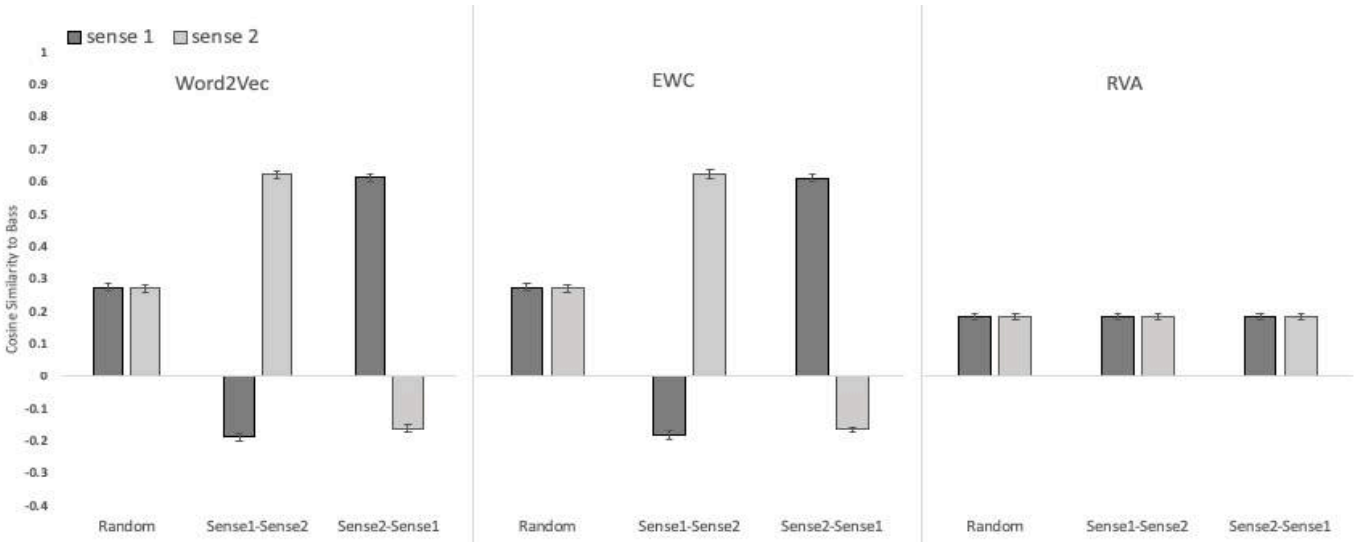

Figure 2. The y-axis represents the cosine similarity of vectors produced by word2vec, EWC, and the RVA. The x-axis represents one of three training orders: random order, sequential order with sense 1 first then sense2, and sequential order with sense 2 first then sense 1. Sense 1 and sense 2 are equally frequent in this case. CI is present in both word2vec and EWC while the RVA is unaffected by CI.

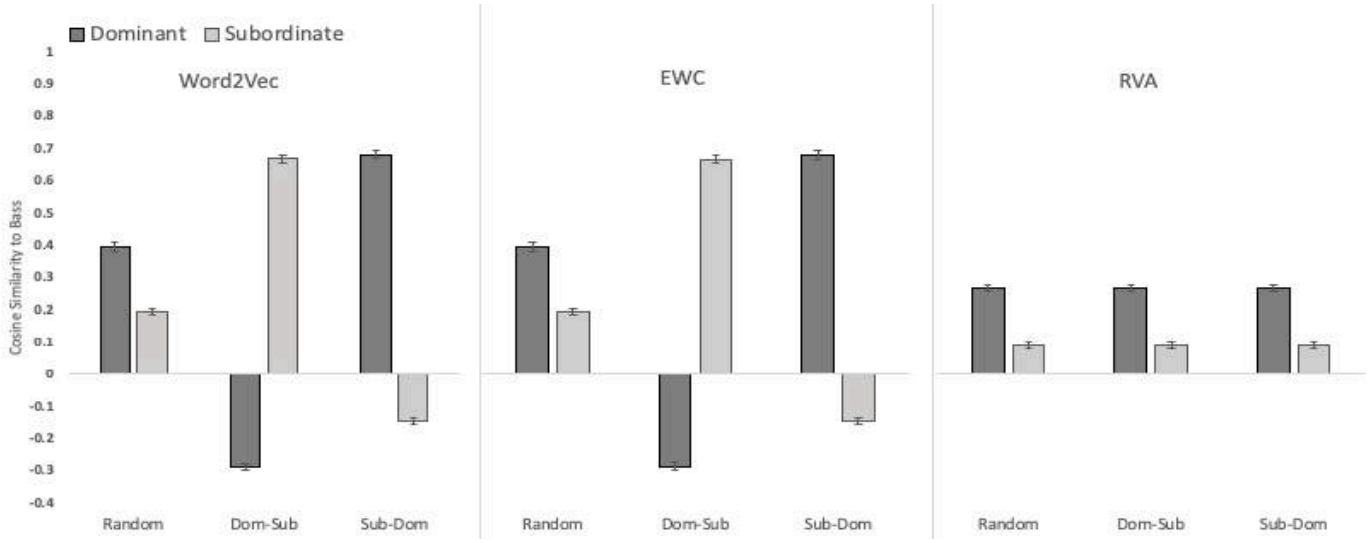

Figure 3. The y-axis represents the cosine similarity of vectors produced by word2vec, EWC, and the RVA. The x-axis represents one of three training orders: random order, sequential order with the dominant first then the subordinate sense, and sequential order with the subordinate sense first then the dominant sense. CI is present in both word2vec and EWC while the RVA is unaffected by CI.

to Task B. For both conditions in the first experiment, the value of λ had little to no effect on the final semantic representations. The results shown in both Figure 2 and Figure 3 are representative of the results obtained by any value of λ.

Experiment 2: Effects of CI on EWC and RVA in Natural Language

The texts used in this experiment are sourced from the TASA corpus (Landauer & Dumais, 1997). TASA contains language from textbooks with metadata tags which allowed us to train the models on distinct senses of a homonym without overlap. The same set of homonyms used in Dachapally and Jones (2018) was used for this experiment. They identified a sample of 14 homonyms that exist in the TASA corpus using the homonym norms from Armstrong, Tokowicz, and Plaut (2012) which determined homonyms with distinct meanings as rated by human participants.

The 14 homonyms were divided into two groups: sense-balanced and sense-imbalanced. We classified the two senses of a homonym as sense-imbalanced if one sense was at least twice as frequent in the TASA corpus, otherwise the two senses of a homonym were classified as sense-balanced. An example of a sense-imbalanced homonym is the word *slip*—the "fallen out of place" sense occurred across science contexts an equal number of times as the "shopping receipt" sense occurred across business contexts. An example of a sense-imbalanced homonym is the word *gum*—the "chewing candy" sense occurs approximately 5 times as often in language arts contexts than the "tissue surrounding teeth" sense occurs in health contexts. The sense-balanced homonyms are the counterpart to the first condition in the first experiment where the two senses of bass are equally frequent. The sense-imbalanced homonyms are the counterpart to the second condition in the first experiment where one sense of the word *bass* was dominant over the other. We then trained the word2vec model, the EWC model, and the RVA model on the entire corpus under three different order conditions. The first condition randomized the training order, the second condition was *sense1* first then *sense2* order, and the third condition was *sense2* first then *sense1* order. Cosine similarities between the target word vector and the two sense vectors were then calculated for each homonym set.

Results

The most common version of word2vec used for non-trivial training data is the model implemented within the Gensim Python library (Rehurek & Sojka, 2010). This model is optimized using C and is consequently very fast and effective. This is the model used by Dachapally & Jones in their second experiment to test for CI in natural language corpora. That model, however, is not directly compatible with the EWC implementation from our first experiment. For this reason, we did not use the Gensim model. Instead, we implemented a model in TensorFlow which is more similar to the model used in our first experiment and is compatible with EWC. However, there are some additional differences between the base models in our first experiment and the current experiment. In order to scale up to natural language, we had to include negative sampling and change the loss function to noise contrastive estimation. The model used in the previous experiment did not use negative sampling, but the model was unable to learn well from the natural language otherwise, so it was added. Additionally, while our first implementation of word2vec used a SoftMax layer to learn with a cross entropy loss function, the implementation in this experiment used noise contrastive estimation because the SoftMax method simply does not scale up well. The RVA model used in this experiment is the same model we used in the first experiment.

Figure 4 shows the results of training word2vec, EWC, and the RVA on the sense-balanced homonyms from TASA. The pattern of cosine similarities produced by word2vec and EWC are consistent with the results from the artificial language. When trained in random order the target words have approximately equal similarities to both of its senses. When trained sequentially, we see the same issue that occurred in the first experiment—the sense that was trained last becomes more similar to the target word. The RVA model shows the same pattern exhibited in Experiment 1—the similarity between the target and its two senses remain consistent no matter the training order.

Figure 5 shows the results of training word2vec, EWC, and the RVA on the sense-imbalanced homonyms from TASA. The cosine similarities produced from word2vec and EWC are consistent again with the results from the artificial language. Similarly, the cosine similarities produced by the RVA are consistent with the results from the artificial language and do not appear to be dependent on training order.

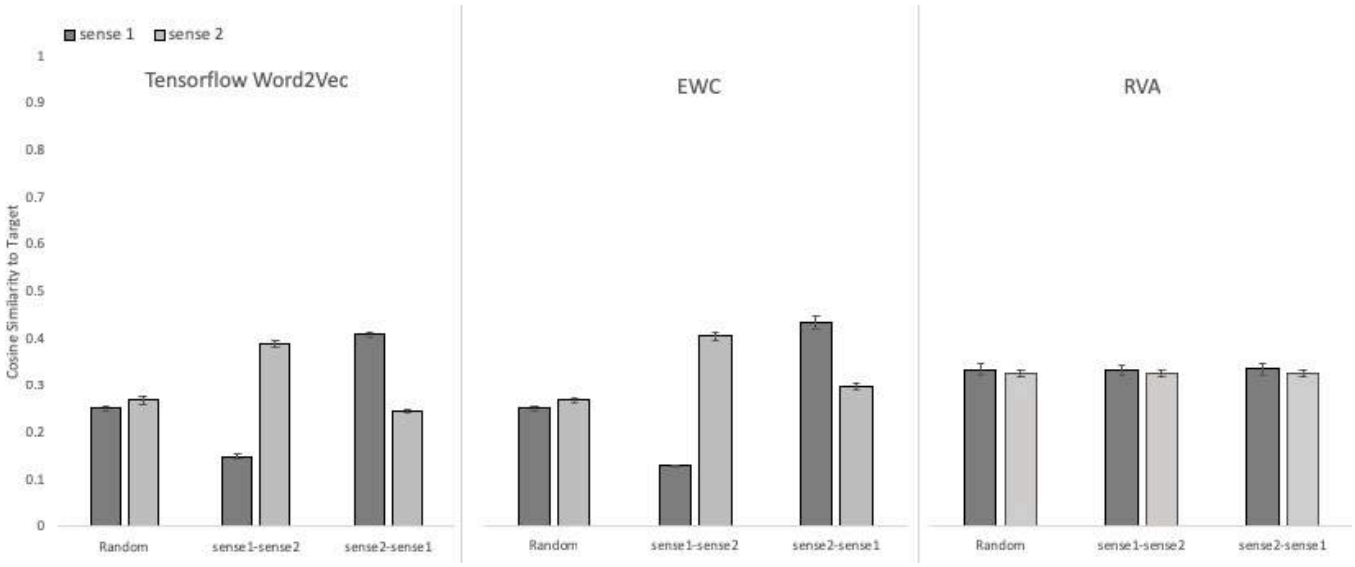

Figure 4. The y-axis represents the cosine similarity of vectors produced by word2vec, EWC, and the RVA when trained on sense-balanced homonyms from the TASA corpus. The x-axis represents one of three training orders: random order, sequential order with sense 1 first then sense2, and sequential order with sense 2 first then sense 1. CI is present in word2vec and EWC while the RVA is unaffected by CI.

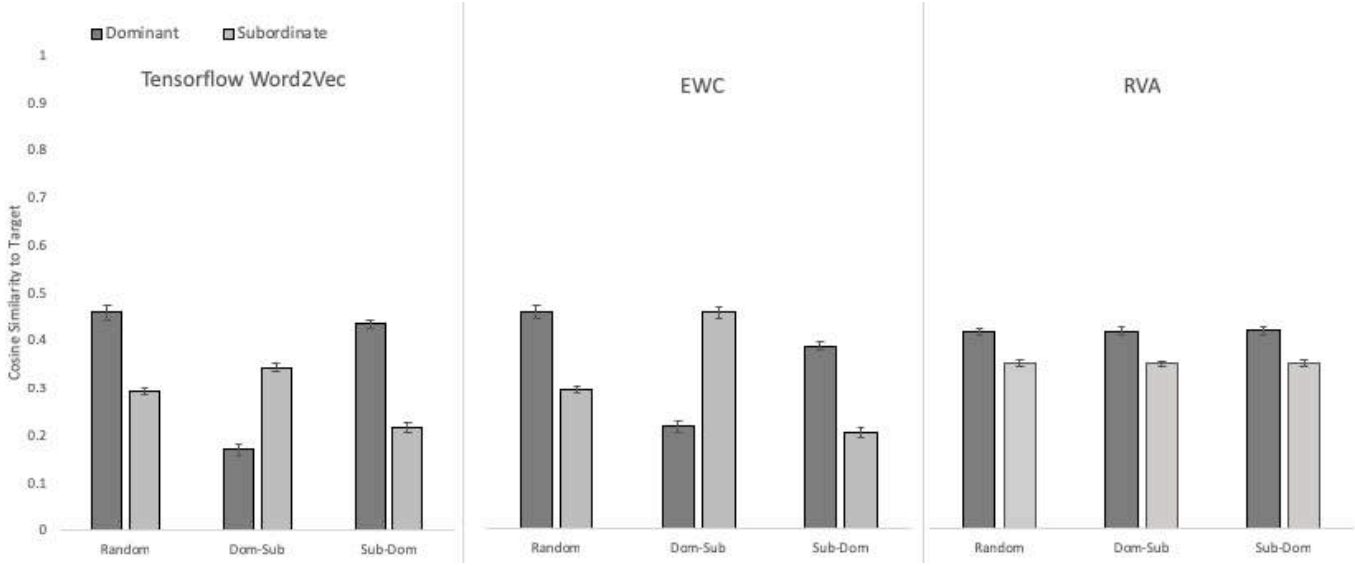

Figure 5. The y-axis represents the cosine similarity of vectors produced by word2vec and the RVA when trained on sense-imbalanced homonyms from the TASA corpus. The x-axis represents one of three training orders: random order, sequential order with the dominant first then the subordinate sense, and sequential order with the subordinate sense first then the dominant sense. CI is present in word2vec and EWC while the RVA is unaffected by CI.

Discussion

The results of this study suggest that efforts to mitigate the effects of CI need to be interdisciplinary. Within the machine learning community, insulating, or "fixing", predictive DSMs from CI is an emerging area that has seen some innovation in recent years. However, suggested solutions so far only consider the problem as it relates to strictly machine learning tasks such as categorization or image classification tasks. This study has shown that solutions from the machine learning community are not guaranteed to work when applied to tasks from different fields.

While Kirkpatrick et al. (2017) were able to show promising results from EWC on categorization tasks, the method was unable to prevent CI when applied to semantic modeling. This may be because the goal of EWC is to prevent the weights of a predictive neural network from changing based on how much information each weight carries about the *true class* of each training item. The connection between training items and their class is very straightforward in categorization tasks but is not as clear in semantic modeling tasks. When a predictive neural network learns a word representation, it is not explicitly predicting the class of a word but is attempting to predict which words belong or don't belong in context with a target word. Additionally, the window size is a variable parameter in these models which can be greater than 2, implying that a target word could have multiple "true classes" if we consider context words the class of the target word.

Additionally, EWC as it is now is not theoretically plausible for any task which requires unsupervised learning because the new loss function must be "turned on" when the network is learning a second task. This is especially cumbersome in NLP where it is impossible to supervise learning to the extent which EWC requires. Furthermore, EWC is unable to scale up well with its current implementation. Because it was designed to prevent CI in categorization tasks, it requires each training item to have a true class. This requirement prevents more efficient sampling methods which have been standardized in the DSM literature, such as noise contrastive estimation, from being used in conjunction with EWC. Similarly, calculating the Fisher Information for each node in a network becomes computationally expensive when the vocabulary and network gets large.

Introducing the RVA model as a possible solution to CI is a preliminary attempt to approach the problem of CI from the perspective of cognitive science. Within the cognitive science community, many researchers assume that the brain is primarily a predictive learner, when in reality it learns using both prediction and co-occurrence methods. Because of the tendency to favor predictive explanations of learning, predictive DSMs are still the most popular learning models in the field even though the existence of CI implies biologically implausibility. This has been documented by Ratcliff (1990) and McCloskey & Cohen (1989) who both use CI to discredit the biological plausibility of predictive DSMs. While RVAs are not a brand-new idea, they have not become as popular within the machine learning or cognitive science communities as predictive DSMs. However, they are continuous learners, can learn sequentially without incurring CI, and are computationally efficient making them a viable alternative to predictive DSMs in both the fields of cognitive science and machine learning.

While RVAs are promising, they have faced some criticism in the past. RVAs are known to have problems with metric space compression—causing most word similarities to be compressed between 0 and 1—which limits the ability of the model to discriminate between related and unrelated words (Asr & Jones, 2017). It was initially believed that predictive DSMs were able to more accurately discriminate between words because of back-propagation or the connectionist architectures they commonly use. However, recently the role of negative sampling in DSMs has been explored in more depth by Johns, Jones, & Mewhort (2019) who find that the success predictive DSMs have at discriminating between words is due to the inclusion of negative information in the training data—not the use of connectionist architecture or predictive learning method. In fact, when negative sampling information is included in the training data for other DSMs, including RVAs, their ability to discriminate words is on par with predictive DSMs.

Though this paper focused on comparing RVAs to predictive DSMs, RVAs aren't the only possible alternative architecture that could present a solution to CI. Architectures like holographic neural networks and exemplar-based models should also theoretically be immune to CI and incorporate different theoretical frameworks of learning. Holographic neural networks use convolution as an association mechanism to learn words rather than backpropagation and are able to learn complex non-linear patterns with a single layer which makes them more space efficient than predictive DSMs. Exemplar-based models, unlike other DSM models which store a semantic representation, store only episodic context. These models construct semantic meaning from the aggregation of episodic context when presented with a memory cue (Jamieson et al., 2018). Both of these models should be evaluated to determine the effect CI has on their internal semantic representations.

Up until now, the fields of machine learning and cognitive science have both been facing similar problems with predictive DSMs. Unfortunately, there has been little to no interdisciplinary communication to propose solutions. When we consider CI from a cognitive science perspective, we find that there are several possible solutions which haven't been considered yet. These solutions, which are arguably more elegant than continuously trying to "vaccinate" predictive DSMs, have the potential to introduce new mechanisms for artificial learning, assisting with new technological advances that require sequential learning and providing a framework for learning that does not exhibit the downfalls brought on by predictive DSMs.

Making the Implicit Explicit: Effects of Verbalization in Decisions from Experience

Abstract

What do people learn from experience with repeated decisions? Is it merely implicit behavioral tendencies? If so, would articulating or summarizing what is learned change behavior? Online participants (N=126) experienced 100 trials of a decisions-from-experience problem with outcome feedback. Some participants then verbally summarized what they had learned and estimated the probability of the risky gain either for themselves (Self condition) or for another hypothetical player (Other condition); others did not summarize (Control condition). Finally, they faced 20 more decision trials. Verbalizing a social message to another person significantly increased sure choices (that is, decreased risk-taking) in subsequent decision making. In general, participants underestimated the probabilities of both certain and risky prospects, and articulating a summary message (Self or Other) seemed to increase this conservatism.

Keywords: decisions from experience; explicit learning; verbalization; dual process theory

Introduction

In recent decades, research on decisions under risk has focused on two major paradigms, decisions from description and decisions from experience. In the descriptive paradigm, participants receive complete and unambiguous descriptions of available options, potential outcomes of their choices, and the associated probabilities. In the experiential paradigm, participants rely on their personal experience of observing samples of outcome feedbacks repeatedly over time (e.g., Hertwig et al., 2004). In recent years, decisions from experience (DFE) have been found to systematically differ from description-based decisions (DBD). These differences have been termed the "description–experience gap" (Hertwig & Erev, 2009).

There has been growing interest in the field to explore the learning mechanisms behind decisions from experience to help explain the description-experience gap (for a meta-analytic review, see Wulff et al., 2018). One such issue is what types of learning are generated from experience and how such learning affects subsequent choices. Some empirical evidence suggests that experience of outcome feedback can modify choices towards maximization of expected value (EV) (Yechiam et al., 2005). Possible mechanisms that might explain this finding include the implicit learning of more linear decision weights (e.g. Jessup et al., 2008), or the explicit learning of EV-maximizing strategies (e.g. Erev & Barron, 2005; Erev et al., 2017), among others. Chen and Corter (2014) argued that dual-systems account of cognition (e.g., James, 1950; Sloman, 1996; Kahneman, 2003), might be needed to explain the full range of findings.

In the broader research literature on learning and cognitive science, implicit learning is sometimes termed "System 1" thinking, in which individuals learn complex information in an incidental manner, without awareness of what has been learned. In contrast, explicit learning is termed "System 2" thinking, which permits abstract reasoning and hypothetical thinking constrained by working memory capacity, and results in explicit knowledge in the form of verbatim or aggregate representations (Seger, 1994; Evans, 2003).

In particular, two major forms of explicit learning have been well studied. *Self-explanation* during problem solving has proven to be an effective instructional strategy across many domains (Chi et al., 1989; VanLehn et al., 1992; Bielaczyc et al., 1995). When prompted to explain to themselves, participants were more likely to make comparisons and notice subtle distinctions, which then led to the discovery of general rules (Edwards et al., 2014). Meanwhile, *social dialogue* has also been found to promote abstract reasoning and rule formation / use in a category learning task (Voiklis & Corter, 2012), as well as when learning complex systems such as moving gears, biological transmissions, and organisms' living requirements (Schwartz, 1995). In these learning domains, it is argued that social pragmatic constraints of communications compel participants in dialogue to negotiate multiple perspectives to find a shareable representation of the problem, which tended to be abstractions of the deep structure rather than surface features. Such dialogic effects might even underlie well-documented examples of "process gain" in group forecasting and decision making (Kerr & Tindale, 2004) – the so-called "wisdom of crowds".

For these reasons, we hypothesize that explicit verbalizations, especially verbalizations aimed at others, might promote abstraction and enable rule-based or formal reasoning about the decision problem, and thus might yield faster learning towards EV-maximization. To our knowledge

no prior study has examined whether verbalization might help in promoting explicit learning in the context of decisions from experience.

In the present study, we consider how self-verbalizations summarizing experience with outcome feedback (which make the implicit explicit) might affect subsequent risky decision making. Specifically, we examine the effects of verbal summaries generated for others or generated for oneself on learning in the decisions from experience context. Finally, we report some content analyses of the types of verbalizations generated by participants.

Methods

Design

Participants made repeated decisions for a single risky decision problem while experiencing outcome feedback (with no provided description of outcome payoffs and probabilities). Following the verbalization manipulation (described below), they made 20 additional decisions with the same problem.

Overall the experiment had a 3×2 between-subjects design: three types of verbalization conditions and two risky-choice decision problems. Each participant was presented with only one verbalization condition and only one problem.

Participants

126 people, 76 of them male, participated through Amazon's Mechanical Turk website. Participation was restricted to individuals whose location was defined as in the United States. Their ages ranged from 23 to 71, with a mean of 39. All of them were native English speakers and 27% of them had studied statistics or decision-making at some point.

Materials

Two simple decision problems in the gain domain were used: for the risky option, one problem has a high probability of payoff and the other has a low probability of payoff. They were: Problem 1 = ($3, 100%; $7, 60%), Problem 2 = ($3, 100%; $28, 15%). So, for example, Problem 1 offered a choice between receiving $3 with certainty and a 60% chance of receiving $7 (and no reward otherwise).

We used the "minimal information" paradigm from Erev and Barron (2005) – also termed the "partial feedback" paradigm by Camilleri and Newell (2011). Decision problems were shown on the computer screen (Figure 1), with two option buttons side by side, labeled only as "P" and "Q". One button provided the participant with the sure outcome of $3 100% of the time, and the other button was a risky gamble which gave participants either $7 60% of the time or $28 15% of the time, depending on the experimental condition, and $0 otherwise. Sure and risky button positions were left-right counterbalanced between participants.

Procedure

Participants went through a training session of 100 trials and a testing session of 20 trials of the same decision problem, either the high probability problem or the low probability problem.

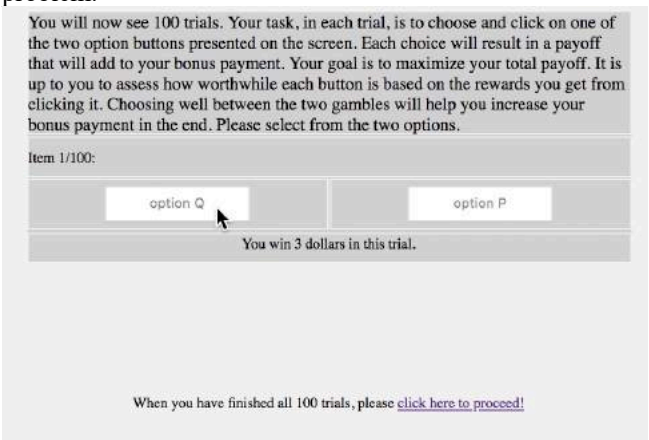

Figure 1: Interface for the training session (first 100 trials): post-trial feedback

In between training and testing blocks, they experienced one of the three verbalization conditions (Other, Self, or Control). In the Self condition, participants summarized for themselves what they had learned (by answering "What have you learned from experience with the 100 trials? What strategy should be used or what choices should be followed in order to maximize total payoff?") and estimated the probabilities of both option payoffs. In the Other condition, participants summarized to another hypothetical player (by answering "Imagine that you have a partner who is about to play this game for 100 trials. What would you advise them in terms of the strategy they should use or the choices they should make, in order to maximize their total payoff?") and estimated probabilities as well. In the Control condition, participants simply answered some demographic questions at this time point, without any requested verbalizations of problem information.

At each trial, once they made a choice using the mouse, the payoff for that selected option was shown. Actual payment for participants varied depending on the outcomes of their decisions. A base payment of $1.50 was adjusted by 0.5% of the participant's total amount of winnings for the total 120 decision trials. Average bonus paid for each participant was US $1.92 (SD = US $0.17).

Results

In this study, we hypothesized that explicit verbalizations of strategies would lead to more accurate probability estimates of option payoffs and a decrease in subsequent sure choices (consistent with EV-maximization), especially when participants were verbalizing to someone else. Thus, the main dependent variables were 1) the proportion of sure choices, calculated as the average proportion of times that participants selected the sure option in the testing session (last 20 trials)

(see b11 and b12 in Figure 2); and 2) participants' estimated payoff probabilities for the sure and the risky options.

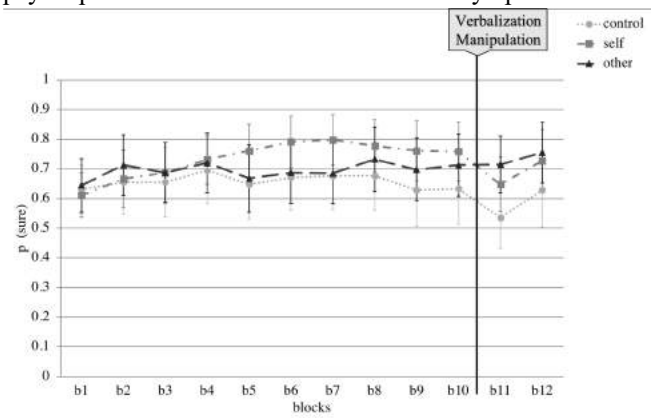

Figure 2: Sure choice proportions over the total 120 trials. Error bars: ± 2 standard errors.

Behavioral Effects: testing session (last 20 trials)

Analysis of covariance (ANCOVA) was conducted to evaluate the effects of verbalization conditions while controlling for the variations among participants' learning experience in the training session. The proportion of sure choices for last 50 trials of training, before the verbalization manipulation, was used as the covariate.

Results showed significant effects of the explicit verbalization manipulation on the proportion of sure-thing choices in the last two blocks (Figure 3), $F(2,119) = 3.80$, $p=.025$. However, the effects were not consistent with our hypothesis of increased maximization in the two verbalization conditions. Rather, in the Control and Self-Verbalization conditions a transient increase in risk-seeking (alternatively, in maximization) was observed (apparent in Figure 2), indicated by a sudden drop in sure choices after the pause between training and testing blocks, mean P(sure) = .641 and .623, respectively. This may indicate a transient increase in exploratory behavior. Participants in the Other-Verbalization condition maintained a relatively consistent high level of sure-alternative choices, P(sure) = .744. Planned contrasts showed that the proportion of sure choices in the last 20 trials after verbalization were significantly higher in the Other-Verbalization condition compared to that in the Control and Self-Verbalization conditions, $t(80)=2.23$, $p=.027$; $t(82)=2.53$, $p=0.013$, respectively.

Subjective Estimates

Participants were quite conservative in their probability estimates, underestimating probabilities of both the sure option (Figure 4) and the risky options (Figure 5). Such probability underestimation is particularly surprising for the sure events, because any sample of a sure option must consist of 100% payoff outcomes. One way to explain this is to note that in this partial-feedback paradigm, when a participant chooses the risky option, the outcome for the button associated with the sure-thing distribution is not revealed. Thus, the participant may believe that some non-payoff outcomes could be occurring for what we know to be the sure-thing option on these "blind" trials. And in any small sample of trials, it is difficult to distinguish a sure-thing from a high-probability event, just as it is known that in decisions from experience people frequently fail to distinguish between low-probability and zero-probability events (see, for example, Kunreuther et al., 2001; Hertwig et al., 2004).

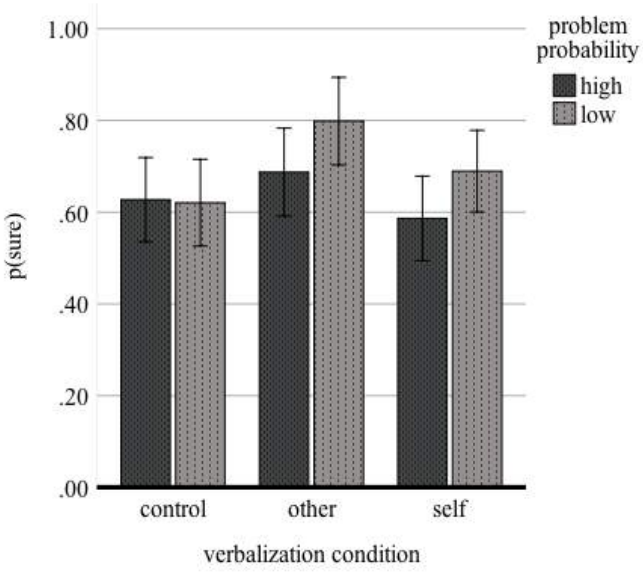

Figure 3: Sure choice proportions across three verbalization conditions in the testing session (last 20 trials). Error bars: ± 2 standard errors.

Furthermore, articulating a summary message (to Self or Other) significantly increased this underestimation of the 100% probability of the sure option, $F(2,123)=10.270$, $p=.012$, again contrary to our hypothesis that verbalization would increase accuracy. However, when participants estimated the probability of payoff for the risky option, this drop in the subjective estimate (an increase in conservatism, again resulting in lower accuracy) due to verbalization was only marginally significant for the high-probability problem $F(2,59)=2.943$, $p=.061$, and was not significant for the low-probability problem, $F(2,59) = 2.222$, $p=.117$, perhaps due to a floor effect, or because conservatism in this case would mean estimating the probability as less extreme (i.e. farther from 0).

Verbalization Content

The above results demonstrate that the explicit verbalization manipulation has an effect on subsequent decision choices as well as on subjective estimates. However, the verbalization manipulations did not increase the accuracy of the subjective estimates as we expected, and even decreased it in some cases.

To explore why, we conducted a content analysis of the strategies reported by participants in the two verbalization conditions (40 statements in the Other condition, 44 statements in the Self condition). Specifically, we were interested in examining the detailed content, both as a manipulation check and to explore the major concepts and terms used by participants in communicating the problem information. We used two raters to categorize the verbalizations (initial κ=0.66), who discussed the disagreements until they reached full agreement, $\kappa \geq .99$.

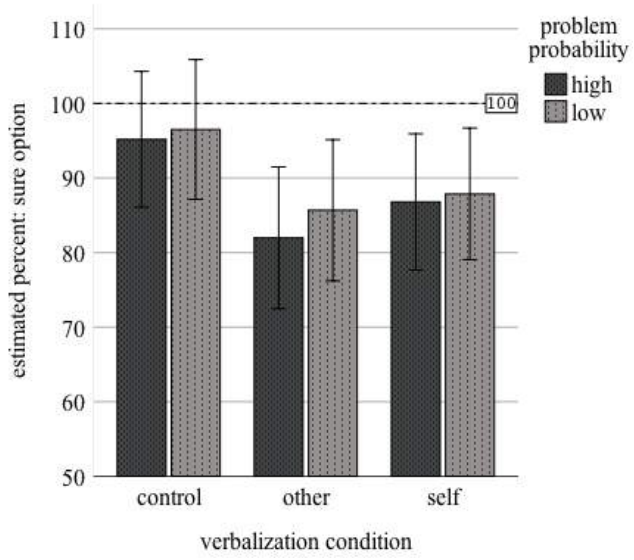

Figure 4: Estimated payoff percent for the sure option (objectively = 100% in both high- and low- probability problems). Error bars: ± 2 standard errors.

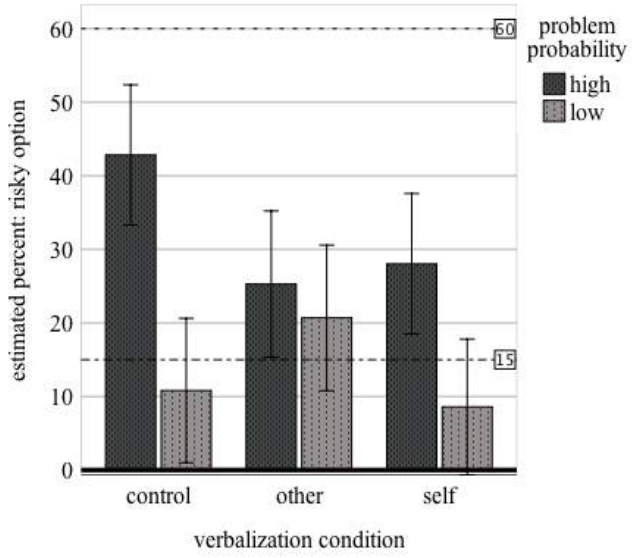

Figure 5: Estimated payoff percent for the risky option (objectively = 60% in the high-probability problem, = 15% in the low-probability problem). Error bars: ± 2 standard errors.

We divided the analysis into two phases. An initial classification suggested ten categories of utterances (which we will refer to as "strategies", for convenience): *no strategy/intuition/luck, payoff value, payoff frequency, temporary switch, sequence, risk-reward tradeoff, probability and EV estimate, recommend the sure option, recommend the risky option,* and *recommend mixed options*. Next, we tested the association of specific strategies with subsequent decision making (specifically, with the proportion of sure option choices after the verbalization manipulation), using one-way analysis of variance.

In general, participants verbalized a wide range of strategies, ranging from 1 to 5 when verbalizing to Others and from 1 to 6 when verbalizing to Self. And a majority of participants in each condition verbalized at least 2 strategies. The two verbalization conditions seemed to have very different profiles of strategy use (Figure 6). Participant who verbalized to themselves were significantly more likely to describe payoff frequency (75%), compared to those verbalized a social message (48%), $\chi^2(1; N=52) = 6.719$, p= .01 < .05. Participants tended to simply recommend the sure option more often when they were writing a social message (55%) compared to verbalizing to themselves (43%), however this difference did not reach significance. In both conditions, only a few participants mentioned calculating probability or expected value (5% in Other-Verbalization and 14% in Self-Verbalization), although more mentioned reasoning about tradeoffs between risk and reward.

Consistent with previous findings, mentions of switching between options to learn about payoff patterns or follow a sequential pattern were observed. Examples include: *"the first option had a pattern between getting 0 and 7 dollars while the other was 3 every time. I thought I could discern the pattern and only hit the first option when I thought the 7 would be there." "Keep pressing the left button until you get more than 2 zeros in a row. Then press the right button about 2 or 3 times, then go back to pressing the left button.").* In the Other-verbalization condition, 15% of participants mentioned switching or sequential dependencies in outcomes, compared to 9% in the Self-Verbalization condition. Some of these utterances may be taken as indicating that a participant exhibits some form of the gambler's fallacy, in which they believe a run of wins will tend to end, or the hot hand fallacy, where they believe such runs tend to continue (Bar-Hillel & Wagenaar, 1991). A number of participants also recommended mixed options as a better strategy than sticking to one option (cf. Chen & Corter, 2006).

Overall, more (85%) Social messages (compared to Self messages) tended to prescribe an action to be taken (example: *"Go with the three dollars most of the time, but occasionally try your luck to get the 7 dollars, since it has fairly good odds."*), $\chi^2(1; N=44) = 32.574$, $p < .001$; while Self messages were more likely (75%) to simply describe the past experience (example: *"Second option had consistent payoff. I am risk averse so I only tried the other a couple of times and*

hit zero so I stayed with the sure thing."), $\chi^2(1; N=45) = 17.058$, $p < .001$ (following "prescriptive rule" vs "descriptive rule", Bell et al., 1988).

In a one-way ANOVA testing if participants' choice behavior differed on the basis of their verbalized content (Figure 7), we found that the proportion of sure choices were significantly higher if participants recommended the sure option, $F(1, 82)=7.063$, $p=.009 < .05$; while significantly lower if they depended on no strategy or pure intuition and luck, $F(1, 82)=4.032$, $p=.048 < .05$, mentioned a temporary switch, $F(1, 82)=4.601$, $p=.035 < .05$, or recommended the risky option, $F(1, 82)=5.296$, $p=.024 < .05$.

Discussion

In this study, we asked participants to articulate what was learned from experience, either to themselves or to others. We did not find evidence to support the original hypothesis that explicit verbalization, especially verbalizing to someone else, promotes abstract rule reasoning and thus yields better learning towards EV-maximization. Indeed, the data revealed a very different pattern. Delivering a social message tended to increase the underestimation of the subjective probability estimates (a form of conservatism), and subsequently led to less EV-consistent decision making, compared to the purely implicit learning condition in which no verbalization was prompted.

We also had hypothesized that the verbalization manipulation may tend to shift people from implicitly motivated behavior to the use of explicit strategies. These strategies can be either rational and effective, such as drawing on memory for outcome feedback and reasoning about tradeoffs, or heuristic in nature, such as choosing a simple strategy or prescribing the same. However, very few participants in either verbalization condition reported calculating probability or expected value. Instead, in Self summaries they tended to simply describe past learning experience, especially summarizing frequency information; while in summaries for Others, they often simply prescribed strategies (positive or avoidance) to others.

One potential reason for this lack of benefit from explicit verbalizations is that prior studies showing learning benefits from social dialogue (e.g., Schwartz, 1995; Voiklis & Corter, 2012) examined situations where participants took many rounds to negotiate multiple perspectives and generate abstractions and rules. In contrast, the one-way, single-round verbalizations in this study may induce considering another's perspective to some degree, but perhaps not enough to spur abstraction and use of explicit or formal strategies. This is consistent with the finding from research on collective intelligence that the equality in distribution of conversational turn-taking is correlated with a higher collective intelligence factor (Woolley et al., 2010). Moreover, relatively naïve participants may lack expert knowledge or language to convey sophisticated strategies like expected value in the risky decision domain.

We found that verbalizations, especially in the form of a social summary message to another person, led to a higher level of sure choices in subsequent decisions, perhaps by "freezing" the recommender's strategy and inhibiting further exploration of decision options (see discussion below). Also, verbalization seemed to increase underestimation of probabilities (for both certain and risky events), perhaps indicating a form of "social conservatism", as if the participants were cautious about their limited information acquired from experience and discounted their judgments to communicate a "safer" message socially. This is consistent with Benjamin and Budescu's (2015) findings about advice giving, in which an implicit learning mode (decisions from experience) resulted in more risk aversion and acknowledgement of information uncertainty.

Moreover, some previous studies using the repeated decisions with description paradigm seem to show that choice behaviors are mainly affected by experience while explicit descriptions are considered only when they carry novel or

inconsistent information that cannot be inferred from the feedback (Barron et al., 2008; Weiss-Cohen, et al., 2016); more often the descriptions seem to be neglected (Jessup et al., 2008; Lejarraga & Gonzales, 2011). When participants were writing a social message to others, they might be more conscious of the utility of information, assuming that their verbalizations would be taken into consideration. It may be that in this situation, underestimation of payoff probabilities (a "sin" of omission, in a sense) is seen as less undesirable than overestimation of payoff probabilities (a "sin" of commission).

As noted, in the Control and Self-Verbalization conditions, the final 20 test trials elicited a period of exploratory behavior, but not in the Other-Verbalization condition. Furthermore, participants in the Self condition tended to describe their past experience with the 100 trials (i.e. payoff frequency and value) while those in the Other condition tended to prescribe a future action (i.e. recommend one option or mixed options). This may indicate a social motive to seem consistent when giving advice, in line with the behavior consistency principle (Cialdini, Trost, & Newsom, 1995), well established by dissonance and balance theories, (Festinger 1957; Heider 1958) and the "foot-in-the-door" effect (Freedman & Fraser 1966). According to Group-Centrism (Kruglanski et al., 2006), the need for cognitive closure within the group induces pressures to opinion uniformity, rejection of deviates, resistance to change, conservatism and the perpetuation of group norms, and results in reduced information exchange and "premature consensus" or "early closure" (Kruglanski & Webster, 1996), and process losses that leads to less optimal group performance (Steiner, 1972). Furthermore, the bias towards shared information, once explicitly formed, can also lead to misinterpretation of new information that is inconsistent with already formed bias (Kerr & Tindale, 2004). Social context, here in the form of a social probe to verbalize strategies explicitly, might also exacerbate individuals' desire to be consistent in their explicit strategy verbalizations, probability estimates, and subsequent behaviors.

In conclusion, our results do show verbalization effects on implicit learning in decisions from experience. This evidence can be seen as supporting accounts that recognize an explicit learning aspect in decisions from experience as well as the importance of social contexts, and also as supporting dual-process accounts of repeated decisions with outcome feedback. Further exploration of the verbalization effect and of the interplay between experience and abstractions of experience might consider a broader range of factors that contribute to rule abstraction, to better understand how people can make informed decisions that combine explicit reasoning and implicit experience. This future research might find a way to integrate research on mental representations in decisions from experience (Camilleri & Newell, 2009), advice giving in decision making (Benjamin & Budescu, 2015) and information shareability in the general learning domain (Freyd, 1983).

Same Words, Same Context, Different Meanings: People are unaware that their own concepts are not always shared

Abstract

A long-standing assumption in cognitive science has been that concepts are shared among individuals for common words. However, given that concepts are formed by the data we observe, and observations vary wildly across individual experiences, our concepts are not likely identical. Here, we present data in which 104 participants answer questions regarding their beliefs about the definitions of common everyday words, and the degree to which they think others agree. Our results suggest that even for common words, there exist many distinct extensions of ordinary and political concepts across individuals. There is also a pervasive bias which leads individuals to overestimate the degree to which others agree, which may explain why "talking past each other" is an anecdotally common experience when discussing important topics.

Keywords: Concepts; Metacognition; Individual Differences; Miscommunication

Introduction

In 1964, the United States Supreme Court heard Jacobellis v. Ohio, a case in which theater owner Nico Jacobellis was fined for exhibiting a dramatic French film about adultery that contained material which the state considered obscene. Justice Potter Stewart, in explaining why he believed the film did not violate the state's obscenity laws, stated that he was unable to define pornography but also said "I know it when I see it". In this instance, the highest authority in the country was tasked with categorizing an edge-case which would affect the lives of millions and he admitted that his criteria for categorization was difficult to articulate.

Even words with seemingly precise meanings can be deceptively ambiguous. Especially if neither party anticipates a problem because of the word's commonality. These non-obvious misalignments can have serious consequences. For example, toxicologists and non-toxicologists likely have different concepts for the word "hazard". Toxicologists define the word as referring to anything that could potentially cause harm—even if unlikely. For example, a toxicologist would categorize water as a hazard because it is possible to overdose if excessive quantities are consumed. However, for non-toxicologists, the word "hazard" refers to things which are dangerous—*likely* to cause harm, not simply capable of causing harm under specific or unlikely circumstances. This misalignment caused problems when toxicologists with the World Cancer Association labelled coffee as a known hazard for developing cancer in mice and cell cultures. A California judge, who likely possessed the concept synonymous with "dangerous", interpreted the report as meaning coffee was dangerous for consumers and ruled that California had to warn consumers.

These examples illustrate that not only can words be hard to define, but we sometimes have very different ideas about what they mean. When two people use the same word, they may assume that they are each referring to the same (or at least a similar) concept. But how often is this assumption correct? Communication requires involved parties to understand each other correctly. A necessary component of this during language use is that words map onto the same meanings for all conversation partners, or, alternatively, that they are at least aware of the possibility for misalignment. If this is not in fact occurring, it could provide new insights into why and how people disagree and misunderstand one another. Understanding these dynamics could, likewise, be used to facilitate better communication in general. Thus, conceptual misalignment has important implications in a wide range of domains, including public policy, diplomacy, education, and politics.

All theories of concepts involve learning via interaction with and data accumulation from the world. These experiences vary (often wildly) across individuals. If individuals are using the same word to refer to two different concepts, confusion and miscommunication may occur. There is some empirical evidence that at least some of people's concepts do in fact vary across individuals (McCloskey & Glucksberg, 1978). Labov (1973) asked participants to categorize objects as either a "cup" or a "bowl" as he varied the heights and widths of the objects. For extreme values of either height or width, there was widespread agreement on the classification. However, as the values became more moderate, the classifications became more subjective. This demonstrates that people's concepts are fuzzy along the edges, even with everyday

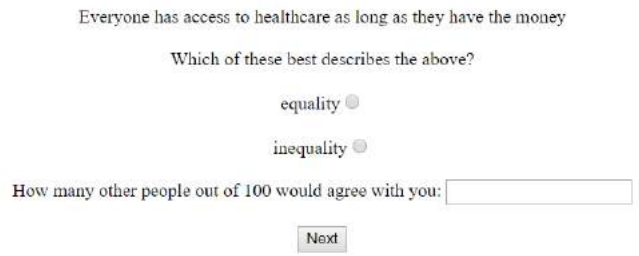

Figure 1: Participants saw 200 randomized trials as above.

objects.

If people do not agree even on category boundaries for concrete objects, how much misalignment might exist among more abstract concepts? And are people aware of the fact that concepts vary across individuals? To date, there has been no work exploring these questions.

Our first goal is to quantify individual differences in conceptual representations. By utilizing an approach which targeted edge-cases, we optimized our chances of detecting differences in definitional boundaries. Edge-cases are both theoretically and functionally important. They are crucial to conceptual definitions, and are arguably where the highest utility can be found due to the possible illusion of confidence people have about others' definitions. For example, common debates about abortion, gun-control, and welfare hinge on edge-cases.

We did this by collecting peoples assessments of whether particular scenarios applied to specific concepts. We then applied a clustering algorithm to group participants by similarity of their conceptual representations. We borrowed techniques from machine learning that have previously been applied in biology and ecology in order to estimate the total number of distinct representations on a population level. Our second goal is to quantify peoples metacognitive awareness of differences in each others conceptual structures. If people are unaware of the variability in others classifications of everyday concepts, it would make communication more difficult. In this paper, we will probe the variability of people's concepts and measure their awareness of any differences.

Methods

We recruited 104 participants on Amazon Mechanical Turk and queried them regarding their beliefs about whether a particular word applied to a given phrase or sentence. For each of 200 trials (see Figure 1) a phrase or sentence was displayed. The participant was then presented with two opposites and asked to classify the phrase or sentence. For example, after reading the sentence "A murderer is killed", participants answered whether they thought it was *justice* or *injustice*. They also answered how many people out of 100 would agree with them.

Word	Sentence	Reliability Pair
justice/injustice	A guilty man is executed	A man who is guilty is put to death
adult/child	A 17-year-old	An individual who is almost 18

Table 1: Sample reliability sentences

Word	Phrase/Sentence
equality/inequality	Taking wealth from the rich and giving it to the poor
fairness/unfairness	Paying none of your workers because you don't have the money for everyone
justice/injustice	A thief's stolen property is stolen
peace/conflict	A field filled with corpses after a war is over
honesty/dishonesty	Making true but misleading statements
safety/danger	Preventing you from drinking soda
freedom/prohibition	Making murder illegal
transparent/secretive	Releasing your taxes behind a paywall
education/ignorance	Home schooling in the US
healthcare/illness	Insurance not paying for your medical bills despite you paying your premiums
day/night	Dusk
hot/cold	A temperate day
light/dark	Classical music
friend/enemy	A close acquaintance who insults you all the time
boy/girl	A transgender woman
love/hate	Spanking a child so that they will not become spoiled
adult/child	A 17-year-old
good/bad	An entire building full of murderers was destroyed
sun/moon	A star that orbits a planet
ceiling/floor	The top surface in an upside-down house

Table 2: Sample stimuli presented to subjects in the experiment.

Word Choices

Stimuli were divided into ten political words and ten frequently used nouns. Half of all participants answered questions regarding political words while the other half answered questions about the nouns. Political concepts were chosen by asking 130 mTurkers to list the top ten words they felt were most relevant to politics. The top ten most frequent words were then chosen as our political concepts. The ten nouns

were chosen by querying the MRC Psycholinguistic Database for the ten most frequent nouns and omitting words which were close semantic duplicates (e.g. boy vs. man). This was done in order to maximize semantic variability in our word pairs as much as possible.

Sentence Construction

The specific sentences participants are responding to for each word are of crucial importance. One might imagine a set of sentences could be chosen for the word "boy" which would result in near universal agreement among participants. On the other hand, sentences could be constructed in such a way as to maximize disagreement (a 50/50 split for each binary response). If our goal is to discover whether people possess different concepts, the latter approach is appropriate. Specifically, since edge cases are often where the greatest variability lies, we will probe people's classifications of edge cases. This approach allows us to get a rough estimate of the maximum conceptual variability for each word (see Table 2 for a sample of phrases/sentences).

Reliability

Each trial had an associated reliability trial which presented the same phrase or sentence except for a minor modification which did not change the meaning. These were added in order to assess subject attention and reliability. (see Table 1 for a sample of phrases/sentences)

Analysis

Ascertaining whether participants possess different conceptual representations for a given word is a non-trivial problem. We first run into the problem of how to quantify differences between conceptual representations. What does it mean for person A's concept of "justice" to be twice as far from person B's as person C's is? We address this by representing each person's concept using a binary response vector. Next, we run into the issue of measurement noise and participant reliability. If person A answers that "A clear night with a full moon" is "light" but also answers that "A cloudless night with a full moon" is "dark", it would be reasonable to label these responses as unreliable noise. The "reliability" sentences provide semantic duplicates for each sentence, allowing us to quantify the reliability of participants in the task.

Once we have quantified participants' reliability and concepts, our last major issue is deciding how much of a difference between two concepts is sufficient to call them distinct. For the concept blue, one individual might be centered on the 470 nanometer wavelength while another might be centered on 480 nanometers. What would not be clear, however, is whether that disparity is sufficiently different so as to reasonably characterize the individuals as having separate concepts for blue. We approach this challenge by clustering our participants such that people with similar concepts will be grouped in the same cluster. We do this by adopting Bayesian approaches that find the optimal partition of participant responses using a trade-off between data-fit and simplicity. If the responses of one participant are very similar to those of another participant, they will likely be placed in the same cluster. On the other hand, if two participants have very different responses, they will likely be placed in different clusters, despite the process's overall conservative preference for fewer total clusters (Anderson, 1991). More specifically, we will use a Chinese Restaurant Process prior. If $[x_1, x_2, \ldots, x_k]$ is a vector denoting how many of the n subjects have each concept (for a given word), then the CRP prior is

$$P([x_1, x_2, \ldots, x_k]) = \frac{1}{n!} \prod_i (x_i - 1) \tag{1}$$

Within each "table" of the CRP, we use a Beta-Bernoulli likelihood, meaning that subjects assigned the same cluster are assumed to generate the same latent vector of binary answers. This vector is then measured with noise (α), and the latent probabilities are integrated out. Thus, if y_j and n_j are the number of "yes" and "no" responses in a given cluster assignment to the j'th item of a given concept, then the likelihood is,

$$\prod_j \frac{\Gamma(2\alpha) \cdot \Gamma(y_j + \alpha) \cdot \Gamma(n_j + \alpha)}{\Gamma(y_j + n_j + 2\alpha) \cdot \Gamma(\alpha)^2 \cdot y_j! \cdot n_j!} \tag{2}$$

With this setup, we used a Gibbs sampler to sample from the posterior on clusters given the responses for each concept. This analysis provides us with the number of distinct conceptual representations possessed by our participants. While this is useful information, what we are actually interested in is the total number of conceptual representations which exist on the planet. Ecologists have faced a very similar problem in estimating the number of species which exist. Often, they possess observed counts of individuals and of species in a given area (the Amazon rainforest for example) and would like to estimate the true number of species for that area (Bunge & Fitzpatrick, 1993). Here, we use the number of sampled concepts across the number of sampled individuals to estimate the total number of concepts which exist across the population of Earth for each of our words. Given that our clustering algorithm has a conservative preference for fewer clusters, this preference will extend to our global estimate.

Results

We excluded participants who did not have a reliability greater than 70% (9 out of 104 participants). We also excluded participants who gave the same answer to all agreement-prediction questions (2 out of 95 participants). We did not require participants to perform flawlessly, however, as this would be an unrealistically high bar for humans completing so many trials. Of the remaining participants, their probability of giving the same answer to both questions in the reliability pair was a respectable 86%.

There are about five distinct concepts per word

Figure 2 shows the estimated true number of concepts (y-axis) across 4,000 iterations of our clustering algorithm (us-

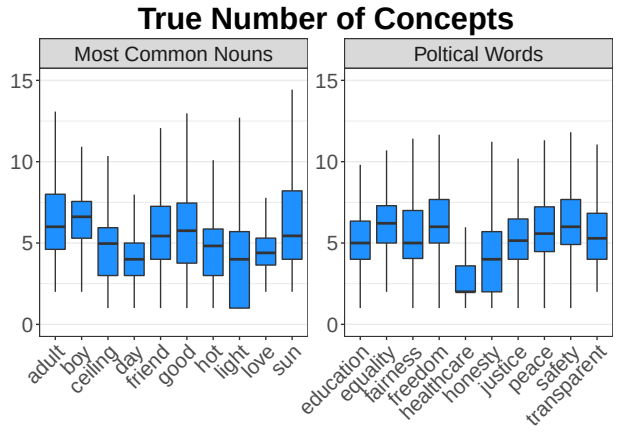

Figure 2: Estimated true number of concepts for 4,000 iterations of our clustering algorithm using a simplicity prior after a 1,000 iteration burn-in. Median estimates are roughly the same regardless of the type of word (about 5).

ing a simplicity prior) after 1,000 iterations of burn-in for each word (x-axis). Across the 4,000 samples from each word, the median estimates are always about the same regardless of word type: roughly five concepts. We also ran our clustering algorithm using a uniform prior which resulted in the same pattern of estimates except increased by two. In comparison to a simplicity prior, a uniform prior will prefer a larger estimate of concepts. That a uniform prior resulted in seven concepts, not 7,000, strongly suggests that the true number of concepts for our chosen words is close to our estimates.

Additional participants are unlikely to significantly increase our estimates

Additionally, we can run our algorithm with varying amounts of data in order to confirm our results. As the number of participants we sample increases, we should expect the distance between our sample estimate and global estimate to narrow and eventually converge. Figure 3 shows the number of concepts (y-axis) by the number of people sampled (x-axis). For most words, as the number of people sampled increases, the true number of concepts (in blue) also increases. This suggests that our estimates for these concepts are relatively conservative, as it is unlikely we have sampled enough to cause this process to plateau. This, in addition to the inherent conservatism in our clustering algorithm (the simplicity prior), suggests these are lower bound estimates for our tested concepts. However, given the slow rate of increase between sample sizes, it is unlikely our estimates would ever grow significantly, even with many more participants.

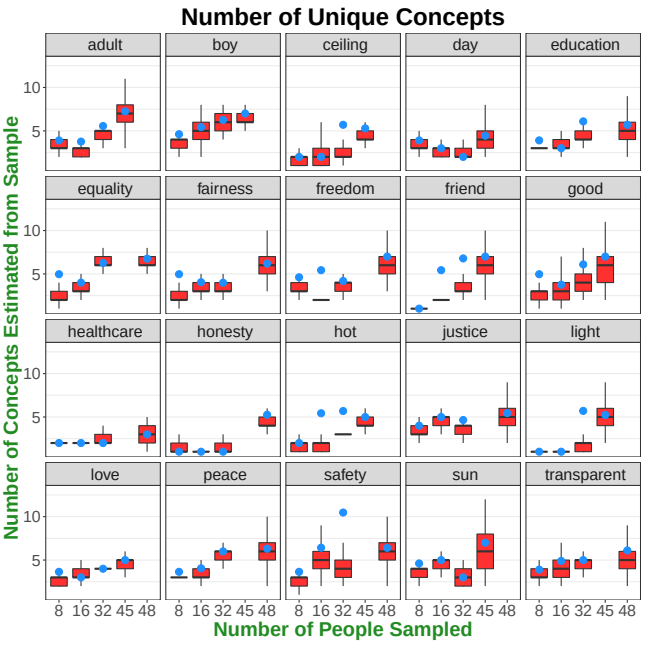

Figure 3: Number of concepts (y-axis) depending on the number of people sampled (x-axis) using a simplicity prior. Box-plots represent 25% to 75% quantiles of the number of concepts in our sample. Blue dots represent the estimated number of unique concepts on Earth based on our sample estimates. As the number of people sampled increases, the number of estimated concepts tends to increase by a slowing amount. This suggests that although our current estimates are conservative, the true number is not much higher.

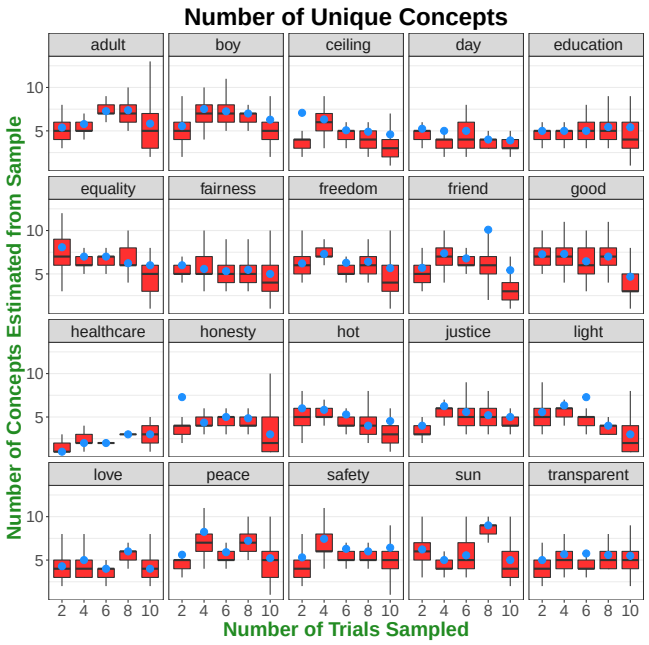

Figure 4: Number of concepts (y-axis) depending on the number of sentences sampled (x-axis) using a simplicity prior. Box-plots represent 25% to 75% quantiles of the number of concepts in our sample. Blue dots represent the estimated number of unique concepts on Earth based on our sample estimates. As the number of sentences sampled increases, the number of estimated concepts tends to stay the same. This suggests that our sentence choices are sufficiently varied enough to capture concept diversity.

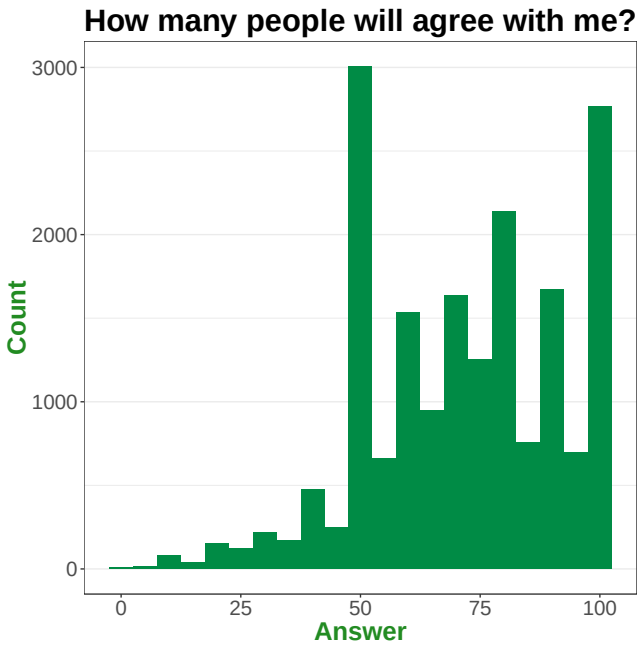

Figure 5: Raw counts (y-axis) of participant answers to the question "How many other people out of 100 would agree with you?" (x-axis). People overwhelmingly think the majority of other people will agree with their assessment.

Additional sentences are unlikely to significantly increase our estimates

Figure 4 shows the number of concepts (y-axis) by the number of sentences sampled (x-axis). If concepts were unique for each individual, one would expect the number of estimated concepts to steadily increase as the number of sentences increased. Instead, we see our estimate as relatively stable, even sometimes *decreasing* as more sentences are sampled. This also suggests that our sentence choices were sufficiently varied to capture concept diversity.

Most individuals underestimate conceptual variability

We then examined people's guesses about how often others' agreed with them. Figure 5 shows raw counts (y-axis) of participant responses (x-axis). The figure illustrates a very strong "like me" bias where the overwhelming number of responses indicate a belief that most others' will agree with their categorization. The second most common response was that *all* others will agree with their assessment.

We then assessed the relationship between people's categorizations to their guesses about the answers of others. Figure 6 presents people's predicted answers (y-axis) and their actual answers (x-axis). As the figure shows, a sizeable number of trials are not well predicted by participants. A perfect prediction rate would result in all trials landing on the y = x line. Although there are many trials which fall on or near this line, there also seems to be a consistent trend of partic-

Figure 6: Participants' actual responses vs. the responses they expected others' to give. Each data point represents the mean response for a trial/choice pair. Most data points are above the y = x line, illustrating that people largely overestimate to which others' agree with their assessments.

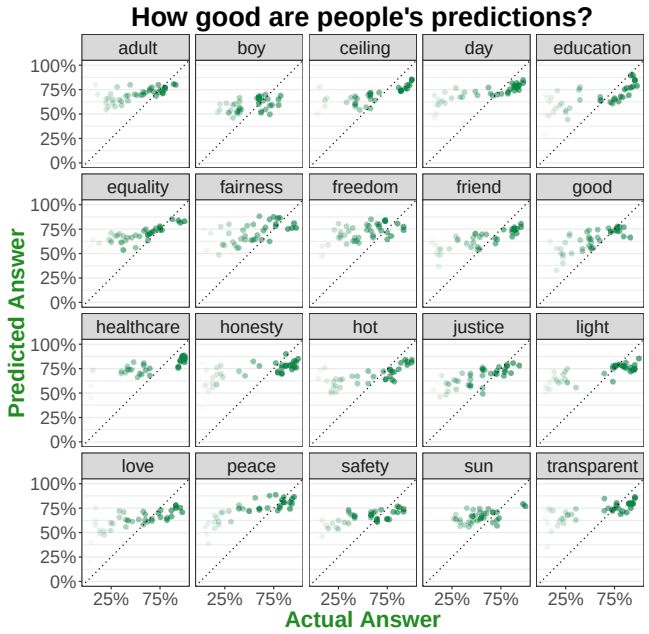

Figure 7: Participants' actual responses vs. the responses they expected others' to give, binned by word. Each data point represents the mean response for a trial/choice pair. People largely overestimate the degree to which others' agree with their assessments, regardless of the concept being assessed.

ipants overestimating the number of people who agree with them as the number of points above the y = x line shows. In fact, very few trials are underestimated and those which are, are only barely underestimated. In contrast, many trial predictions wildly overestimate people's actual responses. Examining the data by word (see Figure 7) shows these trends are not confined to a small subset of words but rather, are widespread.

Conclusions and Discussion

The degree to which conceptual representations are shared and the degree to which people are aware of any differences are also fundamentally important aspects of any theory of conceptual structure, but both have been largely neglected.

These results, along with prior literature, provide strong evidence that the diversity in conceptual representations has been underestimated. As Figure 2 shows, concepts have roughly five to seven different representations, even for basic words such as "day" or "night". This is a surprising finding from multiple points of view. If you believe everyone holds the same concept for the same word, anything greater than one will be unexpected. On the other hand, if you believe concepts are infinitely distinct across individuals and across time, our estimate will also be unexpected.

Furthermore, individuals seem to be unaware of these differences. Figure 6 illustrates the poor relationship between people's actual answers and people's guesses about the answers of others. Taken together, these findings have strong implications for the way humans communicate. Misunderstandings are likely to occur if two individuals are operating with different representations of the same word.

Limitations

It is possible that participants may have interpreted some sentences differently. If two participants have completely different interpretations of the same sentence, they may in reality possess the same concept, but appear to possess different concepts. We do not believe that this possibility could have driven our reported effects, however, because sentences were constructed in order to reduce ambiguity (though, of course, eliminating all ambiguity is impossible).

Summary

There is measurable variability in the conceptual representations attached to particular words (greater than zero but less than infinity); importantly, this variability applies to both concrete words (e.g., "sun") and abstract ones (e.g., "freedom"). More importantly, our data shows that individuals are poorly calibrated to this variability and generally underestimate it. This is important, because communication requires that interlocutors understand one another. These results could help explain a previously unappreciated source of miscommunication and misunderstanding between people.

Do learners' word order preferences reflect hierarchical language structure?

Abstract

Previous research has argued that learners infer word order patterns when learning a new language based on knowledge about underlying structure, rather than linear order (Culbertson & Adger, 2014). Specifically, learners prefer typologically common noun phrase word order patterns that transparently reflect how elements like nouns, adjectives, numerals, and demonstratives combine hierarchically. We test whether this result still holds after removing a potentially confounding strategy present in the original study design. We find that when learners are taught a naturalistic "foreign" language, a clear preference for noun phrase word order is replicated but for a subset of modifier types originally tested. Specifically, participants preferred noun phrases with the order N-Adj-Dem (as in "mug red this") over the order N-Dem-Adj (as in "mug this red"). However, they showed no preference between orders N-Adj-Num (as in "mugs red two") and N-Num-Adj (as in "mugs two red"). We interpret this sensitivity as potentially reflecting an asymmetry among modifier types in the underlying hierarchical structure.

Keywords: language; learning; syntax; typology

Introduction

A large body of work has claimed that sensitivity to abstract hierarchical structure drives the acquisition of syntax (e.g., Chomsky, 1965). At the same time, there is evidence to suggest that language learners track surface-level statistics, including co-occurrence patterns among words (e.g., Saffran, Aslin, & Newport, 1996). In a recent paper, Culbertson and Adger (2014) used a pseudo-artificial language learning task to argue that learners privilege abstract structural relations among words to linear order when they learn syntactic features of a new language. Moreover, they suggest that sensitivity to these structural relations—which in their case pertain to noun phrase word order—can explain a well-studied typological generalisation, known to linguists as Universal 20 (Greenberg, 1963). In the current paper, we highlight some potential methodological issues with the paradigm used by Culbertson and Adger (2014), and test whether their finding is replicated once the paradigm is improved.

Research in generative syntax posits an underlying hierarchical structure for the noun phrase: [Dem [Num [Adj [N]][1] (Adger, 2003; Cinque, 2005; Abels & Neeleman, 2012). In this hierarchy, which can be interpreted as reflecting semantic or conceptual structure, the adjective forms a constituent with the noun to the exclusion of the numeral and demonstrative; that sub-constituent combines with a numeral, and the resulting unit combines with a demonstrative to make a larger constituent. The structure provides a straightforward explanation for why, in most languages, adjectives are placed linearly closest to the noun, while demonstratives are furthest away (e.g., Dryer, 2018). For example, in English *these two red cars*, in Thai (the equivalent of) *cars red two these*. Both these orders can be read directly off the underlying structure, while others, like N-Dem-Num-Adj cannot. While such orders can in principle be derived by movement, they are rarely found. Culbertson and Adger (2014) refer to orders like Dem-Num-Adj-N and N-Adj-Num-Dem (as well as any other order that can be read directly off of the structure [Dem [Num [Adj [N]]) as *isomorphic*—they preserve an isomorphic relation between the proposed underlying hierarchical structure and the surface linearisation.

Culbertson and Adger (2014) sought to provide evidence that learners are sensitive to this underlying structure, and use it to infer word order, rather than simply copying the linear order in their native language. To show this, they taught English speakers simple noun phrases in a pseudo-artificial language, with English words, but non-native-like word order. Participants saw an English phrase like *red shoe*, and were taught it would be *shoe red* in the new "language"; similarly *this car* would be *car this*. Participants were subsequently shown phrases with multiple modifiers, like *this red car*, and asked to guess the relative order of post-nominal modifiers in the language. The authors reason that if learners' inferences are guided by their knowledge of surface-level features of English, they should guess the non-isomorphic order (i.e., *car*

[1] Abbreviations: N(oun) (e.g., *car*), Adj(ective) (e.g., *red*), (Num)eral (e.g., *two*), Dem(onstrative) (e.g., *this*).

this red), which has its modifiers in English order. By contrast, if their inferences are guided instead by knowledge of the abstract structure described above, then they should infer the isomorphic order (i.e., *car red this*). Participants in their experiment overwhelmingly inferred isomorphic orders, suggesting sensitivity to the hypothesised universal structure rather than surface statistics of English.

While this result is intriguing, the paradigm used by Culbertson and Adger (2014) is unusual in several respects. First, even relative to other work using artificial language learning paradigms, this task is very non-naturalistic. Second, the task may encourage a particular strategy. Specifically, English phrases along with their "translations" in the language–also English words–were presented visually. Participants may have adopted an explicit strategy of reversing or "flipping" the English words to determine their responses. For example, during training participants could relate a translation like *shoe red* to the English phrase *red shoe* shown onscreen by reversing the words. Using the same strategy to guess the correct two-modifier phrase translation would then mean flipping the English *this red shoe* to *shoe red this*. Here, we aim to determine whether the apparent bias for isomorphic orders reported by Culbertson and Adger (2014) is replicated using a standard artificial language learning task, with a more naturalistic, completely novel language.

Experiment 1

The experiments we report on in the present paper are part of a larger cross-linguistic comparison project. We followed the methodology reported by White et al. (2018) and designed artificial languages using only sounds contained in all of the languages we plan to test. The phonological inventory of our artificial languages was thus reduced to five vowels, and a small set of voiceless (non-aspirated) stops, nasals, and the voiceless glottal fricative, all shared by the languages we plan to test in.[2] The languages all have lexical tone (for planned experiments with speakers of tonal languages), though the tones do not serve to contrast words from one another (thus the English-speaking participants can simply ignore them). As in Culbertson and Adger (2014), we taught participants phrases with a noun and a single modifier (either and adjective and a demonstrative, or an adjective and a numeral), and then asked them to guess the relative order of modifiers when both were present. Crucially, in contrast with Culbertson and Adger (2014), we used completely novel stimuli and did not present written L1 equivalents of the phrases participants were learning. This was done to reduce the possibility, present in Culbertson and Adger (2014), that participants would simply "flip" L1 word orders to translate into the artificial language they were learning.

Methods

Stimuli The artificial language had five lexical items. There was a single noun meaning *feather*, represented by the label /jè/. There were two adjectives (meaning *red* and *black*), and two items that served as either demonstratives (*this* and *that*) or numerals (*two* and *three*) depending on the condition the participant was assigned to. Labels for these modifier classes were created in pairs:/púkù/, /tàká/ and /hìmí/, /hónò/. The two pairs of stimuli were randomly assigned to be either adjectives or demonstratives/numerals. We privileged within-pair similarity (so /púkù/ and /tàká/ both contain only voiceless stops for example) to facilitate the learning process.[3] Stimuli were produced by a trained phonetician. All stops were produced with near zero VOT and each syllable was produced with either a high or a low tone.

Visual stimuli were pictures of simple cartoon scenes. Objects (always feathers) were depicted on a table behind which stood a cartoon girl. In trials featuring the noun alone, or the noun with an adjective and/or numeral, the girl was simply shown behind the table. In trials featuring a demonstrative, the girl was shown pointing to an object or objects (either near to her, or on the other side of the table from her). The presence of the girl and table on all trials was meant to keep demonstrative trials from being more visually salient (or complex). When no adjectival meaning was expressed, feathers were drawn in light grey; feathers were only coloured in (in red or black) on trials involving adjectives. Examples of the visual stimuli for single modifier trials are shown in fig. 1.

Procedure Participants were instructed that they would be learning part of a new language called Nápíjò, spoken by around 10,000 people in a rural region of Southeast Asia. All words and phrases were presented both auditorily and orthographically. The experimental session lasted about 15 minutes, and was divided into (1) noun training, (2) noun-modifier training, (3) noun-modifier testing, and finally, (4) extrapolation to two modifiers. Participants were first trained on the (single) noun in the language. On each trial, participants saw the object and were given its label in Nápíjò. They were instructed to click on the image to move on to the next trial. There were five such trials. They were then trained on noun-modifier combinations. Each trial had two parts. First, two images appeared, each illustrating one of the two modifiers for a given modifier type (e.g., "black" and "red", or "this" and "that"). A description of the first picture was provided, while the second picture was greyed out. Then, a description of the second picture was provided while the first was greyed out. Recall was tested immediately following this: The two pictures appeared again (in random order), and the description for one was given. Participants were instructed to click the picture matching the description. The first eight such trials were blocked by modifier type, with random choice of which modifier type was introduced first (two trials per modifier), followed by a further 16 trials with

[2]Experiment 3 contains some additional fricatives that will not be used with non-English-speaking populations.

[3]We designed the language to encourage participants to perceive it as a real "foreign" language. Therefore, while the words do not overtly contradict English phonotactics, they are not particularly English-like. This makes them difficult to learn. Piloting suggested that keeping the vocabulary relatively small would be necessary.

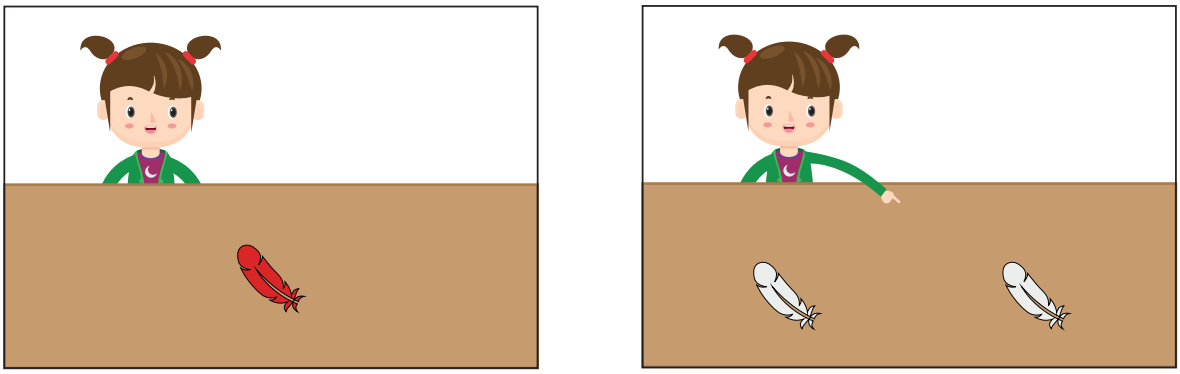

Figure 1: Single modifier trial visual stimuli examples. On the left, an example of an adjective trial, meaning "red feather", and on the right an example of a demonstrative trial, meaning "that feather".

both types intermixed. Feedback was given after each trial (image background turned green or red, plus a beep sound if incorrect). Participants were then tested on their knowledge of the noun-modifier combinations. On each trial, a picture appeared, with two potential descriptions below it. Participants were told to click on the matching description (16 trials total, four for each modifier, random order). The foil description always included a modifier of the same type. Feedback was given on each trial (button colour turned green or red, the correct description played, regardless of response).

In the critical testing phase, participants were tested (without training) on phrases with a noun and *two modifiers*. On each trial a picture appeared, with two potential descriptions below it. Participants were told to click on the matching description (16 trials total, four for each modifier, random order). The two descriptions always included the correct lexical items, in post-nominal order. They differed only in whether the order was isomorphic (e.g., N-Adj-Dem) or not (e.g., N-Dem-Adj). No feedback was given.

Participants All participants were recruited through Amazon's Mechanical Turk online recruiting platform and received 3.50 USD as compensation. We recruited a total of 70 participants who were randomly assigned to either the Demonstratives or Numerals condition. A total of eight participants were excluded (four in each condition) because they failed to reach at least 85% accuracy in the single modifier test trials (this is the same exclusion criterion reported by Culbertson and Adger (2014)). We thus analysed data from 35 participants in the Demonstratives condition and 27 in the Numerals condition.

Results

Following the analyses reported in Culbertson and Adger (2014), we analysed, for each condition, whether participants demonstrated an average preference for isomorphic orders on two modifier trials. Results from Experiment 1 are presented on the lefthand side of fig. 2. All analyses were performed by implementing logistical mixed-effects models in the `lme4` package in R (Bates, 2014). We designed full models with the binary dependent variable Isomorphic along with by-participant random effects. We used likelihood ratio tests to compare these models to null models with no intercept term to see if on average participants chose isomorphic orders above chance level. We found no isomorphic preference in either the Demonstratives ($\chi^2(1) < 1$) or the Numerals conditions ($\chi^2(1) < 1$).

Discussion

Contrary to Culbertson and Adger (2014), we did not observe any preference for isomorphic order in our artificial language learning task. However, given that our methodology differed in a number or respects from the original studies (and replications), we considered possible explanations for our null result. First, Culbertson and Adger (2014) used English words in their experiment, whereas we used nonce words. It is therefore worth verifying that participants in our experiment interpreted the words as intended. In a debrief questionnaire, participants were asked to report the meanings of the words they had learned. Participants invariably reported correct translations for adjectives (colour words) and numerals. However, meanings given for demonstratives and nouns varied to some degree. For demonstratives, most participants reported translations such as *this* and *that*, or *here* and *there*. Both these translations are consistent with a demonstrative interpretation: although *here* and *there* are sometimes called adverbs, their meaning and syntax are similar to *this* and that, and indeed they are the demonstrative words in many languages (Diessel, 2006). However, some participants gave responses such as *left* and *right* (indeed, the absolute and relative positions were confounded in our stimuli). The variation in interpretation of the demonstrative may have weakened the results to some degree. However, the interpretation of the noun suggests a more obvious issue.

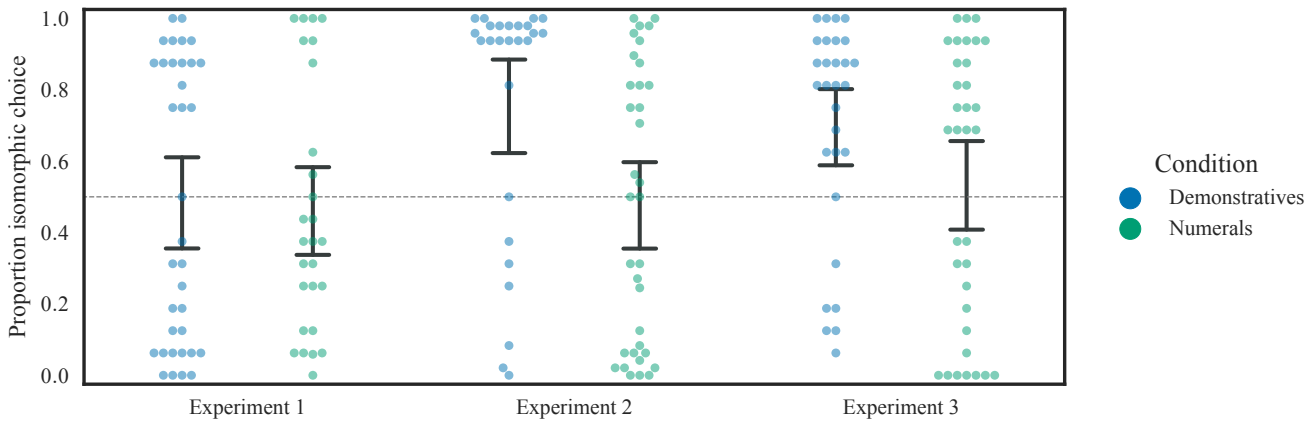

Figure 2: Proportion isomorphic preference in each experiment by condition. Each point represents an individual participant and error bars represent 95% confidence intervals.

While some participants correctly reported the English word *feather* for the word /jè/. Some, did not report a translation at all, suggesting they may not have understood its meaning. Others reported incorrect meanings, giving function words like *the* as translations. Note that the set size of the nouns differs dramatically from Culbertson and Adger (2014), where 20 nouns were used: we used a single noun in Experiment 1. Given that every trial always consisted of /jè/ + *x*, it was therefore possible for participants to completely discount that word (or indeed treat it as a determiner). This suggests the possibility that participants may not have been treating our stimuli as noun phrases (i.e., not attending to the noun head), but simply as strings of modifiers. If so, participants may have adopted any number of response strategies. For example, they could have interpreted the strings as copulative sentences (e.g., "this (one) (is) red"), or simply strings of modifiers. In either case, they would not have learned the intended Noun-modifier structure of the language. In Experiment 2, we therefore expanded the set of nouns in the artificial lexicon. We hypothesised that variability in the noun would cause participants to treat our stimuli as noun phrases, resulting in a preference for isomorphic orders.

Experiment 2

Methods

Stimuli The stimuli for Experiment 2 were similar to those in Experiment 1; only the nouns differed. We created audio and visual stimuli for three objects (*feather*, *ball*, *mug*) which were assigned the names /éjè/, /úhù/, and /ítì/, respectively. All modifier stimuli were identical to Experiment 1.

Procedure The procedure was identical to Experiment 1 except the initial training and testing phases were slightly lengthened. Noun training was composed of 15 trials (five trials for each of the three nouns). This was immediately followed by 15 trials of noun testing in which a picture appeared with two labels beneath it. Participants were instructed to click the matching label. Feedback was given (button colour turned green or red, the correct description played regardless of response). Noun-modifier exposure was composed of 12 trials blocked by modifier type (six trials per block, two for each noun-modifier combination), followed by an additional intermixed block of 12 trials (one trial for each noun-modifier combination). Noun-modifier testing was composed of 24 trials (two trials for each noun-modifier combination). The foil labels for each picture were either an incorrect noun *or* an incorrect modifier of the same type. Finally, for the critical test phase, a random set of 16 trials was constructed for each participant.

Participants As in Experiment 1, all participants were recruited through Amazon's Mechanical Turk online recruiting platform and received 3.50 USD as compensation. We recruited a total of 71 participants who had not participated in Experiment 1. Participants were randomly assigned to either the Demonstratives or Numerals condition. A total of 11 participants were excluded (seven in the Demonstratives condition and four in the Numerals condition) because they failed to reach at least 85% accuracy in the single modifier test trials. We thus analysed data from 26 participants in the Demonstratives condition and 34 in the Numerals condition.

Results

Results from Experiment 2 are presented in the middle of fig. 2. The analysis of Experiment 2 was identical to that of Experiment 1. We found an isomorphic preference in the Demonstratives condition ($\beta = 2.25$, $SE = 0.60$, $\chi^2(1) = 11.35$, $p < 0.001$) but not in the Numerals condition ($\chi^2(1) < 1$).

Discussion

The results of Experiment 2 revealed a preference for isomorphic word orders, but only if the set of modifiers learned was adjectives and demonstratives. That is, participants preferred noun phrases with the order N-Adj-Dem (as in "mug

red this") over the order N-Dem-Adj (as in "mug this red"). However, they showed no preference between orders N-Adj-Num (as in "mugs red two") and N-Num-Adj (as in "mugs two red"). Interestingly, this asymmetry has been reported numerically in all previous experiments on isomorphism. As discussed above, Culbertson and Adger (2014) found statistically significant isomorphism preferences for all pairs of modifiers (adjective, numeral and demonstrative), and when all three modifiers were present (not tested here). However, they report a numerical difference among the groups such that the isomorphism preference is strongest with adjective and demonstrative. Indeed, they cite this as further evidence that English speakers are sensitive to the underlying hierarchical structure, since adjectives and demonstratives are structurally more distant than adjectives and numerals (or numerals and demonstratives). In a lab replication of the original study (which was conducted on Mechanical Turk), A. Martin, Ratitamkul, Abels, Adger, and Culbertson (in press) replicated both the general isomorphism preference and the difference among modifier pairs. They also report a replication with Thai speakers, whose L1 order is N-Adj-Num-Dem. These speakers were trained on an artificial language with prenominal modifiers, and they then inferred prenominal isomorphic orders like Dem-Adj-N in the criticial two-modifier test phrase. There again the same difference among modifier pairs was present. These studies report only numerical differences. Our findings therefore present the clearest evidence yet that the isomorphism preference may be sensitive to modifier type.

Nevertheless, we did not replicate an isomorphism preference for the Numerals condition. Additionally, the isomorphism preference found for the Demonstratives condition is (numerically) weaker than reported in these previous studies. By design, we have reduced the likelihood that participants are relying on an explicit "flipping" strategy, and we have made the language itself more naturalistic. Thus, one possibility is that our results are a better representation of English speakers' underlying bias for isomorphism: it is present, but not categorical for adjectives and demonstratives, and not present for adjectives and numerals. We return to this in the general discussion. There is, however, one other major difference between our experiment and previous experiments which could plausibly weaken or mask an isomorphism preference, namely the relative size of the modifier categories. In both Culbertson and Adger (2014) and A. Martin et al. (in press), the relative class sizes approximately match what one would typically find in a natural language: largest set size for adjectives, then numerals, and a small set of demonstratives.[4] In our experiments, all modifier classes contained two elements. In Experiment 3, we test the possibility that using a more naturalistic relative size for the modifier classes might amplify the isomorphism preference, perhaps revealing the isomorphism preference between numerals and adjectives reported in previous work.

[4]For example, 694 adjective vs. 172 numeral, 5 demonstrative types among all noun phrases in the English Universal Dependencies Treebank (Nivre et al., 2017).

Experiment 3

Methods

Stimuli The stimuli for Experiment 3 were similar to those for Experiments 1 and 2. The only difference was in the number of adjectives. Specifically, four adjectives were created (/tàkás/, /pùkúf/, /kàpáθ/, and /kùtúʃ/) and mapped to four colour meanings ("black", "red", "blue", and "green", respectively). Visual stimuli similar to those in Experiments 1 and 2 were also created.

Procedure The procedure was identical to Experiment 2 except for the following: Noun-modifier training was all blocked (in order to balance frequency of exposure to each combination without increasing the number of trials too much). Each block was composed of 12 trials. In the adjective block, each adjective was shown once with each noun. In the numeral or demonstrative block, each modifier was shown twice with each noun. The noun-modifier testing block was slightly longer than in Experiment 2, with 36 trials total (2 trials for each noun-modifier combination). No changes were made to the critical two modifier testing phase (again, 16 trials total, randomly constructed). Note that the frequency of exposure to each modifier class was the same, only the number of elements in each class differed.

Participants As in Experiments 1 and 2, all participants were recruited through Amazon's Mechanical Turk online recruiting platform and received 3.50 USD as compensation. We recruited a total of 76 participants who had not participated in Experiment 1 or Experiment 2. Participants were randomly assigned to either the Demonstratives or Numerals condition. A total of 13 participants were excluded (nine in the Demonstratives condition and four in the Numerals condition) because they failed to reach at least 85% accuracy in the single modifier test trials. We thus analysed data from 29 participants in the Demonstratives condition and 34 in the Numerals condition.

Results

Results from Experiment 3 are presented on the right-hand side of fig. 2. The analysis of Experiment 3 was identical to that of Experiments 1 and 2. As in Experiment 2, we found an isomorphic preference in the Demonstratives condition ($\beta = 1.24$, $SE = 0.36$, $\chi^2(1) = 10.37$, $p < 0.01$) but not in the Numerals condition ($\chi^2(1) < 1$).

Discussion

In Experiment 3, we tested whether the isomorphism preference found in Experiment 2 would be amplified, and extended to the Numerals condition if the relative sizes of the modifier classes were more naturalistic. This was not borne out; rather we replicated the findings of Experiment 2: an isomorphism preference for noun phrases with a demonstrative

and an adjective, but not for noun phrases with a numeral and an adjective. This finding therefore reinforces the asymmetry reported in Experiment 2, and the numerical patterns reported in both Culbertson and Adger (2014) and A. Martin et al. (in press). In the next section, we investigate statistically the general pattern of results across experiments described here.

Comparison across experiments

Two manipulations distinguished Experiments 1, 2, and 3. First, the size of the noun class. In Experiment 1, participants learned only one noun, while in Experiments 2 and 3 they learned three. Second, the size of the adjective class. In Experiments 1 and 2, participants learned only two adjectives, while in Experiment 3 they learned four. We thus performed an analysis considering these two binary variables, included in our models using contrast coding. This allowed us to explore the interaction between these two factors and the factor Condition in one single statistical model. The model predicted Isomorphic order choice from three fixed binary factors: Condition (Demonstratives or Numerals), Noun Class Size (one noun or three), and Adjective Class Size (two adjectives or four). We also included interactions between Condition and Noun Class Size and between Condition and Adjective Class Size as well as by-participant random intercepts. We then designed reduced models each excluding one factor or interaction, and compared them to the full model (again using likelihood ratio tests).

We found that removing Noun Class Size significantly worsened the model fit ($\beta = 1.08$, $SE = 0.49$, $\chi^2(1) = 4.70$, $p < 0.05$). This indicates that participants who learned an artificial language with three nouns showed a stronger isomorphism preference than those who learned an artificial language with only one noun. We also found that removing the interaction between Condition and Noun Class Size significantly worsened the model fit ($\beta = -2.65$, $SE = 0.98$, $\chi^2(1) = 7.10$, $p < 0.01$). This confirms our observation that amongst the participants who learned artificial languages with three nouns, those in the Demonstratives conditions showed an isomorphism preference while those in the Numerals conditions did not. Removing the factors Adjective Class Size ($\chi^2 < 1$) and Condition ($\chi^2 = 1.46$, $p = 0.23$) did not worsen the model fit, nor did removing the interaction between Condition and Adjective Class Size ($\chi^2 = 1.40$, $p = 0.24$).

General discussion

This paper aimed to test the preferences of English speakers learning about the noun phrase word order of a new language. Previous research using a pseudo-artificial language learning paradigm reported a strong preference for so-called isomorphic noun phrase orders, like N-Adj-Dem or N-Adj-Num, which transparently reflect the hypothesised hierarchical structure of the noun phrase: [Dem [Num [Adj [N]]]] (Culbertson & Adger, 2014; A. Martin et al., in press). This has been claimed to show that speakers' inferences about a new language are not based on the surface linear order of their native language, but on a (potentially universal) underlying hierarchical structure. Moreover, the results suggest the possibility that a preference for orders which are isomorphic to this structure might explain why these orders overwhelmingly outnumber non-isomorphic orders in the typology (Cinque, 2005; Abels & Neeleman, 2012; Dryer, 2018).

We sought to replicate these findings using an improved methodology, designed to address the possibility that the original results reflected the availability of an explicit strategy which may have encouraged participants to choose isomorphic orders by visually flipping the English words. We used a standard artificial language learning paradigm, with a relatively more naturalistic language. In Experiment 1, we used a minimal vocabulary, with only a single noun, and found no isomorphism preference. In Experiment 2, we added additional nouns to encourage participants to treat stimuli as noun phrases. Here, we found an isomorphism preference for phrases including a demonstrative and an adjective, but not for phrases including a numeral and an adjective, an asymmetry which mirrors numerical differences reported in earlier studies. In Experiment 3, we attempted to strengthen the isomorphism preference by making the number of words in each modifier category more naturalistic (in terms of relative size). This did not change the results, but rather again revealed that learners' isomorphism preference was sensitive to the modifier categories involved.

Importantly, our results show that in a more naturalistic artificial language learning task, where participants are unlikely to use an explicit strategy of flipping English words to determine order in the new language, an isomorphism preference is still found. Some confirmation that participants are not using a simple flipping strategy in our experiments comes from self-reports given at the end of the task. Of the 185 participants that were retained for data analysis in our three experiments, only one referred to a flipping strategy in the debriefing questionnaire. Instead, common strategies included "no strategy", "I just went with my gut feeling" (67 such reports), or simple descriptions of their order choices like "I placed colour words closer to the object name, then numbers" (50 such reports). This contrasts starkly with the strategies reported by participants in Culbertson and Adger (2014)'s study. We recovered the data from that study and analysed the 89 participant strategy reports from their Experiment 1: 47 of them reported some kind of explicit flipping-based strategy (compared to only 11 "no strategy"). Our replication of their effect with a more naturalistic artificial language is thus an important contribution to this line of research.

Our results also highlight the persistent difference between modifier types, found numerically in earlier experiments, and confirmed statistically here. While it is possible that something about our task is still masking a (weaker but present) isomorphism preference for numerals and adjectives, there is some reason to suspect that the *asymmetry* at least is real. In fact, using the data collated by Dryer (2018), we can observe that non-isomorphism between numerals and adjectives, or numerals and demonstratives is more common cross-

linguistically (35 and 64 languages respectively) than non-isomorphism between adjectives and demonstratives (27 languages). This may reflect the fact that adjectives and demonstratives are more distant from one another in terms of underlying hierarchical structure.

As mentioned in the introduction, this hierarchy can be conceived of as reflecting semantic composition, or conceptual structure. Indeed linear order patterns more generally have been argued to reflect both (Rijkhoff, 1990; Baker, 1985; Bybee, 1985; Rice, 2000). One possibility is that the underlying hierarchy of nominal modifiers reflects differences in conceptual closeness (or inherentness) between particular modifier types and nouns (Kirby, Culbertson, & Schouwstra, 2018; Culbertson, Schouwstra, & Kirby, under revision). Under this account, adjectives are conceptually closest to nouns because they are more likely to reflect inherent properties of individual nouns (e.g., colour, size, texture, etc). Numerals are typically less closely linked with particular nouns (though some clearly are, e.g., four seasons, seven days of the week). Demonstratives, being deictic elements, are by their nature not associated with particular nouns. If the underlying hierarchical structure reflects these different conceptual relations between elements, then a preference for isomorphism is a preference to hierarchically cluster elements that are more closely related conceptually. Perturbing this preference would then be less costly when it involves elements that differ less in their conceptual closeness to the noun (e.g., Adj and Num), compared to elements that differ quite a lot (e.g., Adj and Dem) (for similar arguments about the relative order of adjectives, see J. E. Martin, 1969; Bouchard, 2002).

To summarise, the experiments reported here aimed to replicate the preference for isomorphic ordering in the noun phrase, first reported in Culbertson and Adger (2014). Using a more naturalistic artificial language learning task, we find that English speakers infer isomorphic orders of demonstrative and adjective. However, we found no evidence of an isomorphism preference for numerals and adjectives. Above we suggest one possible explanation for the difference between these two conditions: assuming that English speakers can either use an isomorphic order, or an order that reflects the surface linear order of their language, they are more likely to go with the latter when this would involve two modifiers that are more similar to each other, either in terms of structural distance, or in terms of conceptual closeness with the noun. That said, learners' sensitivity to the distribution features of the language (e.g., in Experiment 1) leave open the possibility that future experiments will reveal this bias as weaker but still present.

Abstract

The acquisition of the grammar of a second language requires a variety of cognitive mechanisms, including inductive reasoning. In the current study, we examine the cognitive underpinnings of grammar learning with an explicit-inductive (rule search) learning task, designed to capture more of the complexity associated with grammar learning than purely deductive tasks. Research in language aptitude has shown that working memory capacity (WMC) is a key predictor of grammar learning outcomes. Inductive reasoning and grammatical sensitivity are other established aptitude factors. The goal of the present study was to determine the degree to which relevant variables predict learning on an explicit-inductive grammar learning task. Our results indicate that both WMC and inductive reasoning ability predict learning over three days of grammar training.

Keywords: L2 learning; L2 aptitude; working memory capacity; inductive reasoning; individual differences

Introduction

The acquisition of second language (L2) grammar is extremely challenging for adult learners. One of the reasons for this difficulty is the heavy and diverse processing demands associated with learning grammatical rules as well as applying them during comprehension and production of L2 utterances (Doughty & Long, 2003). Insights into the precise cognitive underpinnings of grammar learning come from the field of language aptitude. Importantly, working memory capacity (WMC) has emerged as a key predictor of L2 grammar learning ability (Linck, Osthus, Koeth & Bunting, 2014; Miyake & Friedman, 1998). WMC is defined as the ability to maintain attention on a limited amount of information, even in the face of interference (Engle, 2002, 2018), and underpins many aspects of higher cognition and goal-directed behavior. Another predictor is inductive reasoning ability, the ability to extrapolate rules and patterns from specific examples. While both WMC and inductive reasoning are predictors of grammar learning outcomes, there is a lack of research examining whether the two account for independent portions of variance in learning. In the current study, we examined the cognitive underpinnings of grammar learning using an explicit-inductive learning task. In this task, participants were presented with L2 phrases and asked to figure out the grammatical rules, and then tested on those rules. The goal was to examine the degree to which relevant variables predict grammar learning.

Explicit-Inductive Grammar Learning

In explicit-inductive (or "rule-search") grammar learning tasks, learners are presented with a number of L2 examples (sentences or phrases) exhibiting target grammatical structures in both a foreign language and the individuals' native language and are asked to figure out the rule(s) for subsequent testing. These tasks differ from deductive tasks in which rules are explicitly taught (DeKeyser, 2003). They also differ from artificial grammar learning tasks (also referred to as statistical learning tasks) in that, in artificial grammar learning tasks, rules are acquired without conscious awareness (i.e., implicitly) and there is no meaning ascribed to the material under study (Misyak & Christiansen, 2012). Though, it is very likely that in providing numerous exemplars in explicit-inductive grammar learning tasks, individuals not only infer rules but likely implicitly acquire statistical regularities as well. Thus, explicit-inductive grammar learning tasks likely involve *both* explicit and implicit learning processes (DeKeyser, 1995). Given that both types of learning are known to be involved in grammar acquisition (DeKeyser, 2003), these tasks may better capture the cognitive complexity of grammar learning.

Working Memory Capacity

Individual differences in WMC are strongly predictive of performance on a range of tasks assessing cognitive abilities and processes (Engle, Tuholski, Laughlin, & Conway, 1999; Kyllonen & Christal, 1990) including L1 processing (Daneman & Merikle, 1996) and L2 learning (Linck et al., 2014). Indeed, in a meta-analysis synthesizing the results of 79 studies with a combined sample size of over 3,000 participants, Linck et al. (2014) found that WMC tasks are positively associated with L2 outcomes. Moreover, Tagarelli, Borges-Mota and Rebuschat (2011) found that WMC predicted performance on an explicit-inductive grammar learning task.

Relations observed between WMC and other cognitive tasks are typically explained as owing to the fact that complex cognition requires sustained attention on the task at hand, often while performing various operations, which themselves produce interference (Daneman & Carpenter, 1980;

Daneman & Merikle, 1996). This emphasis on controlled attention has led some to theorize that WMC plays a greater role in L2 learning under explicit, rather than implicit, learning conditions (e.g., Tagarelli, Mota, & Rebuschat, 2011). Indeed, Tagarelli, Mota, and Rebuschat (2011) found that WMC was predictive of learning under explicit, but not implicit, learning conditions.

Inductive Reasoning

Another predictor of L2 learning that figures prominently is inductive reasoning (Gardner & Lambert, 1965; Sparks, Humbach, Patton, & Ganschow, 2011). In inductive reasoning, one infers general principles from specific observations. For example, an adult interested in learning another language for use during a trip may begin by learning "survival phrases" such as "I am American" and "I am sorry." In doing so, one may *infer* grammatical rules and the meaning of certain words in the L2, which can then be used to construct new words and sentences (though of course the accuracy of the constructions will be dependent on the premises, e.g., not all verbs in English can be changed from present to past tense by affixing an *-ed*). Like WMC, inductive reasoning ability has been found to predict grammar learning under explicit, but not, implicit conditions (Gebauer & Mackintosh, 2007).

Relationship between WMC and Inductive Reasoning

An issue arises, however, when one notes that WMC is highly correlated with inductive reasoning ability (Engle et al., 1999; Kyllonen & Christal, 1990). In the individual differences literature, inductive reasoning tasks are often used as indicators of fluid intelligence (Marshalek, Lohman, & Snow, 1983; Wilhelm, 2005). According to a recently proposed theory (see Shipstead, Harrison, & Engle, 2016), WMC and fluid intelligence/inductive reasoning are highly correlated because both rely on attention control; however, while WMC tasks primarily assess the ability to *maintain* attention, fluid intelligence/inductive reasoning tasks additionally assess the ability to *disengage* attention. Consider that in WMC tasks, the goal is to maintain to-be-remembered information (e.g., sets of letters) in mind exactly as they were presented; in inferential tasks, however, the goal is to produce a novel solution, entailing some kind of transformation or restructuring of inputs as multiple solutions or hypotheses are investigated (Oberauer, Süß, Wilhelm, & Sander, 2007). During the reasoning process, one has to maintain relevant pieces of information in mind, implicating WMC, but at other times, one has to abandon an incorrect solution and begin anew, requiring one to disengage attention from one problem representation for another.

The issue is that there is little research investigating whether WMC and inductive reasoning ability *independently* account for variance in L2 learning. To investigate this issue, we included a measure of inductive reasoning and a measure of WMC as predictors in the present study. Given that the outcome variable is an explicit-inductive grammar learning task, we expect inductive reasoning to be predictive of learning, however, a WMC task should account for variance over and above an inductive task, as WMC is a well-established predictor of language learning (Linck, Osthus, Koeth & Bunting, 2014; Miyake & Friedman, 1998).

Grammatical Sensitivity

In addition to WMC and inductive reasoning, a measure of grammatical sensitivity was also included in this study—the Words in Sentences (WIS) subtest from the Modern Language Aptitude Test (MLAT), developed by Carroll and Sapon (1959). According to Carroll (1964), grammatical sensitivity is the "ability to recognize the grammatical functions of words in sentences (p. 95)". Studies have shown the WIS to be a predictor of L2 learning (Li, 2015), particularly under explicit learning conditions (Li, 2014); however, there is also research and theorizing that grammatical sensitivity depends on inductive reasoning (Li, 2015; Sasaki, 1993). Thus, including this measure as a predictor allows us to investigate whether grammatical sensitivity influences novel grammar learning over and above inductive reasoning and working memory.

The Present Study

With the above in mind, this study was undertaken to assess the relative contributions of WMC, inductive reasoning, and grammatical sensitivity on one aspect of L2 learning, grammar learning. For this study, we developed an explicit-inductive (i.e., rule-search) grammar learning task in which individuals were tasked with learning syntactic rules in an L2. During learning, participants were exposed to a number of L2 phrases and their English translations and attempted to infer rules for arranging words in the L2. Superficially, the task is similar to what was described earlier when one learns "survival" phrases and induces rules, however, (and as will be clarified below) this task obviates the need to memorize phrases and thus should be a relatively *pure* measure of grammatical (rule) induction.

Method

Participants

A total of 34 individuals participated in the study; however, three did not complete the entire study, leaving 31 with complete data. All participants were recruited from the university and surrounding community and were compensated for their time. No participant reported experience with Indonesian or related languages.

Procedure

All participants completed a total of three sessions in a room with up to six other participants. Each session contained a grammar learning task. In addition to the grammar learning task, in Session 1 participants also completed a demographics and language history questionnaire, administered before the grammar learning task; in Session 2 participants completed

Letter Sets, an Antisaccade task, and a Speeded Lexical Decision task, administered, in that order, after the grammar learning task; and in Session 3 participants completed the Remember and Count task, another Speeded Lexical Decision task, and the Words in Sentences, administered, in that order, after the grammar learning task. Each session took approximately 60 minutes to complete. All tasks were completed on desktop computers. Below, we offer descriptions of the tasks included in this study.

Instruments

Explicit-Inductive Grammar Learning Task We chose an explicit-inductive task as our criterion measure because research indicates that during the early stages of L2 learning, adults tend to engage control processes to learn grammatical rules, while at later stages, they tend to rely on implicit learning processes (Hamrick, Lum, & Ullman, 2018). Thus an explicit-inductive task likely captures processes similar to those engaged throughout the learning process.

The grammar learning task consisted of three phases: learning, recall, and recognition. During the learning phase, participants were presented with example Indonesian phrases and their English translations, ordered from short/simple phrases to long/complex phrases. Participants therefore had to infer the "simple" rules and then take mental note of how these "simple" rules combined to construct complex phrases. Because participants did not know Indonesian, the Indonesian words and their English translations were color-coded, such that translation equivalents were the same color; Indonesian words without direct translations (e.g., classifiers) were presented in black font with no background color. See Figure 1.

Figure 1. Three example grammar learning items.

During the recall phase, participants were asked to translate English phrases into Indonesian by selecting words from a word bank and placing them in the correct sequence. The word bank included the words needed for the translation as well as all function words. Where possible, English translations were provided (see Figure 2). During the recognition phase, participants saw Indonesian noun phrases and indicated whether they were grammatical or not (see Figure 3).

Participants were *never* given feedback in either the recall or recognition phases, but were given a score of their overall recognition phase performance at the end of the day.

Table 1. Syntactic Structures in the Grammar Learning Task.

	Structure	**Example English Phrase**
1	Demonstrative noun	that uncle
2	Number w/classifier	two apes
3	Single adjective	moody zebra
4	Demonstrative + single adjective	that bold scientist
5	Double adjective	new, red school
6	Possessive	my rabbit
7	Possessive + single adjective	my hungry uncle
8	Number/classifier + single adjective	two small warehouses
9	Number/classifier + single adjective + possessive	my two friendly fish
10	Number/classifier + double adjective + possessive	my two new, crowded stores
11	Triple adjective	fancy, young, skilled lawyer
12	Noun + single adjective + pre-intensifier	very crowded arena
13	Noun + single adjective + post-intensifier	very skilled teacher
14	Noun + number/classifier + single adjective + pre-intensifier	two very clever bears
15	Noun + number/classifier + single adjective + post-intensifier	two very chilly cinemas
16	Noun + possessive + number/classifier + single adjective + pre-intensifier	my two very expensive palaces
17	Noun + possessive + number/classifier + single adjective + post-intensifier	my two very tired bears

Figure 2. Example grammar recall item.

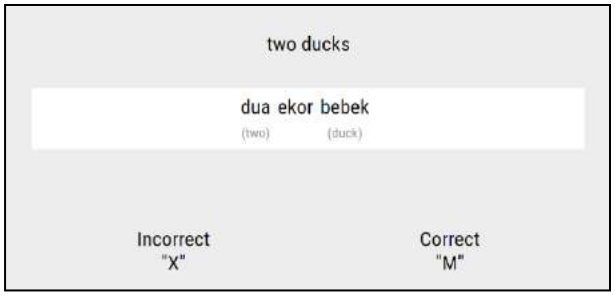

Figure 3. Example grammar recognition item. The correct answer is "M", correct.

Across sessions, the same 111 noun phrases were used in the learning phase. However, because our interest was in *grammar* learning, noun phrases used in the recall and recognition phases were never repeated across sessions, resulting in 123 noun phrases for the recall phase (41/session) and 312 noun phrases for the recognition phase (104/session).

Words in Sentences (WIS) In the WIS, each item consisted of two or more English sentences. One word in the first sentence was printed in uppercase letters. Four or five words in the remaining sentences were underlined and were labeled with corresponding letter answer options (Figure 3). Participants indicated which of these underlined words served the same grammatical function as the word in uppercase letters in the first sentence.

Chidi said THAT Eleanor is incorrigible.

In our (A) session, that (B) lady said that (C) she knew that (D) actor on the (E)

television show.

Figure 3. A sample item from the *words in sentences* test modified from https://lltf.net/mlat-sample-items/mlat-part-iv/. The correct answer is C.

Remember and Count (RAC) WMC was assessed by the RAC task (Hughes et al., 2016; O'Rourke et al., 2017), a visuospatial complex span task. In the RAC task, participants first see a sequence of triangles of different colors presented in a sequence in different quadrants. Next, they see an image of dark and light blue circles and squares; participants are to count and report the number of dark blue circles in the image. Finally, in the critical portion of the task, they must recall the sequence of triangles by indicating the color, the location, and the order of each triangle in the sequence. The number of triangles in a sequence varied between three and five, with four trials of set size 3, nine trials at set size 4, and eight trials at set size 5, for a total of 21 trials. Each trial was scored as a proportion of correctly recalled triangles; thus, participants could achieve a maximum of 1 point per trial.

Letter Sets (LSET) Inductive reasoning was assessed by the LSET task (Doughty, Campbell, Bunting, Bowles, & Haarmann, 2007). In each item, participants are presented with five sets of four letters. Four of the sets are arranged such that they follow the same rule while one does not; participants are to determine which set of letters does not follow the same rule as the others. There were a total of 15 items.

Results

Correlations amongst the predictors and descriptive statistics are provided in Table 2. Figure 4 depicts average learning curves for both the recall and recognition grammar measures.

Table 2. Predictor Correlations and Descriptive Statistics

	WIS	LSET	RAC
WIS			
LSET	0.20		
RAC	0.48*	0.48*	
$\bar{X}$	.42	.76	.53
SD	.13	.13	.18
Skew	-.02	-.10	-.91
Kurtosis	-.54	.16	.19

Note: * p <.05; LSET = letter sets; RAC = remember and count; WIS = words in sentences.

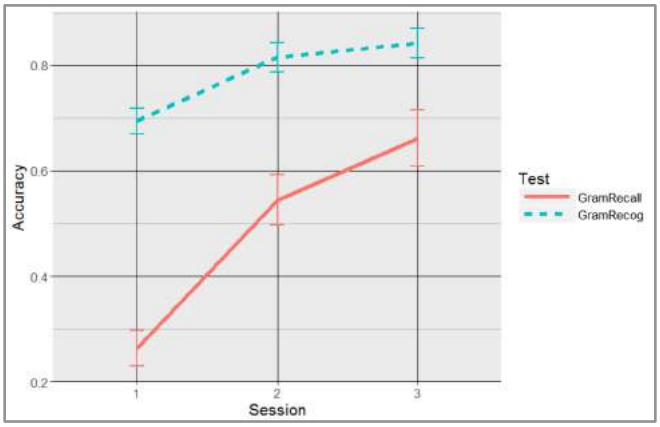

Figure 4. Average Learning Curves. Error bars: ± 1 *SE*.

Next, the recall and recognition data were each submitted to mixed-effects logistic regression modeling using a forward-testing procedure for random slopes and a backward elimination procedure for fixed effects to arrive at the model of best fit using likelihood ratio tests. This procedure allows us to find the most maximal model supported by the data, balancing Type I error and power (Matuschek et al., 2015). For each analysis, the first model included items and participants as random intercepts, session as a fixed effect, WIS, LSET, and RAC as covariates, and each Session x Covariate interaction. In each model, covariate tasks were mean centered.

Table 3 displays the final recall model. There was a significant effect of session, indicating that performance significantly improved across sessions (b = 1.67, SE = .25, z = 7.97, p < .001). There was also a significant effect of Session x RAC (b = .58, SE = .21, z = 2.74, p = .006), indicating that participants with higher RAC scores showed greater gains in recall accuracy over sessions. No other covariates or interactions were significant.

Table 3. Final Recall Model

Fixed Effects	*b*	Odds	*SE*	*p*
Intercept	-3.15	0.04	0.33	<.001*
Session	1.67	5.31	0.25	<.001*

Session x RAC	0.27	1.31	0.11	.014*	
Random Effects	**Var**	***SD***	**Corr**		
Intercept | Item	.77	.88			
Session | Item	.07	.27	-.26		
LSET | Item	.04	.21	.00	.68	
WIS | Item	.09	.30	.45	-.93	-.81
Intercept | Part.	.27	.52			
Session | Part.	.20	.44	.12		

Table 4 displays the final model for the recognition analysis. Session was once again significant (b = .89, SE = .10, z = 8.83, p < .001), as was Session x LSET (b = .23, SE = .10, z = 2.21, p = .027) and Session x RAC (b = .27, SE = .11, z = 2.46, p = .014), indicating that as performance on these measures increased, individuals showed greater gains in accuracy over sessions. No other covariate or interaction was predictive.

Discussion

The primary aim of the study was to investigate the cognitive underpinnings of explicit-inductive grammar learning. In our grammar learning task, participants attempted to learn a subset of Indonesian syntax by inferring the rules of the language from a number of exemplars. Based on prior studies and theory, we chose indicators of grammatical sensitivity, WMC, and inductive reasoning as our predictors. Aware of significant relationships amongst the predictors, we were also interested in investigating whether the predictors uniquely accounted for variance in grammar learning and if so, to what degree. Our analyses indicated that the WMC measure, RAC, and the inductive reasoning measure, LSET, were significantly related to grammar learning, however the grammatical sensitivity measure, the WIS, was not. Moreover, logistic mixed-effects modeling indicated that for our recall measure, performance on our WMC measure interacted with session, such that individuals who performed better on RAC showed greater gains in accuracy over sessions. A similar result was obtained for the recognition measure; however, additional variance in learning performance was accounted for by an interaction between the inductive reasoning measure, LSET, and session.

Overall, the results of the study suggest that WMC and inductive reasoning facilitate grammar learning. The fact the predictors interacted with learning session is likely due to the fact that grammatical learning builds on previous learning. For example, in English, it would be difficult for one to generate, “my two very fancy goats” without also being able to correctly generate “my two goats” or “my fancy goat.” Individuals with greater WMC and inductive reasoning ability were likely more able to learn rules, build upon them, and reinforce their own learning as they learned more complex rules, increasing their learning rate. Individuals with lower abilities, however, may have found it difficult to learn even the simpler rules and therefore struggled to see recurring patterns in more complex sentences, possibly interfering with (rather than reinforcing) learning; thus, their learning rate was slower compared to higher-ability individuals.

While the Session x RAC interaction was a significant predictor of both the recall and recognition measures, it is important to note that the Session x LSET interaction only accounted for a significant proportion of variance in recognition performance. This pattern of results confirms that WMC was generally involved in learning, however, the role of inductive reasoning is somewhat ambiguous. One possibility is that individuals with greater inductive reasoning ability were able to infer more rules but not necessarily retain

accurate representations in long-term memory (a function supported by WMC; Unsworth & Engle, 2007) and thus they were unable to accurately retrieve rules during the recall test. When tested using a recognition paradigm, however, high ability individuals were able to use cues to "fill in" or *redintegrate* their partial representations, and thus were more likely to correctly choose the grammatical phrase. Future research should continue investigating the role of inductive intelligence in explicit-inductive grammar learning.

Despite the fact that the grammatical sensitivity measure, WIS, did not account for variance in the learning tasks above and beyond the other predictors, the results of this study should not be interpreted as suggesting that grammatical sensitivity does not play a role in L2 learning. As noted above, prior research indicates that grammatical sensitivity is related to L2 learning and, in fact, the coefficients observed between the WIS and the grammar learning measures are similar to what have been found in the literature (Li, 2015). The null result observed here may have been due to sample size or characteristics (e.g., a restricted range in performance). Still, to the extent that the estimates are accurate, it is interesting to note that the role of grammatical sensitivity in grammar learning appears to be smaller than that of WMC and inductive reasoning. This may be because grammatical sensitivity is more a measure of English grammatical knowledge than learning (Carroll, 1993).

With the above limitations in mind, this study corroborates prior research indicating that WMC is a robust predictor of L2 learning and, more specifically, L2 grammar learning (Linck, Osthus, Koeth & Bunting, 2014; Miyake & Friedman, 1998). Moreover, while it may be somewhat intuitive that inductive reasoning is predictive of explicit-inductive grammar learning, we found that inductive reasoning accounts for at least one measure of grammar learning above and beyond WMC. Considering the large number of individuals that engage in L2 learning and the significance of knowing an L2, researchers should continue investigating the cognitive components of L2 learning.

Relationship Between Creative Experience, Recognition of Creative Process and Aesthetic Impression in Art-Viewing

Kazuki Matsumoto
University of Tokyo, Tokyo, Japan

Takeshi Okada
The University of Tokyo, Tokyo, Japan

Abstract

This study examined the roles recognition of the creative process behind artworks plays in cognitive processes of art-viewing. To this end, we conducted an experiment (N = 45) in which prior experience of participants was manipulated and investigated whether and how creative experience influences subsequent cognitive processes while viewing artworks. We revealed that having creative experience before art viewing changes viewers recognition of the creative process behind artworks and causes them to have a more positive impression of the artworks. It was also revealed that these two changes are correlated. In particular, the emotion of admiration, which is considered a kind of social emotion, was found to be highly correlated with the recognition of assessed difficulty of the creative process. These results suggest the importance of recognition of the creative process behind artworks and contribute to understanding the cognitive process of art-viewing.

The effects of changing the mental model of one's body and sense of body ownership on pain perception

Abstract

The mental model of one's body plays an important role in determining subsequent actions. We changed the mental model using visual information and observed the effects of such change on pain perception. These effects were compared to the effects of changes in the sense of body ownership, which is the sensation that something is a part of one's own body. Some researchers have shown that the sense of ownership is a factor modulating pain perception. In our experiments, we manipulated the visibility of participants' limbs using Mixed Reality (MR) techniques and measured their perceived pain and feelings while observing their limbs. Results showed the sensation that nothing can touch one's limbs decreased the strength of perceived pain.

Keywords: Sense of ownership, body representation, pain perception, multimodality, mixed reality

Introduction

We determine our next actions based on our own body representation or mental model of our bodies (Barsalou, 2008; Warren, 1984). Some features, such as posture, muscular strength, and size, change every moment or as we grow. Other basic features, such as bone structure, nerve mechanisms, and material properties, remain almost constant through life. If we can modulate such basic features in our mental model, can our perceptions be changed by the model? In this study, we investigate the relationship between the mental model of one's own body and perception, focusing on pain perception.

Sense of Ownership

One of the important sensations affecting the perception of pain is the sense of ownership or physical possession of one's body parts, such as hands and legs. The perception of ownership can be easily extended to non-body parts. The most famous example is the rubber hand illusion (Botvinick & Cohen, 1998): When a rubber hand and a participant's hand are repeatedly touched simultaneously while the participant is watching the rubber hand, he/she feels as if the rubber hand were his/her own.

Obviously, we cannot feel pain if something other than one's own body is attacked. Consistent with this idea, some researchers have shown that the pain threshold increases as the sense of ownership decreases (Martini, Kilteni, Maselli, & Sanchez-Vives, 2015; Martini, Pérez-Marcos, & Sanchez-Vives, 2014; Pamment & Aspell, 2017; Zanini, Montalti, Caola, Leadbetter, & Martini, 2017). However, some have argued that the sense of ownership has no effect on pain perception (Mohan et al., 2012).

Mental Model of Own Body

We propose that another important factor affecting the perception of pain is the material property of skin in a mental model of own body. If you imagine your skin is made with iron, for instance, you may not feel pain if someone hit you. Senna, Maravita, Bolognini, and Parise (2014) introduced the marble hand illusion: Participants in their study heard the sound of marble being struck when a hammer touched their hand. After five minutes, they felt their hands becoming stiffer, heavier, harder, less sensitive, and unnatural. However, Senna et al. (2014) did not investigate whether the manipulation affected the level of pain perception.

Another study showed that just changing the color of the skin was enough to change the threshold for heat pain; however, the effect of the manipulation on the mental model was not investigated (Martini, Pérez-Marcos, & Sanchez-Vives, 2013). These studies suggest the possibility that the mental model of one's body can be modulated to affect pain perception.

Aim of This Study

As previously noted, many previous studies have suggested that a sense of ownership was an important factor in pain perception. However, there is a possibility that the mental model of one's body is also modulated by manipulating ownership. Therefore, it is not clear whether pain perception is really related to the sense of ownership. To clarify the top-down effect on pain perception, we need to identify which of the mental model of the body or the sense of ownership has a stronger effect.

Mixed Reality

In previous studies, most researchers used a rubber hand or virtual body to manipulate participants' ownership or mental model of the body. Before introducing these manipulations, researchers had to increase participants' perception of ownership of these materials. For example, in Martini et al. (2015)'s experiment, participants viewed a virtual environment and virtual body from a first-person perspective for one minute. Afterward, the transparency of the virtual body was increased to decrease the sense of ownership. They showed that a low sense of ownership decreased pain sensitivity.

To be accurate, what the participants observed was not their actual body part but a rubber or virtual hand. Even if researchers made a realistic-looking hand, it would not be

(b) View from the camera

(c) Hand and virtual background

(d) Opacity 50%

Figure 1: Experimental environment and the manipulation of the limb.

a real hand; discrepancies between it and their body might give the participants an uncomfortable feeling. We would not be able to determine whether participants' mental models of their bodies changed or if they constructed new mental models for the fake hand. Additionally, while the manipulations were performed on the fake hand, stimuli were administered to the real hand.

To overcome the limitations of the fake hand, we introduce a Mixed Reality (MR) technique, which allowed us to change the properties of objects in the real environment or add virtual objects to the real environment (Kannape, Smith, Moseley, Roy, & Lenggenhager, 2019). With this technique, we made participants' own limbs appear transparent and observed the change in their perceptions of ownership, mental models of their bodies, and pain perception.

Apparatus

MR Environment

Figure 1 shows the experimental environment. We adopted a video see-through-type HMD (Canon, HM-A1) and MR platform system (Canon, MP-110). We acquired the participant's perspective from the camera on the HMD and manipulated the alpha value for the area of the participant's hand as shown in Figure 1. Five levels of the alpha value were used: 100% (fully visible), 75% visibility, 50% visibility, 25% visibility, and 1% visibility (almost invisible). A background image under the participant's hand had a black-and-white stripe to facilitate the perception of transparency.

Electric Stimulus

The pain presentation device was a boosted current using a Cockcroft-Walton circuit as an electric stimulus generation apparatus through an input/output board (Kyohritsu Electronic Industry Co., Ltd., RBIO - 2 U). A conductor (diameter: 0.12 mm, 10 cores) was fixed to a 1 mm-thick rubber sheet. We presented the pain sensation by applying a current to this conductor. The intensity of electrical stimulation was 320 V at a current of 1.8 mA, and the pulse width was 0.15 s.

Experiment 1

The level of ownership and mental model of their limbs were recorded at each level of opacity from 100% (fully visible) to 1% (almost invisible). We added a blackout (BO) condition in which no visual stimulus was presented.

Method

Participants Fourteen students participated in Experiment 1.

Measurement The participants assessed their levels of pain using a visual analog scale (VAS). We prepared a 100-mm line whose left end indicated "no pain" and whose right side indicated "worst possible pain." The participants were asked to draw a cross on the point reflecting the level of pain they perceived.

We developed a questionnaire to assess the mental model. It consisted of 20 items including feelings thought to be important for pain perception. The order of the items was randomized.

Procedure The experiment consisted of two successive blocks: the questionnaire and a pain perception block. All participants started with the questionnaire and then continued to the pain perception block. Before starting the experiment, the participants were asked to read and sign a consent form.

Questionnaire Block After receiving brief instructions, the participants sat at a desk and rested an arm on the desk as illustrated in Figure 1(a). They donned the HMD and saw their non-manipulated limb through a camera (Figure 1(c)) before watching their limb becoming transparent. At the end of the transformation, they watched their transformed limb (e.g., Figure 1(d)) for 10 seconds. Next, they removed the HMD and completed the questionnaire, which employed a 7-point Likert scale. All participants completed each opacity condition in random order except for the BO condition, in which their limb was completely invisible.

Pain Perception Block The procedure was identical to the questionnaire block until the participant observed their transformed limb. In the pain perception block, they were given an electric stimulus following a cue from the experimenter while they were watching their transformed limb. After the stimulus was given, they removed the HMD and assessed the strength of the pain they perceived. The opacity conditions were presented to participants in random order. In both blocks, two minutes rest was provided between each condition.

[1] These loadings mean the contribution to "less ownership." Score of this factor was reversed to make easy to understand the results.
[2] These loadings mean the contribution to "less anxiety." Score of this factor was reversed to make easy to understand the results.

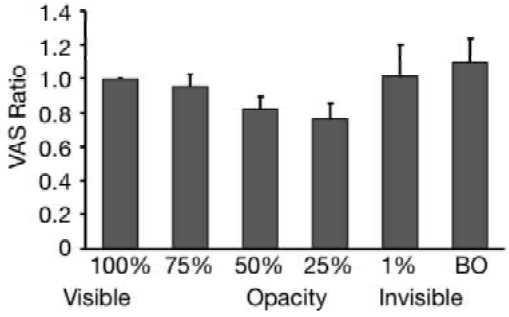

Figure 2: Means of pain assessment in Experiment 1.

Results and Discussion

Pain Perception We measured the distance from the left-most point to the marked point on the pain scale. The length in the 100% condition was the criterion value, and the length in each condition was converted to its ratio to the criterion value (Figure 2). One participant whose ratio deviated over 3 SD from the average was excluded from the following analyses. A repeated ANOVA showed the effect of opacity was significant ($F(5,60) = 2.467, p = .042$). In the 25% condition, the perceived strength of pain was lower than in the fully visible (100%) condition ($p = .036$). Perceived pain was stronger in the 1% and BO conditions than in the 50% and 25% conditions (ps $< .050$).

These findings and the tendencies in Figure 2 show that as the limb became more transparent, the level of perceived pain became weaker. However, when the limb was nearly or completely invisible, the strength of pain rose to near the value of the fully visible condition.

Questionnaire and Pain Perception We conducted a factorial analysis using the ratings of the questionnaire. We found five factors shown in Table 1: ownership, transparency, intangibility (i.e., nothing can touch their limb), anxiety, and weakness. The bigger value means the strong feeling for the factor.

A repeated ANOVA for each factor score (Figure 3) shows opacity value has a significant effect on all factors other than weakness (ownership $F(12,48) = 23.182, p < .001$; transparency $F(12,48) = 64.927, p < .001$; Intangibility $F(12,48) = 25.86, p < .001$; anxiety $F(12,48) = 6.716, p < .001$). For the ownership score, there was a significant difference in all pairs other than the pair of 1% and 25% and the pair of 50% and 75% (ps $< .05$). For the transparency score, the score in the 100% condition was higher than for any other conditions (ps $< .001$). For the intangibility score, the differences in scores between the 100% condition and all other conditions and between the 25% and 75% conditions were significant (ps $< .005$). For the anxiety score, the score in the 100% was bigger than that in all other conditions except for the 75% condition (ps $< .01$).

Table 2 shows the correlation coefficient values for the scores of all pairs among five factors and pain perception. We excluded the 1% condition from this analysis because

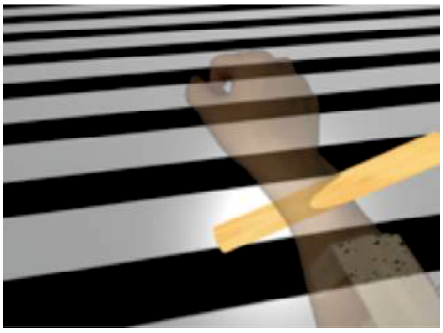

Figure 4: Manipulation in the PT condition: The virtual stick passing through the limb.

some participants shared that they could not see their limbs in this condition, which had a different effect on pain perception than seeing the transparent limb.

The results of correlation analysis show a negative correlation between the level of pain and the scores of transparency and intangibility. Sense of ownership did not correlate to the strength of pain, contrary to the results of the previous studies. In Experiment 2, to identify the most crucial factor for pain perception, we added manipulations changing the perceptions of ownership and intangibility.

Experiment 2

Two manipulations were introduced in Experiment 2. One was "passing through (PT)," in which we passed a virtual stick through the participant's limb as shown in Figure 4. The PT manipulation would increase the sensation of intangibility. Another was "spontaneous movement (SM)," in which the participant moved his/her finger. Many studies showed that observing the body moving in the way as they wanted to increase the sense of ownership. The experiment was a 2 (opacity: 25% and 100%) $\times$ 2 (PT manipulation: PT and no-PT) $\times$ 2 (SM manipulation: SM and no-SM) within-participants design.

Method

Participants Eleven students participated in Experiment 2.

Procedure The procedure was identical to that used in Experiment 1, except that we added the PT and SM manipulations in some conditions. In the PT condition, we moved the virtual stick 10 times as it passed through the participant's limb (Figure 4). In the no-PT condition, we added no manipulation, changing the feeling of intangibility. For the SM manipulation, the participant bent his/her finger as instructed by the experimenter. In the no-SM condition, the participant was told nothing and did not move his/her finger or limb. The manipulation(s) were added before the participant answered the questionnaire and before the electric stimuli were given. The PT manipulation was always conducted before the SM manipulation.

Results and Discussion

Manipulation Check One participant who hardly felt pain in any condition was excluded from the following analyses. At first, we calculated the scores for the five factors found in Experiment 1 to confirm the effects of the manipulations. We conducted a 2 (opacity: 25% and 100%) $\times$ 2 (PT manipulation: PT and no-PT) $\times$ 2 (SM manipulation: SM and no-SM) ANOVA on the scores for ownership and intangibility feelings. The ANOVA for ownership feelings showed that SM manipulation had no effect. The only significant effects were the main effect of the opacity factor ($F(1,9) = 26.396, p < .001$) and the interaction between the opacity and PT manipulation factors ($F(1,9) = 11.505, p = .008$). The score for ownership feeling was generally higher when the limb was fully visible. The PT manipulation decreased the ownership in the 100% condition ($F(1,18) = 9.172, p = .007$). The SM manipulation had no effect on the score of ownership feeling.

On the other hand, PT manipulation efficiently increased the sensation of intangibility. The main effects of the opacity factor ($F(1,9) = 40.490, p < .001$) and the PT manipulation factor ($F(1,9) = 23.802, p < .001$) were significant

Table 3: Coefficient values in Experiment 2.

	Ownership	Transparency	Intangibility	Anxiety	Weakness
Ownership					
Transparency	-0.702 ****				
Intangibility	-0.533 ****	0.670 ****			
Anxiety	-0.540 ****	0.285 *	0.587 ****		
Weakness	0.039	0.140	-0.226 *	-0.394 ****	
Pain	0.218 $^{+}$	-0.363 ****	-0.405 ****	-0.325 ***	0.167

$^{+}p < .01$, * $p < .05$, ** $p < .01$, *** $p < .005$, **** $p < .001$

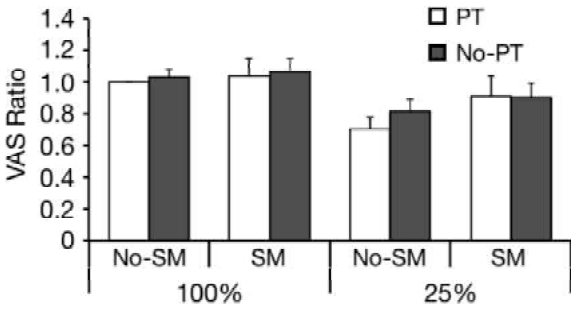

Figure 5: Means of pain assessment in Experiment 2.

for the intangibility score. The interaction between the opacity and PT manipulation factors was also significant ($F(1,9) = 12.091, p = .007$). The effect of PT manipulation was (marginally) significant in both the 25% and 100% conditions (25% $F(1,18) = 4.069, p = .059$; 100% $F(1,18) = 35.888, p < .001$). Although the effect was weak in the 25% condition, the PT manipulation was successful overall.

Pain Perception The VAS rating was converted into the ratio to the length in the 100% condition without either manipulation. Figure 5 shows the mean ratio in each condition. A 2 (opacity: 25% and 100%) $\times$ 2 (PT manipulation: PT and no-PT) $\times$ 2 (SM manipulation: SM and no-SM) ANOVA revealed a significant main effect of the opacity factor ($F(1,9) = 15.244, p = .004$). The interaction between the opacity and SM manipulation factors was marginally significant ($F(1,9) = 3.391, p = .099$). Consistent with the results of Experiment 1, the strength of perceived pain decreased when the participant's limb was transparent. However, the MT manipulation, whose effect was confirmed, had no effect on pain perception.

The Five Factors and Pain Perception The correlation coefficient values among the five factors and pain perception are shown in Table 3. Four factors (ownership, transparency, intangibility, and anxiety) had a (marginally) significant correlation with pain perception, while only ownership and intangibility were related to pain perception in Experiment 1. Many pairs of the scores among the five factors have a strong correlation. Thus, those strong correlations may have caused some spurious correlations.

$^{+}p < .01$, * $p < .05$, ** $p < .01$, *** $p < .005$, **** $p < .001$

We tried to identify the crucial factor for pain perception using regression analysis. The results of all analyses are summarized in Table 4. From the results of simple linear regression analyses, four factors (ownership, transparency, intangibility, and anxiety) could explain the strength of perceived pain. We then conducted multiple regression analyses in which each pair of these four factors was chosen as an explanatory variable, and the strength of perceived pain was a dependent variable. When the intangibility score was paired with other factors' score, intangibility was always the only factor with significant explanatory power, and the paired variables' power was not significant. These results suggest that the sensation of intangibility was the crucial factor directly affecting pain perception.

However, the relationship between other factors and the intangibility feeling cannot be determined from this experiment. Further studies are needed to identify whether the other factors explain the intangibility score or whether the intangibility score explains the scores of other factors. Additionally, the r^2 values in our regression analyze were not sufficiently high. Collecting more data will confirm the results of this study.

General Discussion

We investigated the relationships among the mental model of one's own body and pain perception. The crucial factor affecting pain perception was the sensation that nothing can touch one's limbs (intangibility); as this sensation increased, the perceived level of pain decreased. The sense of ownership could not account for the level of perceived pain.

The properties of the mental model of one's body were easily modulated by visual information. A decrease in the perceived opacity of one's body parts decreased feelings of ownership and increased feelings of transparency, intangibility, and anxiety. The passing through manipulation successfully increased the feeling of intangibility. However, observing spontaneous actions did not increase ownership, contrary to findings in previous studies.

Sense of Ownership

We introduced a novel technique, MR, to manipulate body properties. The MR technique can change participant perceptions of the properties of their own limbs. The observed limb had features identical to their own limb and perfectly mimicked its movement. The participants were able to see every movement of their whole limb even if it was a very small movement such as breathing. This phenomenon had already been used to evaluate the sense of ownership; therefore, the additional spontaneous movement had no effect on the feeling of ownership. In future research, we will be able to use other kinds of manipulation, such as a delayed presentation of action, which was found by Kannape et al. (2019) to decrease the feeling of ownership.

In previous studies, the presented rubber or virtual limb was not the participants' own limb. Therefore, the participants created a new mental model of the presented limb and provided the body ownership to it. Changes to the presented limb took the ownership away from it. In short, the participants did not perceive the presented artificial limb to be their own anymore. For this reason, the feeling of ownership had a strong effect on pain perception (e.g., Martini et al., 2014; Pamment & Aspell, 2017); the participants who left more ownership on the presented body felt strong pain.

On the other hand, the MR technique decreased the inherent ownership of the body leading to the sensation that one's own limbs are not part of one's body. The sensation of intangibility had more of an impact because the participants still believed that the presented limb was their own, even if the sensation of ownership had decreased. We should carefully consider which type of ownership we manipulate, the elicited ownership such as in previous studies or the inherent ownership such as in this study (cf. Kannape et al., 2019); the manipulation may have different effects.

The Mental Model of One's Body

We could change pain perception by changing the properties of the mental model of the body. The results of this study can be explained as a top-down effect on perception (Gregory, 1997; Martini et al., 2013; Senna et al., 2014). The feeling of intangibility in this study meant the sensation that one's body had become something cannot be touched, like that of a ghost. Such creatures are believed to be unable to feel pain. The illusion of transparency triggered this perception, resulting in decreased pain.

Changes in other properties, such as an iron skin, might have the same effect as transparency. This top-down effect could also have an opposite effect: For example, if the material of body is changed to something fragile, such as glass, and the body is hit by a hammer, participants may perceive more pain that with their normal bodies. In addition, some changes have the potential to change task performance.

Abstract

Recent studies demonstrate strong, concurrent relationships between language and EF, particularly during early childhood. However, the literature remains controversial with respect to this relationship. Whereas some studies cite a bidirectional relationship, others suggest that EF is predictive of language gains, while others suggest that it is language which affects EF through conversational practice. Further controversy remains in the literature regarding which components of EF are engaged in the processes. The bidirectionality of current research in this area suggests that perhaps EF and language are best fitted by a curvilinear relationship. This is compounded by the fact that a large number of these studies have employed linear statistical analyses to examine the relationship of the two constructs. Thus, in order to further specify the relationship between EF and language development, we examined monolingual and bilingual infants and toddlers to determine the utility of a curvilinear model to assess the EF and language relationship, what aspect of language inhibitory control most correlates to EF, and whether there is a monolingual/bilingual difference. Results indicate that the EF and language early childhood relationship is best fitted by a curvilinear model.

Development of Verb Morphology: From Item-Specificity to Proficient Use

Jekaterina Mažara (jekaterina.mazara@uzh.ch)

Abstract

The initial phase of linguistic production by children is characterized by rote-learned, lexically restricted forms and constructions. Only during later phases of language acquisition do they develop flexibility across a paradigm and mix lexical and grammatical material more freely. In the development of verb morphology, a correlation between the use of tense and aspect has been observed in many languages. It has been suggested that this leads to an intermediary state of paradigm categorization based on temporal categories. So far the flexibility of individual verbs occurring in different tense-aspect combinations has not been examined in detail. Here we evaluate the flexibility of verb use in a large longitudinal corpus of 4 Russian children. We compute the Shannon entropy of verb stems distributed over individual grammatical forms. Results show that children do not pass through a stage of paradigm categorization based on aspecto-temporal categories. After a brief item-specific phase of rote learned forms, they quickly become flexible users of verbs in both aspects.

Keywords: language acquisition; corpus study; item-specificity; verb morphology; aspect; Russian

Introduction

Usage-based approaches to language acquisition propose an early phase during which children use a small number of lexically specific constructions which are presumably rote-learned (Lieven, Pine, & Baldwin, 1997; Pine & Lieven, 1997; Tomasello, 2000, 2003). During this short phase of lexical specificity, flexibility of word form use is very low, but soon after using the first rote-learned constructions, children start to produce new forms and apply them to new contexts. So far, relatively little is known about this generalization process from lexically specific constructions to full productivity.

In this study, we focus on the acquisition of Russian verb morphology and the role of aspect. Grammatical aspect is the expression of the viewpoint on the temporal structure of an event. *Perfective aspect* describes an external and temporally bounded view of a completed event, while *imperfective aspect* focuses on the internal stages or temporal extension of an event (Comrie, 1976).

Languages differ vastly in how (and if) they mark grammatical aspect but independent of the realizations, aspect has been found to play a pivotal role in the acquisition of the verbal system in relation with tense (Shirai & Anderson, 1995; Shirai, Slobin, & Weist, 1998). Correlations between verbs with a defined end-point (telic verbs) and perfective past marking as well as verbs without a defined endpoint (atelic) and non-past imperfective marking have been found in early acquisition of a number of different languages (cf. Bloom, Lifter, and Hafitz (1980); Harner (1981); Shirai and Anderson (1995); Clark (1996); Johnson and Fey (2006) for English, Bronckart and Sinclair (1973) for French, Antinucci and Miller (1976) for Italian, Li and Bowerman (1998); Shirai and Anderson (1995); Shirai et al. (1998); Li and Shirai (2000) for Japanese; Stoll (1998, 2005); Stoll and Gries (2009); Gagarina (2000); Bar-Shalom (2002) for Russian; Li (1990); Li and Shirai (2000) for Mandarin; Aksu-Koç (1998) for Turkish; Stephany (1985) for Greek; Weist, Wysocka, Witkowska-Stadnik, Buczowska, and Konieczna (1984); Weist and Konieczna (1985) for Polish; as well as self-organizing feature map models (cf. Li (2000); Li and Shirai (2000)).

It has been suggested that due to the presence of this correlation, after the lexically-specific phase, the development of productivity passes through an intermediary stage, during which children are more productive in their use of verbal morphology with the appropriate prototypes of a category (also known as the *Aspect Hypothesis* see Shirai and Anderson (1995)). These correlations are also present in the speech of adults, albeit to a lesser degree. However, to date, only a few studies have systematically compared these correlations in child and child-surrounding speech. For Russian children, Stoll and Gries (2009) have found a gradual decrease of this association in children over the course of development.

The goal of this study is to examine the development of flexibility of verb form use in Russian children. We test whether there is indeed a transition phase based on the tense-aspect correlation during which children are more productive within sub-categories of the verb paradigm before becoming fully productive verb users.

We first establish phases in production based on verb form inventory size. We then compare both type and token distributions in children's use during these phases to that of adults. We show that in token use, both adults and children display distributional bias of tense-aspect correlations. The bias is stronger in children in the first phase of production and approaches adult levels in the second phase. We evaluate the flexibility of use over time by measuring the entropy of lemmas used with individual grammatical forms. We show that, as item-specificity decreases, a great variety of forms is introduced early on and quickly generalized so that both past and non-past marking is used with verbs of both aspects.

Verb morphology in Russian

Russian has relatively complex verbal morphology centering on a semantically and morphologically complex category of grammatical aspect which interacts with tense. Grammatical aspect in Russian is characterized by a perfective/imperfective distinction and each verb is either perfective or imperfective. In contrast to English which has one single aspectual marker (*-ing*), Russian has many different markers for the perfective aspect (mainly prefixes and one suffix) and one suffix (with various allomorphs) for the imperfective aspect or zero marking.

On the functional level, several temporal and contextual features influence the use of the two aspects. Russian imperfective verbs are used when the duration of an action is relevant (e.g. *ona čitaet ves' den'* 'she reads all day') and if the action is presented as a completed event (e.g. *ona včera čitala ves' den'*, 'she spent all day reading yesterday'). Perfective verbs are used when the focus of the utterance is a boundary of the action; this can be either the beginning of an action, the end/result or both (e.g. *ona dočitala knigu*, 'she finished reading the book'). Morphologically, perfectives are typically derived from imperfectives by prefixation. To complicate things, however, the meaning cannot be derived via simple rules (Timberlake, 2004) and always involves some degree of rote-learning. There is no one-to-one relationship between prefixes and the resulting meaning change in the verb they are attached to. Further, most verbs can combine with multiple prefixes, while others are restricted in their combinability.

Verbs of both aspects express other verb categories (person, number, tense, voice, and mood) with the same morphemes. There are, however, some differences in meaning. Non-past morphology denotes present tense when it appears with imperfectives, but expresses the future in combination with perfectives. To express imperfective future, an analytic form is used (consisting of a finite 'to be' auxiliary and the infinitive of the main verb). In this paper, we focus on the acquisition of synthetic morphology and, therefore, exclude the analytic future. Past morphology can be used with both aspects equally.

The broad generalization found in the works cited in Shirai et al. (1998) states that children begin their acquisition of verb forms by using past morphology with achievement verbs and progressive morphology with activity verbs and only later extend it to the other group. Since lexical aspect is not annotated in the corpus we use, we focus on correlations between grammatical aspect and tense. However, this still allows us to assess this hypothesis, since achievements are necessarily perfectives and activities are necessarily imperfectives in Russian. We will, therefore, focus on whether Russian children display correlations between perfective aspect and past tense (e.g. *On doel sup*, 'he ate the soup' (meaning: he finished the bowl)) and imperfective aspect and non-past marking (*On smotrit televizor*, 'he is watching TV').

Methods

Data

The data is extracted from an audio-visual longitudinal corpus of Russian language acquisition (Stoll & Meyer, 2008) comprising data of six monolingual children living in St.Petersburg, Russia. All recordings were done in naturalistic settings at the home of the children and include the focal child and a varying number of surrounding speakers including siblings (excluded here) and adults. The children were recorded for one hour each week. We focus on 4 children, whose recordings started before the age of three. The entire corpus is transcribed and words are annotated for part of speech and morphology. Table 1 summarizes the number of utterances, words, and verbs uttered by each focal child as well as the age range of recording.

Table 1: Age spans of the focal children and number of words produced by the children and surrounding adults

Focal Child	Age span	Number of recordings	N(tokens)			
			Child		Adults	
			words	verbs	words	verbs
1	1;8.10 - 4;8.21	130	241,948	38,843	301,418	60,987
2	1;4.23 - 4;1.24	109	57,929	5,411	354,034	65,173
3	1;3.24 - 4;9.29	123	74,926	10,733	423,078	84,659
5	1;11.28 - 4;3.12	67	97,397	16,585	223,289	43,149

Finding phases in acquisition

First, we establish whether there are phases in verb form acquisition. The phases were derived directly from the target children's verb form production. We computed the additive growth in full verb forms (stem+grammatical markers) over time. The growth curves show a slow rate of increase in the earlier sessions followed by a sudden increase in the rate of newly observed forms [1]. To estimate the age at which this change in rate of acquisition occurs, we conducted a segmented regression on the growth curve of each child. The break points at which the regression created a new segment are summarized in Table 2. We use these points as the estimated end of the first phase of production for the next analysis.

Table 2: Break points in growth curve as identified by segmented regression.

Child	Break-point
Child 1	2;2
Child 2	3;3
Child 3	2;3
Child 5	before recordings started

[1] This was the case for all but Child 5 who already had highly developed speech at the onset of the recordings. Child 5, therefore, did not exhibit this change in rate of newly observed forms.

Entropy of verb form use

To asses the development of flexibility of form use in the observed production, we used Shannon Entropy (Shannon, 1948), the rate at which a process produces information by characterizing the balance of frequency distributions over a set of elements. If the probability of produced elements is distributed equally among them, the output is less predictable. Early child language is usually characterized by the repeated use of a few forms, while other forms might appear only once. This would result in a highly predictable output and low entropy. The formula for Shannon entropy is given in Eq. 1

$$H(X) = -\sum_{i=1}^{N} p(x_i) \log p(x_i) \quad (1)$$

where N is the number of distinct forms and $p(x)$ is the probability of occurrence of a specific form [2].

Analysis 1: Distribution of forms in the first and second phase To gain a better understanding of verb form production during the first and the second phase of development, we extracted the verb lemmas (lexical elements) used before the break point in development. To obtain a sample comparable in size and lexical coverage, we extracted the same lemmas from the adults' production during this phase and sampled the same number of tokens as produced by the focus child. Finally, we conducted the same procedure for both focus child and surrounding adults for the second phase. To gain a first insight into the form use and asses the level of item-specificity, we visualised the data in mosaic plots showing both type and token use of children and adults in both phases. To characterize the difference between the distributions, we computed the Jensen-Shannon divergence (Lin, 1991) between each child and their surrounding adults, and between the child's own first and second phases. Jensen-Shannon divergence (JSD) measures the distance between two probability distributions over the same elements (i.e. verb lemmas in this case). The formula for JSD for two distributions P and Q with equal weight (0.5) is given in Eq. 2.

$$JSD(P\|Q) = \frac{1}{2}D(P\|M) + \frac{1}{2}D(Q\|M) \quad (2)$$

M represents the average distribution $M = \frac{1}{2}(P+Q)$; and D stands for Kullback-Leibler divergence (KLD, sometimes also called *relative entropy*), given in 3.

$$KLD(P\|Q) = -\sum_{x\in X} P(x) log \frac{Q(x)}{P(x)} \quad (3)$$

JSD is based on KLD, but it is symmetric and its value is always finite and non-negative. When P = Q, JSD = 0 (i.e. the two distributions are equal). To evaluate the development of forms use across verbs from the two aspects and different grammatical categories, we computed the distribution of grammatical markers over the lexical elements extracted from the first and second phase of each child and the surrounding adults. First, we compare the probability distributions of the child and the adults during phase 1 and phase 2; then, we also compare the distribution of the child in phase 1 and the same child during phase 2. We do this both for types and tokens of verb forms.

Analysis 2: Flexibility of form use over time While JSD is useful when we can compare the probability distributions for a set of identical items, it is impossible to assess the week-to-week development in this way, since we have no way of controlling the context and lexical content of individual recording session. Cutting the production down to forms that appear in both adults' and children's production would also result in a severe underestimation of the development and a distortion of the actual production. Therefore, we compute the entropy of all elements occurring in an individual recording session. To assess whether certain tense-aspect combinations indeed aid in acquisition, we divide the data into past and non-past marked verbs and compute the entropy of perfective and imperfective verb lemmas used with past and non-past marking. As the children develop away from the item-specific phase, we expect their use of individual grammatical markers to become more flexible, i.e. they learn to combine a variety of verb lemmas with individual forms.

To estimate the time at which children start approaching adult levels of flexibility in their verb form use, we use the entropy computations of adults as a comparison within each session. The children's entropy is divided by the corresponding surrounding adults' entropy within each session. A value below 1 signifies that the child is below the adult level of entropy, values above 1 mean that the child's verb production has a higher entropy than that of surrounding adults. To control for contextual influence and other effects that might lead to particularly high or low entropies, we bootstrapped the data in each recording session for 100 iterations.[3]

Since the corpus consists of naturalistic data, it is difficult to normalize the production for comparative reasons. Sampling a fixed number of tokens from children and adults in each session would distort the data in a number of ways: i) if a fixed number of tokens is sampled across the recording span (e.g. 500 tokens from children and adults), the children's initial production is inflated, while adults and children's later production are underestimated; ii) if the number of tokens is determined by the number produced by the target child in each recording, this – again – severely underestimates the adults' production in the early recordings and does not represent a realistic measure for comparison. Same goes for a restriction of lexical elements used for the computation of entropy, since the fact that children's vocabulary size is growing is also an important factor and should not be ignored. This is

[2] For the computation of entropy used over time, where we looked at each session individually, we did not treat the system as a complete survey of the forms that have been acquired by that point in time.

[3] The relatively low count of bootstraps was chosen for reasons of graphic clarity.

especially important for Russian, where aspect is encoded as part of the lemma.

To evaluate whether the age at which significant changes in the entropy of lemma use with individual forms happen, we fitted a generalized additive model to the data and estimated the change points of the regression to find the age at which diversification starts and when it levels off.

Results

Analysis 1: Distribution of forms in the first and second phase

Looking at the sample of matched verb lemmas and number of tokens in the two phases of each child and their surrounding adults, we see that the type distribution is slightly more diversified than the distribution of tokens. While there are tendencies to use more non-past forms with imperfective verbs and more past forms with perfectives, even during the earliest phase this tendency is not absolute and both past and non-past forms appear with verbs of both aspects early on. While types are distributed fairly equally, the token distribution is less even during both phases. This holds for both adults and children.

Table 3 shows the JSD computed for each child's early production compared to that of surrounding adults and the child's own production during the later phase. In the case of child 5, it was not possible to establish an early phase similar to that of the other children. Additionally, Child 5's earliest recorded production is so varied that it was impossible to obtain a sample of the same lexical items within the same time window from the surrounding adults. Therefore, the results shown for Child 5 represent a comparison of Child 5's production during the first 5 recordings sessions compared to a lexically and size-matched sample from his surrounding adults across the entire corpus.

Table 3: Jensen-Shannon divergence per child.

	Phase1 Child-to-Adults		Phase2 Child-to-Adults		Child Phase1-to-Phase2	
	Types	Tokens	Types	Tokens	Types	Tokens
Child 1	0.124	0.501	0.020	0.056	0.122	0.421
Child 2	0.143	0.505	0.032	0.135	0.115	0.508
Child 3	0.121	0.647	0.074	0.107	0.112	0.609
Child 5	n/a	n/a	0.097	0.327	n/a	n/a

In all samples, the difference between the distributions of tokens is more pronounced than that of types, and shows less of a decrease between the two phases. However, the difference between each child's first phase and second phase sample is comparable to the difference between the child's production and that of adults in phase 1. This suggests that their development approaches a stage where their use of verb forms in spontaneous home interactions is very similar to that of the adults.

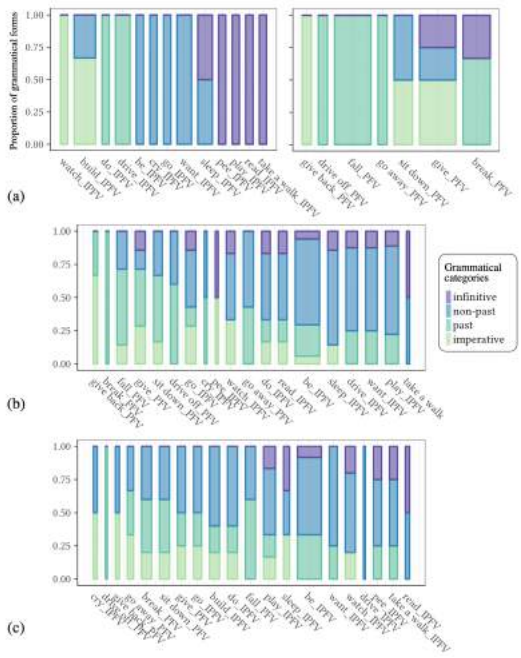

Figure 1: (a) Distribution of full form verb types in the production of Child 1 during phase 1; (b) Distribution of types in a sample of same lemmas and same number of tokens in Child 1's production during phase 2; (c) Distribution of types in a sample of same lemmas and same number of tokens in adults' production during phase 1.

To gain insight into the actual combinations of lemmas and forms used in each phase, Figures 1 a–c and 2 a–c exemplify the visualization of the type and token use within the sample of Child 1 and surrounding adults (we are not able to show the corresponding visualizations of the other children for space reasons). The thickness of the bars corresponds to the distribution of forms across the verb lemmas, while the colors stand for grammatical categories to which the forms belong. For types, only the plot for the child's first phase distribution was split by aspect, because phase 2 did not show the difference as strongly. For the token use, however, all plots are split by aspect, since the token distribution of both children and adults shows more differences between the use of grammatical markers with verbs in the two aspects.

Analysis 2: Flexibility of form use over time

Entropy ratios (child/adults) of the use of lemmas with individual grammatical markers from the sub-sets of non-past and past morphology and the segmented regression reveal that difference in the onset of diversification is not large. For past morphology, perfective lemmas show an earlier increase of entropy, but imperfective lemmas follow suit only a few weeks later and vice versa. The onset of use starts with imperfective+non-past and perfective+past for all children except Child 5, whose production is already diversified at the start of recordings. Only Child 3 shows a lag of more

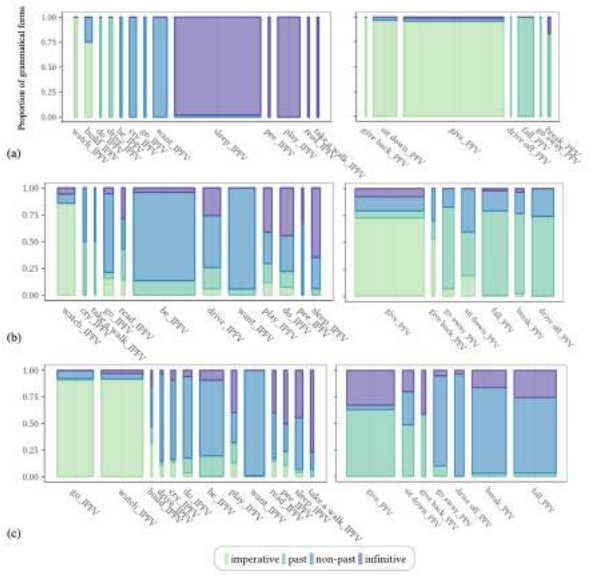

Figure 2: (a) Distribution of verb tokens in the production of Child 1 during phase 1; (b) Distribution of tokens in a sample of the same lemmas and the same number of tokens in Child 1's production during phase 2; (c) Distribution of tokens in a sample of the same lemmas and the same number of tokens in adults' production during phase 1.

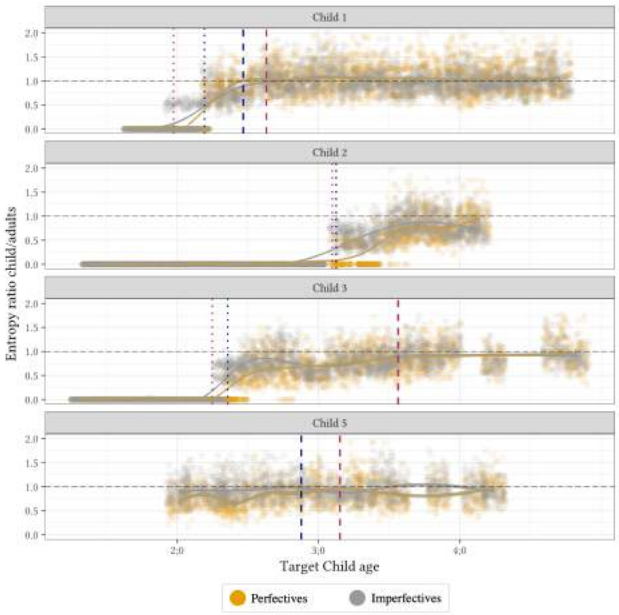

Figure 3: Entropy ratio (children/adults) of lemmas used with non-past marking on perfective and imperfective verbs, computed on bootstrapped data (100 iterations per session). Blue lines indicate changes in entropy increase for perfectives, red lines for the imperfectives.

than a month between the beginning of increased flexibility of perfectives+past and imperfectives+past.

Figures 3 and 4 show the increase of entropy ratios over time as well as the break points of the segmented regression. The break points are indicated by vertical lines: the dotted line represents the point at which the use of lemmas starts to become more diversified and the dashed line indicates the point at which the increase in diversification levels off.

Discussion

The children in our sample started out using verb forms in an item-specific manner during the first phase of verb production. Few verb lemmas appeared with more than one grammatical marker. However, while we did observe some tendencies that are in agreement with the Aspect Hypothesis, there is very little evidence that would make it a compelling argument by itself. Even during the early verb use we encounter past forms used with imperfective verbs. Child 1, for example, uses verbs such as *drive* and *do* with past marking early on; they are semantically activities without an endpoint and not expected to occur with past marking in the earliest phase of verb production. A plausible explanation in this case is the fact that Russian past forms are both quite transparent and appear in a narrower array of contexts, which eases acquisition and generalization.

The onset of the increase in flexibility of use of lemmas with individual grammatical forms is temporally close for verbs of both aspects. This suggests that, rather than passing

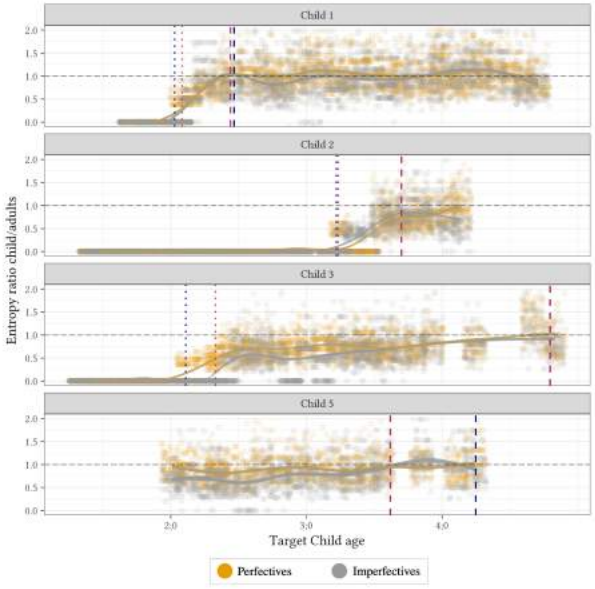

Figure 4: Entropy ratio (children/adults) of lemmas used with past marking on perfective and imperfective verbs, computed on bootstrapped data (100 iterations per session). Blue lines indicate changes in entropy increase for perfectives, red lines for the imperfectives.

through an intermediary phase during which the generalization first occurs within subdivisions of the verb paradigm (for perfective verbs with past marking, for imperfective verbs with non-past), the generalization starts early across the entire paradigm. Soon after item-specificity starts decreasing, children begin applying forms of a grammatical category to verbs of both aspects. This is strengthened by the observation that verb use in the first phase of production shows a stronger distributional bias in the distribution of tokens than in that of types. Coupled with the observation that the same holds for adult production — albeit in a weaker form — this finding suggests that the patterns of aspect-tense combinations found in the literature might be a mirroring of adult distributional patterns. Supporting this view is the fact that hardly any of these studies took the diversity of forms into account and thus have mostly confirmed the Aspect Hypothesis for the preferred use of forms, while making a less firm statement about availability of different forms at any stage of development. Given that distributional bias also factors into adult speech, it is important not to overstate the effect of preferred aspect-tense combinations on learnability of forms in the paradigm. Since children are able to pick up on distributional cues, their initial use of forms might simply be a reflection of the distributions found in adults as well as personal needs (cf. Figure 2b and the large proportion of the imperative form of *give*). A similar observation was already made by one of the authors of the Aspect Hypothesis Shirai (1998), who found that Japanese children do not follow the predictions of the Aspect Hypothesis and, therefore, suggested that multiple factors should be taken into account when examining early acquisition of tense-aspect morphology.

By looking at the use of different lemmas with the individual grammatical forms and thus measuring how flexibly a form is used, we were able to show that the development of form use might be more advanced than indicated by preferential use of certain tokens which skew the distributions. Going forward, it is important to disentangle the issue of tense-aspect marking further and take into account the differences between token and type distributions as well as further factors, such as lexical development and underlying distributions of grammatical markers in individual languages.

Pre-exposure and learning in young children: Evidence of latent inhibition?

Abstract

Previous research by Kaniel & Lubow in 1986 found that young children (aged 4-5 years) exhibited poorer learning (latent inhibition) to pre-exposed stimuli than older children (aged 7-10 years). The aim of our research was to develop a computer-based, child-friendly study that would replicate the work of Kaniel & Lubow. Sixty-three children took part in our experiment. This consisted of a pre-exposure/study phase in which participants were asked to press computer keys in response to clipart pictures of animals and dinosaurs. Each animal or dinosaur picture was preceded by one of two "warning signals" which acted as the pre-exposed stimuli (to which no response was required). In the test phase that followed, the participants had to either press the spacebar or withhold their response to each pre-exposed stimulus and two novel stimuli. They learnt which response was correct by trial and error using the feedback provided. The accuracy and reaction time of the responses during the test phase were analysed and indicated that the youngest children showed significantly lower mean accuracy and longer mean response times to the pre-exposed stimuli than to stimuli they had not been pre-exposed to. In contrast, the older children showed no significant differences in their responses to pre-exposed and novel stimuli. These results are consistent with those found by Kaniel & Lubow and could be taken as evidence for latent inhibition in young children. Further studies are proposed in which variations in pre-exposure procedure are used to rule out explanations based on response inhibition or negative priming.

Introduction

Learning from experience takes place when connections or associations are formed between stimuli and outcomes, e.g. pricking a finger on a needle results in one learning that needles are sharp, so care is needed when handling them. Latent inhibition (LI) occurs as a result of being exposed to a stimulus without a noticeable outcome. For instance, in the laboratory, latent inhibition is observed when rats that have been pre-exposed to a tone are slower to learn that the tone will subsequently indicate a reward (such as food), than rats that had not previously been exposed to the tone, (Lubow and Moore, 1959; for an example with rats see McLaren et al, 1994). LI is relatively easy to find in animals but it is, by comparison, difficult to find evidence for this effect in humans.

In their review of human LI experiments, Byrom et al (2018), suggest that none of them provide sufficient evidence to conclude that pre-exposure to a stimulus is the sole reason for the retarded responding observed. Other factors, such as negative priming (see Tipper, 1985 and Graham and McLaren, 1998), learned irrelevance or relative novelty could also be responsible for their findings. In order to provide a true test of LI, it is necessary to develop human experiments that are able to rule out these potentially confounding factors.

One study that appears to provide evidence for LI in humans is that by Kaniel & Lubow (1986). In their study, there was a simple Study Phase task in which children had to press buttons in response to pictures of plants and animals presented on metal cards in a box divided into three compartments. The cards were presented in sets of three, with one animal card and one plant card on each side of a third card (depicting two different sized black or white squares). During each trial the cards on either side of the middle card were changed and the child had to press a button corresponding to the side on which, for instance, the plant was present. In the following Test Phase, the children were presented with sets of cards showing black or white squares. This time they had to learn to press a button on the side corresponding to the card depicting the square that they had previously been exposed to in the study phase. They found that children aged 4-5 years exhibited poorer learning in this test than older children (7-10 year olds).

Can we take this as evidence of latent inhibition in young children? In one sense, the procedure used in Kaniel and Lubow's experiment is an example of simple exposure to the square stimuli, as they are presented at central fixation. If we accept this, then this may indeed be an example of latent inhibition in young children. On the other hand, the requirement for the children to respond to the pictures of plants or animals could have acted as a masking task during the study phase and diverted their attention from the pre-exposed black or white square stimuli. If this is the case, then an explanation in terms of conditioned inattention to the stimuli (i.e. negative priming, see Graham and McLaren, 1998) would be preferred. One argument against the latter explanation, however, is that the effect is confined to just the youngest group of children. Given that masking task procedures can successfully produce retarded learning in adults (see Ginton, Urca and Lubow, 1975 for an early demonstration of this in the auditory modality as well as Graham and McLaren, 1998 for an example using visual stimuli), why would only the 5 year old children show the effect in this case? For these reasons, this Kaniel and Lubow's results are some of the most interesting and potentially consequential for theories of learning that we are aware of.

This study has, to our knowledge, never been successfully replicated. Our aim was to design an updated and improved version of the Kaniel & Lubow study to see if we could replicate its findings, but without there even being a hint of a masking task involved. Our study uses clipart pictures of animals and dinosaurs for the children to respond to, one computer key for each. Instead of the pictures of different sized squares, we use four simple patterns as our pre-exposed stimuli. Two of the patterns are presented in the study phase as "warning signals" prior to an animal or dinosaur appearing. In the test phase, all four patterns are presented and the participants have to learn to either respond or withhold their response to each pattern. This design brings with it a number of advantages over Kaniel and Lubow's original. Because the stimuli being pre-exposed are

used as warning signals and are not present at the same time as the choice stimuli during the pre-exposure phase, participants do not have to ignore them and focus on the relevant stimuli. And, because we use both pre-exposed and non-pre-exposed stimuli in both conditions (respond and withhold response) in our test, we can see whether any learning deficit depends on whether people have to learn to respond to that stimulus or not.

Experiment

Method

Participants

Sixty-three primary school children took part in the experiment. The number of participants in each age group was as follows: 4-5 year olds (13), 6-9 year olds (40), 10-11 year olds (10). The children were all from a primary school a few miles outside Exeter, Devon.

Materials and Design

The experiment consisted of a **pre-exposure/study phase** of 120 trials (in random order) in which the participant had to respond to clipart pictures of dinosaurs and animals (examples in Fig. 1), each preceded by a "warning signal" (Fig. 2).

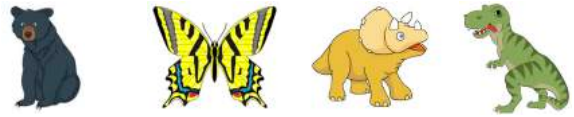

Figure 1. Examples of clipart images (300 x 300 pixels) of animals and dinosaurs presented during the pre-exposure/study phase of the experiment.

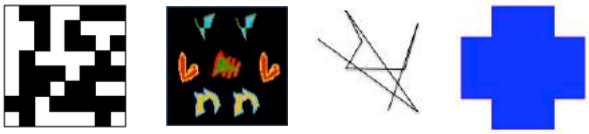

Figure 2. "Warning signal" stimuli (128 x 128 pixels). Two stimuli appeared during the pre-exposure/study phase; all four appeared during the test phase.

During the study phase, two of the stimuli shown in Fig. 2 were presented one at a time to provide a warning that the next animal or dinosaur stimulus was about to be displayed. Each warning stimulus appeared equally often preceding each choice stimulus.

The study phase was followed by a **test phase** of 32 trials in which the participant had to learn to either press the spacebar or withhold their response to each of four stimuli, two of which had been pre-exposed during the study phase. The two stimuli for which a spacebar response was required included one of the pre-exposed stimuli and one of the novel controls, and likewise for the stimuli for which the response had to be withheld. Stimuli were counterbalanced across conditions and subjects by creating four versions of the study (see Table 1).

Table 1. Counterbalance for stimuli pre-exposed during the study phase and responses required in the test phase of each version of the experiment (+ = press spacebar, - = withhold response).

Counterbalance	Study phase stimuli	Test phase response
1	A and C	A+, B-, C-, D+
2	A and C	A-, B+, C+, D-
3	B and D	A+, B-, C-, D+
4	B and D	A-, B+, C+, D-

The experiment was developed using SuperLab 4 software (version 4.0.7b) and was presented on a Macintosh laptop computer.

Procedure

Written consent was obtained from the parents/guardians of the children before they took part in the experiment. The consent form included information on the procedure of the experiment and the participants' right to withdraw at any time.

The experimenter worked with one participant at a time. At the start of the experiment the computer screen showed a picture of an imaginary island with a cartoon child "explorer". Overlaying the picture were written instructions. For each participant, the experimenter read the onscreen instructions out loud, as follows:

Welcome to our study.
Imagine you have just arrived on an island that has never been explored before.
Your job is to look for animals.
You soon find out that some animals look just like dinosaurs. Could this be possible?
Have dinosaurs somehow managed to survive on this remote island?
You need to quickly and accurately record every dinosaur and animal you see.
Press the 'x' key if you see a dinosaur.
Press the '.' key if you see an animal that isn't a dinosaur.
The computer will say 'yiha' if you get it right or 'oops' if you get it wrong.
Try to get as many correct responses as you can.
Please press the 'B' key to see some more instructions.

Before you see them there will be a signal to warn you that the animal or dinosaur is coming!
Remember:
- as soon as you see a dinosaur, press the 'x' key.
- as soon as you see an animal that isn't a dinosaur, press the '.' key.
When you're ready, press the 'B' key

Pre-exposure/study phase: There were 120 trials in two blocks of 60 with a participant break (self-timed) at the end of the first block.

Each trial consisted of a fixation cross (500ms) followed by a warning signal (1500ms) followed by a dinosaur/animal image (up to "x" or "." response, or 2000ms if no response). Feedback was given in the form of a "yiha" sound (correct response) or "oops" sound (incorrect response). If there was no response within the time-limit of 2000ms the feedback (presented on screen) was 'Oops – you took too long!'. Figure 3 shows an example of a trial

sequence during the pre-exposure/study phase.

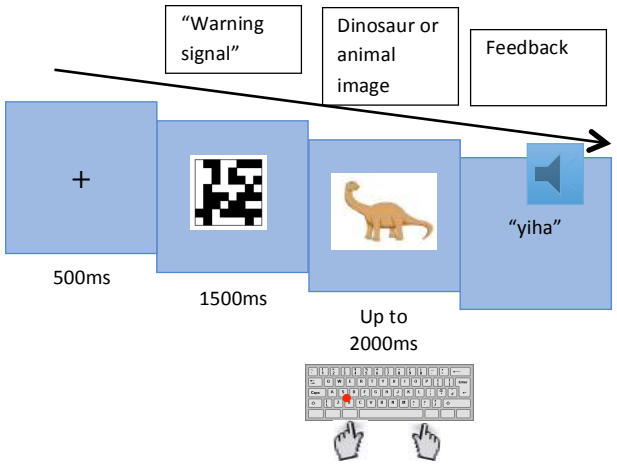

Figure 3. Example of a trial sequence during the pre-exposure/study phase.

During this phase, each of the two warning signals (pre-exposed stimuli) was presented 60 times in random order (equally preceding the animal or dinosaur stimuli). Participants were not required to respond to the pre-exposed stimuli.

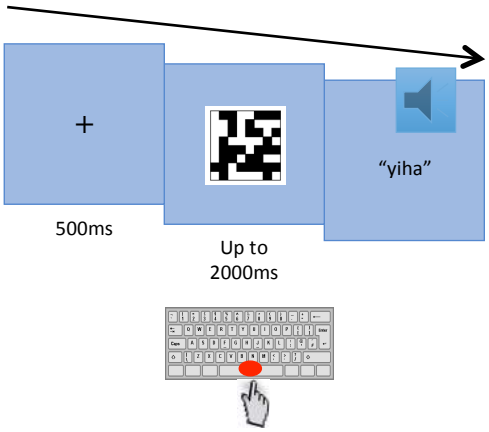
At the end of this phase, the following instruction screen was presented. Again, the experimenter read these instructions out loud when working with children.

Thank you. You have recorded all the dinosaurs and animals on the island.
Now the computer is going to show you some patterns.
These patterns were used to label the island by people who used to live there a long time ago.
Some parts of the island are safe to enter but others may be dangerous!
You need to mark which parts are safe – you do this by pressing the "spacebar"
And which ones aren't safe – for these don't press the "spacebar".
You will just be guessing to start with. Try pressing and not pressing the "spacebar" when you see a pattern and see what happens.
The computer will say "yiha" if you get it right or "oops" if you get it wrong.
Please press the 'B' key to begin.

Test phase: There were 32 trials in two blocks, with a participant break (self-paced) after the first 16 trials. Accuracy and reaction time were recorded for each trial during the test phase.

During this phase, each trial consisted of a fixation cross (500 ms) followed by one of the four stimuli (shown in Fig. 2), presented in a random order. These stimuli remained on screen up to the spacebar response or until 2000ms had elapsed if no response was made. If the spacebar was pressed, feedback ("yiha" or the "oops" sound) was provided immediately. If no response was made, feedback ("yiha" or "oops" sound) was provided after 2000ms. This enabled participants to learn, by trial and error, which type of response was required for each stimulus. Figure 4 shows examples of two trials (one requiring the "spacebar" response, and the other requiring no response) during the test phase. Each stimulus (two pre-exposed during the study phase and two novel stimuli) appeared 8 times. Two of the stimuli (one pre-exposed and one novel) required the "spacebar" response. Two stimuli (one pre-exposed and one novel) required the response to be withheld (i.e. no response).

A) Response = "spacebar" press



B) Response = withhold response

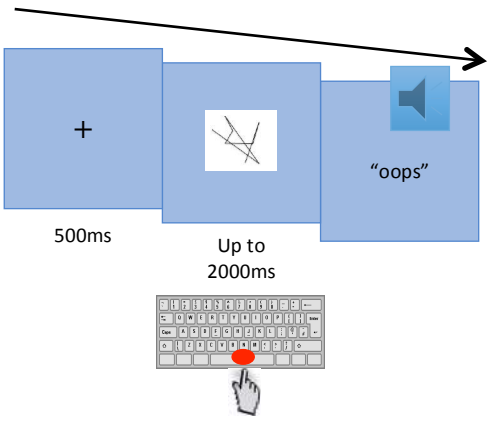


Figure 4. Examples of two Test phase trials in which the "spacebar" was pressed: Trial A required the "spacebar" response so feedback is "yiha". Trial B required the response to be withheld but a spacebar press was made so feedback is "oops".

Results

The accuracy and reaction time data collected during the first block of the test phase were analysed using t-tests to establish whether there was a significant difference between responses to the stimuli that had been pre-exposed during the study phase compared to the novel stimuli, and whether this was dependent on the age of participants. A significance level of $p = .05$ was used for all statistical tests, which were two-tailed unless otherwise specified. Only data from the first block of the test phase were analysed as, by the second block, most children had reached 100% accuracy.

The 4-5 year-old children were the only age group to exhibit significantly lower overall accuracy of responding (averaged over go = spacebar press and nogo = withheld response) to the pre-exposed stimuli than to the novel stimuli, $t(12) = 3.57$, $p = .004$ (see Figure 5). This finding is consistent with a latent inhibition effect in the youngest children, and consistent with Kaniel and Lubow's (1986) findings. The size of the effect was significantly greater than that observed in the oldest children, $t(21) = 2.25$, $p = .035$; and this difference also approached significance when the youngest and the middle age groups were compared, $t(51) = 1.93$, $p = .059$. This also replicates Kaniel and Lubow's (1986) findings.

As would be expected, mean response accuracy tended to increase with the children's age. The mean response accuracy of the oldest children (10-11 year olds) was significantly greater for both the pre-exposed $t(21) = 4.51$, $p < 0.001$, and novel $t(21) = 3.18$, $p = 0.005$, stimuli when compared with the youngest children. Only the difference for the pre-exposed stimuli is significant when comparing the middle group to the youngest, $t(51) = 2.34$, $p = 0.023$.

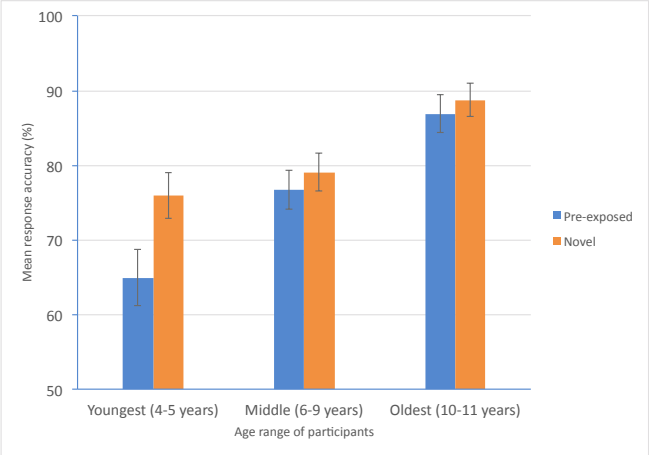

Figure 5. Mean percentage response accuracy (averaged over go and nogo stimuli) for the pre-exposed and novel stimuli for each age group during the test phase. Error bars show SE of the mean.

Figure 6 focuses on the response accuracy for those stimuli requiring a spacebar press (Pre-exposed + and Novel +). In this case, the 4-5 year old and 6-9 year old children both show a significant difference in their response accuracy ($t(12) = 5.50$, $p < 0.001$ and $t(39) = 2.40$, $p = 0.021$ respectively) with a tendency to respond less accurately to the pre-exposed stimuli. In contrast, the older children show no reliable difference in their spacebar response accuracy to the pre-exposed and novel stimuli.

Once again we can look at the differences between groups on this measure. There isn't a significant difference when comparing the oldest to the youngest children (even though numerically the difference is large, this is probably a matter of power), but there is a trend towards significance for the comparison between the middle group and the youngest children, $t(51) = 1.73$, $p = 0.09$, a result that would be significant on a 1-tailed test. There is some evidence, then, that the poorer learning exhibited is in part, at least, due to difficulty in learning to respond to the pre-exposed stimulus that requires a response. There was no sign of such an effect for the pre-exposed stimulus that did not require a response.

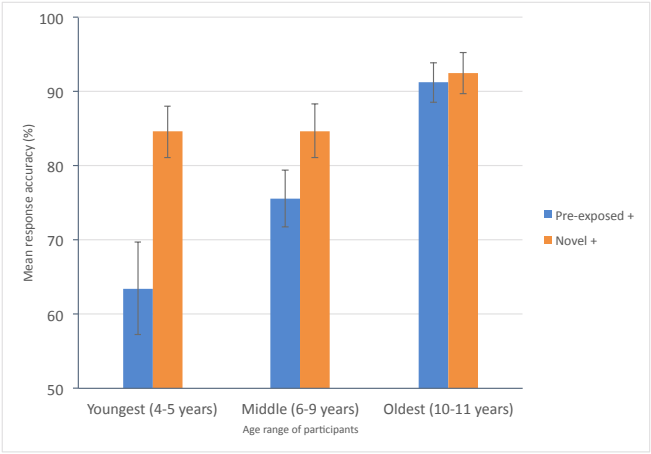

Figure 6. Mean percentage response accuracy for the stimuli requiring a spacebar press for each age group during the test phase. Error bars show SE of the mean.

The mean response times for stimuli requiring a spacebar press (Fig. 7) were significantly longer for the pre-exposed stimuli than the novel stimuli for both the 4-5 year old children ($t(12) = 2.51$, $p = 0.027$) and the 6-9 year old children ($t(39) = 2.21$, $p = 0.033$) but not in the oldest age group. But this difference did not itself differ significantly across groups, despite the extra time taken to pre-exposed stimuli being considerably greater numerically in the youngest children than in the other two groups. As would be expected, the youngest children generally exhibited longer response times for both types of stimulus than the oldest children.

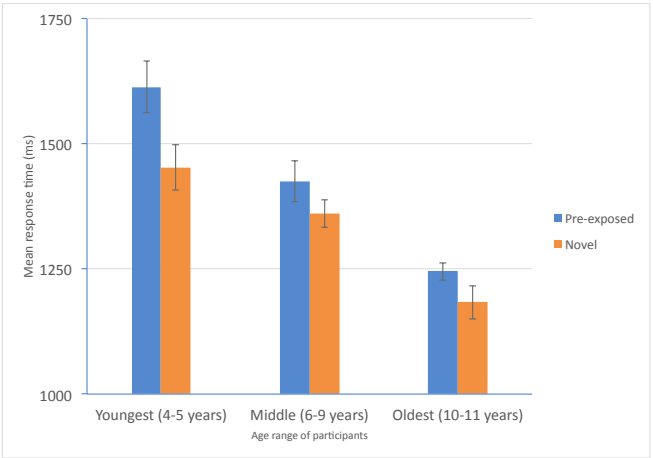

Figure 7. Mean response times (msec) for the pre-exposed and novel stimuli for each age group during the test phase. Error bars show SE of the mean.

General Discussion

The aim of this study was to replicate Kaniel and Lubow's (1986) findings using an updated method that avoided the need to ignore the pre-exposed stimuli while performing the initial task. In this we succeeded. There is really quite strong evidence in our data for retarded learning as a consequence of pre-exposure in our youngest group of children, and this

is the same age group that Kaniel and Lubow obtained their effect with. We have also failed to find a similar effect in older children, again mirroring Kaniel and Lubow's results, and all this with a pre-exposure procedure that uses the target stimuli as warning signals for an upcoming trial, so that there is no obvious need to ignore them. But can we be sure that this is latent inhibition in humans?

The answer to this question has, for the present, to be no. We cannot be sure that this is latent inhibition, but we can, perhaps, rule out some of the other possibilities. As we have argued, there is no particular reason to learn to ignore the pre-exposed stimuli during the initial phase of the experiment, because they actually serve a useful function, warning of the next stimulus to which a decision has to be made. One could always argue that the 4-5 year old children do learn to ignore these stimuli nevertheless, but that would seem a rather ad-hoc explanation of our results. And we would still be left with the conundrum of explaining why older children do not learn to ignore the pre-exposed stimuli.

But in adapting our design to control for possible artifacts in Kaniel and Lubow's study, we may have introduced new ones into our experiment. One plausible explanation for these results takes note of the fact that the larger effect on learning seems to be on the pre-exposed stimulus to which a response was required during the final, test phase. The young children were particularly bad at learning to press the spacebar in the case of the pre-exposed S+, and the middle age group also showed an impairment in learning. Perhaps encountering the stimuli during the initial pre-exposure phase when responses were required to the animal/dinosaur pictures and not having to make a response to the pre-exposed stimuli (because they were used as warning stimuli) has somehow caused this effect?

We can imagine at least two versions of this account. One would have it that being presented with the stimulus, followed by no outcome led to a type of CS->NoUS learning that has been suggested as producing the basic latent inhibition effect in other animals. Learning that this stimulus signals no outcome makes it harder to learn that an outcome does follow later. If this is the mechanism, then it would support the contention that the 4-5 year old children are displaying latent inhibition, as well as providing evidence for a particular theoretical explanation of latent inhibition.

A somewhat more concrete and specific version of this account would appeal to response inhibition developing rather than learning some general CS->NoUS association during pre-exposure. In a context where responses have to be made (press one of two keys), when the warning signal is shown no response is required and so general response inhibition accrues and is associated with the stimuli present at the time. As a consequence, when a response is required to these pre-exposed stimuli, it is harder to learn and perform. This explanation can be distinguished from our earlier one by noting that the result for latent inhibition is that learning of both an excitatory association and of an inhibitory association between CS and US is retarded for a CS that has undergone latent inhibition. But the response inhibition account would predict that learning to withhold a response to a CS would actually be facilitated. The question, then, is how learning to respond to the pre-exposed S- progresses in the last, test phase. The answer in our data is that there is no evidence of a facilitatory effect in the youngest or oldest children, and there is only a hint of one in the middle group ($t(39) = 1.69$, $p = .099$. Given this, a response inhibition account of the poorer learning seen in the youngest children seems unlikely. The fact that we have an effect in our youngest age group for overall performance is also indicative of an effect that is not based on response inhibition.

Perhaps the most important argument for this being a demonstration of latent inhibition in young children, however, is generated by considering the two experiments, Kaniel and Lubow's and ours, in combination. A response inhibition explanation will not obviously apply to Kaniel and Lubow's design, as a response is made while the pre-exposed stimuli are on screen. A learned inattention or negative priming explanation cannot easily be applied to our results because there is no reason to ignore the pre-exposed stimuli. But both experiments give very similar results, which suggests a common explanation for those results, and the only one that seems to fit is latent inhibition.

Which brings us to what may be the most intriguing feature of these results. The younger children, 4-5 years old, are the ones that show the effect. The older children either do not show any significant effect, or display a significantly weaker version of it. This is also something our study shares in common with Kaniel and Lubow's original work and needs some explanation. The explanation given in Lubow's 1989 book "Latent Inhibition and Conditioned Attention Theory" is that this "raw" latent inhibition found in young children is actually present in older children and adults, but that they have compensatory attentional processes that obscure this effect in studies of this type. In essence, latent inhibition reduces learning, but then attention is deployed to take it back up to its original level, hence no difference is observed between pre-exposed and non-pre-exposed conditions.

There is much to commend in this explanation, and one of us has offered something that at first sight is similar in McLaren, Wills and Graham (2010). But there are real differences, stemming from the fact that our account of latent inhibition (which can be found in its earliest form in McLaren, Kaye and Mackintosh [MKM], 1989, and has been updated in McLaren and Mackintosh, 2000, and McLaren, Forrest and McLaren, 2012) differs from that offered by Lubow. In Lubow's account, latent inhibition is due to conditioned inattention, but in ours it is due to a reduction in salience due to the features of the pre-exposed stimuli becoming predicted either by other stimuli present, or by one another. This leads to a reduction in salience (learning rate) for these pre-exposed features, hence latent inhibition. Instead, we use conditioned attention to explain why simple pre-exposure does not lead to observable latent inhibition in older children and adults. We argue that people attend to stimuli that are placed in front of them, and that this attentional response then becomes linked to those stimuli, compensating for any effect of latent inhibition. This attentional response is absent in younger children, which produces our and Kaniel and Lubow's results.

Why should we prefer this explanation to Lubow's? Both explanations are viable for the results obtained here and in Kaniel and Lubow's original study. But our explanation has the advantage of being able to explain Graham and McLaren's (1998) results as well as other demonstrations of retardations in learning in adults using a "masking" task (e.g. Ginton, Urca and Lubow, 1975). We argue that these results are indeed due to conditioned inattention, just as Lubow would have it, but disagree that this is the basis for latent inhibition. The test that Graham and McLaren use is to create two distortions of a pre-exposed stimulus and then train a discrimination between them. In their 1998 paper, they find that this results in slow learning of the discrimination when it is compared to a similar discrimination based on distortions of a novel stimulus. This is the opposite result to that found in animals (see Aitken, Bennet, McLaren and Mackintosh, 1996 for direct evidence on this point), and so suggests that the retardation in learning observed when the pre-exposed stimulus is trained directly is not actually latent inhibition but instead is due to negative priming. In future, we intend to apply this test to our finding. If we are able to demonstrate an enhancement of learning between two distorted versions of the pre-exposed stimulus (i.e. perceptual learning) using this technique then this will be excellent evidence that the effect is the same as that seen with simple pre-exposure in other animals, and confirm that it is latent inhibition and not negative priming.

Conclusions

In conclusion, this study has provided strong evidence for a retardation in learning to a stimulus following pre-exposure to that stimulus in young (4-5 year old) children. This effect was not found in older children. It is possible that what we have here is latent inhibition of the type obtained with simple pre-exposure in animals such as the rat, but more work will be needed to establish whether this is, in fact, the case. Possible alternative explanations are conditioned inattention / negative priming, and generalised response inhibition, but neither receive a great deal of support from the data we have obtained. Further research should focus on either definitively ruling these alternatives out, or providing solid evidence for them.

If we have demonstrated latent inhibition in young children, then this has important implications for theories of learning, particularly in humans. It would confirm that we carry with us the same basic processes affecting learning as other animals, and would also go some way to confirming the MKM model of perceptual learning. More than that, it would also raise the question of why latent inhibition "goes away" in older children. We have given one possible reason here, which offers us one perspective on the development of learning and cognition in children. If it turns out not to be the case, and our results can be explained by some other mechanism, then this problem will still remain. Why do young (4-5 years old) children show this effect and older children do not? Solving this developmental puzzle will add to our understanding of human mental life.

Leveraging Thinking to Facilitate Causal Learning from Intervention

Abstract

Intervention selection is at once crucial in causal learning and challenging for causal learners. While the optimal strategy is maximizing the expected information gain (EIG), both children and adults often combine it with suboptimal ones such as the positive test strategy (PTS). In the current study, we sought to facilitate causal learning from intervention by asking 5- to 7-year-olds to explain why they chose a certain intervention to identify the true structure of a three-node causal system that might work in one of two ways. Our findings suggest that while engaging in self-explaining did not help children select more informative interventions, asking them to think about their intervention choices (explaining or reporting) might help them better utilize interventional data to infer causal structures.
Keywords: causal learning; intervention; explanation; learning by thinking

Once upon a time in China, two men were accused of a murder yet no evidence could be found. The judge gave each of them a "magical" straw that was said to grow longer in the hands of the guilty. As the story goes, the man showing up with a *shorter* straw next day was put in jail. As you might have guessed, straws don't grow; the real magic is that the judge chose the most informative intervention centuries before informative theory came into being. He could not foresee which man would cut his straw in fear but whoever did it must be the murderer. This strategy allowed him to maximally reduce his uncertainty averaged across potential outcomes, or in other words, maximize his *expected information gain* (EIG)

EIG is widely regarded as a normative model for inquiry selection (Coenen, Nelson, & Gureckis, 2018; Nelson, 2005) but it only partially captures people's actual interventions. Both adults (Bramley, Lagnado, & Speekenbrink, 2014) and children (McCormack, Bramley, Frosch, Patrick, & Lagnado, 2016) outperform models that intervene randomly but fall short of pure EIG maximization. On the computational level, a possible explanation is that adults (Coenen, Rehder, & Gureckis, 2015) and children (Meng, Bramley, & Xu, 2018) combine EIG maximization with a suboptimal strategy akin to the *positive test strategy* (PTS) in the rule learning literature (Klayman & Ha, 1989; Wason, 1960). In causal learning, Coenen et al. (2015) defined PTS as a tendency to generate the most expected effects under your current causal hypothesis. A minimal example of PTS is intervening on X when you try to discriminate between your hypothesis, $X \rightarrow Y \rightarrow Z$, and an alternative one, $Y \leftarrow X \rightarrow Z$. If the outcome (e.g., only X and Y are activated) happens to *falsify* your hypothesis, you get to rule it out; otherwise, both could still be true so you remain uncertain. By contrast, a high-EIG intervention (Y) reduces your hypothesis space (in this case, to 1) regardless of the outcome (all variables are activated or only Y and Z).

To ensure successful causal learning from intervention, learners should use an optimal strategy (e.g., EIG) to select interventions and make accurate inferences from interventional data. In the current study, we sought to facilitate both the intervention selection and the belief updating processes by prompting learners to *explain* why they choose a certain intervention to learn about an unknown causal system.

Explanation and intervention

Explaining requires no extra data or instructions; yet, it has profound downstream consequences for learning and inference in various domains (see Fonseca & Chi, 2011; Lombrozo, 2016, for reviews). Typically, learners achieve better learning outcomes simply by engaging in explanation (e.g., how a system works, why an effect occurred, etc.) even without feedback or generating accurate explanations (e.g., Chi, Bassok, Lewis, Reimann, & Glaser, 1989; Chi, De Leeuw, Chiu, & LaVancher, 1994; Walker, Lombrozo, Legare, & Gopnik, 2014; Walker, Lombrozo, Williams, Rafferty, & Gopnik, 2017). Many theories are proposed to explain why explaining facilitates learning, such as that it helps learners fill gaps in their knowledge, repair erroneous mental models, recruit criteria for "good" explanations (simplicity, breadth, or other "explanatory virtues") to constrain reasoning, etc..

How do you explain an intervention? From an EIG perspective, to explain intervention selection, you must consider belief updating (Coenen & Gureckis, 2015): You choose an intervention because on average, it reduces the most uncertainty. Engaging in explanation may benefit both processes.

Explaining may facilitate intervention selection by promoting *comparison* and *abstraction*. A recent study (Edwards, Williams, Gentner, & Lombrozo, 2019) suggested that asking learners to explain exemplars' category membership (e.g., "Why is this robot a Glorp/Drent?") increased their comparison within and between categories. Should explainers compare more across different interventions and the outcomes of each intervention, they might be in a better place to select high-EIG interventions. Moreover, effective learners may realize that on an abstract level, informative interventions are ones that yield distinct outcomes under different hypotheses. Walker and Lombrozo (2017) found that explaining the outcome of a story (e.g., why a character is sad) helped children extract its underlying moral and go beyond the specifics. Should explaining help causal learners achieve such abstraction, it could largely reduce the cost of intervention selection.

Explaining may also facilitate belief updating by encouraging learners to apply their prior knowledge when interpreting interventional data (Williams & Lombrozo, 2013).

(d) Puzzle 4 (e) Puzzle 5 (f) Puzzle 6

Figure 1: Light bulb puzzles used in the experiment.

Current study

In the current study, we investigated whether self-explaining could facilitate causal learning from intervention. We chose to test 5- to 7-year-olds because previous studies (McCormack et al., 2016; Meng et al., 2018) suggested that they were not yet able to reliably select informative interventions, leaving substantial room for improvement. This also allows us to compare our results directly to that in Meng et al. (2018).

Overview of experiments Our causal learning task was adapted from Meng et al. (2018). Children were tested on six unknown causal systems consisted of three light bulbs, some of which could turn on others if activated. Each system could work in one of two ways and children were allowed to turn on one light bulb to identify its correct structure. All causal connections were deterministic with no background noise.

In the first experiment (Experiment 1A), children were asked to explain their intervention choice ("Why did you turn on that light bulb?") after carrying it out. However, since those children observed the outcome before explaining, their explanation might be a *post hoc* justification of their choice ("Because it helped me solve the puzzle.") rather than the actual reason. To address this concern, we conducted a second experiment (Experiment 1B) where children pointed to the intervention they wanted to perform and were asked to explain their choice ("Why do you want to turn on that light bulb?") before carrying it out. In the respective control conditions, children were asked to *report* which intervention they carried out (Experiment 1A) or planned to choose (Experiment 1B).

Modeling intervention strategies To compare intervention strategies across conditions, we took a hierarchical Bayesian approach used by Coenen et al. (2015) and Meng et al. (2018). We compared models of three single strategies (EIG, PTS, and random selection) and a linear combination of EIG and PTS. Below is an overview of the four models.

Learners all begin with a set of causal hypotheses, each of which can be represented as a directed acyclic graph $g \in G$ (G is the space of possible graphs), or a *causal Bayesian network* (Pearl, 2000). In each graph, causal variables are presented as nodes and causal relationships as edges.

1. Expected information gain (EIG)

   The information gain (IG) after intervening on the node $n \in N$ is the difference between the initial entropy, $H(G)$, and the entropy conditioned on the outcome o, $H(G|n,o)$:

   $$IG(n,o) = H(G) - H(G|n,o). \tag{1}$$

   Since o is unknown, the expected information gain (EIG) over all possible outcomes O is used to estimate IG:

   $$EIG(n) = H(G) - \sum_{o \in O} P(o|n) H(G|n,o). \tag{2}$$

   Applying Shannon's entropy equation, we have

   $$H(G) = -\sum_{g \in G} P(g) log_2 P(g), \tag{3}$$

   and

   $$H(G|n,o) = -\sum_{g \in G} P(g|n,o) log_2 P(g|n,o). \tag{4}$$

   The prior probability $P(g)$ of each graph g is assumed to be equal and the posterior probability $P(g|n,o)$ is given by Bayes' rule, $\frac{P(o|g,n)P(g)}{\sum P(o|g,n)P(g)}$. $P(o|g,n)$ is the likelihood of an outcome o given a hypothesis g and an intervention n.

2. Positive test strategy (PTS)

   PTS manifests as the tendency to intervene the node $n \in N$ with the most of direct or indirect descendant links (normalize by the total number of links in each graph $g \in G$):

   $$PTS(n) = \max_g [\frac{DescendantLinks_{n,g}}{TotalLinks_g}]. \tag{5}$$

3. Random selection

   Random selection is equivalent to indiscriminately assigning the same value (e.g., 1) to all possible interventions.

4. Linear combination of EIG and PTS

   Rather than sticking to one strategy, learners may use multiple strategies such as EIG and PTS to select interventions. The value of each possible intervention is a linear combination of its EIG and PTS values (the weight of EIG is θ).

Under one strategy or another, each possible intervention is assigned a value $V(n)$. An ideal learner should always select the intervention with the highest value but due to noise τ in the decision process, an actual learner often does so probabilistically. According to the *softmax choice rule* (Luce, 1959), the probability that an intervention gets chosen, $P(n)$, is a function of its value $V(n)$ and the learner's decision noise τ:

$$P(n) = \frac{\exp(V(n)/\tau)}{\sum_{n \in N} \exp(V(n)/\tau)}. \tag{6}$$

When τ is 0, the learner selects interventions with the highest values; when τ approaches $+\infty$, they select randomly.

Experiments

Participants

Seventy-four 6- to 7-year-olds participated in Experiment 1A, 37 of whom were assigned to the Explanation condition (M = 85 months, range = 74–101 months, SD = 9 months) and 37 to the Report condition (M = 84 months, range = 64–96 months, SD = 8 months). Another forty-three 5- to 7-year-olds participated in Experiment 1B, 22 of whom were assigned to the Explanation condition (M = 77 months, range = 62–90 months, SD = 8 months) and 21 to the Report condition (M = 75 months, range = 50–101 months, SD = 14 months).

Equipment

Three light bulbs (yellow, green, and red) were presented on a laptop screen and controlled by three buttons of corresponding colors located on a response board. During practice, red arrows indicated the causal relationships among the light bulbs. During the test, the arrows were hidden but two possible structures were shown on two cards placed side by side.

Procedure

Both experiments included a familiarization phase, a practice phase, and a test phase. During familiarization, children were taught to use buttons on a response board to control light bulbs of corresponding colors on the computer. During practice, they saw four basic types of structures: Common Cause (*Yellow* ← *Green* → *Red*), Common Effect (*Yellow* → *Red* ← *Green*), Causal Chain (*Green* → *Red* → *Yellow*), and One Link (*Yellow* → *Red*). In Experiment 1A, the presentation order was randomized. For each structure, children decided when to turn on which light bulb and were asked to describe the outcome of each action. In Experiment 1B, each structure was one change apart from the previous one. The simplest structure, One Link, was presented first, which was followed by Causal Chain, Common Cause, and Common Effect. For each structure, children turned on the light bulbs in a designated order (*Yellow–Red–Green* in the first two trials and *Green–Red–Yellow* in the last two) and were asked to predict and then describe each action's outcome.

On each of the six test trials, children were shown two ways in which the three light bulbs might work and were told that they could only turn on one light bulb to find out the true structure. In Experiment 1A, children were asked to explain ("Why did you turn on that light bulb?") or report ("Which light bulb did you turn on?") the intervention that they had just carried out. In Experiment 1B, children were asked to first point to the light bulb they planned to turn on, then explain ("Why do you want to turn on that light bulb?") or report ("Which light bulb do you want to turn on?") their choice, and finally perform the intervention[1]. At the end of both experiments, children were asked to put a smiley face sticker on the correct causal structure. In order to avoid potential discouragement that we observed during piloting, feedback was only provided after the entire experiment.

[1] In the rare event that children's actual intervention differed from what they planned, we used the former for all our analyses.

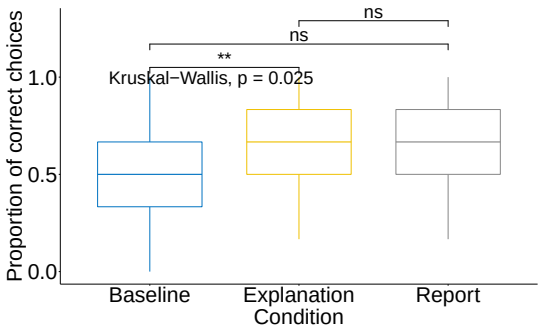

Figure 2: The proportion of causal structures that children correctly identified in each condition.

Results

Our initial analysis revealed no differences between the results of Experiments 1A and 2B, so data from these two experiments were pooled together in all subsequent analyses. To test whether explaining and reporting one's intervention choices could both influence causal learning, we used children in Meng et al. (2018) as our baseline. Apart from the additional explanation/report prompts, our procedure, stimuli, and population were identical to those in the previous study.

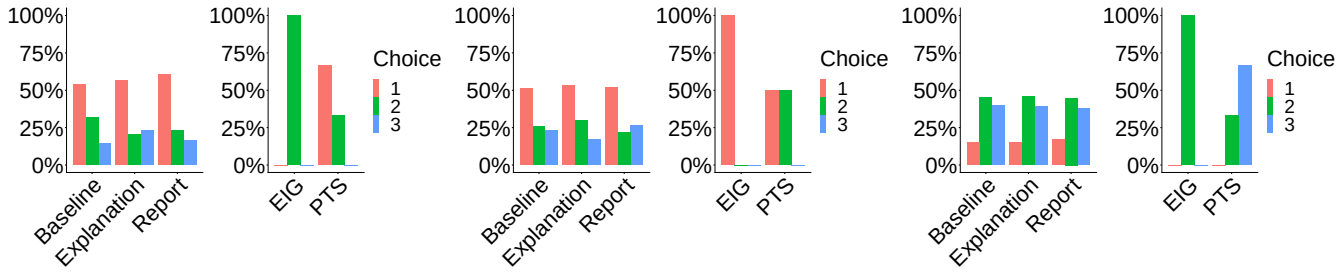
Inference accuracy To begin, we first looked at whether children were able to identify the correct causal structures in the end. As shown in Figure 2, those in the Baseline condition chose the correct structures 54% (SD = 22%) of the time, which was not distinguishable from chance (50%), $t(38)$ = 1.02, p = .31, Cohen's d = .16. However, children performed above chance in both the Explanation (M = 67%, SD = 25%) and the Report (M = 61%, SD = 23%) conditions, $t(58)$ = 5.13, $p < .001$, Cohen's d = .67 and $t(57)$ = 3.77, $p < .001$, Cohen's d = .50, respectively. The only significant difference between conditions was that explainers were more accurate than the baseline, $t(88.53)$ = 2.73, p = .007, Cohen's d = .55.

Intervention choices Before fitting models of intervention strategies, we examined children's interventions choices to see if they were random or biased towards EIG or PTS.

We compared the mean EIG and the mean PTS value of children's chosen interventions against the respective chance levels (.33 for EIG[2] and .55 for PTS[3]) of the two metrics. In the Baseline condition, only the mean PTS value (M = .74, SD = .22) was above chance, $t(38)$ = 5.37, $p < .001$, Cohen's d = .86, but not the mean EIG value (M = .39, SD = .28), $t(38)$ = 1.23, p = .23, Cohen's d = .20. Similarly in the Report condition, the mean PTS value (M = .74, SD = .20) was above

[2] Among all three possible interventions in each puzzle, only one was informative, i.e., having an EIG value of 1.

[3] This was the average PTS value across all interventions.



(a) Causal Chain vs. Common Cause (b) Causal Chain vs. One Link (c) Common Effect vs. One Link

Figure 3: Figures on the left show the proportion of children intervening on each node (n_1, n_2, and n_3) in each type of puzzles: (a) Causal Chain vs. Common Cause, (b) Causal Chain vs. One Link, and (c) Common Effect vs. One Link. Figures on the right show the probability of children intervening on each node in each type of puzzles predicted by EIG and PTS.

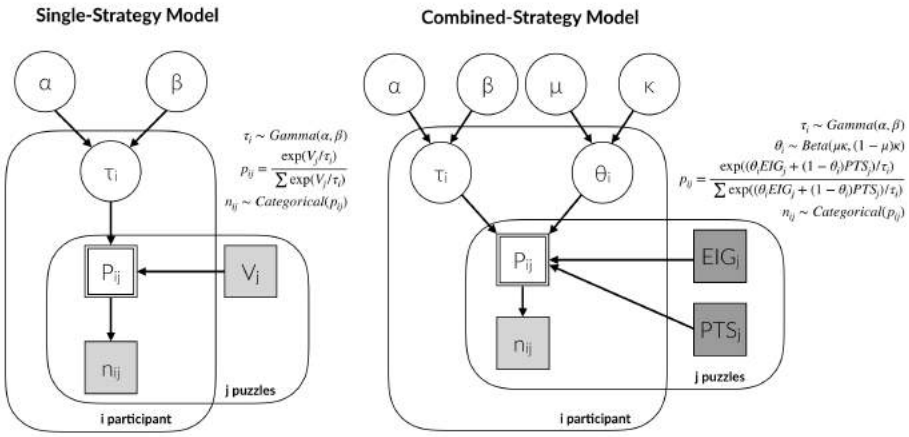


Figure 4: Hierarchical Bayesian models of single (left) and combined (right) strategies. In each puzzle j, each participant i chooses one node n_{ij} to intervene on. V_j, EIG_j, and PTS_j store the values of three possible interventions in each puzzle. p_{ij} stores probabilities of each participant choosing each intervention in each puzzle. τ_i and θ_i capture each participant's decision noise and weight of EIG. α and β are population-level hyper-parameters that generate τ_i; μ and κ generate θ_i.

chance, $t(57)$ =7.17, $p < .001$, Cohen's d = .94, but not the mean EIG value (M = .39, SD = .25), $t(57)$ = 1.63, p = .11, Cohen's d = .21. In the Explanation condition, however, both the mean EIG (M = .44, SD = .32) and the mean PTS (M = .75, SD = .18) value were above chance , $t(58)$ = 2.52, p = .014, Cohen's d = .33 and $t(58)$ = 8.4, $p < .001$, Cohen's d = 1.09, respectively. Neither the mean EIG or the mean PTS value differed significantly across conditions.

We also compared the proportion of children intervening on each node in each puzzle against what EIG and PT would predict. Since the mapping between node positions and light bulb colors is arbitrary, we re-coded Puzzles 1 and 2 as $n_1 \rightarrow n_2 \rightarrow n_3$ (Chain) vs. $n_2 \leftarrow n_1 \rightarrow n_3$ (Common Cause), Puzzles 3 and 4 as $n_1 \rightarrow n_2 \rightarrow n_3$ (Chain) vs. $n_2 \rightarrow n_3$ (One Link), and Puzzles 5 and 6 as $n_2 \rightarrow n_1 \leftarrow n_3$ (Common Effect) vs. $n_3 \rightarrow n_1$ (One Link). As Figure 3 shows, children deviated the most from EIG predictions in "Chain vs. Common Cause". In the other two types of puzzles, children's choices were split between EIG and PTS predictions. A small but non-negligible proportion of interventions were on nodes whose EIG and PTS values were both 0, suggesting that children occasionally chose interventions randomly.

Intervention strategies We used two hierarchical Bayesian models to capture children's intervention strategies (Figure 4). The single-strategy model draws from a single source to evaluate interventions—be it EIG, PTS, or always "1" in the case of random selection. The combined-strategy model assigns a weighted mean of EIG and PTS (the weight of EIG is θ) to each intervention. In both models, each child's decision noise τ_i is sampled from a population-level gamma distribution with two hyper-parameters α (shape) and β (rate). In the combined-strategy model, each child's weight of EIG θ_i is sampled from a population-level beta distribution with two hyper-parameters μ (mean) and κ (standard deviation. Uninformative priors are chosen for all hyper-parameters: α = .001, β = .001, $\mu \sim$ Beta(.5, .5), $\kappa \sim$ Gamma(.001, .001). The probability of selecting a given intervention is a function of its value $V(n)$ as well as the child's decision noise τ. Actual interventions are sampled from a categorical distribution of these probabilities. Parameter values were estimated using

Table 1: The deviance information criteria (DIC) of each model and the weight of EIG θ in three conditions.

	Baseline		Explanation		Report	
Model	DIC	θ	DIC	θ	DIC	θ
Random	514.15	–	777.82	–	764.64	–
EIG	481.98	–	727.00	–	769.45	–
PTS	469.62	–	**706.87**	–	**706.93**	–
EIG + PTS	**454.95**	.24	634.43	.31	746.25	.19

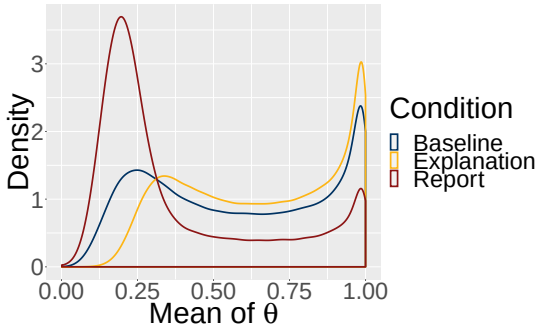

Figure 5: The distributions of the group-level hyper-parameter μ (the mean of θ) under the three conditions.

Markov chain Monte Carlo (MCMC) samples generated by the JAGS program[4] (Plummer, 2003). The deviance information criterion (DIC, Spiegelhalter et al., 2002) was used for model comparison. Models that fit data better (smaller posterior mean of the deviance $\bar{D}$) or are simpler (smaller effective number of parameters p_D) have lower DIC (= $\bar{D}$ + p_D). As a common practice, a difference over 10 is substantial.

As shown in Table 1, the combined-strategy model (EIG + PTS) best captured children's intervention strategy in both the Baseline and the Explanation conditions. However, the PTS-only model turned out to be the best fit in the Report condition. Children in all three conditions relied more on PTS than EIG, with the mean weight of EIG being .24, .31, and .19, respectively. Figure 5 illustrates the distributions of μ—the population-level hyper-parameter that captures the mean of θ—in all three conditions. To see whether μ differed across conditions, we sampled 10,000 estimates of μ in each condition. For each contrast between conditions (Explanation vs. Report, Explanation vs. Baseline, Report vs. Baseline), we paired the estimates randomly and calculated the differences. Since the 95% Highest Density Interval (HDI) of all three difference distributions contained 0, we couldn't claim with confidence that μ differed across three conditions.

[4]In keeping with Meng et al. (2018), we ran MCMC for 100,000 iterations, discarding the first 1,000 samples and drawing one sample every 10 iterations. To ensure that samples were from a stationary distribution, we repeated this process 30 times with different initial parameter values and results from each sequence of samples (or *chain*) successfully converged since Gelman and Rubin's diagnostic $\hat{R}$ (Gelman & Rubin, 1992) of all parameters was smaller than 1.05.

Intervention and inference Lastly, we looked at whether children's intervention choices and strategies predicted if they could accurately identify the true causal structures.

First, for each puzzle, we performed a logistic regression using the EIG value (0 or 1) of children's chosen intervention to predict whether they identified the correct structure later. In the Baseline condition, EIG values did not predict inference accuracy in any puzzles. However, in the Explanation condition, high-EIG interventions strongly predicted successes at identifying the correct structures in all six puzzles. In the Report condition, EIG values predicted inference accuracy in four of the six puzzles (except Puzzles 2 and 6).

We examined the correlation between the weight of EIG θ and children's average accuracy across all puzzles. θ and average accuracy were uncorrelated in the Baseline condition, $F(1,37) = 1.14$, $p = .29$, $\bar{R}^2 = .0038$, but positively correlated in the Explanation and the Report conditions, $F(1,57) = 30.73$, $p < .001$, $\bar{R}^2 = .34$ and $F(1,56) = 25.27$, $p < .001$, $\bar{R}^2 = .30$, respectively. Correlations in the Explanation and the Report conditions were both stronger than that in the Baseline condition, $z = 2.31$, $p = .02$ and $z = 2.08$, $p = .04$, respectively.

Discussion

In the current study, we investigated whether asking children to explain their intervention choices facilitated causal learning from intervention. Specifically, we looked at 1) whether explainers were better able to select informative interventions and 2) make accurate inferences based on interventional data.

Our first hypothesis was not supported by the results. Neither children's weight of EIG θ nor the group-level hyper-parameter μ that captures the mean of θ differed significantly across the Baseline, the Explanation, and the Report conditions; this suggests that children used similar strategies to select interventions across three conditions. Curiously, asking children to report their intervention choices might have slightly "backfired": While a linear combination of EIG and PTS best captured children's intervention strategy in the Baseline and the Explanation conditions, the PTS-only model turned out to best characterize the strategy used in the Report condition. Moreover, unlike in the other two conditions, the distribution of μ was right skewed in the Report condition, indicating heavier reliance on PTS. However, since differences in μ were not statistically significant, further investigation is needed to examine whether this finding was due to random noise or potential drawbacks of the report prompts.

Compared to the chance performance in the Baseline condition, children in both the Explanation and the Report conditions were more accurate at identifying the correct causal structures after performing interventions. Since children in the latter two conditions did not choose more informative interventions, a possible explanation is that when prompted to think about their intervention choices, children were better able to utilize interventional data that were already available. This explanation was supported by our findings: In the Explanation and the Report conditions, children's intervention choices (EIG value = 0 or 1) and interventions strategies

(weight of EIG θ) predicted their inference accuracy, which was not the case in the Baseline condition.

General Discussion

In the current study, we looked at whether asking children to think about their intervention choices might facilitate their causal learning from intervention. In Experiments 1A and 1B, 117 5- to 7-year-olds solved six puzzles where they performed one intervention to identify the true structure of three light bulbs that might be connected in one of two ways. Those in the Explanation condition were asked to explain why they chose certain interventions whereas those in the Report condition were simply asked to report their choices. Meng et al.'s (2018) previous study served as our Baseline condition where children solved the same puzzles without being prompted. Using hierarchical Bayesian models developed by Coenen et al. (2015), we captured children's intervention strategy mainly in terms of how much they relied on the normative strategy, which is maximizing the expected information gain (EIG) of their chosen interventions, and the suboptimal positive test strategy (PTS). Children in all conditions relied more on PTS than EIG; there was no difference across conditions. However, compared to those in the Baseline condition who performed at chance, children in both the Explanation and the Report conditions were more accurate at identifying the correct structures after interventions. Crucially, children's intervention choices and strategies only predicted their accuracy at inferring the true causal structures in the Explanation and the Report conditions but not in the Baseline condition.

Taken together, our findings suggest that while engaging in self-explaining did not help children select more informative interventions, asking them to *think* about their intervention choices (explaining or reporting) might help them better utilize interventional data that were already generated.

Revisiting the self-explaining effect

The major motivation behind this study was the plethora of self-explaining effects in education (Fonseca & Chi, 2011) and cognitive development (Lombrozo, 2016). Given what we found, two questions stood out: Why did self-explaining have no effect on intervention selection? Why was the improvement on causal inferences not unique in explainers?

Further investigation is needed to provide precise answers. Here we offer some speculations. Explaining an intervention is not an easy feat: Not only do you need to contrast the value of your intervention with that of other interventions, but more fundamentally, you need to contrast your strategy of evaluating interventions with other strategies. The cognitive process of generating a good explanation may be too challenging for 5- to 7-year-olds given their limited working memory capacity, knowledge about causal systems and experiments, and metacognitive skills (Horne, Muradoglu, & Cimpian, 2019). A recent study (Ruggeri, Xu, & Lombrozo, in press) suggested that the quality of explanations might matter after all. In their study, 4- to 7-year-olds were asked to explain phenomena in a domain before playing Twenty Questions in that domain; the accuracy of explanations was correlated with the efficiency of question-asking. Since reasonable explanations may be more difficult to generate in our study than in past studies (Walker et al., 2014, 2017), it might limit the benefit children can reap from self-explaining. Regarding the second question, it might be that when asked to reflect on (i.e., explaining or reporting) their intervention choices, children became aware that their interventions played an important role for solving puzzles later and therefore paid closer attention to the intervention outcomes when making causal inferences.

Future directions

Given the importance of intervention selection in causal learning, we seek to explore more effective scaffolding methods in the future. To begin, we can provide feedback after each intervention. A recent study (Liquin & Lombrozo, 2017) found that explaining had greater effects when evidence contradicted what learners' beliefs. Another way to strengthen the scaffolding may be asking children to explain why *each* possible intervention may or may not be useful, rather than just their chosen intervention. Since belief updating is inherently linked to intervention selection (Coenen & Gureckis, 2015), we may help children choose more informative interventions by correcting errors in their belief updating process.

Conclusion

Rather than passively absorbing correlations and crunching numbers, active learners generate explanations and design interventions to learn about causality. Our study is among the first to bridge "thinking" and "doing" in causal learning. While self-explaining did not show benefits of improving children's intervention strategy, prompting children to think about their intervention choices in some way (explaining or reporting) may help them better utilize interventional data generated by themselves to infer unknown causal structures.

Decisions Against Preferences

Abstract

An agent decides against her preferences, if she considers an option x better than another option y but nevertheless decides to do y. A central tenet of rational choice theory states that individuals do not decide against their preferences, whereby we find two kinds of potential counterexamples in the literature: *akrasia*, also known as weak-willed decisions, and decisions based on so-called *deontic constraints* such as obligations or commitments. While there is some empirical evidence that weak-willed choices are a real phenomenon, leading scholars in philosophy of economics debate whether choices based on commitments can be counter-preferential. As far as we know, however, nobody so far has tried to settle this debate empirically. This paper contributes to both debates since we present some empirical evidence that (i) akrasia can also be strong-willed and (ii) choices made on the basis of commitments can indeed be counter-preferential. We will conclude that people can decide against their preferences without being unreasonable.

Keywords: Counter-Preferential Choice; Rational Choice Theory; Akrasia; Commitments; Empirical Studies.

The Putative Irrationality of Deciding against Preferences

A fundamental assumption of most theories of rational choice is that an agent always chooses the option she considers best.[1] Violating this assumption is deemed irrational (Hausman 2012a). This basic tenet applies to both *maximizing* and *optimizing* concepts of rational choice, e.g., if one is a maximizer, one chooses the option that one believes maximizes one's utility. The option that is considered best (or at least not worse than any other) is the one the agent prefers.

What does it mean to *prefer* an option? Savage (1954) takes the notion of preference "in an ordinary mathematical usage by saying that the relation is a simple ordering among acts" (Savage 1954, p. 18). In contrast, philosophers often understand preferences as mental states, e.g., Hausman states "to say that Jill prefers x to y is to say that when Jill has thought about everything she takes to bear on how much she values x and y, Jill ranks x above y" (Hausman 2012b, p. 34). Of course, Hausman's notion of preference as *total subjective comparative evaluation* is controversial. Angner (2018), for instance, argues that economists neither *do use* nor *should use* such a conception of preference. However, note that Angner himself accepts that Hausman develops a useful model of preferences. For the purposes of our paper, Hausman's conception is specifically effective because it illustrates why choosing a worse option doesn't seem to make sense. According to such an understanding, an agent follows her preference ordering because she will then do what she values the most, or in other words, what she believes is best for her.

Saying that the agent chooses what she prefers to do is not to say that the agent chooses what is always best for her. In cases of uncertainty, an agent might choose an option that does not maximize her utility since unexpected states of the world might materialize. Agents might also base their preference ranking on false beliefs.[2] They might be mistaken about their preferences, or are simply not able to form a preference ordering (Messerli & Reuter 2017). It seems also false to postulate that agents always take into account all the available information like utilities and probabilities of options (Kahneman & Tversky 2000). Some of these aspects have been used to criticize models of rational choice theory. Nonetheless, these points of criticism do not apply to the fundamental tenet that agents choose what they consider best.

So, are advocates of rational choice theory right that counter-preferential choices do not exist? Or do agents sometimes choose options they consider worse than another, and hence violate this basic assumption of rational choice theory?[3]

[1] Some advocates of satisficing concepts of rational choice would disagree. If one is a satisficer, one settles for any alternative one considers satisfactory (Simon 1953; Slote 2004).

[2] Paul (2014), for instance, argues that agents who contemplate so-called *transformative choices* cannot form reasonable beliefs about the content of their experiences, and, thus, cannot make a rational choice. For a critical reply, see, e.g., Reuter & Messerli (2018).

[3] One might object that the assumption that agents choose what they consider best cannot be falsified. Revealed preference theorists, for example, assume that decisions reflect preferences. Consequently, there is no conceptual gap between a person's preferences and the actions she decides to perform. However, on most philosophers' interpretation, expected utility represents the strength of an agent's preference for the outcome, where preferences are understood as psychological states. Given this inter-

As far as we know, there are at least two kinds of potential counterexamples challenging this assumption. First, decisions can be *deontically constrained*, a technical term used to refer to constraints that arise when morality requires us to act in ways that are contrary to self-interest (see, e.g., Heath 2008). Put differently, a deontic constraint can be understood as a form of duty or rule that makes people refrain from the pursuit of individual advantage. That may sound fairly abstract, but we all are familiar with situations in which we act because we have given a promise, not because we actually prefer to act that way. We will come back to this issue in the General Discussion when discussing whether commitments can be counter-preferential.

Second, weak-willed decisions (or akratic decisions) are also potential counterexamples violating the assumption that agents choose what they consider best. To illustrate akratic decisions, take the case of Lewd Larry: Larry believes that staying in his room and staying faithful to his girlfriend is better than having an affair with his flatmate Jackie, but then finds himself trying to seduce her. Davidson (1970) defines weak-willed actions as follows:[4] In doing y an agent acts weak-willed if and only if: (i) the agent does y intentionally; (ii) the agent believes there is an alternative action x open to him; (iii) the agent judges that, all-things considered, it would be better to do x than to do y. Lewd Larry seems to fulfill all the requirements for being weak-willed. Weak-willed decisions not only seem to violate a fundamental assumption of rational choice theory, the intuitive plausibility of Lewd Larry demonstrates that weak-willed actions are real. However, most scholars at least agree with advocates of rational choice theory that such a decision is irrational: he should not have decided to seduce Jackie, given his belief it is not his best option.

In the rest of this paper, we do three things: First, we describe a case illustrating a violation of the aforementioned fundamental assumption of rational choice theory, which is not (at least not intuitively) an akratic decision, and, we present a first experiment showing that these cases are real. Second, we discuss an objection against our study and results, and we counter this objection using a second study. Third, taking ideas from Amartya Sen, we argue that we have good reasons to believe that such decisions are reasonable choices. In other words, such choices can be understood as acting out of commitment, whereby the commitment is counter-preferential.

pretation of rational choice theory, the assumption that agents actually choose options they consider worse than another is empirically testable.

[4] For discussions on the concept of akrasia as well as criticisms on Davidson's definition, see, e.g., Mele (1991), Holton (1999), and May & Holton (2012).

Experimental Study 1

Examples in which an agent decides against her preferences almost always seem to have the following pattern. The agent values x more than y, and hence prefers x to y, but "lower" desires triggered by lust or sloth, move the agent to do y. It need not be the case, however, that an agent decides against her preferences only if she is weak-willed. An agent might value x more than y, and hence prefers x to y, but is moved by his "higher" commitments or obligations to do y. To illustrate such a case, take the following example. Today, a colleague of yours has asked you whether you would help him move some furniture, and you agreed to be at his place the next morning. The next morning, however, friends of yours ask you whether you would like to join them for a beautiful day at the lake. It seems at least possible that in such a situation, you value going to the lake more than helping your colleague move furniture. Nonetheless, you decide to be at your colleague's place and help him move furniture. Note that similar to typical weak-willed decisions, you might loathe the fact that you have acted contrary to what you considered the best option. While such actions satisfy Davidson's definition of being weak-willed, it seems highly odd to call them weak-willed.[5]

The decision we described above violates the basic tenet of rational choice theory just as much as weak-willed decisions. The agent does not maximize her utility by choosing an option she considers worse than an available alternative. But are these decisions actually real? Or are they mere figments of philosophers' imaginations? The following experiment strongly suggests that these decisions are part of many people's reality.

Methods

120 participants were recruited on Amazon Mechanical Turk and paid a small fee for their participation. 5 participants were excluded for not having completed the survey. The remaining 115 participants (51 women, M_{age} = 39.09, SD = 15.69) all indicated that they were native English speakers. All participants were randomly assigned to one of three conditions, two test conditions (*Acquaintance*, *Colleague*) and one control condition. The

[5] Davidson discusses similar, so-called incontinent cases, in which a person follows a duty or principle when doing y intentionally (e.g., getting up and brushing her teeth), although all-things considered, she judges x to be better than y, e.g., it is more pleasurable to stay in bed. However, there is an important difference between our cases and Davidson's incontinent cases. In Davidson's examples, the agent does not believe she has very good reasons to follow a certain duty or principle, e.g., the agent reasons that her teeth are very strong anyway. In our examples, the agent is likely to believe that she has good reasons to keep a promise. In other words, the agent believes that helping a colleague move is the right thing to do. This contrast explains why Davidson believes that in incontinent cases an agent cannot understand herself and that she recognizes something absurd in her intentional behavior, while this would not be true in our case.

vignettes of the two test conditions read as follows:

Test condition Imagine that an acquaintance (a colleague) of yours asks you whether you would help him move some furniture and household appliances into his new apartment. You agree to be at his place at 10am the next day. The next morning, it is a beautiful warm summer day. At 8am you get a call from friends who ask you whether you would like to join them for a nice day at a lake. All things considered and independent of how you decide in the end, how do you value each of the two options:

- Spending the day at the lake and tell my acquaintance (colleague) that I cannot come.
- Moving furniture and household appliances and tell my friends that I cannot join them.[6]

The vignette for the control condition read:

Control condition Imagine that you plan your yearly holidays. On the one hand, you could go to the seaside and spend a week relaxing at the beach. On the other hand, you could book a trip to a city you have not seen before and experience some cultural highlights. All things considered and independent of how you decide in the end, how do you value each of the two options:

- Spending the holidays on the beach and not going to a city.
- Spending the holidays in a city and not going to the beach.

After the participants rated both options, they were then directed to the second question reading:

Decision Question You have just valued each of the two options. But how do you decide in the end? Please tell us what you will do:

For the two test conditions, the participants were presented with two options: (1) I choose to go to the lake and tell my acquaintance (colleague) I cannot come. (2) I choose to move furniture and household appliances and tell my friends I cannot join them. In the control condition, the options were: (1) I choose to go to the seaside and spend a week relaxing at the beach. (2) I choose to go to a city and experience some cultural highlights. Participants had to choose which decision they would take.

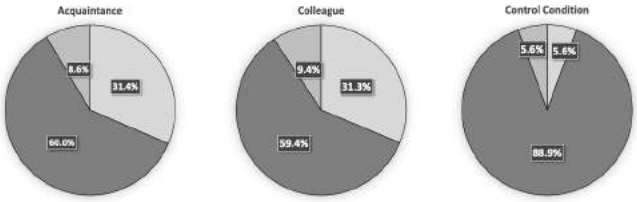

Figure 1 Responses in % to the two test conditions and the control condition. Dark grey depicts the percentage of participants who would decide in line with their preferences. Light grey represents the percentage of participants who would decide against their preferences. A few participants (medium grey) indicated an equal preference for both options.

Results

The results of people's responses are summarized in Figure 1 above. In both the *Acquaintance* as well as the *Colleague* condition, around 31% of the participants who decided in favor of helping to move furniture, considered going to the lake more valuable. The response profiles were significantly different between the test condition *Acquaintance* and control, $\chi^2 = 8.70, p = 0.013$, as well as *Colleague* and control, $\chi^2 = 8.64, p = 0.013$.

Discussion

The results indicate that a substantial portion of the participants would decide in favor of a less valuable option when they consider the scenario we presented them with. Simply put, the results suggest that there are situations in which many people will decide against their own preferences. The study was not designed to investigate which percentage of people are likely to make a decision against their preferences. Obviously, the scenarios were quite specific and for many the situation did not even present them with a "difficult" choice. Thus, it is likely that for many more people than just the recorded 31%, there exist choices in which option x is preferred but they still decide in favor of option y. Of course, for most decisions, people's choices will nicely align with their preferences. In fact, the control condition was specifically designed as a base rate for decisions in which preferences are the sole determiner of the decision in question. The significant differences between the test condition and the control demonstrates, however, that not all decisions are like that. Other factors may determine which option we are going to choose.

Before we discuss a possible explanation for the recorded data, let us first address the most obvious objection against our study. In order to counter this objection, we then briefly present the results of a second study.

[6] Both options were presented in randomized order and participants were asked to rate the value of each option on an 11-point Likert scale anchored at 0 meaning "Not at all valuable" and 10 meaning "Extremely valuable". Which concept of utility is relevant here? Importantly, we do not understand utility as a more precise ranking than an *ordinal one* (e.g. *cardinal measure* or *ratio scale*). The strength of a value judgement can be understood in purely ordinal terms, respectively, the experiment is perfectly consistent with an ordinal interpretation. If a participant evaluates two options within this scale, e.g. $a = 9$ and $b = 3$, this simply means that he or she ranks a above b. In other words, the only information these numbers provide is that an agent prefers a to b without saying how much he or she values a more than b.

Objection

The experiment reveals a potential decision against one's preferences, only if people gave all-things-considered value ratings when considering their options. It is indeed possible that some people merely considered the positive value of spending a day on the lake without considering the negative value of telling one's acquaintance or colleague that one is not available for moving after all. If that were the case, then it would not surprise to see decisions made against one's *rated* preferences.

We do not believe, however, that this is a likely possibility. When we asked the participants to rate the value of the options, we specifically named the positive as well as the negative aspect of the choice, e.g., one of the options read: "Spending the day at the lake and tell my colleague that I cannot come." Moreover, the number of participants who would decide against their own value judgements might even be greater, because some participants might have self-censored themselves so as to appear to be consistent when making a decision.

However, one might insist on the ambiguity of the term "value", respectively, that we and the participants do not refer to the same concept here. It is our understanding that the concept of value can be understood in terms of the agent's ends and desires. "I judge that a is more valuable than b" means that I believe that a is more valuable than b in terms of my ends and desires.[7] Now the objection that arises is that participants must have some different concept of value in mind, because there is not only the end of enjoying a great day at the lake but also the end of helping other people, which is obviously more important to them. If the objection stands, participants do in fact decide in line with their values and do not decide counter-preferentially. [8]

The objection we raised should be taken seriously. We have, therefore, conducted a second experiment where we first explained to participants which concept of value is involved. We will see that our results are robust, even if we change the experimental setting in this way.

[7] In accordance with rational choice theory, we do not make any proposal concerning the content of these ends. This means that we recognize no distinction between goals such as making a million dollar, helping other people and being a sadist. Also note that there are no implications regarding risk-taking. The value judgement that a is more valuable than b might be risk-neutral such as in standard approaches or risk-averse such as in *prospect theory*.

[8] One way of testing the objection would be to further specify the alternatives, e.g., instead of stating one of the options as "Spending the day at the lake and tell my colleague that I cannot come," we could state "Spending the day at the lake and break my promise to my colleague". The reason why we opted for a different way to tackle the objection is that "breaking a promise" or "breaking a commitment" (we will come back to the role of commitments in the General Discussion) is a very negative trigger. The wording "tell my colleague that I cannot come" is relatively neutral in this regard. However, we agree that the empirical evidence for decisions against preferences would be even greater if the negative aspects of a decision would be highlighted even further. In a follow-up study, we plan not only to investigate a larger variety of experimental stimuli but also the impact of the exact wording on the empirical effect.

Experimental Study 2

In order to address the objection stated above, we decided to rerun both test conditions (*Acquaintance*, *Colleague*) to see whether the results would change or remain robust. If the objection is correct, then we should see a substantial drop in the percentages of people who indicate decisions that go against their preferences.

Methods

100 participants were recruited on Amazon Mechanical Turk and paid a small fee for their participation. 2 participants were excluded for not having completed the survey. The remaining 98 participants (48 women, M_{age} = 36.92, SD = 12.38) all indicated that they were native English speakers. All participants were randomly assigned to one of two conditions (*Acquaintance*, *Colleague*). The vignettes of the two conditions were exactly the same as the vignettes of the test conditions in Experiment 1 with one exception: after participants had given their consent to this study, they were informed about the task ahead in the following manner.

Instructions On the next screen we will ask you to value certain events. Before you do so, please consider the following example: Imagine you have to value a one week trip to Europe. On the positive side there might be aspects like relaxing, eating new and exciting food, being able to tell your friends of an amazing trip when you are back, etc. On the negative side there might be aspects like being jetlagged, longing for your loved ones at home, missing an important meeting at work, etc. Thus, if you value an option or an event, you take into account all its positive and negative aspects and then make an overall judgement.

After these instructions, participants rated both options (see Experiment 1 above), and then answered the decision question (see also Experiment 1 above).

Results

In the *Acquaintance* condition, 36.6% of the participants who decided in favor of helping to move furniture considered going to the lake more valuable. In the *Colleague* condition, 26.3% of the participants who decided in favor of helping to move furniture considered going to the lake more valuable. The results of people's responses are summarized in Figure 2 below.

Discussion

The data we received in Experiment 2 are highly similar to those we collected in Experiment 1. While the percentage of people who decided against their preference in the

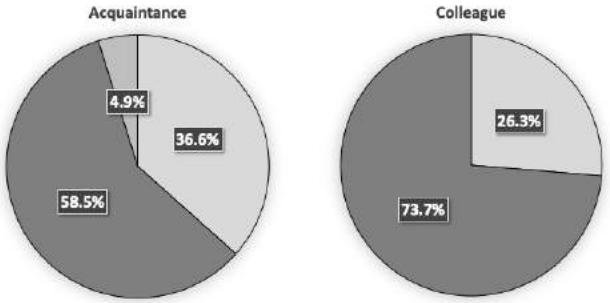

Figure 2 Responses in % to the two conditions. Dark grey depicts the percentage of participants who would decide in line with their preferences. Light grey represents the percentage of participants who would decide against their preferences. A few participants (medium grey) indicated an equal preference for both options.

Acquaintance condition rose from 31.4% to 36.6%, the percentages in the *Colleague* condition decreased from 31.3% to 26.3%. Thus, overall the results of Experiment 1 were very robust. It seems therefore very likely, that the participants in Experiment 1 entertained a notion of *value* not only similar to the one in Experiment 2, but also of the right kind.

General Discussion

The studies suggest that people often make decisions in favor of options they consider less valuable.[9] If our results are correct, there are crucial implications for both the discussion on *akrasia* and the debate on *rational choice*, respectively, the connection between rational choice and *deontic constraints*.

First, let us briefly mention the implication for akrasia. Importantly, some philosophers mention that akrasia can also be strong-willed (e.g., see Holton 1999; Yao 2017). However, as far as we know, (i) nobody thus far has interpreted such cases as actions out of commitment, (ii) there is currently no empirical evidence for such cases, and, (iii) other cases of strong-willed akrasia are related to violations of resolutions and preference change. In contrast, our example illustrates a case in which no such additional machinery is necessary.

Second, our results are crucial for rational choice and the debate on commitments. Most rational choice theorists are likely to consider counter-preferential decisions as unreasonable or irrational, similar to typical weak-willed decisions. However, while people in weak-willed decisions usually act out of lower desires, we have described a case in which people seem to be rather strong-willed when acting against their most valued option. Does this difference allow us to frame such decisions as reasonable? This largely depends on what ultimately motivates people to decide against preferences in *strong-willed* decisions. A possible explanation of such decisions takes into account the importance of commitments. After all, many people are likely to decide to help their acquaintance or colleague move furniture because they have committed themselves to do so, not because they like moving furniture. However, shouldn't these commitments be reflected in peoples' evaluations of the two alternatives? According to Sen (1977) this need not be the case.

Sen distinguishes three kinds of motivations: narrow self-interest, sympathy, and commitment. Both, narrow self-interest as well as sympathy, directly affect a person's own welfare and should be reflected in people's value judgements. In contrast, Sen (1977, p. 326) characterizes *commitments* as altruistic attitudes towards others. Accordingly, a person who acts out of commitment chooses an option that she considers the right thing to do, even if that option is less preferable than an alternative. Sen admits that within the framework of rational choice theory, there is no place for a notion like commitment because it does not lead to any difference in terms of one's expected advantage.[10] Speaking purely in terms of rational choice theory, decisions against preferences, are therefore irrational. That said, Sen's theoretical work on commitments has caused a lot of attention, because it seems that people who act out of commitment, are *irrational* only in the skewed notion of rational choice theory. At least, intuitively, it seems that people who act against their preferences but in favor of an option they consider the right thing to do, are reasonable agents.

Given the importance of Sen's contribution, some philosophers have started to question Sen's depiction of commitments as factors that may have a motivating force beyond expected advantage. Contra Sen, Hausman (2007) agues that we need to distinguish among the variety of factors responsible for agents' preferences, rather than distinguish between preferences and commitments. According to his view, commitments are not counter-preferential but rather influence all-things considered judgements. Thus, while Sen believes commitments can directly determine our choices, Hausman argues that they do so only via preferences. As far as we know, the role of commitments in the decision making process has not yet been empirically investigated.[11] And

[9] One might object that there is a gap between the participants *rated* preferences and their real decisions or real behavior. Put differently, participants are not actually making a decision but provide inconsequential responses after reading abstract descriptions of some options. However, while some studies have shown an inconsistency between people's rated preferences and real behavior, a variety of empirical studies have also shown high consistency between people's ratings and their behavior. Importantly, we are not aware of any empirical or theoretical arguments why people systematically deviate in our respective context.

[10] It is important to keep in mind here that Sen distinguishes different notions of preferences. The two most important ones are (i) preference as (revealed) choice ranking and (ii) preference as expected advantage ranking.

[11] Note that we do not claim that there's no empirical research on commitments. See, e.g., Székely & Michael

therefore, we do not yet know whether Sen or Hausman are right. However, our experiment may provide a first step to settle this debate. According to our results, it seems that commitments may sometimes influence our choices directly and not via preferences. At a minimum, opponents of Sen would need to explain why some people decide to move furniture, even if the other option is considered better, all-things-considered.

Before we conclude, let us briefly mention one other account that could be drawn upon to explain our data. Heath (2008) argues that theories of rational choice can be modified in order to incorporate rule following behavior. His model distinguishes between one's desire for an outcome (its expected utility) and how appropriate the outcome is (the normative appropriateness of that outcome). The basic idea is that an agent's utility function combines two things: Getting the best outcome and doing the right thing. According to Heath's approach, participants would distinguish two stages. First, they would rank permissible actions as more or less appropriate. Second, they would add these values to the expected utilities. It would take more experiments to find out whether participants indeed proceed in the way suggested by Heath. In any case, Sen's account provides a straightforward explanation of our data.

Conclusion

In closing, let us summarize what we have done. Adherents of rational choice theory assume that agents choose the option they consider best. In this paper, we have discussed a case that violates this basic assumption. Crucially, we have not merely relied on our own intuitions of whether such a case is real, but conducted two studies, the results of which strongly suggest that many people make decisions against their preferences. Some might argue that this case is just one out of many showing rational choice theory to be mistaken. In particular, weak-willed decisions have been largely accepted to be real-world cases in which agents act contrary to their best judgements. However, weak-willed decisions can be distinguished from our case study in two important respects: First, while in weak-willed decisions, people act out of their lower desires, our case shows that people can decide against their preferences by being strong-willed. Second, at least according to Sen's account, there are good reasons to believe, agents may act against their preferences but at the same time make a reasonable choice. Our results provide evidence that Sen is right, respectively, that commitments can be counter-preferential.

Abstract

Adaptive learning systems that generate spacing intervals based on learner performance enhance learning efficiency and retention (Mettler, Massey & Kellman, 2016). Recent research in factual learning suggests that initial blocks of passive trials, where learners observe correct answers without overtly responding, produce greater learning than passive or active trials alone (Mettler, Massey, Burke, Garrigan & Kellman, 2018). Here we tested whether this passive + active advantage generalizes beyond factual learning to perceptual learning. Participants studied and classified images of butterfly genera using either: 1) *Passive Only* presentations, 2) *Passive Initial Blocks* followed by active, adaptive scheduling, 3) *Passive Initial Category Exemplar* followed by active, adaptive scheduling, or 4) *Active Only* learning. We found an advantage for combinations of active and passive presentations over *Passive Only* or *Active Only* presentations. Passive trials presented in initial blocks showed the best performance, paralleling earlier findings in factual learning. Combining active and passive learning produces greater learning gains than either alone, and these effects occur for diverse forms of learning, including perceptual learning.

Keywords: adaptive learning; perceptual learning; spacing effect; memory; active learning; passive learning

Introduction

The well-known *spacing effect* is a boost in long-term retention that results when recurrent learning episodes are spaced across gaps in time (Carpenter, 2017; Cepeda, Pashler, Vul, Wixted & Rohrer, 2006; Delaney, Verkoeijen & Spirgel, 2010). Spacing effects apply to a wide variety of learning domains and learners, and also influence diverse learning modes such as perceptual learning (Mettler & Kellman, 2014).

Recent research has shown that spacing effects can be enhanced by dynamically adjusting the size of spacing intervals during a learning session using an adaptive algorithm, Adaptive Response-Time-based Scheduling (ARTS; Mettler, Massey & Kellman, 2011; Mettler, Massey & Kellman, 2016). In ARTS, spacing delays are updated to match changes in learning strength as learning progresses for individual learners and items. Learning strength can be reliably estimated from response time (RT), with slower response times indicating retrieval difficulty and correspondingly lower learning strengths (Pyc & Rawson, 2009; Benjamin & Bjork, 1996; Karpicke & Bauernschmidt, 2011). ARTS updates the spacing among items in real time, by tracking the underlying learning strengths using an individual's accuracy and RT for learning items or for categories, producing highly efficient learning (Mettler, Massey & Kellman, 2011, 2016). In perceptual learning and other category learning domains, the same adaptive learning approach is applied to categories, such that learning strength for each category influences the priority of a learning trial involving a new exemplar of that category. Such adaptive spacing, and the interleaving of exemplars of different categories, also produces strong learning benefits relative to other arrangements (Mettler & Kellman, 2014).

Achieving the benefits of adaptive spacing requires interactive learning trials from which performance data are obtained. Recent work, however, suggests that the benefits of adaptive spacing may be further enhanced by combining active trials with passive presentations during learning. In a study investigating the learning of geography facts, Mettler, Massey, Burke, Garrigan & Kellman (2018) compared delayed retention rates following passive learning, active learning, and combinations of passive and active learning. Combinations of passive and active learning resulted in better performance than active learning alone. Passive presentations alone fared worst. In addition, the specific manner of combining passive and active modes mattered: learning which began with multiple blocks of passive trials followed by active, adaptive learning resulted in the best performance.

In the current study, we investigated whether the same learning advantages for passive combined with active learning might exist for perceptual learning (PL), which presumably rests on different mechanisms (changes in information selection and encoding vs. explicit storage of memory items). For factual information, spacing was manipulated among individual factual items. Here spacing was manipulated among categories of perceptual stimuli, but with each re-presentation of a category, a new exemplar was shown. Some earlier work suggested that combining

passive and active modes might benefit PL (Thai, Krasne & Kellman, 2015); however, no work has explored different modes of combining active and passive trials.

Why might including some passive learning trials among active learning trials result in better PL than active trials alone? One benefit of passive trials may be to prevent the negative cognitive and motivational consequences of asking learners to generate answers in initial interactive learning trials - similar to the hypothesized benefits of initial passive trials in factual learning. Specific to PL, passive trials might focus attention on some characteristics of categories, and active trials might complement this learning by targeting other characteristics. For example, Carvalho & Goldstone (2015) suggested that passive trials can increase attention to commonalities between members of the same category when certain between-category and within-category similarity relations hold, but that active trials provide greater benefits to learning when the inverse similarity relations hold. Combining passive and active trials could be a strategy then to increase overall learning due to the complementary strengths of active and passive presentations in the learning of categories that possess a variety of internal structures. In the current study, we systematically compared learning schedules that included passive and active trials alone, and two different combinations of passive and active trials. We analyzed subsequent retention of perceptual classification after a delay, and we examined whether passive and active training was affected by internal category structures such as between and within-category similarity.

We compared four conditions: a) *Passive Only* presentations of learning items, b) *Passive Initial Blocks* followed by active, adaptive scheduling, c) *Passive Initial Category Exemplar* followed by active, adaptive scheduling for each category introduced, and d) *Active Only* learning with no passive presentations. We hypothesized that introductory presentations of passive trials, followed by active learning would fare the best, however, the effect of passive learning might be better if passive trials were limited to single presentations rather than blocks.

Method

Participants One hundred twenty undergraduate psychology students participated to partially fulfill course requirements.

Materials 12 categories (genera) of butterflies (lepidoptera) were used, where each genus contained images of 9 exemplars. On each learning trial, an image of one category exemplar was presented on the left side of the screen. In Active trials, the 12 possible category name responses were shown in a two-column list organized alphabetically on the right side of the screen. In Passive trials, only the correct category label was shown and the alternate category names were omitted.

Figure 1: Images of 2 butterfly genera with 3 exemplars from each genus. Danaus (top) and Neptis (bottom).

Design A 4x3x2x2 mixed factorial design was used. There were four between-subject passive/active conditions (*Passive Only, Passive Initial Block, Passive Initial Category Exemplar,* and *Active Only*). A pretest/posttest design consisted of three test phases (Pretest, Immediate posttest, and 1 week delayed posttest). In addition there was a within-subject factor of Familiarity (Familiar vs Unfamiliar); that is, at each test, each category was tested twice with both new and previously seen exemplars. Finally, there was a between-subject factor of Assessment List, such that the familiar and unfamiliar exemplars for each category were randomly selected differently for each of the two lists.

Procedure Participants completed two sessions separated by one week. The initial session consisted of a pretest, training phase and immediate posttest. The second session consisted of a delayed posttest only. In all tests and training, participants were shown a genus exemplar and were asked to identify the matching genus name from a list of all 12 category names. No feedback was provided. Tests consisted of two presentations of each genus: one presentation was a 'familiar' exemplar shown during training, and the other exemplar was an 'unfamiliar' exemplar withheld from training. There were two assessment lists and each participant was randomly assigned one of the versions. Each participant saw the same test version, and thus the same familiar and unfamiliar exemplars for each category, across pre, post and delayed tests.

In the *Passive Only* condition, butterflies were presented in 12 blocks of 12 passive trials. Each category appeared once per block, in random order, and a random exemplar from the category was chosen for each presentation. In the *Passive Initial Blocks* condition, participants first completed 2 blocks of passive trials, with blocks having the same structure as the *Passive Only* condition, followed by adaptive scheduling. In the *Passive Initial Category Exemplar* condition, the first presentation of each category was a passive trial followed by a fixed spacing interval of two intervening trials, so that the correct response was not still in working memory. All trials in this condition that did not involve the first presentation of a category were

adaptively scheduled. In the *Active Only* condition, all trials were adaptively scheduled.

The ARTS algorithm determined the adaptive scheduling for active trials. After every response, ARTS calculates a priority score for each learning item and compares scores across items to determine which item will be presented next. Equation 1 shows the priority score calculation.

$$P_i = a(N_i - D)[b(1 - \alpha_i)\, Log(RT_i / r) + \alpha_i W] \qquad (1)$$

Detailed description of the ARTS algorithm can be found in Mettler, Massey & Kellman (2011, 2016). ARTS parameters were the following: the enforced delay *D* was set to 2 trials, the incorrect penalty *W* was set to 20, parameters *a*, *b*, *r* were set to 0.1, 1.1, and 1.7 respectively, and the timeout was 30 seconds.

Learning for each category continued until 5 out of the last 6 presentations were correctly answered with all correct response times less than 7 seconds. Learning criteria, adopted from previous studies, included both speed and accuracy, where speedy responses also ensured that final presentations were widely spaced.

Participants were assigned to Condition using a pretest balancing algorithm (similar to a procedure called Minimization; Pocock & Simon, 1975; Mettler et al., 2018). The condition balancing algorithm was constrained so that, across conditions, the largest difference in number of assigned participants never exceeded one. There were exactly 30 participants in each of the 4 conditions.

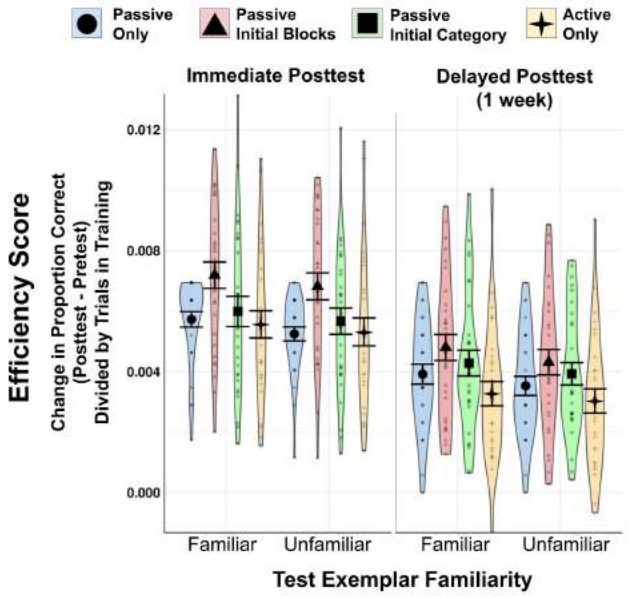

Figure 2: Learning Efficiency in Immediate and Delayed Posttest by Test Item Familiarity. (Violin plot shows mean, +/- 1 standard error of the mean, density estimate and individual data points).

Dependent Measures and Data Analysis

Because all adaptive conditions used learning to criterion, our primary measure was learning *efficiency*, defined as accuracy gain from pretest to posttest divided by the number of trials invested in learning. Efficiency gives a way of measuring learning that incorporates both variations in posttest performance, and variations in the number of learning trials required to reach the learning criteria. It may be thought of as a rate measure, indicating performance improvement per trial. The number of passive trials was determined based on pilot work to be roughly equal to the number of trials needed to reach mastery in active conditions. In the two conditions combining passive and active trials, all trials were included in trial and efficiency calculations.

In addition to efficiency we measured change in accuracy and reaction time. All measures were assessed using standard parametric statistics, such as ANOVA. Because we sought to compare differences across learning conditions, we conducted planned comparisons between pairs of conditions. All statistical tests were two-tailed, with a 95% confidence level, all effect sizes d are Cohen's d, and all error bars in graphs show +/- 1 standard error of the mean.

Results

Pretests A 4x2x2 ANOVA on Condition, Assessment List and Familiarity showed no significant main effect of Condition ($F(3,112)=0.213$, $p=.887$, $\eta_p^2=.006$), Assessment List ($F(1,112)=0.457$, $p=.500$, $\eta_p^2=.004$) or Familiarity ($F(1,112)=2.395$, $p=.125$, $\eta_p^2=.021$).

Efficiency *Efficiency*, defined as posttest accuracy gain from pretest divided by learning trials to criterion, is shown in Figure 2 for each of the posttests, the 4 learning conditions and for familiar vs. unfamiliar test items. The *Passive Initial Blocks* condition appeared to have higher efficiency at immediate posttest and highest numerical efficiency at delayed posttest. A 4x2x2x2 mixed factorial ANOVA on Passive/Active Scheduling Condition, Test Phase (Immediate vs. Delayed Posttest), Item Familiarity (Test exemplar seen vs. withheld in training) and Assessment List (1 vs 2) showed a significant main effect of Condition ($F(3,112)=2.921$, $p=.037$, $\eta_p^2=.073$) a significant main effect of Test Phase ($F(1,112)=277.127$, $p<.001$, $\eta_p^2=.712$), a significant main effect of Familiarity ($F(1,112)=17.832$, $p<.001$, $\eta_p^2=.137$), and no significant main effect of Assessment List ($F(1,112)=0.018$, $p=.893$, $\eta_p^2<.001$). Interactions were not significant (ps>.127) but there was a marginally significant interaction between Condition and Phase ($F(3,112)=2.197$, $p=.092$, $\eta_p^2=.056$) and Assessment List and Familiarity ($F(1,112)=3.391$, $p=.068$, $\eta_p^2=.029$).

The marginally significant interaction between Condition and Test appears to be driven by the clear superiority of

Passive Initial Blocks at immediate test that is less pronounced at delayed test. Paired comparisons revealed significant differences between conditions at immediate test (*Passive Only* vs. *Passive Initial Block*, t(58)=3.12, p=.003, d=0.84; *Passive Initial Blocks* vs. *Active Only* , t(58)=2.53, p=.014, d=0.65), and a marginally significant difference between *Passive Initial Blocks* vs. *Passive Initial Category* (t(58)=1.868, p=.067, d=0.48). Other comparisons did not reach significance (ps >.51). Paired comparisons at delayed posttest showed significant differences between *Passive Initial Blocks* and *Active Only* (t(58)=2.514, p=.015, d=0.65). There was a marginally significant difference between *Passive Initial Category* and *Active Only* (t(58)=1.74, p=.088, d=0.45). The remaining comparisons did not reach significance (ps > .105). Between immediate and delayed posttests, all pairwise comparisons were significant (p<.05) except for between *Active Only* at immediate test and *Passive Initial Blocks* at delayed posttest (t(58)=1.47, p=.147, d=0.38).

Trials in training Mean trials to reach learning criteria or the end of the session are shown in Figure 3. A 3x2 mixed factorial ANOVA was conducted on Condition and Assessment List. The *Passive Only* condition was removed from the ANOVA and paired comparisons due to its fixed (preset) number of trials. There was a significant effect of condition ($F(2,84)=3.448$, $p=.036$, $\eta_p^2=.076$). Paired comparisons showed significant differences between *Passive Initial Blocks* and *Passive Initial Category* (t(58)=2.068, p=.043, d=0.554) and between *Passive Initial Blocks* and *Active Only* (t(58)=2.707, p=.009, d=0.732), but not between *Passive Initial Category* and *Active Only* (t(58)=0.623, p=.536, d=0.161). One sample t-tests were used to compare each Active condition against the *Passive Only* condition mean of 144 trials. There was a significant difference for *Active Only* (t(29)=2.69, p=.012) and a marginally significant difference for *Passive Initial Category* (t(29)=1.97, p=.057), but no significant difference for *Passive Initial Blocks* (t(29)=0.70, p=.49).

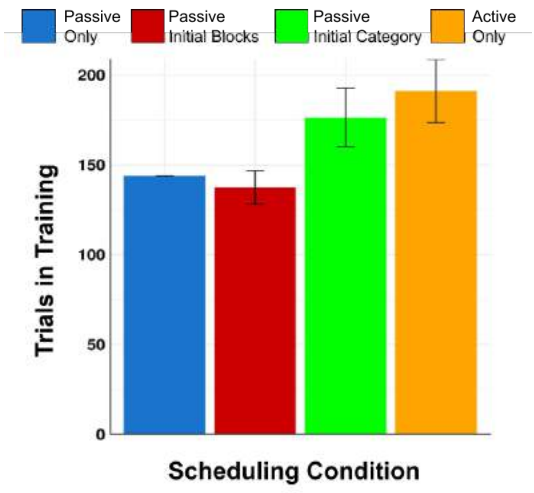

Figure 3: Trials in training session by 4 scheduling conditions.

Learning Analytics

In order to explore the reasons why performance was highest for *Passive Initial Blocks* conditions and lower for *Active Only*, we explored trial-by-trial data during learning. In prior work with learning of factual items we determined that initial blocks of passive items significantly reduced the severity of certain deleterious trial sequences. Specifically, the incidence of errors followed by correct responses (dubbed 0,1 sequences) across conditions, and these sequences followed by another error (0,1,0 sequences), were reduced in conditions that included initial passive blocks, relative to the other active conditions.

We examined 0,1 trial sequences during learning across the three adaptive scheduling conditions. First, the incidence of 0,1 sequences was highest in the *Active Only* condition and lowest in the *Passive Initial Blocks* condition, even when adjusting for the first few trials where there are necessarily errors in the *Active Only* condition due to initial guessing. The frequency of 0,1 instances across the three conditions and for groups of initial trials are shown in Figure 4. Trials 4+ are most instructive, showing that *Passive Initial Blocks* had the fewest occurrences of 0,1 among the three conditions. A 3 way ANOVA run on Condition for Trials 4+, found a significant effect of condition ($F(2,87)=5.23$, $p=.007$, $\eta_p^2=.107$) and paired comparisons showed significant differences between *Passive Initial Blocks* and *Passive Initial Category* (t(58)=2.52, p=.014, d=0.66), *Passive Initial Blocks* and *Active Only* (t(58)=3.15, p=.003, d=0.82), but not between *Passive Initial Category* and *Active Only* (t(58)=0.65, p=.519, d=0.17).

We also examined accuracy following 0,1 sequences. Again, the first 3 trials were removed to equate conditions with respect to number of prior presentations. Figure 5

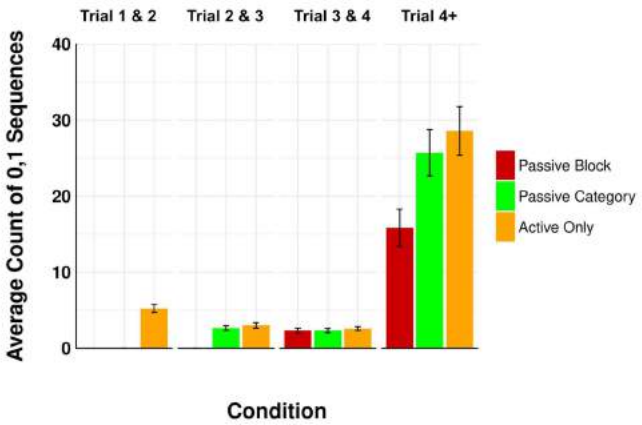

Figure 4: Frequency of 0,1 sequences by condition and by trial in learning session.

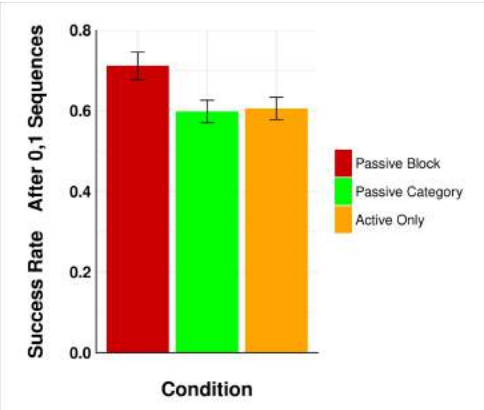

Figure 5: Success rate after 0,1 sequences, corrected for initial guessing (beginning at trial 3 for all conditions).

shows accuracy following 0,1 sequences. A 3 way ANOVA on success rate after 0,1 sequences found a significant effect of Condition ($F(2,87)=4.34$, $p=.016$, $\eta_p^2=.091$). Paired comparisons showed significant differences between *Passive Initial Blocks* and *Passive Initial Category* ($t(58)=2.71$, $p=.009$, $d=0.7$), *Passive Initial Blocks* and *Active Only* ($t(58)=2.22$, $p=.030$, $d=0.57$), but not between *Passive Initial Category* and *Active Only* ($t(58)=0.62$, $p=.539$, $d=0.16$).

Within-category and between-category similarity relations Since prior research indicates the importance of within and between category similarity for benefits from passive or active trial scheduling, we examined passive only and active only learning efficiency as a function of between and within-category similarity. Similarity relations were determined by subject ratings of each category, first for between-category relations and then again, separately for within-category relations. All 12 categories were rated on a 3 point similarity scale for between-category similarity with 3 being highest and 1 lowest. Subject ratings were averaged for each category and categories were divided into 1 of 3 between-category similarity groups based on the tertile of their averaged rating. The same procedure was repeated for within-category ratings. Thus, within and between-category similarities were estimated independently. Posttest efficiencies were compared for two scheduling conditions, *Passive Only* and *Active Only*, across the three levels of within and between-category similarity.

Average efficiency differences, plotted separately for each within and between-category similarity group are shown in Figure 6. Two 2x2x3 ANOVAs were conducted, each with training schedule (*Passive Only, Active Only*), and Test phases (Immediate vs. Delayed posttest) as factors. One ANOVA also included within-category similarity as a factor, and the other also included between-category similarity as a factor. The ANOVA with within-category similarity as a factor showed no significant effect of Condition ($F(1,176)=1.63$, $p=.204$, $\eta_p^2=.009$), a significant

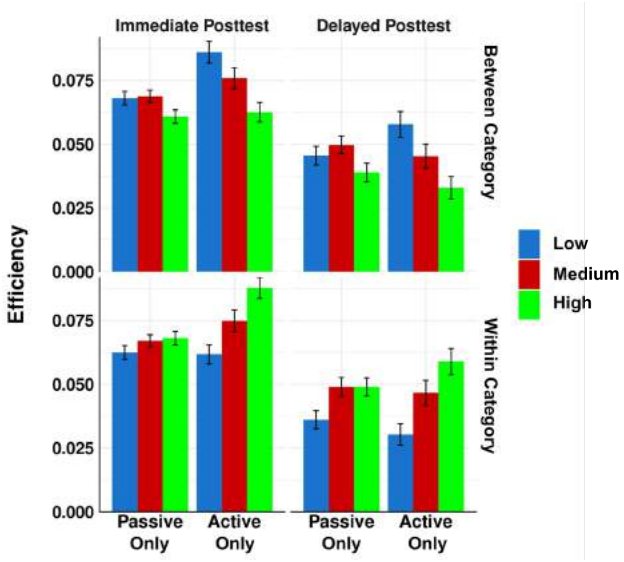

Figure 6: Efficiency for between-category similarity groups (top) and within-category similarity groups (bottom) for low, medium and high similarity, by *Passive Only* and *Active Only* conditions at immediate and delayed posttests.

effect of within-category similarity ($F(1,176)=15.92$, $p<.001$, $\eta_p^2=.083$) and an effect of Test phase ($F(1,176)=223.67$, $p<.001$, $\eta_p^2=.56$). There were two significant interactions, Condition with Similarity group ($F(1,176)=3.92$, $p=.049$, $\eta_p^2=.022$) and Condition with Test phase ($F(1,176)=6.04$, $p=.015$, $\eta_p^2=.033$).

The most instructive interaction, Condition x Similarity group, indicated that similarity relations modulated the effect of Condition. Paired comparisons indicated that differences in efficiency varied more across levels of similarity in the *Active* condition than in the *Passive* condition. Specifically, the greater the within group similarity, the greater the efficiency in the *Active Only* condition. In the *Active Only* condition, there were significant differences in learning efficiency between low within similarity and high within similarity ($t(238)=4.96$, $p<.001$, $d=0.64$), between medium within similarity and low within similarity ($t(238)=2.7$, $p=.007$, $d=0.35$), and between high within similarity and medium within similarity ($t(238)=2.13$, $p=.034$, $d=0.28$). In the *Passive Only* condition, the difference between low within similarity and medium within similarity was significant ($t(238)=2.226$, $p=.027$, $d=0.287$) and the difference between low within similarity and high within similarity was significant ($t(238)=2.388$, $p=.018$, $d=0.308$), but the difference between medium within similarity and high within similarity was not significant ($t(238)=0.136$, $p=.892$, $d=0.018$).

The ANOVA with between-category similarity included as a factor showed no significant effect of condition ($F(1,176)=1.73$, $p=.190$, $\eta_p^2=.01$), a significant effect of between-category similarity ($F(1,176)=12.34$, $p<.001$, $\eta_p^2=0.066$), and a significant effect of Test phase

($F(1,176)=236.08$, $p<.001$, $\eta_p^2=0.573$). There was one significant interaction, between Condition and Test phase ($F(1,176)=6.38$, $p=.012$, $\eta_p^2=.035$), and a marginally significant interaction of Condition x Similarity group ($F(1,176)=3.79$, $p=.053$, $\eta_p^2=0.021$). As with within-category relations, paired comparisons showed that between-category similarity modulated the effects of Condition. In the *Active Only* condition, there were significant differences in efficiency between high between-category similarity and low between-category similarity ($t(238)=4.26$, $p<.001$, $d=0.55$), between medium and low similarity ($t(238)=2.36$, $p=.019$, $d=0.31$), and a marginally significant difference between high similarity and medium similarity ($t(238)=1.94$, $p=.054$, $d=0.25$). In the *Passive Only* condition, there was one significant difference between the medium and low similarity conditions ($t(238)=2.43$, $p=.016$, $d=0.31$) and a marginally significant difference between high and low similarity conditions ($t(238)=1.76$, $p=.080$, $d=0.23$).

Discussion

The synergy of passive and active presentations in perceptual learning was remarkably similar to that found previously in factual learning (Mettler et al., 2018). In both studies the following conditions were compared: 1) passive presentations alone, 2) initial blocks of passive presentations followed by active, adaptive learning, 3) initial passive presentations for each category that unlocked later adaptive learning, or 4) active, adaptive learning alone with no passive presentations. In this experiment the learning consisted of perceptual learning across multiple categories (butterfly genera). We found an advantage for combining passive with active presentations such that initial passive presentations, especially when grouped into initial blocks of passive trials in which all learning categories were interleaved, resulted in the greatest efficiency of category classification at posttest. Learning persisted across time as measured by a 1-week delayed test. In addition, the benefits of passive and active combined schedules generalized to unfamiliar category exemplars that had not been shown during the learning phase. Unsurprisingly, combinations of passive and active presentations were better than passive presentations alone. More important, combinations of passive and active trials were much more effective than active, adaptive presentations alone: a few initial presentations (1 or 2 presentations for each category) was enough to generate learning gains beyond those found with purely active, adaptive schedules. Passive block and adaptive trial synergy was so strong that the *Passive Initial Blocks* condition at delayed test was not statistically different from the *Active Only* condition performance at immediate test. Further analysis of trial-by-trial learning data including sequences of correctness supported the idea that the benefits of a *Passive Initial Blocks* condition extended well into the active, adaptive learning component.

In addition to these results, we investigated the effect of category similarity on passive + active synergies. The overall apparent lower performance in the *Active Only* condition compared to the *Passive Only* condition appears to hold only when similarity between categories is high or when within-category similarity is low. For lower levels of between-category similarity and for greater levels of within-category similarity, *Active Only* conditions fared better than passive presentations. These effects of category similarity are somewhat different than results by Carvalho & Goldstone (2015) who showed that passive presentations result in slightly worse performance when categories have relatively low within-category similarity.[1] Unlike Carvalho & Goldstone, we found that active presentations had the greatest benefit when between-category similarity was lowest and when within-category similarity was highest. By one interpretation, high similarity between categories implies greater difficulty of making category discriminations. Thus active presentations are best when categories are more discriminable from each other. A natural interpretation of the effects in adaptive category sequencing is that with low within-category similarity (and potentially with high between-category similarity) assessments of category learning strength gotten from each active trial by the adaptive algorithm are less reliable when category instances are more diverse, making learning less efficient.

To conclude, we investigated the contribution of including passive presentations with interactive, adaptive learning. We found that combining passive with active presentations such that an initial passive phase (passive blocks) in which passive presentations were given for all learning categories resulted in the greatest retention performance at posttest. In perceptual learning, the effects of passive presentations appear to temper differences in category structure across variable within and between-category relations, and to enhance active, adaptive learning with fewer errors throughout the learning session.

Adaptive learning frameworks that leverage learner performance data to arrange spacing and sequencing in learning substantially improve learning across diverse types of learning, including perceptual learning. These benefits are further enhanced by combining active responding with passive modes of learning at the start of learning. The present results may help lead to a theoretical understanding of the mechanisms that enable passive + active synergies across different types of learning, and they contribute to a practical understanding of how to optimize these effects in instructional technology.

[1] It should be noted that blocking in Carvalho and Goldstone referred to massing exemplars from the same category, whereas in our Passive Initial Blocks condition all of the passive trials were presented as a block, but we interleaved exemplars from every category consistently in all conditions.

Abstract

We compare the performance of humans (English and French listeners) versus an unsupervised speech model in a perception experiment (ABX discrimination task). Although the ABX task has been used for acoustic model evaluation in previous research, the results have not, until now, been compared directly with human behaviour in an experiment. We show that a standard, well-performing model (DPGMM) has better accuracy at predicting human responses than the acoustic baseline. The model also shows a native language effect, better resembling native listeners of the language on which it was trained. However, the native language effect shown by the models is different than the one shown by the human listeners, and, notably, the models do not show the same overall patterns of vowel confusions.

Keywords: linguistics; language acquisition; machine learning; speech recognition

Introduction

Comparing cognitive models with human behaviour often involves some idealization. The ideal comparison between a model and a human behavioural experiment would simply have the model "participate" in the experiment, exposed to the same stimulus files as are presented to the humans, responding as if it were just another human subject. Its responses would be compared to human subjects' on a stimulus-by-stimulus level. This ideal is reached only rarely (for example, Riochet et al., 2018). Most settings either simplify the stimuli given to models (for example, showing images of objects to human participants, but providing the model instead with a discrete input indicating whether the object was a dog or a cat, as in Xu & Tenenbaum, 2007), or compare highly aggregated results rather than predictions on individual stimuli (for example, Gulordava et al., 2018). These simplifications, while often essential, may mask aspects of the real task which have a major impact on the results.

Meanwhile, a large body of recent research has proposed to evaluate acoustic models trained on speech databases, particularly those trained in an unsupervised way, using an *ABX phone discrimination task* (Schatz et al., 2013). This evaluation considers pairs of speech stimulus items (A and B) coming from two different phonemic categories, assessing whether the model's representation of a third stimulus (X) is more similar to its representation of A or of B.

While this task is analogous to the standard human ABX perception task, a direct comparison of the two to evaluate models or better understand human behaviour has not yet been done. We propose a direct, stimulus-by-stimulus comparison of an acoustic model with human perception in an ABX perception task. Additionally, the stimuli for our task come from two different languages. We examine the behaviour of human subjects, and trained models, for whom one of the languages is a second language (L2). Previously, unsupervised acoustic models have typically been evaluated by assessing how well they discriminate phonemes of the language on which they are trained (L1), their objective being to reach perfect discrimination of all pairs of phonemes in the L1 (Schatz et al., 2013; Versteegh et al., 2015). A few studies have investigated patterns of L2 discrimination in acoustic models, looking at overall accuracy on phonemic contrasts from languages other than the training language. But their conclusions have been based on qualitative summaries of the behaviour of the models, with no human reference data on the same stimuli (Schatz et al., 2017; Schatz & Feldman, 2018).

A stimulus-by-stimulus comparison of an acoustic model with human performance on a speech perception task might reveal major differences between the two. If a trained acoustic model is seen as an acoustic baseline, the comparison will highlight aspects of human speech perception which are surprising given properties of the signal alone. On the other hand, if the goal of the acoustic model is to be human-like, such a comparison shows us where the model falls short.

We train an unsupervised acoustic model which is known to perform globally well on corpus-based ABX evaluations (Chen et al., 2015). We train the model on English and French corpora. We expose both the English-trained model and the French-trained model to novel, experimental stimuli. We evaluate the models' ABX discrimination accuracy. We give English and French human native listeners the same task.

Our results show that the model is globally more predictive of the human results than a baseline based on low-level acoustic features. The model also shows a native language effect: when trained on French, its error pattern is more like French native speakers', and similarly for English. However, we analyze these error patterns, and show that the native language effects shown by the models, while globally predictive, differ importantly from those shown by the human participants.[1]

[1] All modelling code, analysis code, stimuli, and anonymized

Methodology: Human ABX evaluation

In an ABX paradigm, participants hear three sounds in sequence, and indicate which of the first two sounds (A or B) is more similar to the last (X), a sound always drawn from the same category (for example, phoneme) as either A or B. The task is intended to tap the perceptual similarity between A and X, on the one hand, and B and X, on the other, to assess the overall distinctness of the categories A and B belong to.

We develop stimuli to test cross-linguistic (English/French) perception of vowels in an ABX discrimination paradigm. Within each stimulus triplet, A and B always consist of CVC non-words contrasting one English vowel with one French vowel, with the flanking consonants held constant. We use the American English vowels [ɪ], [ʌ], [ʊ], and [æ], and the Hexagonal French vowels [a], [ɔ], [ɛ], [i], [u], [y], and [œ].[2] Only consonants appearing in both languages are used: [v], [z], [s], [ʃ], [f], in both consonant positions, and, additionally, [p], [b], [g], and [k] in coda.[3] While the stimuli are designed to differ only in the vowel, there are inevitable phonetic differences in the realization of these consonants across the two languages, which may provide additional cues to the correct answer. Real words in either language are excluded. For details of stimulus construction, see **Experiments: Humans** below.

We expect that human listeners will vary in their discrimination ability, with triplets like [vip]–[væp]–[vip] being generally more difficult than more acoustically similar triplets such as [vʌp]–[vɔp]–[vʌp]. We also expect cross-linguistic differences, with English listeners doing better than French listeners on acoustically similar contrasts which do not exist in French, such as [i]–[ɪ]. We examine the patterns of confusions shown by both listener groups, and present the same experimental stimuli to models trained on English and on French, to evaluate the models' internal representations.

Methodology: Model ABX evaluation

Unsupervised acoustic models are models that learn representations of speech by exposure to speech without associated phonemic category labels. They can be seen as learning the organization of a perceptual space for speech.

We train a Dirichlet Process Gaussian Mixture Model (DPGMM) as an acoustic model. It is a non-parametric Bayesian clustering model. It finds, in an unsupervised way, a set of multi-dimensional Gaussian distributions appropriate to cluster the observations (here acoustic features). It adapts its number of Gaussian distributions automatically depending on the training data. The computations needed by the model training can be parallelized (Chang & Fisher III, 2013), making training on a reasonable amount of speech data possible. The resulting trained model (learned set of Gaussian distributions) can then be applied to any new speech example, yielding a sequence of probability vectors that can be seen as the model's perceptual representation of the example. In this way, the model can be seen as learning the organization of a perceptual space. Chen et al. (2015) applied parallel DPGMM training and achieved the best performance in the 2015 ZeroSpeech Challenge, a machine learning challenge seeking state-of-the-art unsupervised acoustic models (Versteegh, Anguera, Jansen, & Dupoux, 2016).

The representations we extract from the DPGMM model are posteriorgrams. A speech signal consists of a sequence of audio frames: for a sequence of k audio frames, a posteriorgram is a sequence of k vectors. The vector $\mathbf{x_i} = (x_1, x_2, ...x_N)$ gives the probabilities of the i^{th} frame having been generated by each of the model's N learned Gaussian distributions.

Performing ABX evaluation of an encoding learned by an acoustic model relies on extracting the representations of triplets of stimuli (A, B, and X), and computing the distance $d(\mathrm{A},\mathrm{X})$, between A and X, and $d(\mathrm{B},\mathrm{X})$, between B and X. X is of the same category as either A or B. Taking A to be the correct answer, we compute $\delta = d(\mathrm{B},\mathrm{X}) - d(\mathrm{A},\mathrm{X})$. If $\delta > 0$, we can consider the model to have chosen A; if $\delta < 0$, we consider it to have chosen B. In previous work evaluating acoustic models with this method (Versteegh et al., 2015; Dunbar et al., 2017), the percentage of correct responses for each pair of categories is tabulated, and these averages are combined into a global ABX discriminability score.

Because it relies only on computing distances, the model ABX evaluation is applicable to a broad variety of learned representations. It can be applied to posteriorgrams, but also to Mel-frequency cepstral coefficients (MFCCs), a compact representation of acoustic cues derived from the spectrum, commonly used to train ASR models. We train our models here on MFCC inputs, and MFCCs also serve as our low-level acoustic baseline (each audio frame is a MFCC vector).

The distance function most appropriate for the comparison may vary as a function of the type of representation. Because the representations we evaluate contain one vector per audio frame, differing-length stimuli will have different-length representations. To deal with those differences, we follow previous literature in the domain and use dynamic time warping (DTW) to align the sequences (see Senin, 2008 for a review). This algorithm computes an optimal match between two sequences based on a secondary distance function used for comparing individual elements across the two sequences (individual vectors in the speech representations). Every frame in each of the two representations is matched with at least one frame in the other representation, following the order of each sequence. The final distance between the two sequences is the mean of the distance between the matched frames.

As secondary distance functions, we use the same frame-level distances as in previous evaluations of DPGMM acous-

data for this paper are available in the following online repository: `https://github.com/geomphon/CogSci-2019-Unsupervised-speech-and-human-perception.git`.

[2]This reduced set of vowels is constructed with special attention to French native listeners' perception of the English vowel [ʌ]. Previous research shows (Peperkamp, 2015) that French native listeners identify this vowel with a number of different French vowels, suggesting that a fair number of pairs will be difficult for subjects.

[3]Stops are excluded in onset position because of the marked differences between English and French VOT.

tic models. For MFCC representations, we use the cosine distance. For N-dimensional vectors $\mathbf{x}$ and $\mathbf{y}$, it is defined as:

$$D_{cos}(\mathbf{x},\mathbf{y}) = \frac{1}{\pi}\arccos\left(\frac{\sum_{i=1}^{N} x_i y_i}{\sqrt{\sum_{i=1}^{N} x_i^2}\sqrt{\sum_{i=1}^{N} y_i^2}}\right)$$

For comparing the posteriorgrams of our trained models, we use the symmetrized Kullback–Leibler (KL) divergence. For positive[4] N-dimensional vectors $\mathbf{x}$ and $\mathbf{y}$, the symmetrized KL-divergence between x and y is:

$$D_{KL}(\mathbf{x},\mathbf{y}) = \frac{1}{2}\left[\sum_{i=1}^{N} x_i \log(\frac{x_i}{y_i}) + \sum_{i=1}^{N} y_i \log(\frac{y_i}{x_i})\right]$$

Although this model ABX task is inspired by a speech perception task, the test is different from a typical speech discrimination experiment in an important way. By tabulating the proportion of triplets with $\delta > 0$ (correct), gradient information about individual stimuli triplets is lost. Such a test cannot measure how well separated or "discriminable" individual speech stimuli are, but only the separation of a pair of categories A and B. Rather than directly using model ABX discriminability scores, we relate human discrimination of individual stimuli to δ; see below, and see also Schatz, 2016.

Experiments: Humans

The stimuli were recorded in a carrier phrase. Six speakers read the stimuli in an anechoic chamber. Two were early bilinguals of American English and Hexagonal French, both female, and read both the English and the French vowel stimuli. Both had extensive exposure to both languages throughout most of their early and adult lives, and regularly used both languages. These stimuli were used for A and B. The other four speakers were male: two North American English natives, who read the English stimuli, and two Hexagonal French natives, who read the French stimuli. Their productions were used as X. Phonetically trained listeners (one French and one English native), listened to the stimuli in isolation and verified that they were native-like in the target language and corresponded to the intended vowel.

All A and B pairs were cross-language comparisons. If A was a French stimulus, B was English, and vice versa. The A and B speakers always differed. The experiment used 500 ms silence for both the A–B and B–X intervals.

The final set of stimuli consisted of 112 triplets, matched to the same intensity, downsampled to 16000 Hz. The list was a subset of the complete set of possible triplets, optimized to balance combinations of speaker, vowel pair, consonantal context, and whether A or B was the correct answer. Each vowel pair appeared four times, factorially combining which of the two vowels was the correct answer, and whether the correct answer was presented first (A) or second (B).

The task was performed on Amazon Mechanical Turk with the LMEDS software (Mahrt, 2016), with participants from the United States and France. Listeners were paid for participation. Previous research shows that Mechanical Turk can successfully be used for speech perception tasks, and that results are comparable to a lab setup (for example, Kleinschmidt & Jaeger, 2015). We asked the participants to use headphones, to do the task in a quiet environment, and to check the sound volume before the experiment began.

A total of 144 participants were tested, 72 in France and 72 in the United States. We filter out those who did not finish the task, did not report English or French as their first language, had previously taken a linguistics class, failed two out of three catch trials[5] or reported hearing or vision problems. In the end, there were 63 English and 55 French participants.[6]

Experiments: Models

To build the models for comparison with the human experiment, we train the DPGMM on the same LibriVox audio book source corpora used to construct the English and French data sets in the 2017 ZeroSpeech Challenge (Dunbar et al., 2017). We use a different subset of the corpora than the one used previously, to construct two data sets of comparable size. Our English data set is made of 34 hours and 8 minutes of read speech, and our French dataset contains 33 hours and 42 minutes of read speech. Recordings were sampled at 16000Hz.

We use Kaldi (Povey et al., 2011) to pre-process the data: we extract 13-dimensional MFCCs (25 ms analysis window, 10 ms window shift), to which we apply a vocal tract length normalization (VTLN). We add the Δ and $\Delta\Delta$ for a total of 39 dimensions, and apply centered windowed mean normalization (with a window size of 300 frames).

For each corpus, we use 90% of the data for training and 10% as a validation set. We obtain two models, one for each dataset (**English-DP**, **French-DP**). Model training is stopped after 1500 iterations, as in Chen et al., 2015. We obtain 611 clusters for **English-DP**, and 1565 for **French-DP**.

The **English-DP** and **French-DP** models are applied to the one-second and ten-second test stimuli from the across-speaker condition of the 2017 ZeroSpeech Challenge (also drawn from the LibriVox corpora) and subjected to the corresponding ABX evaluation. We test the French model on the French stimuli and the English model on the English stimuli. The ABX triplets are each made up of a sequence of three extracts of speech from the stimuli, where each extract consists of a sequence of three phones, and A and B differ only in the

[4]We replace zero elements with a very small constant to avoid division by zero.

[5]Catch trials played a tone and gave an audio instruction as to which response to give.

[6]Not all participants used headphones, in spite of our instructions, and a few reported distractions; here we do not exclude these participants. Following a reviewer suggestion, we examined the results of such an exclusion, which leaves 50 English and 26 French participants. All qualitative results remain as reported. The results of this alternate analysis can be found in the online repository.

centre phone, while the context phones are held constant. All triplets constructible from the test stimuli are tested. This test serves to ensure that the models are performing as expected.

We apply each of the two models, separately, to the experimental stimuli (see **Methodology: Human ABX evaluation**), to simulate English and French native listeners. We apply the same pre-processing steps as were applied to the training corpora, transform the files into DPGMM posteriorgrams from the trained models, and obtain only the frames corresponding to the stimuli.[7] We calculate δ for each triplet, for each of the models, and for the MFCC representations.

Results: Humans

The overall ABX discrimination accuracy across all stimuli, across all participants, is 72%. The English listeners obtain a score of 69%, and the French listeners 75%. Figure 1 shows the average accuracy across vowel pairs.[8]

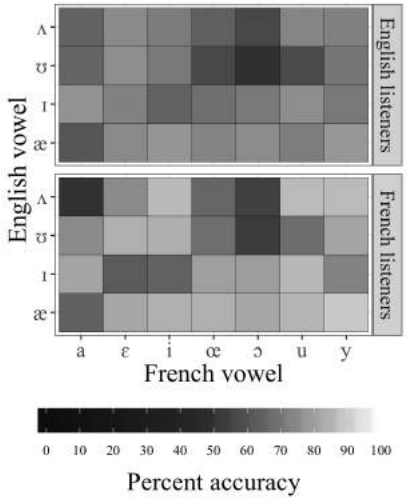

Figure 1: Human accuracy (English and French listeners) averaged by vowel pair. Lighter indicates higher accuracy.

Before comparing the accuracies across native language group, we apply a correction to make the groups' scores comparable. We numerically remove effects of response bias, potential bias to respond A or B, and overall group-level baseline accuracy. We quantify these nuisance effects using a generalized linear model. We fit a probit regression because of its interpretation as a d-prime analysis (DeCarlo, 1998; Macmillan & Creelman, 2004) using the *lme4* package for R (Bates et al., 2015). We code responses as 1 (accurate) or 0 (inaccurate). The model contains an intercept and a random intercept by subject, modelling response bias; a main effect of subject group (English: −1, French: 1), modelling group-level differences; an effect of A/B presentation order (A correct: −1, B correct: 1), modelling tendencies to respond A or B; and an interaction of these last two. We correct each observation by subtracting the predicted probability of correct response. We average the corrected responses within each stimulus triplet, and average these corrected accuracies down to the vowel pair level as before, obtaining corrected accuracies by vowel pair. Correlation between the two groups' corrected accuracy at the stimulus triplet level is 0.63. After averaging to the vowel pair level, the correlation is higher, at 0.79, indicating that many group differences are due to effects of individual stimuli, rather than the vowel contrasts we intended to test. The vowel pairs are compared in Figure 2.

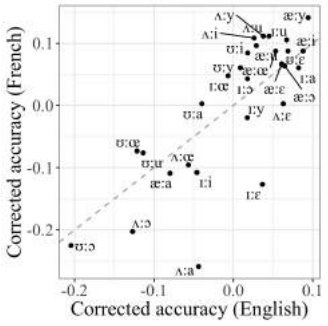

Figure 2: Discriminability of vowel pairs compared between the two language groups. The dotted line is $y = x$; pairs above the line are better discriminated by French listeners, while pairs below show better discrimination for English speakers.

Figure 2 shows that most vowel pairs were relatively well discriminated (upper right), but some were poorly discriminated by both groups (lower left). [ʌ]–[a], [ʌ]–[ɔ], and [ɪ]–[ɛ], are all perceived better by English listeners. This is consistent with Peperkamp (2015), who reports tests of French listeners on identification of English vowels, similarly indicating that, for example, [ʌ] was identified as [a], [œ], or [ɔ].

Results: Models

The scores that **English-DP** and **French-DP** obtain on the ZeroSpeech 2017 stimuli are presented in Table 1. Repeated averaging is done as for the human data, across context (flanking phones), across speakers, and then across all centre phones, to obtain a single score. We observe that the DPGMM model obtains better scores than the MFCCs, consistent with previous results. Results are reported as accuracies. **English-DP** shows 88.4% ABX accuracy on the experimental stimuli we design, and **French-DP** 86.6%, both better than **MFCC** (81.2%). Thus, the models continue to do better, globally, at discriminating speech contrasts, than the acoustic baseline, on novel recordings, from novel speakers.

[7] This was done on the longer source files, rather than directly using the short audio files used in the experiment to avoid window problems, since frames at the beginning and end of files are dropped during preprocessing. Processing the longer source files also gives the vocal-tract length normalization transformation an advantage, leading to an improvement in speaker normalization.

[8] This was a repeated average, similar to that done for the model ABX scores below: first, the accuracy across subjects for a given stimulus was calculated; then, these scores were averaged across contexts; then, across speakers. This was done for consistency with the ABX model evaluation literature (Versteegh et al., 2016; Dunbar et al., 2017).

Model	French		English	
	1s	10s	1s	10s
MFCC	74.8%	74.5%	76.6%	76.6%
French-DP	83.7 %	84.4 %	–	–
English-DP	–	–	88.8%	89.3%

Table 1: ABX accuracy for the trained models and low-level acoustic baseline on the 2017 ZeroSpeech benchmark.

Results: Model–human comparison

To compare the models as models of human perception, we ask how well the continuous machine discriminability score δ for each of the models (distance to incorrect minus distance to correct answer: see **Methodology: Model ABX evaluation**) predicts the human results. As each stimulus is associated with a δ value for a given model, good models are those for which the probability that human subjects respond correctly increases monotonically in the δ value. We compare the three δ values: **English-DP**, **French-DP**, and **MFCC**.

We begin by pooling English and French participants, to assess whether either or both DPGMM models are globally more human-like than the low-level acoustic baseline. We again use probit regression including δ as a predictor. The dependent variable is whether the subject responded correctly (1: accurate, 0: inaccurate). We fit three separate probit regressions, one per δ. Since the model includes a coefficient for δ, this can be seen as taking δ to quantify the subjects' perceived degree of distinctness for a given triplet, up to some scaling factor. We rescale the δ scores for numerical stability and for cross-model interpretability by dividing by the root mean square.[9] We again include both an overall and a (random) by-subject intercept to account for response bias, a coefficient for whether the correct answer was A or B, native language of the participants, and an interaction between these last two, plus a random intercept for individual stimulus triplet (experimental item).[10] We do not include an interaction between subject language and δ: we test for a native language effect separately below. We compare the three models using AIC (Akaike, 1974). Results are in Table 2 (smaller AIC is better). Both DPGMM models predict the human responses better than the MFCC baseline.

If the DPGMM model is really capturing adult perception, we should also expect a "native language effect": the English-trained DPGMM should show results which more closely resemble those of the English listeners than the French listeners, and the French-trained DPGMM should show results which more closely resemble those of the French listeners than the English listeners (see **Results: Humans**). We assess this as follows: we associate each human observation with the appropriate "native language" δ (**English-DP** for trials by English listeners, **French-DP** for French listeners), and with the "non-native language" δ (**French-DP** for English listeners, **English-DP** for French listeners). We construct two alternative probit regression models with the same nuisance predictors as above. In one, the independent variable of interest is the native δ score; in the alternative, the non-native δ. If the representations are equally good at predicting both groups, neither of these models should be better than the other. Results (Table 3) indicate a better fit in AIC for the native-language δ predictor (-21.12 in favour).

To verify that -21.12 is a reasonable model comparison criterion, we examine 9999 instances of the same model comparison over a randomized baseline. Each sample modifies the original data only in that the δ value considered "native" or "non-native" (**English-DP/French-DP**) is determined by a random permutation of the original native language indicator.[11] The random baseline does not yield similar improvements in AIC scores: in the baseline sample, the add-one smoothed left tail probability of -21.12 is 0.0089.

Models	French-DP	English-DP	MFCC
Coefficient for δ	0.2682	0.2790	0.1804
AIC	12675.83	12672.91	12684.15

Table 2: Regressions of human responses against machine representations, compared over the whole experiment (coefficient of δ and AIC). Lower AIC indicates better fit.

Predictor	Native δ	Non-native δ
Coefficient for δ	0.2693	0.1452
AIC	12667.98	12689.1

Table 3: Regressions of human responses against native (**French-DP** for French listeners, **English-DP** for English listeners) versus non-native (switched) trained DPGMM models (coefficient of δ and AIC). Lower AIC indicates better fit.

Discussion

Overall, the DPGMM shows itself to be a passably human-like acoustic model. Furthermore, when it is trained on subjects' native language, it predicts their responses better.

To better understand this effect, we calculate a "degree of native language effect" score for each stimulus triplet in the

[9] We keep zero in place for interpretability, as it is the decision threshold for the model ABX. Note, however, that zero is not guaranteed to be the *optimal* decision threshhold, either for predicting the correct answer in the task, or for predicting human behaviour. The inclusion of an overall intercept allows for the model to adjust to the best decision threshhold for predicting human responses.

[10] We include a stimulus-triplet level random intercept here, but not for the purpose of removing extraneous variability from the accuracy scores in generating Figure 2 above, or Figure 3 below. Those graphs are comparisons of behaviour on different items, and so item-level variability is not a nuisance factor. In contrast, here we are trying to explain away item-level variability, using δ as a predictor. It does not diminish the value of this model comparison to include a predictor capturing additional item-level variability.

[11] By permuting across the data set, we keep the unbalanced proportions of French- and English-native responses. The coefficients for subject language are still fit to the true native language of the subjects.

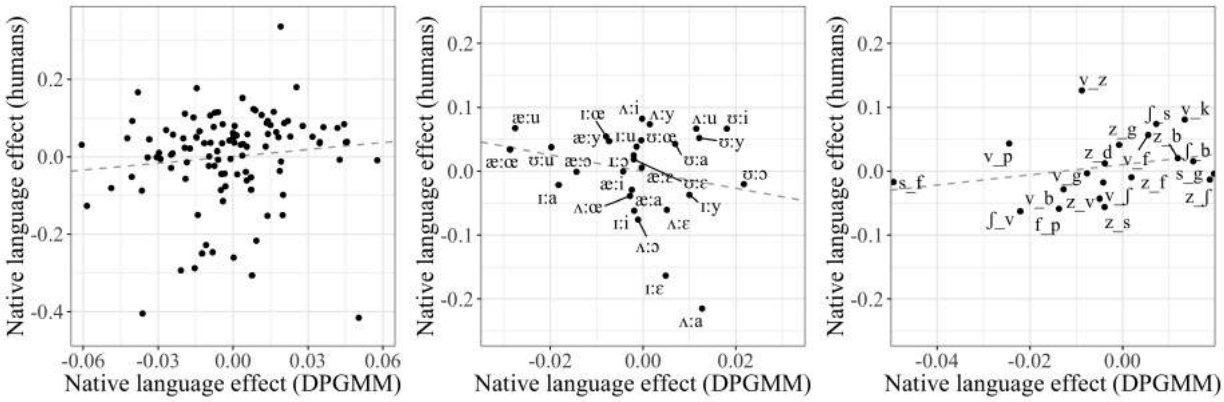

Figure 3: **(a)** Native language effect (French minus English), plotted for human accuracy against probabilities predicted from δ. Each point is one stimulus triplet. **(b)** The same points, averaged by vowel pair. **(c)** The same points, averaged by flanking consonant context. Dotted lines are linear regressions. Graphics do not show the same part of the plane, but all are on the same aspect ratio (13:7), meaning that slopes are visually comparable.

experiment, as the difference between French and English listeners' mean corrected percent accuracy (see **Methodology: Humans**). We calculate an equivalent score for the models, a predicted correct-response probability. Because the mapping between the δ values and response probabilities is indeterminate, we select an optimal mapping: we use a probit regression fit to the human data including the native-language δ as a predictor, and extract the predicted probability for each observation.[12] To isolate the part of the resulting score due to the DPGMM model itself, we subtract from each predicted probability the probability predicted by the regression if δ were zero for the given observation, obtaining a corrected probability analogous to the corrected accuracies derived for the humans above. For each stimulus triplet, we take the average corrected probability across all observations. The native language effect for the DPGMM model, for a given stimulus triplet, is the subtraction of the French and the English models' average corrected probabilities on this triplet.

These quantities are plotted against each other in Figure 3a. The slight trend towards a positive relation is consistent with the results of the model comparison, although most of the variance is unexplained. However, when averaged by vowel contrast, as in Figure 3b, it becomes clear that the native language effect in vowel confusions is not human-like: the trend in the graph is toward a negative relation. Interestingly, in Figure 3c, in which items are instead grouped by consonant frame, shows a slight positive trend, indicating human-like behaviour. But the behaviour the model captures is the fact that the impact of the flanking consonants on performance differs across listener groups. This is clearly not the behaviour we expected it it to capture: the flanking consonants were not intended to have an impact on performance at all. The fact that they contain information that facilitates the task is an artefact of the imperfectly controlled stimuli. It is also not this behaviour that makes the biggest contribution to the native language effect in humans: Figure 3 shows greater variance across vowel pairs than across consonant frames.

This unexpected effect may be due to the nature of the DPGMM model. The large number of categories it learns likely discriminate contextual variants and temporal subcomponents of individual phonemes. The participants in our experiment presumably detect coarser distinctions, beyond this sub-phonemic variability. Vowels, in particular, consist of a long steady state. The DPGMM's representation may fluctuate too much to maintain coarser-grained information. Whatever the explanation, the trained DPGMM models do not match the stimulus-by-stimulus profile of human subjects.

Conclusion

We tested human listeners, English and French native speakers, and an unsupervised acoustic model (trained once on English, once on French) on the same cross-linguistic ABX discrimination task, comparing the model with human performance on a stimulus-by-stimulus level. Our results show that the acoustic model predicts human results better than a low-level acoustic baseline, and predicts certain effects of native language on perception, while missing critical features.

We take this detailed and direct comparison to be an important step in improving the evaluation of quantitative models of human speech perception. Given that the DPGMM shows a limited, but incomplete, correlation with human speech perception, it may also prove useful as a measure of acoustic distance which is adapted to a particular language. Our approach permits detailed investigation of the differences between humans and computational models on speech perception tasks, which will be essential to using these models to gain insight into the underlying cognitive processes.

[12] We use a modified version of the "native language" regression model described in **Results: Model–human comparison**, with all nuisance predictors included, except the random effect of stimulus triplet. We exclude this for reasons discussed already: we are seeking here to examine residual differences between items.

Explanatory Virtues and Belief in Conspiracy Theories

Abstract

Conspiracy theories are "alternative" explanations of well-understood events or phenomena. What makes them attractive explanations to so many people? We investigate whether people ascribe characteristics typical of good explanations to conspiracy theories and whether they are perceived as more appealing explanations when they are articulated as a refutation of the official version of events. In two experiments, participants read explanations of four conspiracy theories and rated them along six dimensions of explanatory quality. We find that some explanatory virtues are ascribed to conspiracy theories even by people who do not believe the conspiracy. Contrary to our predictions, we also find that framing a conspiracy as a refutation did not generally elicit higher ascriptions of explanatory virtues. These results suggest that explanatory considerations may play a more central role in conspiracist beliefs than was previously thought.

Keywords: Explanation; conspiracy theories; open science

Introduction

People who believe in conspiracy theories should be characterized, or so the thinking goes, by their inability or unwillingness to identify these theories as being not only false but also as exhibiting clear epistemological flaws (e.g., Hofstadter, 1965; Robins & Post, 1997). However, this characterization obscures the possibility that people subscribe to conspiracy theories not because they are foolish but because they think that they qualify as justified beliefs (Sunstein & Vermeule, 2009), and in particular, that these theories might exhibit explanatory virtues.

The study of conspiratorial thinking is not merely an academic issue: conspiratorial thinking has real-world social and political consequences. Conspiracy theories incite acts of violence (Knopf, 2017), allow fear-mongering politicians to exert undue influence on the outcome of democratic votes (Kuzio, 2011; Nefes, 2013), scare off individuals from accessing life-preserving health care (Jolley & Douglas, 2014), and interfere with the dissemination of scientific knowledge (Goertzel, 2010).

Conspiracy theories can have lasting societal and psychological repercussions. Consequently, psychologists have begun examining the factors that are predictive of conspiratorial thinking with the hope that studying them inspires corrective interventions (Sunstein & Vermeule, 2009). Most people do not believe in conspiracy theories, but there are also individual differences in their adoption, prompting researchers to investigate what personality factors lead some people to believe in conspiracy theories (Freeman & Bentall, 2017). In the last three decades, psychologists have primarily focused on examining individual psychological differences of people who engage in so-called "conspiratorial ideation" (e.g., Swami et al., 2011; Brotherton & French, 2014). For instance, this research has examined how paranoia (Wulff, 1987), believing in the existence of paranormal phenomena, mental health disorders (Darwin, Neave, & Holmes, 2011), low levels of interpersonal and governmental trust, and political orientation predict believing in conspiracy theories (Miller, Saunders, & Farhart, 2016). This line of research is based on the observation that individuals who endorse a given conspiracy theory are more prone to endorse further (Goertzel, 1994), even contradictory (Wood, Douglas, & Sutton, 2012) or fictitious, conspiracy theories.

Philosophers have also taken an interest in understanding conspiratorial thinking, but rather than focusing on the types of people who believe in conspiracy theories, they have examined the epistemology of believing in conspiracy theories (Sunstein & Vermeule, 2009; Coady, 2006; Räikkä, 2009). This research has suggested that conspiracy theories owe their popularity to the fact that they display certain qualities (e.g., apparent simplicity, ability to produce a feeling of understanding) that are normally the hallmark of good explanations (Keeley, 1999). In particular, Keeley (1999) has suggested that conspiracy theories are often presented by their advocates as being broader than the official theory, as being able to include more phenomena in their explanation for a given phenomenon. Despite the suggestion that conspiracy theories might have a special type of explanatory appeal, there has been comparatively little research on the *features* of conspiracy theories that may make them attractive to believe (but see Wagner-Egger, Delouvé, Gauvrit, & Dieguez, 2018).

If conspiracy theories have a distinctive ability to pass for good explanations, they might draw some of their influence from their ability to satisfy what philosophers and cognitive scientists have called the human "obsession with the search for explanations" (Lipton, 2003). This would also explain why conspiracy theories tend to give rise to strong feelings of attachment in those who believe in them (Sunstein & Vermeule, 2009) and why they are often used successfully as tools of psychological manipulation by individuals (so-called "conspiracy entrepreneurs," Sunstein & Vermeule, 2009) who seek to increase their political power. An empirical investigation of the explanatory virtues of conspiracies might therefore shed light on why a substantial portion of

people—at least more than one would hope—believe in at least one conspiracy theory (Lewandowsky, Oberauer, & Gignac, 2013).

Explanatory virtues and belief

If the way conspiracy theories explain events is what makes them appealing, we may expect some of this appeal to stem from their ability to display explanatory virtues typical of good explanations. We may also expect that people who believe in conspiracy theories will be particularly sensitive to these virtues in their favored conspiracies. What virtues characterize good explanations?

Recent research has investigated the determinants of people's explanatory preferences by examining how people assess the quality of explanations they generate or consider. Some of these studies have shown a correspondence between people's preferences and the explanatory virtues identified by normative work on the epistemology of explanations (Thagard, 1978). For instance, people appear to favor qualities such as simplicity (Pacer & Lombrozo, 2017), and breadth or coherence. Other studies have revealed certain cognitive biases, i.e. preferences that do not necessarily track the goodness of an explanation, for instance the preference for explanations referring to inherent characteristics of the explanandum (e.g., Horne, Muradoglu, & Cimpian, 2019). Finally, some researchers have identified so-called "explanatory vices" (Lombrozo, 2016): these are explanatory characteristics that are mistaken for virtues and that allow flawed explanations to pass as good ones. For instance, using technical jargon can improve the apparent quality of an explanation, but it is not a reliable characteristic because it can also be used to mask the poor quality of an explanation to non-experts.

The inquiry into the nature of good explanations also bears on understanding how people reason. Given that a search for knowledge often involves the search for true explanations, what guiding principles should people trust when they reason about explanations? The theory of Inference to the Best Explanation (known as IBE, Lipton, 2003) offers such a principle: if an explanation is good enough (Lipton, 2003) and if it is better than all other rival explanations, then we are warranted to infer that that explanation is correct. Experimental work has also shown that people's beliefs can be modeled as conforming to such an inference rule. For instance, in a recent study by Douven and Mirabile (2018), subjects were asked to decide between two competing explanations for six everyday scenarios. They also rated the explanatory quality of both explanations. Two important trends were apparent in the responses: First, subjects tended to choose those explanations they judged as better explanations. Second, the quality of the competing explanation also affected the subjects' decisions: when the rival explanation was too close in goodness to the best explanation, the choice of the best explanation decreased. This latter result suggests that if a rival—but not as good—explanation is able to cast doubt on the superiority in quality of the better explanation, then it could also undermine the acceptance rates of that explanation.

Conspiracy theories are attempts to provide an explanation for events. Consequently, we might expect them to behave similarly to other cases of explanatory reasoning, that is, situations where it is reasonable to infer to an explanation if it is better than all available competitors. Following the results from Douven and Mirabile (2018), we predict that people will think that a conspiracy theory is a true explanation when it appears to them as being the best explanation of an event, with the official version of events as a prominent competitor.

One implication of this hypothesis is that conspiracy theories should be regarded as explanations and display characteristics typical of explanations: they should be seen as good explanations by some people, otherwise they will not be considered as the *best* explanations by anyone. A second implication is that a conspiracy theory might also be able appear as the best explanation because it casts doubt on the explanatory abilities of its competitors, and in particular of the official version of events.

How could this be? First, a conspiracy theory may appear to offer a simple, broad or coherent explanation of an event, or elicit a feeling of understanding. We call these characteristics "explanatory virtues" because they are generally expected of good explanations, not because they track the objective quality of actually virtuous explanations. Second, a conspiracy theory might highlight the flaws of rival explanations (a common strategy for conspiracy theorists, Keeley, 1999), and in particular cast doubt on the superiority of the official theory. A conspiracy theory that successfully undermines its rivals might be able to enhance the appearance of displaying explanatory virtues, and thus appear as the best explanation.

The present experiments sought to explore whether some of the properties of conspiracy theories may induce people to believe in them. In particular, we investigate the hypothesis that conspiracy theories have explanatory virtues, such that people believe in them when they perceive them as being the best explanations available. We seek to test two questions. First, what explanatory virtues, if any, do people ascribe to conspiracy theories and how does their ascriptions relate to their belief in the conspiracy itself? Second, can the appeal of conspiracy theories in part be explained by their ability to produce the illusion of discrediting the official version of events? We examined these questions in two experiments.

Experiment 1

Methods

Preregistration The projected sample size, predictions, and priors used in the data analysis both for Experiment 1 and for Experiment 2 were preregistered through the Open Science Framework. Materials, experimental scripts, analyses, and data are available at https://osf.io/wh78v/.

Participants A power analysis determined that, after accounting for an expected rate of participant drop-out of 50 subjects, 375 participants would be needed in order to detect a within-subjects condition effect of Cohen's d = 0.16 (the modal effect size in social psychology) with 80% power. Therefore, we recruited 375 participants (51% women, M_{age} = 37 years old) through Amazon Mechanical Turk. After excluding participants who missed questions checking their attention, 301 participants remained in our sample. Our exclusion criteria were determined a priori and were in accordance with our experiment's preregistration.

Procedure Experiment 1 examined the relationship between belief in a given conspiracy theory and the perception of explanatory virtues in that conspiracy theory, which was framed in one of two ways (either as a direct explanation of the theory or as a refutation of the official explanation) in a within-subjects design. We selected four familiar conspiracy theories to examine how framing affected the perceived explanatory virtues in a conspiracy theory: 1) The terrorist attacks on the World Trade Center on 9/11/2001 were orchestrated by the American government, 2) Condensation trails left by airplanes contain toxic chemicals and are actually part of a weather engineering program, 3) Free and environment-friendly energy generation devices are being suppressed by oil companies, 4) Fluoride, which is added to tap water in the US, is actually an unsafe toxin.

Experiment 1 consisted of three parts: a pretest questionnaire, an explanation of a given conspiracy, and a questionnaire about the explanatory virtues of each conspiracy. After completing this portion of the experiment, participants completed demographic questions. We describe each component below.

Pretest Questionnaire We first measured how strongly participants believed in each conspiracy theory based on their prior knowledge. For instance, participants were told that the following theory has been suggested as an explanation for why the 9/11 attacks on the World Trade center occurred: "9/11 occurred because the government wanted to gain support for wars in the Middle East." Participants read this statement and indicated their agreement with it on a seven-point Likert scale. There were four such items in total (one per conspiracy theory), which were presented in a randomized order (see Table S1 of the SOM).

Conditions Experiment 1 had two conditions, which were manipulated within-subjects: the direct explanation condition, where the main arguments in favor of the conspiracy theory were explained and the refutation condition, which highlighted the shortcomings of the official version of events as an indirect way to provide evidence for the conspiracy theory (see Table S2 of the SOM). Participants only received one version (i.e., direct explanation or refutation) for each conspiracy theory, which was counterbalanced and randomized. Thus, participants received two direct explanations and two refutations of the official view. We created the materials for each condition by searching websites that contained explanations written by people who endorse the selected conspiracy theories. Based on these explanations, we constructed two (edited) short passages per conspiracy theory, one for each condition. The two passages for each conspiracy theory were approximately matched for word count ($\pm$ 15 words).

Explanatory Virtues Questionnaire After reading a given conspiracy theory, participants assessed the explanatory virtues of each of the four conspiracy theories. As noted, two of the conspiracy theories were presented in the direct explanation condition, and the two others were presented in the refutation condition. In both conditions, participants first read a short passage which explained the main theses of the conspiracy theory. Then, they rated their agreement with twelve statements about the explanatory virtues of that conspiracy on a seven-point Likert scale (see Table S3 of the SOM). We measured participants' judgments about six virtues, using two statements per virtue: simplicity, coherence, breadth, description of a mechanism, use of technical sounding language (denoted *expertise* in the figures below) and ability to induce a feeling of understanding.

Participants were instructed to assess these explanatory virtues in light of the passage they had just read rather than their personal beliefs about the conspiracy under consideration (though we nonetheless expected people's pretest beliefs to be related to their virtue ratings). For instance, after reading a passage about the chemtrails conspiracy, participants rated how strongly they agreed with statements such as "this theory is a clear and easy to understand explanation for [phenomenon]" (virtue = feeling of understanding) or "this theory provides a complete explanation for [phenomenon]" (virtue = breadth). The order of presentation of these twelve statements was randomized. After reading the passage that described a given conspiracy and providing their ratings, participants advanced to the next conspiracy theory and completed the questionnaire again.

Predictions In Experiment 1, we sought to answer three questions. First, will participants in the refutation condition be more likely to judge that it has explanatory virtues than participants in the direct explanation condition (main effect of condition)? Second, to what extent, if any, would this tendency depend on the virtue in question (Condition $\times$ Virtue interaction)? Third, even if a participant does not believe in a given conspiracy, what virtues if any would they think the conspiracy nonetheless has?

Results and Discussion

We tested our predictions by fitting two Bayesian ordinal mixed-effects using the R package `brms` (Bürkner, 2017). Both models estimated explanatory virtue ascriptions, treated pretest belief predictor as a monotonic effect and included group-level effects which we detail below. Because of the

exploratory nature of our analyses, we confirmed the improvement in a given model's fit using an approximation of Leave-One-Out cross-validation.

First, we tested whether conspiracy theories were more likely to be perceived as having explanatory virtues when they were framed as attempts to refute the official version of events, which was interacted with the virtue under consideration—Model 1:

```
Model 1 <- Virtue Rating ~
Virtue*Condition + mo(Pretest) +
(1 + Virtue*Condition|Subject)
```

To model the joint probability distribution of responses, we specify regularizing priors over the possible effects each parameter could have on the response variable. Model 1 priors are shown below:

$$\beta_{Intercept[1]} \sim \mathcal{N}(0.84, 1)$$
$$\beta_{Intercept[2]} \sim \mathcal{N}(2.19, 1)$$
$$\beta_{Intercept[3]} \sim \mathcal{N}(2.44, 1)$$
$$\beta_{Intercept[4]} \sim \mathcal{N}(2.75, 1)$$
$$\beta_{Intercept[5]} \sim \mathcal{N}(3.18, 1)$$
$$\beta_{Intercept[6]} \sim \mathcal{N}(3.89, 1)$$
$$\beta_{Pretest} \sim \mathcal{N}(3, 2)$$
$$\beta_{Condition} \sim \mathcal{N}(0, .5)$$
$$\beta_{\forall_{Virtues}} \sim \mathcal{N}(0, 1)$$
$$\beta_{\forall_{Virtue \times Condition\ Interactions}} \sim \mathcal{N}(0, .5)$$
$$\Omega_k \sim LKJ(1)$$
$$\text{Group-level parameters} \sim \mathcal{N}(1, 3)$$

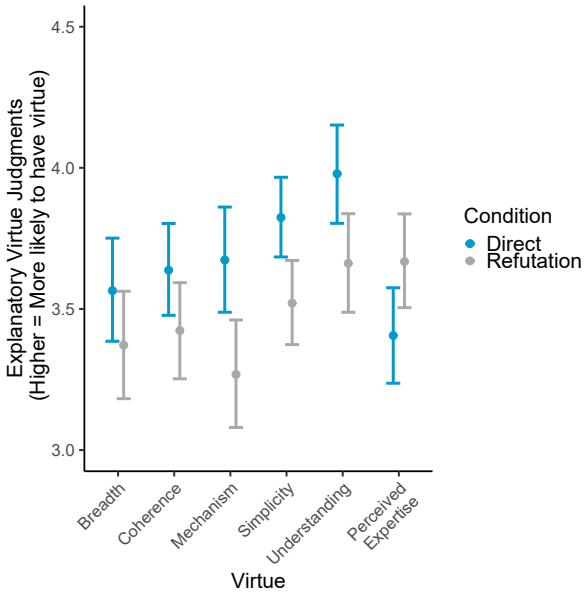

Figure 1: A marginal effects plot of ascriptions of explanatory virtues by condition (direct explanation vs. refutation). Error bars represent 95% CIs.

This analysis indicated an interaction between virtue and condition: the perceived expertise virtue received higher ratings in the refutation condition and all other virtues received higher ratings in the direct explanation condition (see Figure 1). These results contradicted our predictions: in general, participants rated conspiracy theories as presenting explanatory virtues *more* when they read a passage in the direct explanation condition but this effect did depend on the virtue in question. pretest belief in each condition.

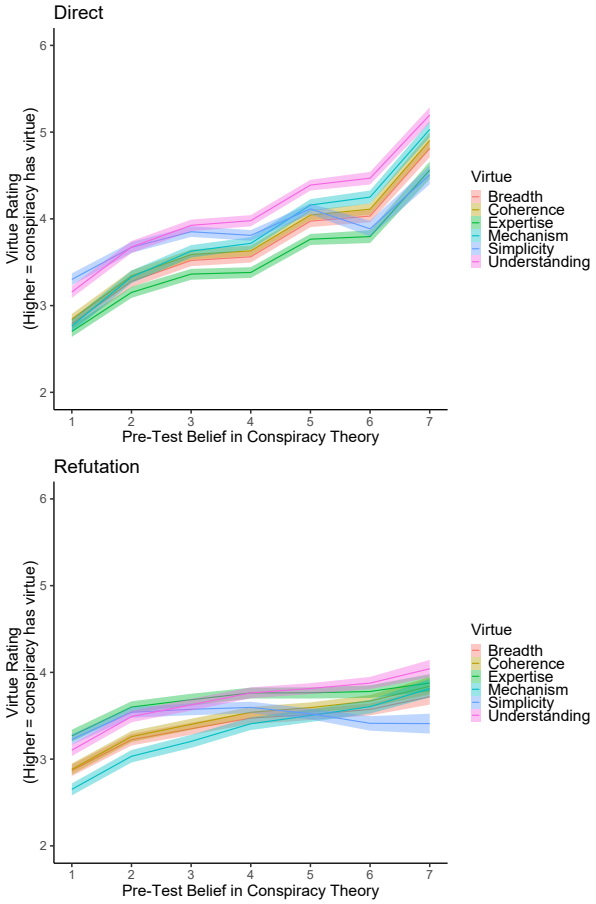

Figure 2: A marginal effects plot of ascriptions of explanatory virtues depending on pretest belief in conspiracy theory in the direct explanation and refutation conditions. Error bars display 50% CIs for legibility.

Next, we fit a model to assess whether, regardless of pretest belief in a conspiracy theory, people were more likely to think conspiracy theories had some explanatory virtues but not others, and whether this varied depending on whether the conspiracy was framed as a direct explanation or as a refutation. Model 2 regressed explanatory virtue ascriptions on the three two-way interactions between condition, explanatory virtue and pretest belief in each condition.

```
Model 2 <- Virtue Rating ~
Virtue*Condition + Virtue*mo(Pretest) +
Condition*mo(Pretest) +
(1 + Virtue*Condition|Subject)
```

Experiment 1 - Model 2 Priors:

$\beta_{Intercept[1]} \sim \mathcal{N}(0.84, 1)$
$\beta_{Intercept[2]} \sim \mathcal{N}(2.19, 1)$
$\beta_{Intercept[3]} \sim \mathcal{N}(2.44, 1)$
$\beta_{Intercept[4]} \sim \mathcal{N}(2.75, 1)$
$\beta_{Intercept[5]} \sim \mathcal{N}(3.18, 1)$
$\beta_{Intercept[6]} \sim \mathcal{N}(3.89, 1)$
$\beta_{Pretest} \sim \mathcal{N}(2, 2)$
$\beta_{Condition} \sim \mathcal{N}(0, .5)$
$\beta_{\forall_{Virtues}} \sim \mathcal{N}(0, 1)$
$\beta_{\forall_{Virtue \times Condition\ Interactions}} \sim \mathcal{N}(0, .5)$
$\beta_{\forall_{Virtue \times Pretest\ Interactions}} \sim \mathcal{N}(0, .5)$
$\Omega_k \sim LKJ(1)$
Group-level parameters $\sim \mathcal{N}(1, 3)$

This analysis revealed that ascriptions of explanatory virtues were higher in the direct explanation condition and were predicted more strongly by pretest belief than in the refutation condition (see Figure 2). Furthermore, Model 2 revealed that the virtue Understanding, for example, was more likely to be attributed even at lower-levels of pretest in both conditions relative to other virtues. Most striking, even people who did not believe in conspiracies were nearly as likely to ascribe expertise in the refutation condition as those who believed in the conspiracy theory.

Altogether, these findings suggest that stronger beliefs in a conspiracy theory are associated with higher ascriptions of explanatory virtues. However, these ascriptions did not interact with the way a conspiracy theory was framed in the way we predicted: direct explanations of the theory received higher ratings of quality than refutations of the official theory, with the exception of perceived expertise. This might be due to the fact that the passages in the refutation condition often needed to explain *details* of the official version in order to then refute them, leading participants to be more likely to ascribe expertise in this condition. However, one limitation of Experiment 1 is that participants' responses to the explanatory questionnaire hovered around the midpoint of the scale, suggesting that participants might not have had fine-grained opinions (or any opinion at all) about the virtues of a conspiracy. Therefore, in Experiment 2 we simplified the response scale to be dichotomous to confirm that our results were not simply due to unknown and problematic psychometric properties of the explanatory virtues scale used in Experiment 1.

Experiment 2

Methods

Participants Based on a power analysis and exclusion criteria identical to those from Experiment 1, we recruited 376 participants (50% women, M_{age} = 38 years old) through Amazon Mechanical Turk. After excluding participants who failed questions checking their attention, 335 participants remained in our sample.

Procedure The procedure and analytic approach were a replication of those from Experiment 1, with one key difference. In the Explanatory Virtues Questionnaire, participants were asked about each conspiracy theory: "Do you agree or disagree with the following statements describing that theory?" and responded on a dichotomous scale with "Agree" and "Disagree" as available options.

Results

We first performed logistic regression predicting virtue ratings on the basis of the interaction between Virtue and Condition controlling for pretest belief in a given conspiracy (see Model 1 formula in Experiment 1). We based our priors on the Experiment 1 - Model 1 posteriors:

$\beta_0 \sim \mathcal{N}(-0.85, .65)$
$\beta_{Pretest} \sim \mathcal{N}(1.30, 2)$
$\beta_{Condition} \sim \mathcal{N}(0, .5)$
$\beta_{\forall_{Virtues}} \sim \mathcal{N}(0, 1)$
$\beta_{\forall_{Virtue \times Condition\ Interactions}} \sim \mathcal{N}(0, .5)$
$\Omega_k \sim LKJ(1)$
Group-level parameters $\sim \mathcal{N}(1, 3)$

Experiment 2 replicated the effects we observed in Experiment 1 (see Figure 3).

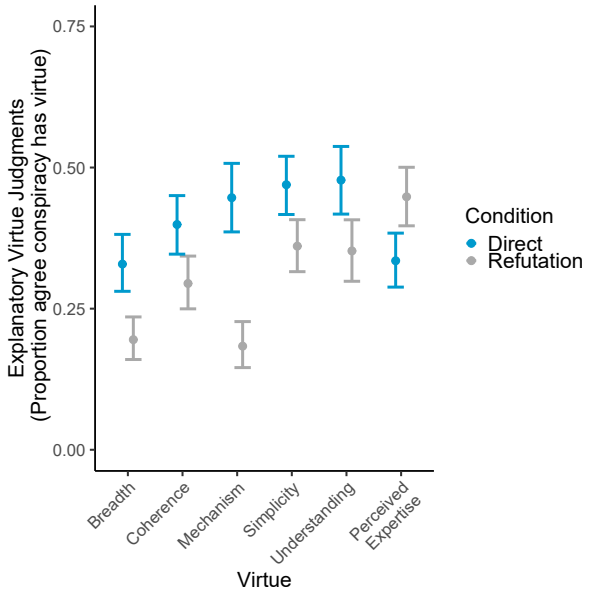

Figure 3: A marginal effects plot of ascriptions of explanatory virtues by condition (direct explanation vs. refutation). Error bars display 95% CIs.

We then tested whether pretest beliefs, virtue, and condition exhibited the three two-way interactions we observed in Experiment 1 (see Model 2 formula in Experiment 2). Priors were specified as follows:

$\beta_0 \sim \mathcal{N}(-.85, .65)$
$\beta_{Pretest} \sim \mathcal{N}(1.30, 2)$
$\beta_{Condition} \sim \mathcal{N}(0, .5)$

$$\beta_{\forall_{Virtues}} \sim \mathcal{N}(0,1)$$
$$\beta_{\forall_{Virtue \times Condition\ Interactions}} \sim \mathcal{N}(0,.5)$$
$$\beta_{\forall_{Virtue \times Pretest\ Interactions}} \sim \mathcal{N}(0,.5)$$
$$\Omega_k \sim LKJ(1)$$
$$\text{Group-level parameters} \sim \mathcal{N}(1,3)$$

This analysis revealed that ascriptions of explanatory virtues in the direct explanation condition were predicted more strongly by pretest beliefs than in the refutation condition. In the refutation condition, perceived expertise was most likely to be ascribed regardless of pretest belief in a conspiracy and people who did not believe in a conspiracy were nearly as likely to ascribe it the virtue of simplicity as people who believed in the conspiracy theory. Together, these results replicate the findings from Experiment 1.

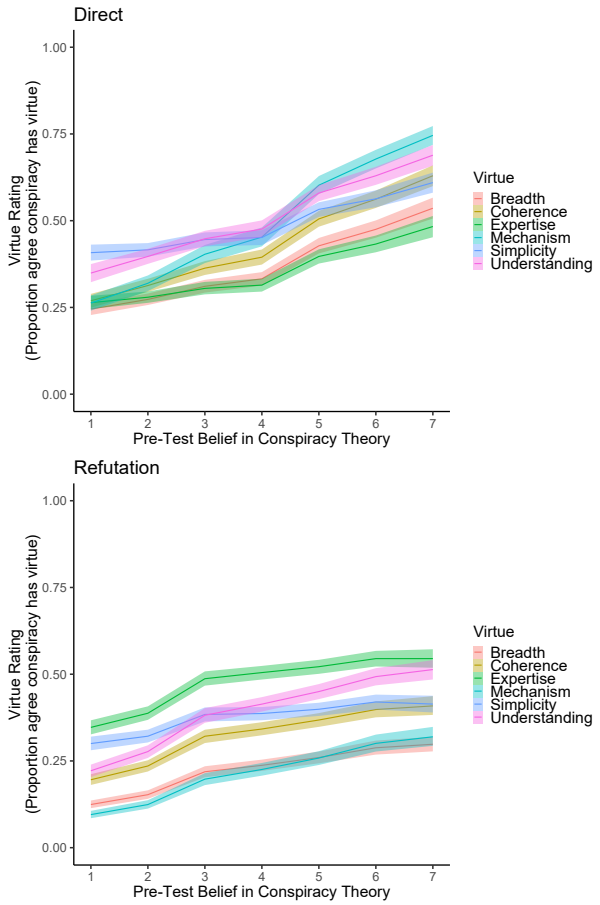

Figure 4: A marginal effects plot of ascriptions of explanatory virtues depending on pretest belief in conspiracy theory in the direct explanation and refutation conditions. Error bars represent 50% CIs.

General Discussion

Conspiracy theories are no-longer fringe beliefs (Barkun, 2016) and perhaps they never were (Goldberg, 2008). One-third of adults believe in at least one conspiracy theory (Lewandowsky et al., 2013). Here, we sought to understand the properties these theories have that may lead people to believe in them. Specifically, we investigated whether people believe conspiracy theories have explanatory virtues and whether ascription of virtues depends on how they are framed. We hoped to answer two questions: First, what explanatory virtues do people ascribe to conspiracy theories and how do they relate to belief in a given conspiracy theory? Second, can the appeal of conspiracy theories in part be explained by their ability to produce the illusion of discrediting the official version of events?

Experiments 1 and 2 indicate that people do in fact ascribe certain explanatory virtues to conspiracy theories. Although this effect is stronger for those who believe these theories, it is of note that even among participants who do not endorse a given conspiracy theory, nearly one-third of participants reliably attribute an explanatory virtue to that conspiracy theory, an effect that is more or less pronounced depending on the virtue in question and its framing.

Second, and contrary to our predictions, we found that conspiracy theories framed as refutations of the official version of events were *less* likely to be ascribed explanatory virtues. Only in the case of perceived expertise were refutations more likely to be ascribed an explanatory virtue. One possible explanation for this finding is that in order to refute the official version of events, the conspiracist also needs to provide details about the accepted theory – this often means that they need to reuse the technical language employed by the experts they criticize, which would account for the higher ascriptions of perceived expertise. Ironically, the conspiracy theory itself might have then suffered from the comparison to the accepted explanation.

What are the implications of this ascription of explanatory virtues to conspiracy theories? For everyday explanations, people are more prone to believe a hypothesis if they think it explains the available evidence well (Douven & Mirabile, 2018). Moreover, researchers have identified some explanatory qualities that are typical of preferred explanations (Lombrozo, 2016). However, in the case of conspiracy theories, psychologists have focused the irrational dimension of belief in conspiracy theories, suggesting that it points to pathological tendencies (Wulff, 1987) and constitutes a violation of epistemological or simply logical norms (Brotherton & French, 2014). Integrating our results with these analyses, the positive relationship between ascription of explanatory virtues and belief might indicate an incorrect application of inference to the best explanation: people might be led astray by the impression that a conspiracy theory has qualities typical of good explanations and thus are led to believe the conspiracy theory. Indeed, we found that participants who did not believe in a conspiracy theory still ascribed it certain explanatory virtues. For example, perceived expertise was attributed nearly 50% of the time in the refutation condition and varied little as a function of pretest belief in the conspiracy theory. Altogether, these results suggest that conspiracy theories are not perceived as

unequivocally bad explanations of events. Rather, along some explanatory dimensions they are perceived as having the same attributes as good explanations more often than we would hope, leading some people to prefer them to the official, scientifically-supported, explanations.

One limitation of these findings is that they do not allow for a comparison between the explanatory virtues of conspiracy theories and those of official explanations of events. Further research could therefore collect explanatory virtue ascriptions for conspiratorial and non-conspiratorial explanations of the same events and investigate whether they predict belief in a conspiracy theory. Identifying the explanatory virtues that make conspiracy theories more appealing than their official counterparts would be an important step for assisting scientists and governmental agencies interested in debunking misinformation.

Statistical Learning of Conjunctive Probabilities

Abstract

Most statistical learning studies focus on the learning of transitional probabilities between adjacent elements in a sequence, however, other statistical regularities may underpin different aspects of processing language and regularities in other domains. Here, we investigate how conjunctive statistical regularities (of the form A and B together predict C) can be learned, and how this learning is impacted by similarity in representations analogous to that in unambiguous words, homonyms with multiple unrelated meanings, and polysemes with multiple related meanings. We observed that provided the stimulus structure is relatively simple, participants are readily able to learn conjunctive probabilities and display sensitivity to relatedness among representations. These results open new theoretical possibilities for exploring the domain-generality of how the learning and processing systems merge conjunctive information in simple laboratory tasks and in natural language.

Keywords: Statistical Learning; Lexical Ambiguity; Transitional Probability; Conjunctive Probability

Introduction

Statistical learning has been proposed as a powerful mechanism for how individuals learn regularities across time and space. Foundational work by Saffran, Newport, and Aslin (1996) first established human sensitivity to transitional probabilities (TPs) in identifying word boundaries in streams of auditory syllables. Most research on this subject to date has focused on variations of TPs such as non-adjacent dependencies (Gómez, 2002) and visual co-occurrences across scenes (Fiser & Aslin, 2001), illustrating a range of applications for statistical learning. While fundamental, the various forms of TPs do not account for all types of statistical regularities that must be learnt to explain other types of behaviours. For example, learning something akin to a conjunctive probability (CP) may be important in explaining how individuals learn to disambiguate the meanings of semantically ambiguous words in natural language. To illustrate, the word BAT can refer to either an animal or to sporting equipment, and the correct meaning of this word is extracted by integrating the constraints on overall meaning offered by BAT with the broader context (e.g., a discussion about baseball).

The present work sought to investigate several major issues that relate to learning CPs, as they might relate to natural language statistics such as those relevant to word meaning disambiguation. The first was how different elements in a stream could be more or less constraining on the expected outcome of a conjunction. For example, in natural language, knowing that the topic of conversation is "SPORTS" provides only vague constraint on what particular meaning should be evoked in a sentence. This knowledge therefore provides only low constraint (high entropy) in determining which particular meaning should be evoked (e.g., the discussion could relate to hockey, baseball, etc.). In contrast, the word "BAT" provides relatively high constraint (low entropy) on what meaning should be evoked (it should relate either to "baseball" or to "flying mammal"). Furthermore, critical to present purposes, only by combining both of these elements can a context-specific interpretation of a word be evoked. Using this analogy to words (which are low entropy), contexts (which are high entropy), and context-specific meanings (which are fully determined by the combination of the previous two elements) we examined how low- and high-entropy items combined to predict an upcoming element. In a related vein, we also examined how the order in which low- versus high-entropy information is presented shaped performance. How is the process of computing CPs impacted by having more versus less constraint early in processing?

Additionally, unlike typical statistical learning research which employs highly and equally distinct elements during learning, we also explored how representational similarity could shape performance in computing a CP and relate to word disambiguation processes. In the case of natural language, the semantic ambiguity continuum can be broken down into three main subdivisions: (1) unambiguous words like CHALK which evoke effectively the same meaning in different contexts. That is, the word itself predicts the meaning with 100% accuracy, the context does not provide any additional unique information. (2) homonyms such as BANK which evoke completely distinct meanings in different contexts. That is, the word narrows the meaning down to two completely distinct interpretations, but context is necessary to select among those representations. (3) polysemes such as CHICKEN, which evoke related representations (in this example, the animal or its meat) in distinct contexts. That is, the word alone may predict the majority of the evoked representation, but context is needed to select

exactly the right interpretation.

With these aims in mind, we developed a variant of a standard self-paced statistical learning paradigm that allowed us to contrast standard TP learning with the learning of CPs between low-entropy items (analogous to words) and high-entropy items (analogous to contexts) in predicting a third item (analogous to context-sensitive meaning). We also employed representations that varied in their similarity to one another to assess the impact of meaning relatedness on learning. Performance was assessed using a combination of online and offline measures of learning. In so doing, we aimed to contribute to knowledge of how a broader range of statistics such as conjunctive probabilities can be incorporated into general theories of statistical learning. We also aimed to connect this work with important statistical properties that are at the heart of other areas of cognition such as semantic ambiguity resolution. If successful, this work could open new possibilities for how artificial language learning experiments using statistical learning paradigms could complement existing studies of semantic ambiguity in natural language, for example, by allowing the development of well controlled artificial languages that avoid the complex confounds in natural language stimuli used to study semantic ambiguity (Armstrong & Plaut, 2016).

Experiment 1

The first experiment served as a baseline for evaluating how the learning of standard triplet structures with perfect predictability (TPs of 1) across successive items takes place using our specific experimental procedure. We then use these results as a platform for understanding the impact of ambiguity on processing in subsequent experiments using variations of the same basic design but changing the probability structure between elements.

Methods

Participants A total of 60 participants (16 male; mean age=20) completed the experiment. All participants were undergraduate students from the University of Toronto participant pool and were compensated with course credit. All completed an informed consent and debriefing procedure.

Materials A total of 48 images of unusual objects (hereafter, symbols) were the targets for learning in the experiment. These symbols were selected so as to not have clear verbalisable labels, and therefore encourage learning of the statistics between the visual representations of each element. These symbols were used to create sequences containing two single-symbol elements and one four-symbol complex element. Eight such simple-simple-complex sequences with unique elements were randomly generated for each participant. The use of varying complexity across visual elements (one symbol vs. four symbols) allows us to assess the impact of visual complexity per se, and also enables rich variation in the statistical structure of the relationship between elements and symbols in the subsequent experiments.

Procedure The experiment was administered on desktop computers using PsychoPy (v1.85.4).

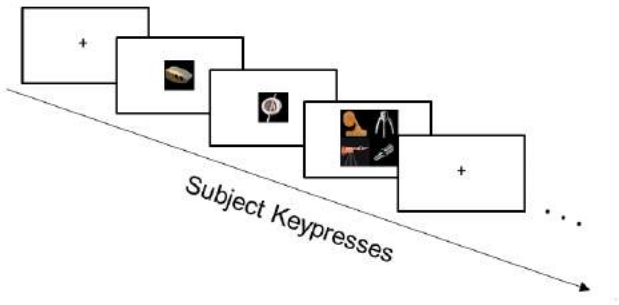

Figure 1: Familiarisation

Familiarisation/On-line Learning Participants were exposed to 30 randomised sweeps through the eight sequences and were instructed to pay attention to the order of the elements. A fixation cross was presented between sequences to focus learning on the relationships between elements (see Figure 1). The task was self-paced and participants advanced through the elements by pressing the space key. The time spent on each element was recorded. On average, the familiarisation task took approximately 20 minutes to complete.

Off-line Tests Two offline tasks were used to assess learning. The first was a sequence completion task, in which participants had to complete a missing element in a sequence. Participants selected from among four choices for completing the first and last element, and two choices for completing the middle element. This corresponded to later experiments where one of the first two elements had only two valid possibilities. The presented choices all came from the same position in a sequence, sampled from among the different sequences (e.g., the choices were always taken from position 1 when completing a missing element from position 1). Eight questions each were asked about the first two elements and 12 questions were asked about the third element. The four extra questions about the third element in this experiment were only included in order to match the number of questions used in subsequent experiments regarding CPs (as described later). Test questions were blocked by order of position in the sequence.

The second task had participants choose from among four sequences which was the most familiar. One of these sequences was actually seen during familiarisation, the others were made-up sequences that mixed elements from different sequences while preserving position in a sequence (e.g., a sequence would be made up of an element selected at random from all elements in position 1 across

sequences, an element selected at random from position 2 across sequences, etc.). Sequences were presented one element at a time at a fixed rate of one element per second. Six questions were asked: two for coarse-grained distinction, where all non-target sequences comprised entirely unfamiliar combinations of elements; four for fine-grained distinction, which included a distractor item containing two elements from one sequence combined with one element from another sequence. Again, number of questions were matched to those of subsequent experiments on conjunctive probability. While only one element is needed to predict a sequence in TP, subsequent conjunctive probability experiments will require looking at two elements together to predict the third.

Results

Due to space constraints, we report only the differences that were significant at p¡0.05. Error bars in graphs denote standard error. For this experiment, it is expected that there is a speed up between Elements 1 and 2 as the first element is unpredictable while the second element is perfectly predictable from the first element. It is also expected that the last element requires more processing effort due to higher visual complexity.

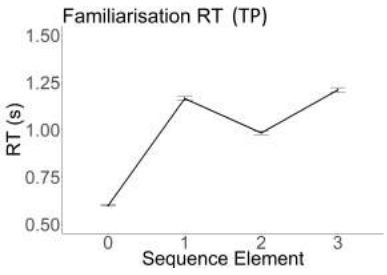

Figure 2: Element 0=fixation; 1-3=sequence

Familiarisation The average reaction time (RT) during online familiarization to the sequences is presented in Figure 2. We used mixed-effect linear models with random intercepts for participants to test for differences in RT across sequence elements (positions) 1-3. Participants sped up between Elements 1 and 2 but slowed down between Elements 2 and 3 such that Element 3 took significantly longer time to process than Element 1.

Offline Test One sample t-tests showed participants had learnt all three elements in the sequence above chance performance in the sequence completion task, as reflected in their accuracy in questions regarding each element. Note that due to the aforementioned difference in number of options at test (but not in training), chance is 0.25 for Elements 1 and 3 and 0.5 for Element 2 (Figure 3). To compare relative learning across the sequence, accuracy was modeled with items and participants as random intercept. Significant differences were found among all three elements, with the highest accuracy at Element 2 and lowest accuracy at Element 3. However, due to difference in chance level, only Elements 2 and 3 can be directly compared. Above-chance performance was also found for all elements in sequence selection for familiarity. There were no significant differences between coarse-grained and fine-grained test items.

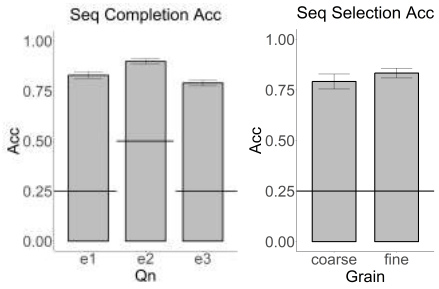

Figure 3: Solid lines mark chance performance.

Discussion

Experiment 1 showed that participants were sensitive to the statistical properties associated with each sequence element in the online learning measure. Participants displayed good performance (˜75% correct) on all the elements in the offline test. Both of these results are consistent with a similar prior study by (Siegelman, Bogaerts, Kronenfeld, & Frost, 2018). In contrast to that experiment, however, participants exhibited overall slower responses for the final element in the sequence, which we attribute to the increased visual complexity of that item. These results provide an important measure of baseline performance in the task to evaluate the impact of CP learning in the following experiments.

Experiment 2

Experiment 2 used the same overall procedure but different statistical relationships between elements to probe how CPs, as well as different levels of ambiguity, influence behaviour. As in the case of natural language, disambiguating information can be precede or follow an ambiguous word. Hence, two sub-experiments were run, in which the order of the first two elements were interchanged so that the first element either provided high constraint (low entropy, Expt 2a) or low constraint (high entropy, Expt 2b) for predicting the final element, which was the same in both experiments. The experiments thus evaluated the impact of conjunctive probability learning and on the order of the more constraining versus less constraining elements on learning. If people integrate information in a manner analogous to CPs, it is expected that they would show slowdown according to ambiguity type, as illustrated by overlaps in sequence elements, over and beyond slowdown caused by visual complexity. We also expect differences as a result of informativeness of different elements. However, whether more informative elements will be faster to process due to the time to

hone in on a specific interpretation or slower due to the number of competing predictions is not clear.

Methods

Participants. A separate sample of 60 undergraduate participants who have not participated in other experiments were recruited for each of the experiments (2a: 15 male; mean age=19; 2b: 22 male; mean age=19).

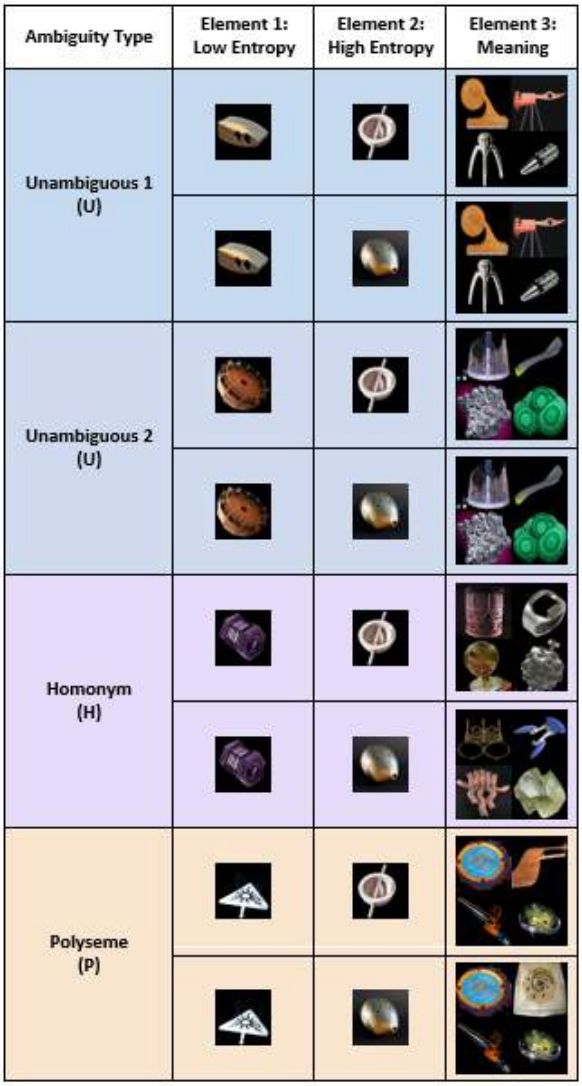

Figure 4: Example sequences depicting ambiguity types.

Materials. The same elements used in Experiment 1 were re-arranged to reflect different statistical relationships between the items, both in terms of how well each of the first two elements predicted the last element, and in terms of how distinct the last element is relative to its counterpart. These sequences were structured to represent three levels of ambiguity in how the low-entropy (word) representation merged with the high-entropy (context) representation. Across two contexts, Element 3 in an unambiguous sequence was identical, Element 3 in a polyseme sequence overlapped by 25% (one symbol), and Element 3 in a homonym sequence was distinct (see Figure 4). Single-symbol elements were used for the low- and high-entropy elements (words and contexts), whereas four-symbol elements were used to denote "meanings", so as to enable studying the effects of representational overlap. Symbols forming each element were randomized across participants.

Procedure The procedure was identical to that in Experiment 1, except the items were re-arranged to have the conjunctive probability structure outlined above and illustrated in Figure 4 for Experiment 2a (in Expt 2b, the position of the low-entropy and high-entropy items were swapped). The sequence completion task now contained eight coarse-grain and four fine-grain questions regarding Element 3 (meaning) instead of 12 questions of equal difficulty. In this experiment, fine-grained questions for both off-line tests refer to items where the choices given contain both options corresponding to the two possibly correct third elements, depending on context. Because the unambiguous sequences evoke the same meaning (Element 3) regardless of context (Expt 2a: Element 2; Expt 2b: Element 1), tests relating to the second item (first item in Expt 2b) were omitted since both context items were valid responses. This left six sequence familiarity items. Having more trials for one offline task type was due to our aims of efficiently extracting the learning of coarse- and fine-grained information.

Results

The analytical procedures were the mostly the same as Experiment 1, only now we collapsed across performance of the same ambiguity type and applied the linear model within each type.

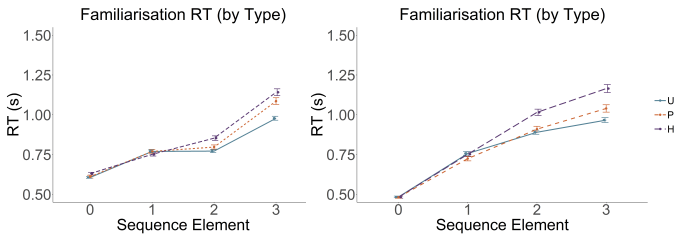

Figure 5: *Experiment 2a.* Element 0=Fixation; 1=Low Entropy; 2=High Entropy; 3=Meaning (left)
Experiment 2b. Element 0=Fixation; 1=High Entropy; 2=Low Entropy; 3=Meaning (right)
U = Unambiguous; P = Polyseme; H = Homonym

Familiarisation *Experiment 2a.* Figure 5 plots the results from familiarization for Experiment 2 and 2b. In Experiment 2a, RT for homonym sequences showed increase across all consecutive elements while polyseme sequences and unambiguous sequences showed slowdown only from Element 2 to Element 3. At the second position (high-entropy), the linear model for RT against ambiguity type showed homonym sequences to be sig-

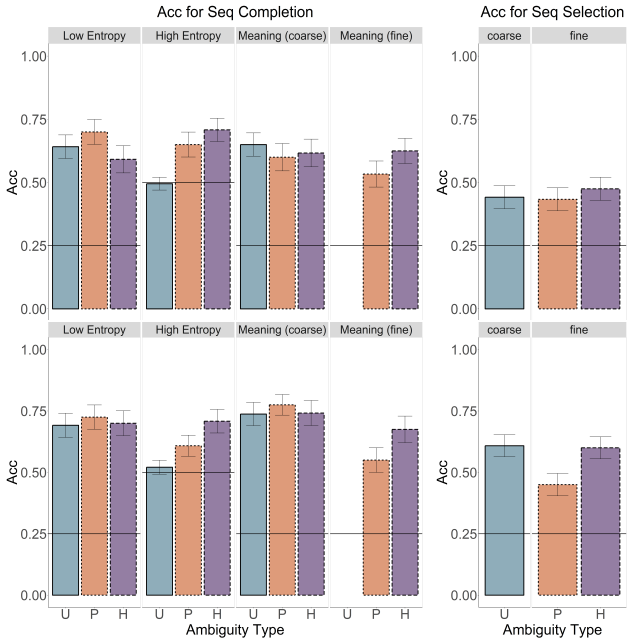

Figure 6: Experiment 2a (top) and 2b (bottom) offline tests. Horizontal lines denote chance.

nificantly different from unambiguous and polyseme sequences, which were comparable to each other. All three conditions were significantly different at meaning output (Element 3), with fastest performance for unambiguous items and slowest performance for homonym items.

Experiment 2b. In every ambiguity type, RT increased between consecutive elements. Similar to experiment 2a, there was no difference between ambiguity types in the first position, but at the second position (now low-entropy), divergence began where homonym sequences showed significant difference from unambiguous and polyseme sequences and by the third position (meaning output) all three ambiguity types were significantly different from each other.

Offline Test *Experiment 2a.* Figure 6 shows the offline task accuracy for experiment 2a and 2b. One sample t-test showed above-chance performance for all questions, indicating learning. A linear mixed effect model showed higher performance for polysemes than homonyms in the second position (low entropy) but no other differences between ambiguity types. Participants also performed above chance for the selection of familiar sequence. Performance did not differ by ambiguity.

Experiment 2b. All question types had above-chance accuracy. Fine-grained meaning (Element 3) in homonym was significantly more accurate than polyseme. There was comparable performance between ambiguity types for other elements. In the sequence selection task, performance were significantly above chance for all ambiguity types. Linear mixed model showed significant differences between polyseme and homonym sequences. Furthermore polyseme sequences were significantly more affected by the presence of context-inappropriate foils than homonym sequences.

Discussion

Experiment 2 showed an increased slowdown starting at the integration of contextual element according to the increased overlap in interpretations across contexts. In contrast to the unambiguous items and to the results obtained in Experiment 1, participants were slower to respond in the online task when learning CPs in ambiguous sequences. The amount of slowdown in the online task showed that these effects were modulated both by the amount of overlap in the meaning representations, and whether the more informative (lower entropy) item was presented earlier or later in the sequence. The lack of differentiation at Element 1 suggested that only with two elements was there enough information to integrate in order to predict the third element based on CPs. This is different from words in context-free tasks (Armstrong & Plaut, 2016) and tasks with contextual constraints for natural language (Klein & Murphy, 2001), where we see ambiguity effects for the ambiguous words themselves. This might be because participants are trying to integrate words both within and across trials in linguistic tasks, which would lead to task performance more similar to that observed for Elements 2 and 3 here (Klein & Murphy, 2001). Another possibility is that natural language tasks, as opposed to current artificial stimuli, engage in consistent, rapid, and automatic processing which results in detectable effects for the first element, whereas the slower and less natural processing of artificial stimuli do not elicit those effects.

We also investigated whether the slowdown for Element 3 was due to information integration per se, or was due to visual complexity. In a separate experiment not reported here due to space constraints, Experiment 2a was modified to have four symbols for all three sequence elements. We nevertheless still found significant slowdown between Elements 2 and 3 in polyseme and homonym sequences. This indicates that the slowdown observed in Experiment 2 was not solely attributable to differences in visual complexity for Element 3.

In contrast, the offline tests pointed to broadly similar performance regardless of the order in which the first two elements in the sequence were presented, with some detailed differences (e.g., changes in polyseme accuracy across Experiments 2a and 2b in sequence selection). This in turn suggests that the exact time-course of processing varies based on whether the more or less informative element is presented first, but the end result of processing is a relatively similar (although not identical) order-independent final representation.

Overall Comparisons

A striking difference between transitional probability and conjunctive probability sequences is in the long RT for Element 1. This may be explained by the ability of the first element to predict the following two elements in TP whereas both the first two elements need to be considered to predict the third in conjunctive probability.

In offline sequence completion, performance of high-entropy and low-entropy elements were similar for Experiments 2a and 2b in spite of their reversal in position within the sequence, supporting the hypothesis that performance on an element-level is tied to informativeness of the element. Generally, performances for offline tasks showed similar levels of accuracy across all experiments, suggesting that CPs do not pose much extra challenge in learning as compared to TPs.

General Discussion

Statistical learning is theorised to be a domain-general ability for detecting regularities across time and space, yet the bulk of extant research has focused on learning TPs between elements. This type of statistic, although clearly very useful for enabling some abilities like speech segmentation, is insufficient to understand other abilities, such as how words and contexts conjoin to evoke context-specific meanings in specific contexts (Swaab, Brown, & Hagoort, 2003). CPs, although certainly not capable of fully explain such behaviors, may be an alternative form of statistical computation that are critical for such information processing.

The present research merged a recent statistical learning paradigm, a self-paced learning task, with new statistical relationships among items that relate to CPs. Our results showed that CPs, like TPs, are learnable. By varying the amount of information content (entropy) in each position in the sequence, we were also able to ascertain that the order in which high- and low-entropy elements were presented in a sequence modulated online learning, but nevertheless resulted in similar patterns of performance in the offline test. Thus, the time-course of processing may differ based on the order in which information is presented (e.g., whether an ambiguous word like BAT precedes or follows a disambiguating context such as a discussion of SPORTS), but the end result of this processing is similar. Similarly, our manipulation of the relatedness between the "meaning" elements modulated performance in both the online and offline task, suggesting that the microstructure of each element can interact with the overall statistical regularities in the sequence. This suggests that multiple types of statistics among the individual elements of each sequence interact to determine overall performance.

This research represents an important proof of concept for how an alternative statistic than TPs can be learnt, and how such a structure could potentially interact with relatedness of interpretation to shape overall performance. In so doing, it opens up new possibilities for studying how simple statistical learning principles could interact with the rich structure of linguistic domains to explain at least some aspects of complex language behaviors such as context-sensitive meaning processing. As current models of statistical learning do not look at the problem of integrating constraints across elements, the current experiments can serve as a motivation to look at how this type of probability can be incorporated into such models. The ability to test even the domain-generality of some new language processes in a simple form is therefore very valuable. It also represents an important complement to existing methods using natural language, which have their own complexities in terms of controlling for confounding psycholinguistic properties. Having a new approach for developing convergent insights into statistical learning of CPs and other language abilities is therefore likely to be a powerful tool for advancing theory in related domains.

Abstract

Although process data indicate that people often rely on simplifying processes when choosing between risky options, current models of heuristics cannot predict people's choices very accurately. To address this apparent paradox, it has been proposed that people might adaptively choose from a toolbox of simple strategies. But which strategies are contained in this toolbox? And how do people decide when to use which decision strategy? Here, we develop a model according to which the decision maker selects a decision strategy for a given choice problem rationally from a toolbox of strategies; the content of the toolbox is estimated for each individual decision maker. Using cross-validation on an empirical data set, we find that this model of strategy selection from a personal adaptive toolbox predicts people's choices better than any single strategy (even when it is allowed to vary across participants) and better than previously proposed toolbox models. Our model comparisons show that both inferring the content of the toolbox and rational strategy selection are critical for accurately predicting people's risky choices. Furthermore, our analysis reveals considerable individual differences in the set of strategies people are equipped with and how they choose among them; these individual differences could partly explain why some people make better choices than others. These findings represent an important step towards a complete formalization of the notion that people select their cognitive strategies from a personal adaptive toolbox.

Keywords: decision making; bounded rationality; strategy selection; heuristics; computational modeling

Introduction

How do people make decisions under risk? This question is commonly studied by asking people to choose between gambles as in "Would you prefer a 20% chance of winning $1000 (Gamble A) or a 95% chance of of winning $200 (Gamble B)?" According to expected utility (EU) theory (von Neumann & Morgenstern, 1944), people should evaluate all possible outcomes that each available action might have and weight them by their respective probabilities. Empirical research, however, has demonstrated that human decision making systematically deviates from EU theory (e.g., Kahneman & Tversky, 1979). These deviations are commonly interpreted as an indication of human irrationality. Recent work, however, suggests that they could also reflect people's rational use of limited cognitive resources (Lieder & Griffiths, 2019; Griffiths, Lieder, & Goodman, 2015).

To date, the most prominent descriptive theory of risky choice is cumulative prospect theory (CPT; Tversky & Kahneman, 1992). CPT accounts for many violations of EU theory by postulating that people's decision mechanisms systematically distort the stated probabilities (i.e., overweighting rare and underweighting common events) and payoffs (diminishing sensitivity to additional increases in the outcome as the outcome gets larger, and an amplification of losses relative to gains). Interpreted as a cognitive process model, CPT predicts that information is processed exclusively within each option and that the information processing is identical across all problems. Process-tracing studies, however, show that people often compare options along individual attributes and that the processing varies across problems. These process data are instead consistent with processing policies of simple heuristics (Payne & Braunstein, 1978; Pachur, Hertwig, Gigerenzer, & Brandstätter, 2013) such as the lexicographic heuristic, that usually only looks at each gamble's most probable outcome while ignoring all other possible outcomes. Yet, model comparisons have found that assuming that people use a single heuristic across all problems, no single heuristic predicts risky choices nearly as well as CPT (Glöckner & Pachur, 2012).

One way to resolve this apparent paradox is to postulate that people are equipped with a toolbox of several, often heuristic, strategies and that they use different strategies on different trials. This raises the question of which strategies their toolbox is equipped with and how people select between them. Previous work on strategy selection has found that people adapt their strategy use to the structure of individual choice problem and the situation's requirements for speed versus accuracy (Payne, Bettman, & Johnson, 1988). The rational strategy-selection model by Lieder and Griffiths (2017) captures this adaptive flexibility as well as the variability and the learning-induced changes in people's strategy selection. It does not, however, specify the set of strategies from which people select among. To address this question, Scheibehenne, Rieskamp, and Wagenmakers (2013) developed a hierarchical Bayesian measurement model for inferring the contents of the cognitive toolbox. This model, however, assumes that peo-

ple's tendency to select a given strategy is not systematically related to the choice problem at hand and the requirements of the current situation. Strategy selection, however, has been shown to be sensitive to problem-specific features (Payne et al., 1988).

Here we develop an integrative model of risky choice with a *personal adaptive toolbox*. Our approach combines inferring the content of a person's cognitive toolbox with a rational model of strategy selection (Lieder & Griffiths, 2017). We validate this approach using a large empirical data set of risky choice data collected by Glöckner and Pachur (2012), testing it against single strategies, non-adaptive toolbox models, and CPT. Our model constitutes the first complete formalization of the notion that strategies are selected from a personal adaptive toolbox. It thereby enables more accurate inferences on people's cognitive toolbox than was previously possible, and we find that it predicts people's choices better than single strategies as well as other existing toolbox models.

The outline of this paper is as follows: We start by describing 11 extant (heuristic) strategies for risky choice, which might be contained in people's toolbox of decision strategies. We then introduce our computational model of the adaptive toolbox theory as well as several competitors. Next, we present a cross-validation method for inferring the set of strategies considered by an individual decision maker. We then evaluate our adaptive toolbox model against single strategies, non-adaptive toolbox models, and CPT. Finally, we apply our model to estimate the content of people's toolboxes—thereby elucidating why some people make better decisions than others. In closing, we discus the implications of our findings for the debate on human rationality as well as directions for future work.

Heuristics as Models of Risky Choice

A number of different strategies have been proposed as models of how people make decisions under risk. Following Glöckner and Pachur (2012), we consider the following ten heuristic strategies: the priority heuristic (PH), better-than-average (BTA), tallying (TALLY), probable (PROB), minimax (MINI), maximax (MAXI), lexicographic (LEX), equal-weight (EQW), least-likely (LL), and most-likely (ML). These heuristics cover a wide range of processing assumptions that differ in important aspects, such as whether they focus exclusively on the payoffs (BTA, TALLY, EQW, MINI, MAXI) or process both outcomes and probabilities (PH, PROB, LEX, LL, ML). For example, the minimax heuristic chooses the gamble with the highest minimum outcome and the least-likely heuristic identifies each gamble's worst outcome and then chooses the gamble with the lowest probability of the worst outcome.[1] Additionally, we include the weighted-additive strategy (WADD), which chooses the gamble with the highest expected payoff. Each of these strategies breaks ties between gambles by choosing randomly. We consider eleven simple models of risky choice according to which all people use one single strategy (either PH, BTA, TALLY, PROB, MINI, MAXI, LEX, EQW, LL, ML, or WADD) to make all their risky choices. Relaxing the assumption that all decision makers use the same strategy, we also tested a more flexible model (BEST), according to which each person might use a different strategy. That is, the BEST model has one parameter per person that encodes their strategy and has to be fitted to their choices.

[1]The equiprobable heuristic was not considered as it makes the same choice predictions as the equal-weight heuristic

Toolbox Models of Decision Making

According to the notion of an adaptive toolbox, each person is equipped with multiple strategies and employs them adaptively. In this section, we present three types of toolbox models that differ in whether the contents of the toolbox are inferred or assumed to be known and in their assumptions about how strategies are selected.

Strategy Selection Based on a Rational Cost-Benefit Analysis (RCBA)

Simulation studies by Payne et al. (1988) have shown that adaptively choosing between simple strategies can allow people to make many good decisions even when only little time is available. Assuming that decision makers are aware of the relevant properties of the choice problem (e.g., the magnitude of the possible outcomes), contextual factors (e.g., time pressure), and the speed and accuracy characteristics of the strategies in their toolbox, the adaptive decision maker (Payne et al., 1988) should choose strategies according to a rational cost-benefit analysis.

Building on the theory of rational metareasoning (Russell et al., 1991), the rational cost-benefit analysis (RCBA) model assumes that the expected payoff of making decision i using strategy h is integrated with the expected cost of the time $T(h,i)$ that it would take to do so. Together, they yield an estimate of the Value of Computation (VOC), defined as

$$\mathrm{VOC}(h,i) = \mathbb{E}\left[R(i,h(i))\right] - \delta \cdot T(h,i), \qquad (1)$$

where $R(i,h(i))$ is the payoff of decision $h(i)$ that strategy h would make in situation i, and $T(h,i)$ is the time it takes strategy h to make that decision. The balance between these two factors is determined by the relative opportunity cost δ. To model how long it takes to execute each strategy (i.e., the cost), we decompose the strategy into elementary information processes (EIPs) as introduced by Johnson and Payne (1985). Specifically, when a strategy is used to make a decision in a given choice problem, the number of EIPs required is recorded as $T(h,i)$. The RCBA model has two free parameters that can be estimated to accommodate individual differences: the set of available strategies H in the toolbox and the relative opportunity cost δ. For a given choice problem the strategy with the highest VOC in the toolbox is selected to make the choice.

Rational Strategy Selection Learning (RSSL)

The assumption of a full cost-benefit analysis for each strategy, as assumed by the RCBA, may be unfeasible for a boundedly rational mind. However, it might be possible to approximate the VOC. As one possible approach to do such an approximation, the rational strategy selection learning (RSSL) model assumes that the mind learns to predict each strategy's VOC based on the features of the choice problem at hand (Lieder & Griffiths, 2017). Specifically, the RSSL model assumes that people predict both the expected payoff and the expected time cost for each strategy (which are important for then determining the strategy's VOC) at a given problem based on a weighted sum of the features of the choice problem, such as the maximum probability or the range of outcomes; the weights for the estimation, in turn, are learned from the payoffs and decision times of past choices (with the latter is determined based on the number of EIPs the chosen strategy performed). The learning process is simulated using Bayesian linear regression and stochastic predictions are made by sampling from the posterior distribution.

The free parameters of the RSSL model are the number of samples drawn to predict the performance of each strategy, ζ, the set of strategies H, the opportunity cost δ and the amount of prior experience Λ (i.e., on how many choice problems the predictive models were trained on). For the latter parameter we assume that participants are equipped with some amount of prior experience in making choices using their strategies; hence we let the RSSL model learn from Λ randomly generated pairs of gambles prior to applying it to our participants' choices.

Toolbox Models Without Adaptive Strategy Selection

To assess how the assumption of rational strategy selection contributes to the predictive accuracy of the adaptive toolbox models introduced above, we evaluate them against simpler toolbox models that chooses strategies randomly for a given choice problem (rather than adaptively based on characteristics of the problems). In our first null model (NULL-TB1), every time a decision is made a strategy is selected from the set of 11 strategies introduced above. Our second null model (NULL-TB2) is like the first one except that the set of strategies it selects from is estimated on a participant-by-participant basis. Our third null model (NULL-TB3) extends the second one by allowing some strategies to be chosen more frequently than others. Specifically, following Scheibehenne et al. (2013), each strategy h is selected with probability θ_h, which is estimated from the participant's choices.

Cumulative Prospect Theory

According to CPT, the outcomes x_i of a gamble are transformed into subjective values according to the value function

$$v(x_i) = x_i^{\alpha} \text{ if } x_i \geq 0 \tag{2}$$

$$v(x_i) = -\lambda \cdot x_i^{\alpha} \text{ if } x_i < 0, \tag{3}$$

with an outcome sensitivity parameter $\alpha \in [0,2]$ that modulates the curvature of the value function and captures that people's sensitivity to changes in a payoff depend on its magnitude. Values of $\alpha < 1$ entails a concave value function with diminishing sensitivity to larger outcomes.

The probabilities p of the cumulative probability distribution function are transformed according to the probability weighting function

$$w(p) = \frac{p^{\gamma}}{(p^{\gamma} + [1-p^{\gamma}])^{1/\gamma}}, \tag{4}$$

whose shape is determined by the parameter $\gamma \in [0,2]$, which is defined separately for gains and losses. The shape of the probability weighting function reflects the degree of nonlinear distortion when the probabilities are mapped onto decision weights. Values of $\gamma < 1$ entail an inverse S-shaped probability weighting function, indicating a reduced sensitivity to probabilities in the middle range and a relative amplification of the sensitivity to differences among extreme probabilities. The overall valuation of a gamble is determined by multiplying each of the subjective values of the gamble's outcomes x_i by a decision weight π_i that follows from the weighted cumulative probabilities of obtaining an outcome at least as good as x_i if the outcome is positive, and at least as bad as x_i if the outcome is negative (for details see Tversky & Kahneman, 1992), and then summing the products:

$$V = \sum_i \pi_i \cdot v(x_i). \tag{5}$$

To derive the probability that gamble A is chosen over gamble B we apply the softmax choice rule to the gambles' subjective values V; this choice rule which has a choice sensitivity parameter ϕ (for details see Glöckner & Pachur, 2012).

Next, we describe the data set and our approach to evaluate the models introduced in the previous sections.

Data

We evaluated our models using data collected by Glöckner and Pachur (2012), who presented 64 participants with a set of 276 two-outcome gamble problems. The payoffs of the gambles ranged from -1000 to 1200 and the set of gambles consisted of pure gain (all payoffs> 0), pure loss (all payoffs < 0), and mixed (both positive and negative payoffs) gambles. The presentation of the gamble problems was distributed over two sessions that were one week apart (i.e., there are 138 choices from each session). For more information, see Glöckner and Pachur (2012).

Model Evaluation

We evaluated the predictive accuracy of each of the models using a simplified cross-validation method (Friedman, Hastie, & Tibshirani, 2001). Specifically, for each model a score was calculated indicating how often it correctly predicted the participants' choices on a held-out test set, that was not used to fit the model's parameters. The predictive accuracy for a given

participant was computed by averaging the model's performance in forward prediction (i.e., fitting the model on choice data from Session 1 (t_1) and testing it on data from Session 2 (t_2)) and backward prediction (i.e., fitting choices from t_2 and testing on data from t_1). To perform forward-prediction and backward-prediction, the data set was split into three subsets: a *training set*, a *validation set*, and a *test set*. The training set was used to fit the parameters (e.g., the subjective time cost δ) of a given sub-model (e.g., a strategy selection model with a particular set of strategies). The validation set was used to select among sub-models based on unbiased estimates of their generalization errors (e.g., to select the model's toolbox). The test set was used to obtain an unbiased estimate of the selected sub-model's generalization error that could be compared to the performance of the other models.

Model Fitting and Prediction

Given a set of choice problems and the corresponding choices made by an individual, we fitted each model's parameters by maximizing the proportion of gambles from the training set for which the model's predicted choice agreed with the participant's choice. The model parameters were estimated using participants' choices from t_1 and then used to predict choices from t_2—and vice versa. For forward-prediction, we used the 138 gamble problems and choices from t_1 (training set) and split the gamble problems and choices from t_2 into a validation set comprising 103 problems and a test set comprising 35 problems. Backward prediction was performed in the same way as forward prediction except with t_1 and t_2 reversed.

BEST model For the BEST model, according to which each participant uses a single strategy across all choice problems, we determined for each participant the strategy that achieved the highest accuracy (in terms of overlapping choices) on the training set choices and the validation set.

RCBA We estimated each participant's set of strategies H along with their subjective time cost δ using the following procedure: In the first step, H included only the strategy h_1 with the highest accuracy on the validation set. Next, we determined which strategy h_2, if added, would result in the set of two strategies with the highest predictive accuracy on the validation set. In doing so, we estimate δ by optimizing the accuracy of each candidate sub-model on the training set using Bayesian adaptive directed search (BADS) (Acerbi & Ma, 2017). We then proceeded to evaluate toolboxes that added a third strategy to the toolbox and re-estimated δ until toolboxes containing up to 11 strategies had been evaluated. That is, we estimated a set H_k of k strategies for each $1 \leq k \leq 11$ and estimated each participant's toolbox by the set $H_{k_{\max}}$ for which our model achieved the highest predictive accuracy on the validation set.

RSSL As described above, to define a toolbox of strategies, the RSSL model estimates each strategy's VOC based on previous experience with gamble problems. To simulate this experience, we first randomly generated pairs of two-outcome gambles; their payoffs and probabilities were samples from the uniform distributions $\text{Unif}([-1000, 1200])$ and $\text{Unif}([0, 1])$ respectively. The amount of prior experience (Λ) was set to 20 000 gamble problems. Each choice problem was represented by a feature vector comprising the maximum probability of each gamble, the payoffs associated with the maximum probability (i.e., the most likely outcome), the ranges of payoffs within each gamble, and the range of payoffs across both gambles. These features were then used to predict the strategy's accuracy and effort for the problem at hand. The number of predictions ζ sampled from the posterior was set to 3. The parameters H and δ for the rational cost-benefit analyses model (which the RSSL shares with the RCBA model) were estimated following the same iterative procedure as described for the RCBA model.

Null models The Null-TB1 model has no free parameters. For the models NULL-TB2 and NULL-TB3 we estimated the set of strategies H using the same procedure as for the RCBA model. For NULL-TB3, we estimated the proportion parameters $\theta_1 \ldots \theta_{|H|}$ for a toolbox H by solving the constrained optimization problem to maximize the expected accuracy of participants' choices.

Cumulative prospect theory CPT's parameters were fitted to minimize G^2 based on the observed choices in the respective session. To reduce the risk of being stuck in local minima, we first conducted a grid search to identify the 20 best-fitting combinations of parameter values; these combinations were then used as starting values for subsequent optimization using the simplex method. For prediction, we derived deterministic choice predictions from CPT.

Results

Predictive Accuracy

Figure 1 shows how accurately single strategies, simple toolbox models, adaptive toolbox models, and CPT predicted the risky choices in the test set. Out of the eleven single strategies, WADD and minimax predicted people's choices best, with 65.8% and 61.3% accuracy, respectively. Relaxing the assumption that all participants use the same strategy and instead inferring a potentially different strategy for each participant (i.e., the BEST model) increased predictive accuracy to 69.4%, which is significantly higher than that of the best-performing single strategy WADD ($t(34) = 2.90$, $p = .004$). The simplest toolbox model Null-TB, which chooses randomly among all the strategies, was less predictive of people's choices than the BEST model (57.5% vs. 69.4%, $t(34) = -8.79$, $p < .001$). Its predictive accuracy increased, however, when we allowed the content of the toolbox to be estimated for each participant separately (65.7% vs. 57.5%, $t(34) = 6.66$, $p < .001$). Additionally estimating the relative frequency with which each strategy is selected

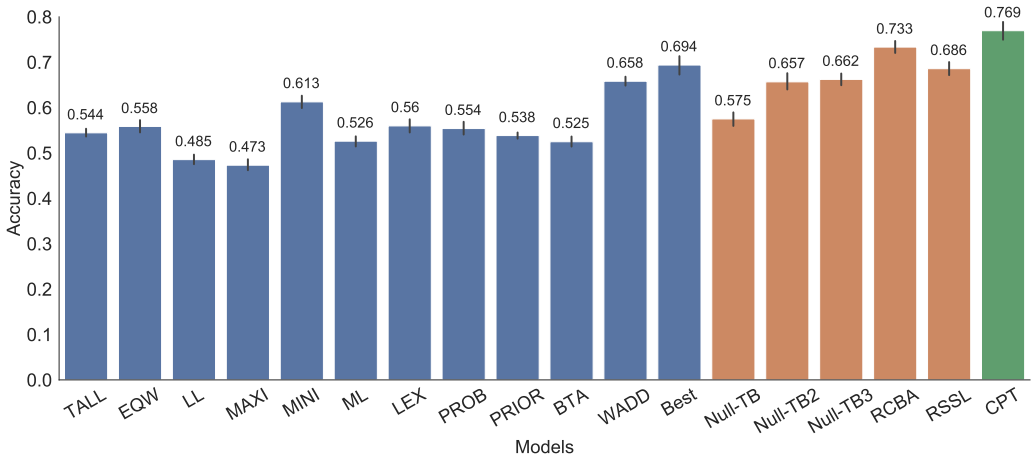

Figure 1: Comparison of how accurately each model predicted people's choices in the validation set. The single-strategy models are shown in blue, toolbox models in orange, and CPT in green.

independently of the problem (Null-TB3) further improved the toolbox model's predictive accuracy to 66.2% vs. 65.7% ($t(34) = 0.46$, $p = .64$). While the benefit of this choice problem-unspecific strategy-selection mechanism was rather small; adding an adaptive, problems-specific selection mechanism to the RCBA model drastically improved the accuracy of the toolbox approach to 73.3% vs. 65.7% ($t(34) = 6.50$, $p < .001$). The RSSL model, which approximates the rational cost-benefit analysis of strategy selection using the features of the choice problems as predictive cues, did not perform as well as the RCBA model (68.6%).

Critically, the RCBA model predicted people's choices better than the best-performing single strategy WADD ($t(34) = 8.80$, $p < .001$) and the BEST model ($t(69) = 3.02$, $p = .003$). This suggests that decision makers indeed adaptively choose from a personal toolbox of strategies when solving a sequence of different choice problems.

The RCBA model also achieved higher predictive accuracy than all null models, NULL-TB ($t(34) = 15.51$, $p < .001$), NULL-TB2 ($t(34) = 6.51$, $p < .001$) and NULL-TB3 ($t(34) = 7.56$, $p < .001$). These results corroborate the usefulness of combining inference about the content of the toolboxes with a model of how people's strategy choices are informed by the specific requirements of each individual decision. This finding strongly supports adaptive toolbox theories of human decision-making (Gigerenzer & Selten, 2002) in general and the idea of an adaptive *personal* toolbox in particular. Despite the substantial improvement in predictive accuracy we achieved by combining inference on the toolbox with adaptive strategy selection, the resulting RCBA model predicted people's choices not as well as CPT (73.3% vs. 76.9%, $t(34) = 3.03$, $p = .003$). While the RCBA model may thus not capture all aspects of how people make decisions, it being a process model still affords many practical advantages for understanding people's choices that cannot be obtained by modeling the choices with CPT (but see Pachur, Suter, & Hertwig, 2017). For example, the estimated contents of the toolbox and estimated parameters of the strategy selection mechanism provide a window onto the cognitive mechanisms underlying risky choice and how they vary across individuals.

Comparing Predicted and Actual Performance

Next, we compared the models and people in terms of their performance of their risky choices. Performance here is measured as the average expected value (EV) of the chosen gambles. WADD achieved an EV of 149.02, which therefore represents the upper bound on how well one could perform in this task. The RCBA model predicted a higher performance than what was actually observed for people's choices (143.41 vs. 130.83, $t(69) = 5.57$, $p < .001$). CPT, on the other hand, predicted a lower performance than people actually achieved (113.1 vs. 130.8, $t(69) = 5.68$, $p < .001$). The performance of the RSSL model and the toolbox model Null-TB3 fell in between, with 124.83 EV and 126.81 EV, respectively, and were closer to people's actual performance. These findings suggest that while people may not choose strategies optimally, they may still be substantially more resource-rational than CPT would make us believe.

Which Strategies Are In The Adaptive Toolbox?

Given our finding that the best-suited model to predict people's choices is the RCBA model, we next analyze its estimated parameters H and δ. Figure 3 shows how many strategies were in the estimated toolboxes of all participants. 28.91% of all toolboxes included 4 strategies, and 60.15% of all toolboxes included between 3 and 5 strategies. The average toolbox size was 4.3.

Next, we counted how often each of the eleven strategies was included in the estimated toolboxes (see Figure 2). Interestingly, with 79.68% and 71.09% WADD and minimax are the most frequently included strategies in the toolboxes. These two strategies also predicted people's choices most ac-

curately (see Figure 1).

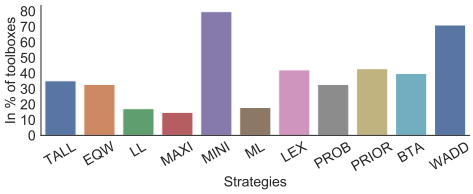

Figure 2: Percentage of cases each strategy was included in the toolboxes estimated by the RCBA model.

Minimax is especially useful as a risk-minimizing strategy when the probabilities of the possible outcomes are similar. The high inclusion rate of WADD suggests that at least when there are only two choices with only two possible outcomes, maximizing expected value is a viable and cognitively feasible strategy.

Furthermore, our results suggest that individual differences in decision quality might be due to the fact that different people are equipped with different toolboxes. For example, participants whose inferred toolbox included WADD performed better (144.59 EV) than participants whose inferred toolboxes did not include WADD (140.52 EV). Conversely, participants whose toolboxes were estimated to contain minimax achieved a lower performance than participants who did not use minimax (140.99 EV vs. 152.91 EV). These observations suggest that inferences obtained with the RCBA model can shed light on why and how people make the choices that they make. Additionally, our analysis identified another source of individual differences in decision performance: people's subjective cost of their time and effort. Specifically, our parameter estimates revealed a negative rank correlation between performance (in terms of EV) and the subjective opportunity cost δ (Spearman's $\rho(62) = -0.58$, $p < .001$), reflecting that higher opportunity costs favour less resource-intensive strategies even when they lead to less accurate decisions.

Finally, we found that the estimated size and content of the toolbox and the objective opportunity cost together explained 27% of the variance in individual differences in performance ($R^2 = 0.27$, $F(21,106) = 2.25$, $p < .001$).

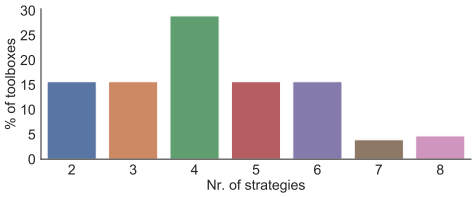

Figure 3: Toolbox sizes estimated by the RCBA model.

Discussion

We presented a model that represents the first complete formalization of the adaptive toolbox metaphor of human judgment and decision making (Gigerenzer & Selten, 2002). Our personal adaptive toolbox model predicted people's risky choices better than single strategies, non-adaptive toolbox models, or adaptive toolbox models that assume that all decision makers have the same strategies in their toolbox. Furthermore, the mechanistic nature of our model makes it possible to draw inferences about the cognitive architecture and processes underlying people's decisions. Furthermore, unlike CPT, our rational model of strategy selection can be applied to a wider range of domains, including inferential problems, such as those used by Gigerenzer and Goldstein (1996), by adapting the set of strategies (which can be deterministic or stochastic) and the reward function.

The success of the model that chooses strategies according to a rational cost-benefit analysis provides additional support for the view that people make rational use of their limited cognitive resources (Griffiths et al., 2015; Lieder & Griffiths, 2019). Our model is an important step towards reverse-engineering the mechanisms underlying the adaptive flexibility of human decision-making and individual differences in risky choice. But the mechanisms by which people efficiently approximate its rational cost-benefit analysis and the resulting suboptimalities need be investigated further before any definite conclusions can be drawn.

Future work will revisit the comparison with CPT using more complex decision problems, including problems with many alternatives and many possible payoffs (Payne et al., 1988), where people's selective processing of only a small subset of the available information might have a notable impact on their choices. We will also compare our models to other psychologically plausible models of risky choice including the utility-weighted sampling model (Lieder, Griffiths, & Hsu, 2018) and decision-field theory (Busemeyer & Townsend, 1993; Rieskamp, 2008; Bhatia, 2014) and apply likelihood-based model selection methods.

Future work will refine the strategy selection learning model with more realistic assumptions about decision makers' prior experience and the features they use to predict the performance of their strategies. In particular, future refinements of this model might take into account that people's strategy choices are informed by them learning from how well each strategy worked when they previously used it in the real world. This prior experience could be simulated by training the RSSL model on choice problems that are more like those that people encounter in everyday life (e.g., in having more possible outcomes and larger differences between the alternatives' expected values). The eleven strategies considered here are unlikely to cover all the decision mechanisms people use. Hence, we will consider additional strategies derived from resource-rational analysis (Lieder & Griffiths, 2019; Lieder, Krueger, & Griffiths, 2017; Gul, Krueger, Callaway, Griffiths, & Lieder, 2018) and process tracing.

Reward Function Complexity and Goals in Exploration-Exploitation Tasks

Abstract

People are often faced with choices where there is a conflict between seeking reward and gathering information. In many of these cases there exists a functional relationship between the features associated with actions and their corresponding rewards. Accounts of how people make decisions in these circumstances have not considered how peoples' strategies depend on the complexity of this function, as well as the person's goal. In a sequential decision making task we found that people chose between a number of different exploration strategies, but that strategy selection did not necessarily align with goal or account for function complexity.

Keywords: Decision Making; Exploration-Exploitation; Contextual Multi-Armed Bandits

Introduction

In many of the decisions that people make in life there is a conflict between choices that are likely to have good results and choices where the result is more uncertain, but could possibly lead to a better outcome than the known option. For example, one might choose to eat at a familiar restaurant that is known to be good, or a new restaurant where the quality could be either better or worse. This trade-off is known as the explore-exploit dilemma. A structurally similar problem, with a slightly different goal is identifying the best candidate from a set of possible choices within a fixed time frame. For example, someone planning a party might wish to sample several possible caterers in order to find who will provide the best meal. Unlike the dilemma of choosing a restaurant for dinner, it is only important that the best option is found; the quality of any single meal is unimportant.

A common task for studying how people navigate explore-exploit dilemmas is the multi-armed bandit (MAB) task (Steyvers & Wagenmakers, 2009; Lee, Zhang, Munro, & Steyvers, 2011), where a decision-maker chooses between discrete actions, each with an unknown reward distribution, in order to maximize total reward over the course of several trials. While these tasks provide a simple environment for studying decision-making, real world tasks often contain additional contextual information about how rewarding an option might be. For example, we might have the option between two new restaurants, where the first has a menu with similar items to a past favorite, and the second has a menu that is full of new options. If we want to maximize the chance we will be satisfied, it would be prudent to pick the first. If we want to learn something new, we should choose the second. More formally, we can describe each option, a_i with the set of features s_i, with a_i yielding the reward $r_i = f(a_i, s_i)$, where f is a reward function mapping actions and features (or contexts) to rewards. We can call this a *contextual* multi-armed bandit (CMAB) (Li, Chu, Langford, & Schapire, 2010). In this setting, successful learners must make inferences about what this function might be – especially if there are many actions to choose from.

How people learn mappings between inputs and outputs, or *function learning*, has been widely studied (DeLosh, Busemeyer, & McDaniel, 1997). Recently, Gaussian process regression (GPR) has been presented as a model of function learning (Lucas, Griffiths, Williams, & Kalish, 2015). In addition to being a flexible non-parametric model capable of representing a wide range of functions, GPR is distinct from other accounts in that it directly allows for the representation of uncertainty in outputs. For CMAB tasks, this lays bare the trade-off between exploration and exploitation: An exploration-oriented agent can target options where uncertainty is greatest, an exploitation-oriented agent can target options with the highest expected reward, and it is possible to strike a balance between the two extremes. Bayesian optimization (Snoek, Larochelle, & Adams, 2012) is a flexible framework for transforming predictions from GPR models into actions. Several algorithms have been proposed for handling these tasks (Snoek et al., 2012) and have shown to both perform well (Srinivas, Krause, Kakade, & Seeger, 2010) and describe human behavior (Schulz, Konstantinidis, & Speekenbrink, 2018) in CMAB tasks. However, these accounts do not consider how one's strategy might be contingent on their ability to learn the reward function. This ignores a prominent result from the function learning literature: that some families of functions (e.g. linear) are easier to learn than others (e.g. periodic) (Kalish, Lewandowsky, & Kruschke, 2004).

While most work on MABs and CMABs study tasks where the goal is to maximize cumulative reward, there are circumstances where a decision-maker might instead be interested in finding the best action (Audibert & Bubeck, 2010). In the case of CMABs, this can be understood in terms of optimization, where the goal is to find some configuration of features (contexts) that maximize an objective function (reward). Bayesian optimization has shown to be of great practical use in these cases, in particular when the objective

function is expensive to evaluate as in the optimization of machine learning algorithm hyperparameters (Snoek et al., 2012). Bayesian optimization typically selects actions that have both a high expected reward and are highly uncertain, as in upper confidence bound (Auer, Cesa-Bianchi, & Fischer, 2002) and expected improvement (Mockus, 1974) algorithms. While these are reasonable strategies when the goal is to earn large rewards on each trial while still exploring new actions, they are ill-suited for optimization, where rewards on each trial are not important. Algorithms based instead on reducing uncertainty about the maximum of the reward function have been recently introduced (Hennig & Schuler, 2012; Wang & Jegelka, 2017) and appear better suited to this goal. Other recent work has examined the idea that people adapt their strategies to the tasks they face, accounting for both the expected performance of a strategy and the cost (e.g., in time) of executing it (Lieder, Helen, & Griffiths, 2017). If one hypothesis is that people adapt their strategies to the task at hand, and distinguish between optimization problems and ongoing trade-offs between exploration and exploitation, another is that people use a "one size fits all" strategy that supports multiple goal types reasonably well, as suggested by some past results, e.g., (Borji & Itti, 2013; Wu, Schulz, Speekenbrink, Nelson, & Meder, 2018).

For both reward maximization and optimization problems, good strategies must seek out information or reduce uncertainty. They can do this in an explicit or *directed* way, or achieve it implicitly by adopting a *stochastic* policy. In *directed* exploration one seeks actions that are most informative about the underlying reward distributions. One popular class of algorithms choose actions with high *upper confidence bounds* (UCB) (Auer et al., 2002), which typically include a free parameter β that controls the width of the confidence bound, directly controlling the preference for exploration over exploitation. In the case of UCB, exploration is directed by uncertainty about individual actions, where those with high uncertainty about their reward are more appealing than those with low uncertainty. In contrast, entropy-based strategies (Hennig & Schuler, 2012; Wang & Jegelka, 2017) are directed by uncertainty about global properties of the function – in particular uncertainty about the function maximum. In *stochastic* exploration, one seeks to explore the space of actions by applying some level of randomness to one's actions. While these methods are implicitly sensitive to reward uncertainty, they do not explicitly minimize it. Thompson sampling (Thompson, 1933) applies randomness to actions by first sampling a reward structure given previous observations, and then choosing the best action given the sampled rewards. Another method of random exploration is to choose actions with probabilities based on the softmax function

$$p(a_t = k) = \frac{\exp[m_t(k)/\tau]}{\sum_{k' \in A} \exp[m_t(k')/\tau]}$$

where $m_t(k)$ is the expected reward of arm k on trial t, and τ controls the level of randomness of actions, with all actions being equally likely as $\tau \to \infty$ and one deterministically choosing the action with the highest expected reward as $\tau \to 0$. While evidence for both directed and random exploration has been found in human behavior (Gershman, 2018), it has yet to be determined whether the criteria for directed exploration is dependent on the goal of the task or is exclusively based on uncertainty about individual actions, and under what conditions random exploration might be preferred over directed exploration.

Many of the real world explore-exploit dilemmas faced by people require learning a mapping between contexts and rewards, making CMABs an attractive environment for studying this phenomenon. While Bayesian optimization and other GPR-based approaches have been widely demonstrated to be a good model of human behavior in these tasks, there has been little research investigating how these frameworks capture different behaviors across distinct environments. While there has been work demonstrating that people are capable of learning functions and applying that representation to their decisions (Schulz et al., 2018), it is unclear how people's strategies might change when faced with functions of varying complexities, though some have varied function complexity by comparing smooth and rough non-parametric functions (Wu et al., 2018), and compared linear to quadratic reward functions (Stojic, 2016). While Bayesian optimization has been shown to describe human behavior well both when the goal is to maximize cumulative reward and when the goal is to find the best arm, it is unclear whether people choose a strategy to match their goal or use a more general strategy regardless of goal. Our contribution is to demonstrate how these factors influence people's strategies. We introduce a model based on Bayesian optimization that is capable of representing a rich set of behaviors revealed in prior work, and how different reward function complexities and goals might result in different parameterizations describing behavior.

Methods

Experiment. We designed a CMAB task in which participants were allowed to click one of several "actions" represented by a set of vertical bars situated along the x-axis of a plot. Upon clicking a bar, the reward of the associated action was revealed to the participant by displaying the height of the bar. Actions (bars) were related to rewards by their position on the x-axis: the i^{th} bar from left to right, a_i, was associated to the reward r_i by the function $r_i = f(a_i, i)$. We tested behavior on CMABs with three different reward functions of varying complexity:

$$f_{linear}(a_i, i) = i$$
$$f_{quadratic}(a_i, i) = -(i - 55)^2$$
$$f_{sinc}(a_i, i) = \frac{\sin(i/2 - 30.000001)}{i/2 - 30.000001}$$

Reward functions were scaled to fall within minimum and maximums drawn from uniform distributions, $\mathbf{U}(0,100)$ and $\mathbf{U}(400,500)$ respectively. Participants were shown 10 reward sample functions before they began the task. The quadratic and sinc samples were generated by uniformly sampling the location of the maximum, the function minimum, and function maximum ($\mathbf{U}(1,80)$, $\mathbf{U}(0,100)$, and $\mathbf{U}(400,500)$ respectively). Linear functions were generated by samples of the intercept and slope drawn from uniform distributions $\mathbf{U}(0,250)$ and $\mathbf{U}(0,6.25)$.

Participants were given one of two possible goals: In the maximum-finding condition, participants were asked to find the bar associated with the maximum possible reward. Participants final score in this condition was equal to the maximum reward uncovered across all trials. In the score-maximization condition, participants were asked to maximize their cumulative scores across all trials.

Procedure and participants. Participants (n=69, mean age=33.0 years) were recruited using Amazon's Mechanical Turk service. They were randomly assigned one of 6 (3 reward functions $\times$ 2 goals) conditions. They were first shown 10 different sets of 80 bars with their heights already revealed. Depending on a participant's function condition, the heights of the bars in each set was determined by either linear, quadratic, or sinc functions. Participants were then shown a new set of 80 bars, each 500 pixels tall and gray in color, and instructed to either find the bar with the largest height (find-max) or to maximize the cumulative heights of bars clicked across all trials (max-score) for a new set of bars. Participants were invited to click on any of the 80 bars over 25 trials. When a gray bar was clicked its color changed to black and its height was adjusted to match its corresponding reward (between 0 and 500 pixels). After each trial the reward associated with the chosen bar was used to update the participants goal-specic reward, displayed on the screen alongside the bars. On each trial, any bars that were clicked on previous trials remain black and the height in pixels of their associated rewards. To incentivize performance participants were given a bonus up to \$0.75 proportional to the total number of points they earned.

Model

Our goal was to uncover strategies used in an CMAB task with different reward function complexities and goals. We take inspiration from Bayesian optimization, taking action probabilities to be a function of a GPR predictions of the reward function. Like previous accounts, we characterize exploration as a mixture of directed and random behavior. However, While previous accounts have assumed that directed exploration only uses uncertainty about each action, we extend this framework to include uncertainty about the function maximum.

In GPR a kernel function is used to encode prior beliefs about a function. We use the radial basis function (RBF) kernel:

$$k(x,x') = \sigma^2_{var}\exp(-\frac{(x-x')^2}{2l^2})$$

where l determines the smoothness of the function, or how quickly the similarity of two points falls off as they become more distant, and σ^2_{var} determines the average distance of the function from its mean. This kernel function is well suited to flexibly modelling function learning, as it is capable of learning any smooth function. For each reward function condition a set of 10 functions from the same family that were shown to participants prior to the CMAB task were used to fit the hyperparameters of the kernel function by maximizing the log marginal likelihood of the sample functions (Rasmussen & Williams, 2005). Fitting kernel hyperparameters in this way for each function allows us to model participants' expectations about the smoothness of the reward function, given the observed set of sample functions.

To estimate each participant's trial-by-trial predictions we compute the posterior mean and variance of the reward function at each action:

$$m_t(a) = \mathbf{k}_t(a)^\top(\mathbf{K}_t + \sigma^2_{noise}\mathbf{I})^{-1}r_t$$
$$v_t(a) = k(a,a) - \mathbf{k}_t(a)^\top(\mathbf{K}_t + \sigma^2_{noise}\mathbf{I})^{-1}\mathbf{k}_t(a)$$

where $k(a,a')$ is the covariance of two actions given the hyperparameters learned from a participant's training functions, $\mathbf{k}_t(a)$ is a vector of covariances for the action a and all previous observed actions, and $\mathbf{K}_t$ is the covariance matrix of all previously observed actions. σ^2_{noise} is the noise observed in the data. The reward functions in our task are deterministic, so we set this to a very small but non-zero number 10^{-4} to avoid numerical instability. We encode exploration directed by uncertainty about the function maximum by approximating the mutual information between the reward r revealed by action a and the highest possible reward r^*, $I(\{a,r\};r^*)$, the approximation used in max-value entropy search (Wang & Jegelka, 2017). We define the *utility* of each action on trial t to be

$$u(a,\beta,\lambda) = m_t(a) + \beta v_t(a) + \lambda I(\{a,r\};r^*)$$

and the probability of each action was defined using the softmax function

$$p(a|\beta,\lambda,\tau) = \frac{\exp[u(a,\beta,\lambda)/\tau]}{\sum_{a'\in A}\exp[u(a',\beta,\lambda)/\tau]}$$

We use an infinite groups model (Navarro, Griffiths, Steyvers, & Lee, 2006) to uncover common strategies across participants. Using the probability of actions, if the i^{th} participant belongs to group z,

$$p(a^i_T|g_i = z) = \prod_t^{T-1} p(a^i_{t+1}|a^i_t, r^i_t, \beta_z, \lambda_z, \tau_z)$$

where a^i_T is the set of all actions performed by the i^{th} participant. Groups were assigned priors according to a

stick-breaking procedure (Ishwaran & James, 2001). Under this prior we imagine a stick of length 1 that we break in two, keeping the length of the first stick to be the prior probability of our first group. We can then break the remaining piece in two again, with one of its pieces representing the prior probability of our second group. This process can be extended to represent a countably infinite number of groups, with the sum of their prior probabilities guaranteed to sum to 1. The stick-breaking prior has one parameter, α, that determines the dispersion among groups, with a higher α resulting in likelihoods being spread across a greater number of groups. We place a Gamma(a,b) prior over α, setting $a = b = 10^{-10}$ to represent our ignorance of the true number of groups in the data. We set Gamma priors with $a = b = 0.1$ over β, λ, and τ to represent equal preferences for each type of exploration.

Results

We used the python package PyMC3 (Salvatier, Wiecki, & Fonnesbeck, 2016) to perform inference. MCMC sampling was performed using the NUTS sampler, with 4 chains of 1000 samples each.

To inspect the range of strategies used by participants we assigned each participant to their most likely group, maximizing $p(g|a_T^i)$ for the i-th participant. Nine groups were assigned at least one participant. We summarize the behavior of each of these groups by their parameter means in Table 1. The largest four groups were assigned 48 out of 69 participants. The largest group has a much larger average τ than other groups, indicating that participants in this group heavily utilized random exploration. The second largest group had a larger average β and λ and smaller average τ, indicating that participants in this group utilize directed in addition to random exploration, using both uncertainty about each action and uncertainty about the reward function maximum. The third largest group also had a relatively large average β and λ, but a smaller average τ than the previous group. This indicates that participants in this group also used both forms of directed exploration, but relied much less on random exploration. The fourth largest group had relatively low average values for all three parameters, indicating that participants in this group did comparatively little exploring, instead choosing actions based on their expected reward. We refer to these groups as *stochastic*, *mixed*, *directed*, and *greedy* respectively.

To better understand how behaviors differed between groups, we measure the distance between participants' actions and both their previous action and their reward function maximum across trials (Figure 1). First, we plot the distribution of the distances between a participant's action and their previous action. Participants across all four of the top groups made a large proportion of their actions in close proximity to their previous action. This proportion was largest for the random group, followed by mixed, directed, and greedy. As we might expect, participants in the random group demonstrated more aggressive exploration with respect to their previous action, while those in the mixed and directed groups were more reserved. In contrast, participants in the greedy group rarely deviated far from their previous action. Next, we plot the median distance from the reward function maximum by trial for each group. For the random and mixed groups, the median distance from the reward function maximum stays level across trials, indicating that participants in these groups favor exploration over converging on the best action. For the directed and greedy groups, the median distance decreases towards zero with the number of trials. While the distance continues to decrease and eventually flattens out for those in the greedy group, the distance for those in the directed group increases after a number of trials, indicating that participants were willing to continue exploring even after the region containing the reward function maximum was located.

If participants were selecting there strategy based on their goal, we would expect the actions of participants in the max-score condition to be best predicted by a strategy that minimizes balances exploration and exploitation, and those of participants in the find-max condition to be best predicted by a strategy that minimizes uncertainty about the reward function maximum. While none of the groups show a preference for the source of uncertainty used to direct exploration (either about rewards of individual actions or the function maximum), these groups do differ in their preference for random and directed exploration. To investigate how reward function complexity and goal determine how people choose between these strategies we compare how well each strategy predicts the actions of participants grouped by experimental condition (Table 2). Participants selecting a strategy in the max-score goal condition are expected to choose a strategy that favors actions with high rewards, while those in the find-max condition are expected to choose a strategy that puts more of an emphasis on exploration. Our results contradict this assumption, with those in the max-score condition best described by the directed strategy and actions of those in the find-max condition best described by the greedy strategy. With function learning being increasingly difficult as function complexity increases, participants in less complex reward function conditions are expected to use this learning to engage in more directed exploration, while those in the more complex reward function conditions are expected to rely more heavily on random exploration. Our results show some evidence for this, as actions of participants in the linear condition were best explained by the directed strategy, while those in the quadratic condition were best explained by the mixed strategy. However, our results also show that the actions of those in the sinc condition were also best described by the directed strategy rather than the mixed or random strategy as we might expect.

	β	λ	τ	*N* Participants
Stochastic	0.29 ± 0.17	6.01 ± 8.87	5.23 ± 3.57	15
Mixed	1.58 ± 1.15	8.56 ± 8.32	1.77 ± 2.43	14
Directed	1.4 ± 1.29	11.19 ± 9.21	0.24 ± 0.22	11
Greedy	0.77 ± 0.44	0.61 ± 0.84	0.14 ± 0.19	8

	1.12 ± 0.39	6.98 ± 6.09	0.89 ± 0.63	2

Table 1: Mean parameters for each group

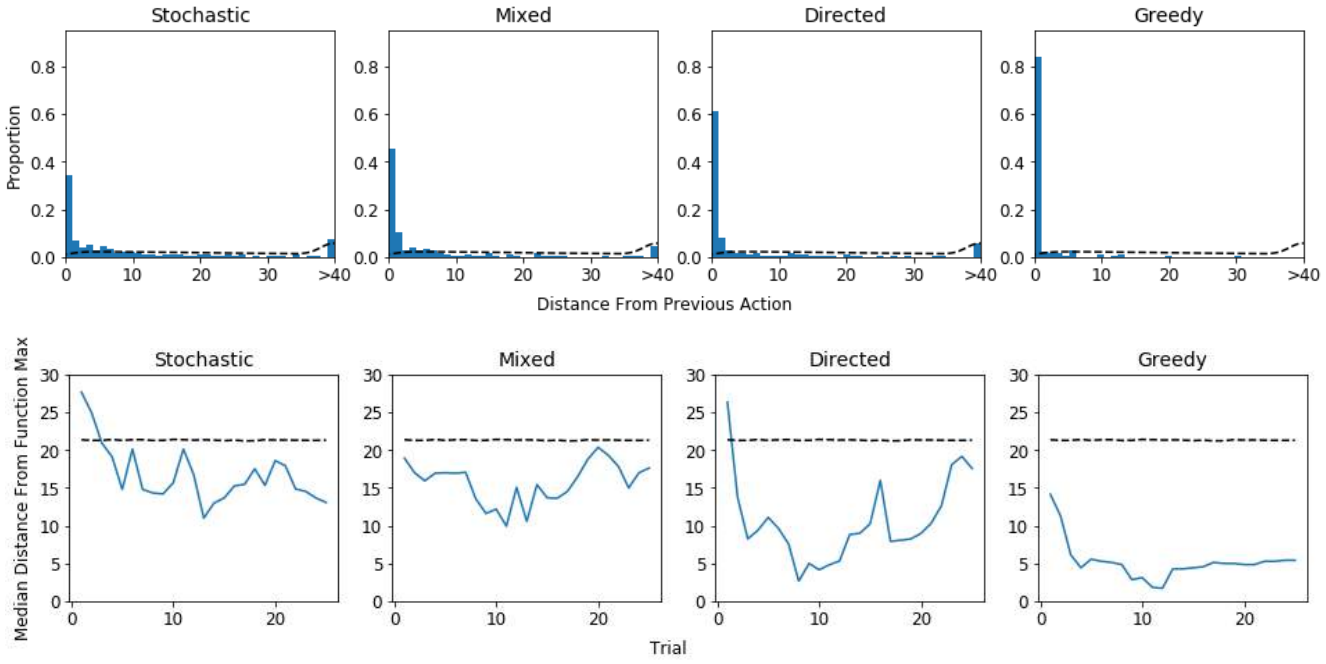

Figure 1: Distance of each action from the previous actions (top) and the reward function maximum (bottom) for the top four groups compared to a random baseline (dashed lines) reflecting uniform random action selection averaged over all conditions.

Discussion

In this study we compared behavior in an explore-exploit task across different reward function complexities and goals. While previous studies have characterized behavior in these tasks as some combination of exploitation and directed and random exploration, it was uncertain how these components might vary with different environments. Additionally, while previous studies only considered uncertainty about individual actions in directed exploration, it had yet to be established how measures of global uncertainty, such as uncertainty about the function maximum, might also be used by people to guide exploration.

Participants in this study each completed a CMAB task where the underlying reward function was either linear, quadratic, or sinusoidal, and their goal was to either maximize their score across all trials (max-score) or to find the best action (find-max). We found that behavior could be described by a relatively small set of strategies, characterized by varying exploration parameters. We found some evidence that strategy was impacted by reward function complexity, as participants in the linear condition were better described by a directed exploration strategy while those in the quadratic condition were better described by a mixed strategy utilizing both stochastic and directed exploration. However, those in the sinc condition were also best explained by a directed strategy, suggesting that these participants relied less on stochastic exploration than those in the quadratic condition despite their relatively complex reward function. Finally, we found that global uncertainty was indeed a measure used in directed exploration alongside uncertainty about individual actions, though we did not find evidence that preference for one form of uncertainty over the other was determined by goal. However, this could have been due to participants underestimating the complexity of the sinc reward function by only exploring around local maxima. Accounts of how reward function complexity influences strategy selection should also consider perceived complexity.

While we were able to describe a wide range of exploration behaviors, it is likely that alternative strategies exist. For example, some have suggested that people approach explore-exploit tasks in two qualitatively different phases, starting with a "pure exploration" phase, designed to reveal what options are most rewarding, and switching to a "pure exploitation" phase focusing on the most rewarding options (Steyvers & Wagenmakers, 2009). Another possibility is that some people do not utilize information about the reward function at all, instead exploring locally as often observed in ecological search strategies (Hills, 2006). A complete account of the types of strategies that people utilize under different circumstances should include a wider array of possible sources for guiding exploration.

Outgroup Homogeneity Bias Causes Ingroup Favoritism

Abstract

Ingroup favoritism, the tendency to favor ingroup over outgroup, is often explained as a product of intergroup conflict, or correlations between group tags and behavior. Such accounts assume that group membership is meaningful, whereas human data show that ingroup favoritism occurs even when it confers no advantage and groups are transparently arbitrary. Another possibility is that ingroup favoritism arises due to perceptual biases like outgroup homogeneity, the tendency for humans to have greater difficulty distinguishing outgroup members than ingroup ones. We present a prisoner's dilemma model, where individuals use Bayesian inference to learn how likely others are to cooperate, and then act rationally to maximize expected utility. We show that, when such individuals exhibit outgroup homogeneity bias, ingroup favoritism between arbitrary groups arises through direct reciprocity. However, this outcome may be mitigated by: (1) raising the benefits of cooperation, (2) increasing population diversity, and (3) imposing a more restrictive social structure.

Keywords: ingroup favoritism; outgroup homogeneity; direct reciprocity; Bayesian learning; conditional expected utility

Introduction

Ingroup favoritism is the tendency for people to favor members of their own group over members of other groups. It manifests as a bias in how people evaluate others (Brewer, 1979; Galinsky & Moskowitz, 2000), distribute rewards (Tajfel, Billig, Bundy, & Flament, 1971), mete out punishments (Bernhard, Fischbacher, & Fehr, 2006), and decide whether or not to cooperate (Dorrough, Glöckner, Hellmann, & Ebert, 2015). Though readily elicited in both natural (Rand et al., 2009) and arbitrary groups (Efferson, Lalive, & Fehr, 2008; Galinsky & Moskowitz, 2000), the existence of ingroup favoritism is puzzling. It often neither improves the population's average outcome, nor maximizes that of the individual (Nakamura & Masuda, 2012). Disagreement even exists as to whether ingroup favoritism is better understood as a preference for improving the welfare of ingroup over outgroup, or as a product of divergent beliefs about how these groups behave (Everett, Faber, & Crockett, 2015). However, empirical work suggests that people generally expect ingroup members to act in a cooperative manner (Brewer, 2008; Yamagishi, Jin, & Kiyonari, 1999), and meta-analysis confirms that this expectation is indeed stronger toward ingroup than outgroup (Balliet, Wu, & De Dreu, 2014). A promising avenue for explaining ingroup favoritism therefore seems to be understanding how people arrive at these beliefs. In short, why are ingroup members seen as more cooperative than outgroup ones?

Many theoretical models have addressed this question. One common approach is to assign phenotypic tags to individuals, and then see what is required to elicit ingroup favoritism. Such models have shown that ingroup favoritism may be selected for when tags are not arbitrary, but rather correlate with behavioral traits (Jansen & van Baalen, 2006; Masuda & Ohtsuki, 2007; Traulsen, 2008). These traits typically include willingness to cooperate, or suitability as a cooperative partner. Ingroup favoritism may thus occur when tags convey information useful in guiding the individual's own actions. Other models explain ingroup favoritism as a product of intergroup conflict (Choi & Bowles, 2007; García & van den Bergh, 2011; Konrad & Morath, 2012), where group membership may be arbitrarily decided, but remains relevant from a competitive point of view. However, a classic empirical finding is that humans show ingroup favoritism even when groups are both explicitly arbitrary and functionally irrelevant (Billig & Tajfel, 1973; Locksley, Ortiz, & Hepburn, 1980). So why should ingroup favoritism occur even when group membership is meaningless, and such outcomes are maladaptive?

One explanation is that ingroup favoritism may arise through cognitive or perceptual limitations (Masuda, 2012). For instance, humans are known to perceive outgroup members as more similar to one another than ingroup members, a bias known as outgroup homogeneity (Judd & Park, 1988). By approximating individuals' characteristics through a single group stereotype, this may serve to reduce cognitive burden (Masuda, 2012). Masuda (2012) studied the implications of such a bias on indirect reciprocity, where cooperation is conditioned on whether or not partners maintain a good reputation. In the simplest such scheme, an individual's reputation improves when it is observed to cooperate, and suffers when it is observed to defect; in more complicated schemes, reputation may, for example, also be gained by being observed punishing a defector, or lost by being observed cooperating with one. To simulate outgroup homogeneity, individuals were allowed to observe accurate reputation information about ingroup members, but only group-level information about outgroup members. Ingroup favoritism occurred, but only when additional assumptions were invoked, such as individuals using a different rule for attributing reputation to ingroup than

to outgroup members. A follow-up model by Nakamura and Masuda (2012) eliminated the need for such double standards, and also produced ingroup favoritism through indirect reciprocity. However, this time the result was contingent on reputation information being only shareable within groups, but not between them.

Here, we show that complex rules for assigning and sharing reputation are not needed to explain ingroup favoritism between arbitrary groups. Rather, outgroup homogeneity bias may drive ingroup favoritism through a much simpler mechanism: direct reciprocity (learning through personal experience). We create an agent-based computational model, where individuals are assigned arbitrary group tags, and then play a prisoner's dilemma (PD) game. These individuals use Bayesian inference to learn how likely others are to cooperate or defect, and then act rationally by maximizing their conditional expected utility. We show that introducing outgroup homogeneity bias into this minimal setting is sufficient to produce strong ingroup favoritism, and propose several ways of mitigating this outcome.

Model

Prisoner's Dilemma

We consider a PD game where pairs of neighboring individuals interact by either cooperating (C) or defecting (D). The game is parameterized by two values: the benefit of receiving cooperation, b, and the cost of cooperating, c. When both individuals cooperate, both receive the benefit of cooperation, but pay the cost of cooperating, $b-c$. If one individual defects while the other cooperates, then the cooperator pays the cost while receiving no benefit, $-c$, while the defector pays no cost but receives the full benefit, b. When both individuals defect, neither receives the benefit nor pays the cost. The following table summarizes the row player's payoffs:

	C	D
C	$b-c$	$-c$
D	b	0

As long as $b > c > 0$, each player's payoff is always improved by defecting, no matter what the other player does. This makes the game a dilemma, because although the best individual outcome is unilateral defection, the best average outcome is mutual cooperation.

Social Structure

In PD, ingroup favoritism is operationalized as a higher rate of cooperation toward ingroup partners than outgroup ones (Dorrough et al., 2015; Fu et al., 2012; Gray et al., 2014; Masuda, 2012). For ingroup favoritism to be possible, cooperation must also be possible. By constraining which individuals interact, we promote repeat interactions, which in turn promotes cooperation (Szabó & Fáth, 2007). For each run, we generate a random r-regular graph (Bollobás, 2001) with 1000 vertices, using Steger and Wormald's (1999) algorithm. Each vertex represents an individual, and each edge represents a connection between neighbors. This graph governs interactions by limiting individuals to playing PD exclusively with their neighbors.

Group Tags

Individuals are divided into m groups, where group membership is represented by a tag visible to all other individuals. By default, $m = 2$, though it may take other values, as long as $m > 1$. Otherwise, tags cease to represent group membership, and instead become a universally shared characteristic. Each individual is randomly assigned a tag, such that each group has the same initial number of members. When replacement occurs, newcomers are assigned a tag uniformly at random.

Rational Bayesian Learning

Learning involves estimating a pair of parameters for each partner i that the individual interacts with. The first parameter p_i represents the estimated probability that partner i will cooperate with the individual, given that the individual cooperates with that partner, $Pr(C_i|C)$. The second parameter q_i estimates the probability that partner i will cooperate, given that the individual defects against that partner, $Pr(C_i|D)$. Because the game is simultaneous, actions cannot be conditioned on those of the partner. However, there is no *a priori* reason for individuals to know this, and indeed repeated interactions cause p_i and q_i to diverge, as individuals change their behavior in response to that of their partner. Individuals use Bayesian inference to arrive at point estimates for p_i and q_i. Here, the posterior predictive distribution corresponds to the posterior mean (Griffiths, Kalish, & Lewandowsky, 2008),

$$p_i := \frac{n_{CC}+\alpha+1}{n_{CC}+n_{CD}+\alpha+\beta+2} \quad q_i := \frac{n_{DC}+\alpha+1}{n_{DC}+n_{DD}+\alpha+\beta+2}, \tag{1}$$

where n_{AB} counts the number of times the individual took action A when partner i took action B. Similarly, α and β are pseudocounts (Griffiths et al., 2008) that encode prior knowledge or expectations about the frequency of cooperation and defection, respectively. These take the value $\alpha = \beta = 0$, which represents a neutral prior (uniform distribution), where neither cooperation nor defection is seen as inherently more likely.

By default, individuals maintain a pair of p and q values for each partner i. However, individuals exhibiting outgroup homogeneity bias do not distinguish between outgroup members, so they instead track a single pair of values, p_j and q_j, for each outgroup j. Outgroup homogeneity thus causes individuals to treat outgroups as if they were a single individual.

Individuals act rationally on their Bayesian estimates, so as to maximize their conditional expected utility (Jeffrey, 1990). More formally, an individual cooperates if

$$pb - c > qb, \tag{2}$$

and defects otherwise. To give individuals a chance to sample both actions, we implement a small trembling-hand parameter (Selten, 1975). When an individual selects an action, with a small probability $\varepsilon = 0.01$, it takes the opposite action

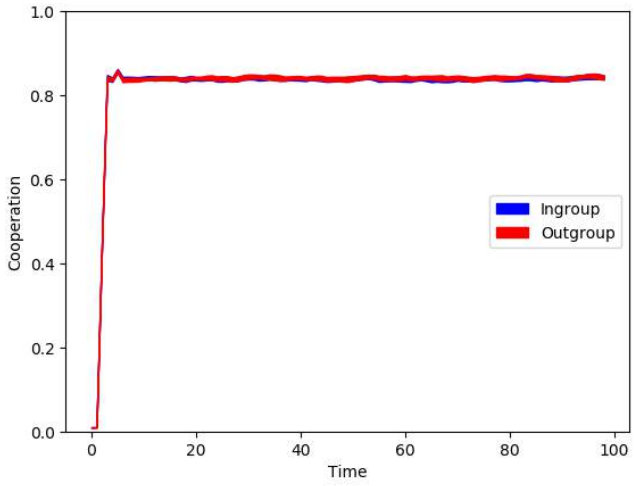

Figure 1: Ingroup and outgroup cooperation rates over time, in the absence of outgroup homogeneity bias. Cooperation rates climb rapidly as individuals learn that defection is met with defection. Ingroup cooperation rates mirror outgroup cooperation rates, because group membership is irrelevant.

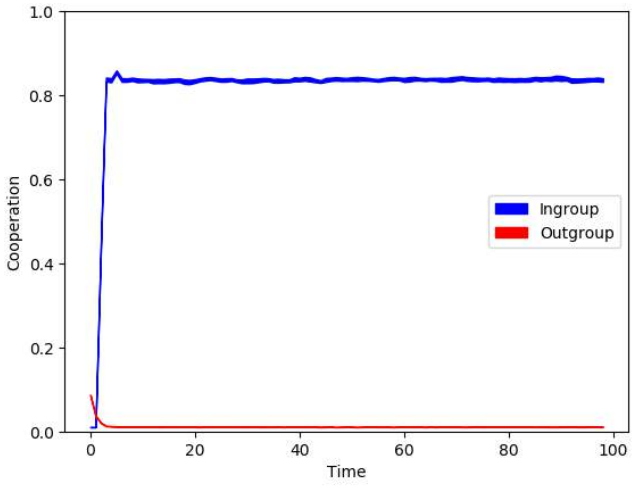

Figure 2: Ingroup and outgroup cooperation rates over time, with outgroup homogeneity bias. Here, individuals track outgroup members' behavior at a group rather than individual level. Breakdowns in cooperation result in cascades of defection involving entire groups, rather than just the offending individual, resulting in strong ingroup favoritism.

instead. Removing this parameter (setting $\varepsilon = 0$) does not qualitatively alter our results.

Simulation

At each time step, individuals interact with their neighbors in random order. Interactions involve selecting an action (C or D), and then playing PD. After each interaction, individuals note the outcome of the game, and then update their estimates p and q. Once everyone has finished playing, individuals are subjected to a 0.01 probability of being replaced. Newcomers are assigned a group tag uniformly at random, and have no knowledge of their predecessor's p and q values. Because there is no selection over genotypes, ingroup favoritism cannot evolve, but arises through phenotypic plasticity (i.e. learning) instead. We run simulations for 1000 time steps, by which time cooperation rates have long stabilized. All results are averaged across 20 independent runs, and stabilized cooperation rates are further averaged over the last 100 time steps. In all figures, line width represents 95% confidence intervals.

Results

We first consider unbiased individuals, connected to $r = 10$ random neighbors, where the benefit of receiving cooperation ($b = 3$) moderately exceeds the cost of giving it ($c = 1$). In the first few time steps, cooperation rates are near-zero (Figure 1). Recall that naïve agents have a uniform prior, meaning that cooperation and defection are seen as equally likely. However, the expected utility of unilateral defection is higher than that of mutual cooperation (Inequality 2), and so virtually everyone defects, hoping to take advantage of a cooperating partner. Individuals quickly learn that defection is met with defection, which lowers their estimate of q. With unilateral cooperation seeming increasingly unlikely, qb falls below $pb - c$, and individuals seek out mutual cooperation instead. As cooperation is met with cooperation, estimates of p increase, and high rates of cooperation ($\sim 84\%$) are established. Although individuals are assigned to $m = 2$ random groups, group membership is irrelevant, and so ingroup and outgroup cooperation rates do not differ.

When outgroup homogeneity bias is introduced, outgroup members cease being treated as individuals, but as representatives of their group. By generalizing the outcome of each interaction to other members of the outgroup, individuals learn that defection does not yield cooperation even more rapidly than when playing against ingroup members. This causes an initial spike in outgroup cooperation (Figure 2). However, although ingroup cooperation is a bit slower to get going, it alone persists. To understand why, consider what happens when an individual cooperates, but its partner defects. If partner i is an ingroup member, then the individual revises its beliefs about that partner's willingness to cooperate, and p_i declines. Soon, $pb - c$ drops below qb, and the individual ceases to cooperate. Once partner i learns that defection does not evoke cooperation, its q falls low enough for it to also seek mutual cooperation. Any successful instance of mutual cooperation promotes further cooperation, causing p values to increase, entrenching that behavior. However, if partner i is an outgroup member, then the individual does not know who to blame for the partner's unilateral defection. The individual thus revises its beliefs about the entire group's willingness to cooperate, and p_j declines. This causes the individual to punish not just the defecting partner, but also any others from that

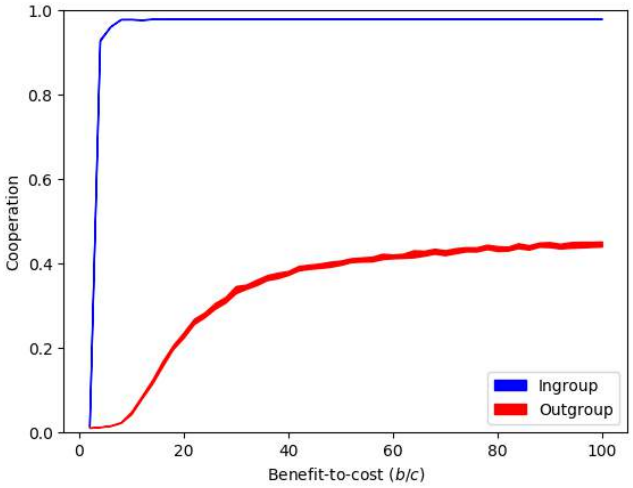

Figure 3: Stabilized ingroup and outgroup cooperation rates for various benefit-to-cost (b/c) ratios. Increasing the b/c ratio favors cooperation more broadly by making the temptation to defect less appealing, thus reducing ingroup favoritism.

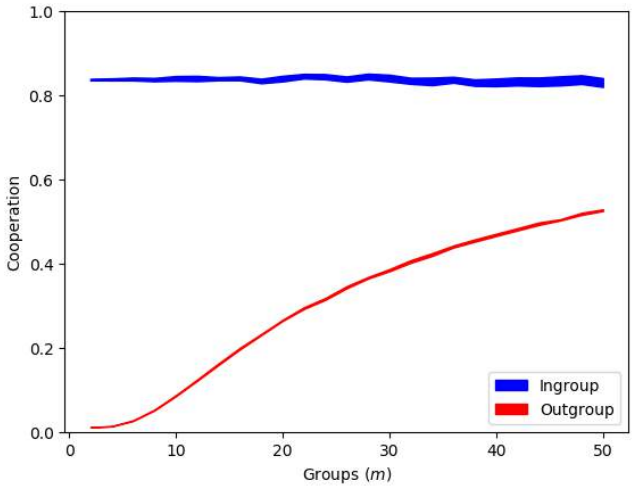

Figure 4: Stabilized ingroup and outgroup cooperation rates for various numbers of groups (m). Increasing population diversity reduces ingroup favoritism, because fewer neighbors share the same outgroup. This limits the scope of breakdowns in cooperation caused by outgroup homogeneity bias.

group. Those neighbors then punish the focal individual, as well as members of its group, for this seemingly unprovoked hostility. Intergroup defections thus bring about not just punishment of the offending individual, but also a cascade of retributive defections. Outgroup cooperation is prohibitively difficult to establish and maintain under such conditions, resulting in strong ingroup favoritism.

We next consider various parameters that may mitigate this outcome. For example, increasing the trembling-hand parameter ε reduces ingroup favoritism, albeit in a somewhat trivial manner. The more errors individuals commit in taking their desired action, the more this increases (unwanted) outgroup cooperation and decreases (desirable) ingroup cooperation. Such effects offer relatively little additional insight, however, because ingroup favoritism is merely harder to enact, rather than less sought after.

Of greater theoretical interest is the effect of increasing the benefit-to-cost ratio of cooperation. Doing so raises both ingroup and outgroup cooperation, which in turn reduces ingroup favoritism (Figure 3). Higher b/c ratios represent more cooperative games, where mutual cooperation is more rewarding, and the temptation to defect is reduced (i.e. Inequality 2 becomes primarily driven by p and q values, rather than c). Whereas the ingroup cooperation rate rapidly approaches a ceiling, the outgroup cooperation rate has more room to grow.

Another parameter of interest is the number of groups, m. This may be regarded as a measure of the population's diversity. Increasing the number of groups does not affect ingroup cooperation, but increases outgroup cooperation, thus reducing ingroup favoritism (Figure 4). Intuitively, if an individual's neighbors all belong to different groups, then tracking these groups' aggregate behavior is equivalent to tracking individual behavior. The more diverse the population, the less meaningful outgroup homogeneity is as an approximation. More practically, when fewer neighbors share group membership, breakdowns in cooperation result in smaller cascades of retributive defections.

Finally, the number of neighbors that individuals interact with, r, is also relevant. If there are relatively many groups in the population (e.g. $m = 20$), then reducing the number of neighbors alleviates cascading breakdowns in cooperation, because fewer neighbors belong to the same group. This promotes higher rates of outgroup cooperation, which in turn reduces ingroup favoritism (Figure 5). However, if there are few groups (e.g. $m = 2$), outgroup cooperation remains unsustainable, even if the number of neighbors is drastically reduced (e.g. to $r = 3$), and ingroup favoritism remains high.

Discussion

We have presented an agent-based computational model of a PD game, where outgroup homogeneity causes ingroup favoritism between arbitrary groups. Previous models have relied on indirect reciprocity (observing others' interactions) to produce such an outcome. However, these only produced ingroup favoritism if they invoked additional factors. For instance, Masuda (2012) found that reputation assignment rules had to differ for ingroup and outgroup members, while Nakamura and Masuda (2012) found that the flow of reputation information had to be severed between groups. By contrast, our model's results are driven by direct reciprocity (learning from personal experience), which obviates the need for additional assumptions about how others' interactions are evaluated, or how that information is shared. The individuals we model leverage a minimal set of cognitive capacities.

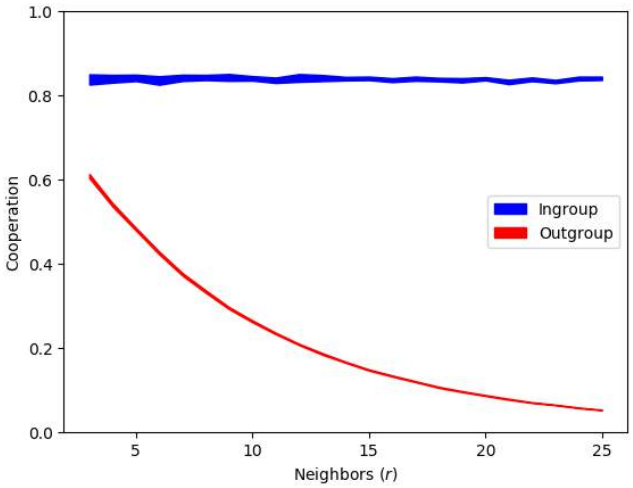

Figure 5: Stabilized ingroup and outgroup cooperation rates for various neighborhood sizes (r). If there are many groups in the population (here $m = 20$), reducing the number of neighbors reduces ingroup favoritism, by limiting the scope of defection cascades.

Namely, they learn from past experience through Bayesian inference, and make rational decisions by maximizing expected utility. In fact, they operate under similar assumptions to those found in game theoretical "fictitious play" (Berger, 2007): They estimate others' probability of cooperating as a stationary strategy, and then select the best response to observed behavior.

In our model, outgroup homogeneity causes ingroup favoritism, because outgroup defections lower an entire group's perceived cooperativeness, rather than just the individual's. Outgroup cooperation is difficult to establish and maintain not only because punishing a defector involves punishing its entire group, but also because it triggers a cascade of retributive action from those caught in the crossfire. Our findings shed light on several empirical observations about ingroup favoritism. For instance, ingroup favoritism is infamously easy to evoke even when it confers no advantage, and group membership is transparently arbitrary (Billig & Tajfel, 1973; Locksley et al., 1980). Moreover, meta-analysis suggests that ingroup favoritism between transient, experimentally-induced groups is often as strong as between natural ones (Balliet et al., 2014). The fact that this is often maladaptive from both the group and the individual's point of view makes it challenging to explain as a product of selection (Nakamura & Masuda, 2012). In our model, individuals all share the same learning and decision rules, and are assigned groups at random. There is no selection over genotypes. Rather, strong ingroup favoritism arises rapidly as a phenotypic consequence of Bayesian learning, rational decision-making, and a well-established perceptual bias: outgroup homogeneity.

One implication is that reducing or eliminating outgroup homogeneity bias may erode ingroup favoritism. In reality, ingroup favoritism can be mitigated by taking the perspective of outgroup members (Galinsky & Moskowitz, 2000). The apparent mechanism behind this result is that perspective-taking reduces reliance on group stereotypes (Brewer, 1996), causing outgroup members to be perceived as individuals. Greater intergroup contact may also reduce intergroup bias, both against that outgroup (Pettigrew & Tropp, 2006), as well as against uninvolved others (Pettigrew, 2009). In line with with our model's predictions, this too appears to be driven by reduced reliance on group stereotypes (Tadmor, Hong, Chao, Wiruchnipawan, & Wang, 2012).

Similarly, ever since Sherif's (1954) original Robbers Cave experiment, ingroup favoritism has often been both evoked and understood through the lens of competition (Sherif et al., 1961). In the experiment's final phase, intergroup tensions were deliberately reduced by encouraging cooperation. Consistent with this view, our model predicts that incentivizing cooperation alleviates ingroup favoritism. PD is a social dilemma precisely because it rewards both competition and cooperation. Increasing the b/c ratio thus minimizes these competitive aspects, and emphasizes the cooperative ones instead. Reducing the temptation to defect, relative to the benefits of mutual cooperation, causes individuals to take more risks to establish mutual cooperation, and to recover it more readily when it breaks down.

Finally, our model also predicts that ingroup favoritism may be reduced by increasing population diversity. When fewer neighbors belong to the same group, this limits the cascades of defection caused by outgroup homogeneity bias. This is also why lowering the number of neighbors can be effective. In both cases, the chances of being punished for an ingroup member's actions are reduced. However, this reasoning only applies if group membership is indeed arbitrary. The role of diversity in ingroup favoritism is typically studied through the lens of group differences, which add considerable complexity (Everett et al., 2015). Similarly, if conflicts exist along group lines, increased diversity may not necessarily reduce ingroup favoritism (Hewstone et al., 2014). No doubt, a great deal of real-world ingroup favoritism is intertwined with such pragmatic concerns. However, because ingroup favoritism occurs even when such concerns are irrelevant, understanding such social factors could offer promising ways of addressing it.

Pressure to communicate across knowledge asymmetries leads to pedagogically supportive language input

Abstract

Children do not learn language from passive observation of the world, but from interaction with caregivers who want to communicate with them. These communicative exchanges are structured at multiple levels in ways that support support language learning. We argue this pedagogically supportive structure can result from pressure to communicate successfully with a linguistically immature partner. We first characterize one kind of pedagogically supportive structure in a corpus analysis: caregivers provide more information-rich referential communication, using both gesture and speech to refer to a single object, when that object is rare and when their child is young. Then, in an iterated reference game experiment on Mechanical Turk (n = 480), we show how this behavior can arise from pressure to communicate successfully with a less knowledgeable partner. Lastly, we show that speaker behavior in our experiment can be explained by a rational planning model, without any explicit teaching goal. We suggest that caregivers' desire to communicate successfully may play a powerful role in structuring children's input in order to support language learning.

Keywords: language learning; communication; computational modeling.

Introduction

One of the most striking aspects of children's language learning is just how quickly they master the complex system of their natural language (Bloom, 2000). In just a few short years, children go from complete ignorance to conversational fluency in a way that is the envy of second-language learners attempting the same feat later in life (Newport, 1990). What accounts for this remarkable transition?

Distributional learning presents a unifying account of early language learning: where infants come to language acquisition with a powerful ability to learn the latent structure of language from the statistical properties of speech in their ambient environment (Saffran, 2003). A number of experiments clearly demonstrate the early availability of such mechanisms and their utility across a range of language phenomena (Saffran, 2003; Smith & Yu, 2008). However, there is reason to be suspicious about just how precocious young learners are early in development. For example, infants' ability to track the co-occurrence information connecting words to their referents appears to be highly constrained by their developing memory and attention systems (Smith & Yu, 2013; Vlach & Johnson, 2013). Further, computational models of these processes show that the rate of acquisition is highly sensitive to variation in environmental statistics (e.g., Vogt, 2012). Thus, precocious unsupervised statistical learning appears to fall short of a complete explanation for rapid early language learning.

Even relatively constrained statistical learning could be rescued, however, if caregivers structured their language in a way that simplified the learning problem. Indeed, evidence at a variety of levels– from speech segmentation to word learning– suggests that caregivers' naturalistic communication provides exactly this kind of supportive structure (Gogate, Bahrick, & Watson, 2000; Thiessen, Hill, & Saffran, 2005; Tomasello & Farrar, 1986). Under distributional learning accounts, the existence of this kind of structure is a theory-external feature of the world that does not have an independently motivated explanation. Indeed, because of widespread agreement that parental speech is not usually motivated by explicit pedagogical goals, the calibration of speech to learning mechanisms seems a happy accident; parental speech just happens to be calibrated to children's learning needs. In this work, we take the first steps toward a unifying account of both the child's learning and the parents' production: Both are driven by a pressure to communicate successfully (Brown, 1977).

Early, influential functionalist accounts of language learning focused on the importance of communicative goals (e.g., Brown, 1977). Our goal in this work is to formalize the intuitions in these accounts in a computational model, and to test this model against experimental data. We take as the caregiver's goal the desire to communicate with the child, not about language itself, but instead about the world in front of them. To succeed, the caregiver must produce the kinds of communicative signals that the child can understand and respond contingently, potentially leading caregivers to tune the complexity of their speech as a byproduct of in-the-moment pressure to communicate successfully (Yurovsky, 2017).

To examine this hypothesis, we first analyze parent communicative behavior in a longitudinal corpus of parent-child interaction in the home (Goldin-Meadow et al., 2014). We investigate the extent to which parents tune their communicative behavior (focusing on modality– i.e. gesture vs. speech) across their child's development to align to their child's developing linguistic knowledge (Yurovsky, Doyle, & Frank, 2016). We take this phenomenon to be a case study of pedagogically supportive structure in the language environment.

We then experimentally induce this form of structured language input in a simple model system: an iterated reference

game in which two players earn points for communicating successfully with each other. Modeled after our corpus data, participants are asked to make choices about which communicative strategy to use (akin to modality choice). In an experiment on Mechanical Turk using this model system, we show that tuned, structured language input can arise from a pressure to communicate. We then show that participant behavior in our game can be explained by a rational planning model that seeks to optimize its total expected utility over the course of the game.

Corpus Analysis

We first investigate parent referential communication in a longitudinal corpus of parent-child interaction. We analyze the production of multi-modal cues (i.e. using both gesture and speech) to refer to the same object, in the same instance– an information-rich cue that we take as one instance of pedagogically supportive language input. While many aspects of CDS support learning, multi-modal cues (e.g., speaking while pointing or looking) are uniquely powerful sources of data for young children (e.g., Baldwin, 2000). Multi-modal reference may be especially pedagogically supportive if usage patterns reflect adaptive linguistic tuning, with caregivers using this information-rich cue more for young children and infrequent objects. The amount of multi-modal reference should be sensitive to the child's age, such that caregivers will be more likely to provide richer communicative information when their child is younger (and has less linguistic knowledge) than as she gets older (Yurovsky et al., 2016).

Methods

We used data from the Language Development Project– a large-scale, longitudinal corpus of parent child-interaction in the home with families who are representative of the Chicago community in socio-economic and racial diversity (Goldin-Meadow et al., 2014). These data are drawn from a subsample of 10 families from the larger corpus. Recordings were taken in the home every 4-months from when the child was 14-months-old until they were 34-months-old, resulting in 6 timepoints (missing one family at the 30-month timepoint). Recordings were 90 minute sessions, and participants were given no instructions.

The Language Development Project corpus contains transcription of all speech and communicative gestures produced by children and their caregivers over the course of the 90-minute home recordings. An independent coder analyzed each of these communicative instances and identified each time a concrete noun was referenced using speech (in specific noun form), gesture (only deictic gestures were coded for ease of coding and interpretation– e.g., pointing) or both simultaneously.

Results

These corpus data were analyzed using a mixed effects regression to predict parent use of multi-modal reference for a given referent. Random effects of subject and referent were included in the model. Our key predictors were child age and logged referent frequency (i.e. how often a given object was referred to overall across our data).

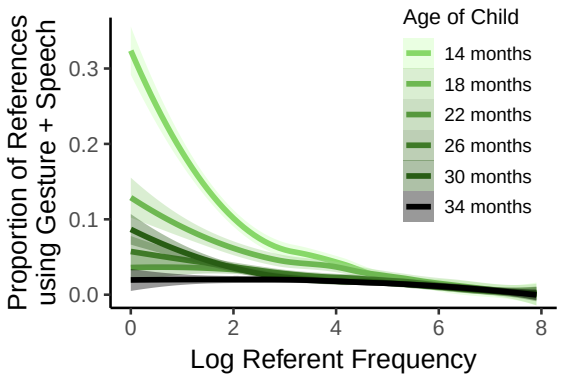

Figure 1: Proportion of parent multi-modal referential talk across development. The log of a referent's frequency is given on the x-axis, with less frequent items closer to zero.

We find a significant negative effect of child age (in months) on multi-modal reference, such that parents are significantly less likely to produce the multi-modal cue as their child gets older ($B <$ -0.04, $p < 0.0001$). We also find a significant negative effect of referent frequency on multi-modal reference as well, such that parents are significantly less likely to provide the multi-modal cue for frequent referents than infrequent ones ($B <$ -0.13, $p < 0.0001$). Thus, in these data, we see early evidence that parents are providing richer, structured input about rarer things in the world for their younger children.

Discussion

Caregivers are not indiscriminate in their use of multi-modal reference; in these data, they provided more of this support when their child was younger and when discussing less familiar objects. These longitudinal corpus findings are consistent with an account of parental alignment: parents are sensitive to their child's linguistic knowledge and adjust their communication accordingly (Yurovsky et al., 2016). Ostensive labeling is perhaps the most explicit form of pedagogical support, so we chose to focus on it for our first case study. We argue that these data could be explained by a simple, potentially-selfish pressure: to communicate successfully. The influence of communicative pressure is difficult to draw in naturalistic data, so we developed a paradigm to try to experimentally induce richly-structured, aligned input from a pressure to communicate in the moment.

Experimental Framework

We developed a simple reference game in which participants would be motivated to communicate successfully on a trial-by-trial basis. In all conditions, participants were placed in the role of speaker and asked to communicate with a computerized listener whose responses were programmed to be

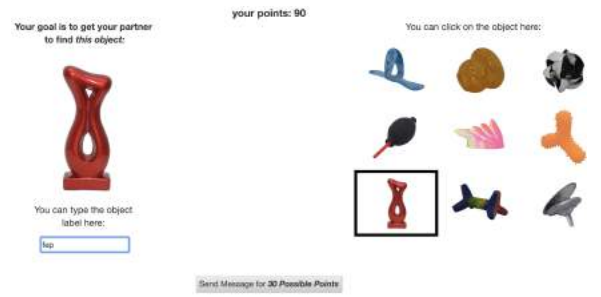

Figure 2: Screenshot of speaker view during gameplay.

contingent on speaker behavior. We manipulated the relative costs of the communicative methods (gesture and speech) across conditions, as we did not have a direct way of assessing these costs in our naturalistic data, and they may vary across communicative contexts. In all cases, we assumed that gesture was more costly than speech. Though this need not be the case for all gestures and contexts, our framework compares simple lexical labeling and unambiguous deictic gestures, which likely are more costly and slower to produce (see Yurovsky, Meyers, Burke, & Goldin-Meadow, 2018). We also established knowledge asymmetries by pre-training participants and manipulating how much training they thought their partner received. Using these manipulations, we aimed to experimentally determine the circumstances under which richly-structured input emerges, without an explicit pedagogical goal.

Method

Participants 480 participants were recruited though Amazon Mechanical Turk and received $1 for their participation. Data from 51 participants were excluded from subsequent analysis for failing the critical manipulation check and a further 28 for producing pseudo-English labels (e.g., 'pricklyy-one'). The analyses reported exclude the data from those participants, but all analyses were also conducted without excluding any participants and all patterns hold ($ps < 0.05$).

Design and Procedure Participants were exposed to nine novel objects, each with a randomly assigned pseudo-word label. We manipulated the exposure rate within-subjects: during training participants saw three of the nine object-label mappings four times, two times, or one time. Participants were then given a recall task to establish their knowledge of the novel lexicon (pretest).

Prior to beginning the game, participants are told how much exposure their partner has had to the lexicon and also that they will be asked to discuss each object three times. As a manipulation check, participants are then asked to report their partner's level of exposure, and are corrected if they answer wrongly. Then during gameplay, speakers saw a target object in addition to an array of all nine objects (see Figure 2 for the speaker's perspective). Speakers had the option of either directly click on the target object in the array (gesture)- a higher cost cue but without ambiguity- or typing a label for the object (speech)- a lower cost cue but contingent on the listener's shared linguistic knowledge. After sending the message, speakers are shown which object the listener selected.

Speakers could win up to 100 points per trial if the listener correctly selected the target referent. We manipulated the relative utility of the speech cue between-subjects across two conditions: low relative cost for speech ('Low Relative Cost') and higher relative cost for speech ('Higher Relative Cost'). In the 'Low Relative Cost' condition, speakers were charged 70 points for gesturing and 0 points for labeling, yielding 30 points and 100 points respectively if the listener selected the target object. In the 'Higher Relative Cost' condition, speakers were charged 50 points for gesturing and 20 points for labeling, yielding up to 50 points and 80 points respectively. If the listener failed to identify the target object, the speaker nevertheless paid the relevant cost for that message in that condition. As a result of this manipulation, there was a higher relative expected utility for labeling in the 'Low Relative Cost' condition than the 'Higher Relative Cost' condition.

Critically, participants were told about a third type of possible message using both gesture and speech within a single trial to effectively teach the listener an object-label mapping. This action directly mirrors the multi-modal reference behavior from our corpus data– it presents the listener with an information-rich, potentially pedagogical learning moment. In order to produce this teaching behavior, speakers had to pay the cost of producing both cues (i.e. both gesture and speech). Note that, in all utility conditions, teaching yielded participants 30 points (compared with the much more beneficial strategy of speaking which yielded 100 points or 80 points across our two utility manipulations).

To explore the role of listener knowledge, we also manipulated participants' expectations about their partner's knowledge across 3 conditions. Participants were told that their partner had either no experience with the lexicon, had the same experience as the speaker, or had twice the experience of the speaker.
