The Macroeconomic Consequences of Disasters

ABSTRACT

Natural disasters have a statistically observable adverse impact on the macro-economy in the short-run. Not surprisingly, costlier events cause more pronounced slowdowns in production. Yet, interestingly, developing countries, and smaller economies, face much larger output declines following a disaster of similar relative magnitude than do developed countries or bigger economies. A close study of the determinants of these adverse macroeconomic output costs reveals several interesting patterns. Countries with a higher literacy rate, better institutions, higher per capita income, higher degree of openness to trade, and higher levels of government spending are better able to withstand the initial disaster shock and prevent further spillovers into the macro-economy. These all suggest an increased ability to mobilize resources for reconstruction. Financial conditions also seem to be of importance; countries with more foreign exchange reserves, and higher levels of domestic credit, but with less-open capital accounts appear more robust and better able to endure natural disasters, with less adverse spillover into domestic production.

JEL Codes: O40, Q54

Key words: Natural disasters, growth

1. Introduction

Natural disasters have resulted in significant economic and human loss for millennia. Major recent catastrophic events — such as the December 2004 tsunami disaster in the Indian Ocean, the Pakistani Kashmir earthquake of October 2005 and the September 2005 inundation of New Orleans following hurricane Katrina — have brought the human and material cost of these crises to the forefront of public attention worldwide.

Natural disasters also figure prominently in discussions on future preparedness, especially in relation to the evident warming of the planet and the attendant changes in the patterns of climatic events that are predicted to accompany such warming (IPCC, 2007).¹ The United Nations, for example, reports that: “Since 2000, some 1.6 billion have lost their homes or livelihoods or have suffered other damage [as a result of a natural disaster – IN]. This continues an upward trend over the past several decades and represents a four-fold annual increase, on average, from the decade of the 1970s.” (Schwartz, 2006).

The United Nation’s *Integrated Regional Information Network* notes, “while the number of lives lost has declined in the past 20 years - 800,000 people died from natural disasters in the 1990s, compared with 2 million in the 1970s — the number of people affected has risen. Over the past decade, the total affected by natural disasters has tripled to 2 billion.” (IRIN, 2005). Therefore, much research in both the social and natural sciences has been devoted to increasing our ability to predict disasters, prepare for them and mitigate their costs.² Curiously, few economists participate in developing this research agenda, and not many attempt to answer the many economically relevant

¹ Increasing levels of greenhouse gases, changing sea, land and air temperatures, rising sea levels, changing patterns of rain and snow and an unstable climate are all likely catalysts of future events.

² Much of this effort can be accessed through: <http://www.colorado.edu/hazards/>

questions relating to natural disasters.

Almost all the current research on the topic focuses on disasters *ex ante*, as is done in the large preparedness literature that aims to describe how societies should better prepare themselves to the onset of disasters and reduce the direct damage they cause. In contrast, we focus on the natural disasters' *ex post* impact on the macro-economy. We measure and estimate the costs of these crises in terms of forgone production, and using a comprehensive international macroeconomic panel dataset, we critically examine several hypotheses regarding the determinants of these costs. Given the importance of the problem, it is somewhat surprising that this has not been done before. Our effort enables us to compare the incidence and costs of disasters across geographical areas and income levels and provide answers to several hypotheses regarding structural and policy-related aspects of these costs.

In the next section, we discuss the existing economic literature and highlight our contribution to it. In the following sections we discuss the data, methodology, and findings of this paper. We conclude by pointing out some policy implications of our findings, and put forth a future research agenda on this topic.

2. The economics of natural disasters in previous research

Economic research on natural disasters is only in its infancy with very few papers examining any facet of disaster phenomena. Two exceptions of well developed research strands are worth noting. There is a significant body of micro-development research which examines the ways in which (especially rural) households prepare and deal with sudden unexpected income shocks (such as draughts) and their ability to insure against

these shocks (e.g., Townsend, 1994; Paxson, 1989; and Udry, 1994). The second existing strand examines specific case studies - disaster events - such as the devastating hurricane Mitch in Honduras, and estimates some of the specific costs and consequences of those individual events (e.g., Benson and Clay, 2004; Halliday, 2006; Horwich, 2000; Narayan, 2001; Selcuk and Yeldan, 2001; and Vos et al., 1999).

The first strand is indirectly related to our investigation as it suggests that institutional characteristics and policy choices may have an impact on the macroeconomic consequences by shaping the individual households' decisions following disasters. The second strand is more directly relevant as a source for our hypotheses. The difficulty in judging the general applicability of the findings reported in these case studies, however, is part of the justification for our comparative work. Our findings may provide indication of any general conclusions that otherwise can only be derived with a meta-analysis relying on a large number of such case studies.

As far as we know, there are only very few papers that examine any macroeconomic facet of natural disasters using a multi-country, multi-event framework. These are briefly discussed below, though none of them attempts to answer the questions we pursue hereafter. The first recent attempt to empirically describe macro-aspects of natural disasters is Albala-Bertrand (1993). In this seminal monograph, Albala-Bertrand develops an analytical model of disaster occurrence and reaction and collects data on a set of disaster events: 28 disasters in 26 countries during 1960-1979. Based on before-after statistical analysis, he finds that GDP increases, inflation does not change, capital formation increases, agricultural and construction output increase, the twin deficits increase (the trade deficit sharply), reserves increase, but no discernible impact on the

exchange rate is observed. The patterns of onset and recovery observable in this dataset are then described with a special emphasis on the political economy aspects of the events themselves. Rasmussen (2004) conducts a similar tabulation of the data for Caribbean Islands. Tol and Leek (1999) survey the literature as far back as the 1960s, and argue that the positive effect on GDP can readily be explained since disasters destroy the capital stock, while the GDP measure focuses on the flow of new production. They emphasize the incentives for saving for and investing in disaster mitigation and recovery efforts. In all these, the empirical work is largely based on a before-after uni-variate analysis of a set of macroeconomic variables for a small set of disaster events (chosen by the authors which they survey).

Skidmore and Toya (2002) examine the long-run impact of natural disasters on growth. They count the frequency of natural disasters for the 1960-1990 period for each country (normalized by land size) and pursue an empirical investigation of the correlation of this measure to average measures of economic growth, physical and human capital accumulation and total factor productivity for this 30 years period. Skidmore and Toya's (2002) paper investigates long-run trends (averages) in contrast with our aim of describing the short-run dynamics of the macro-economy following disasters. Long-run analysis raises questions of endogeneity in disaster impact that are, to a large extent, not relevant for the short-run.³ Furthermore, their use of a cross section is conceptually and empirically very different from our reliance on a panel framework.

³ Skidmore and Toya's (2002) work utilizes the frequency of disasters; yet it important to note that only those disasters that resulted in significant damages get registered in the EM-DAT (see section 3). The issue is highlighted by the finding of another strand that identifies per capita income as a significant determinant of the direct costs of natural disasters (see Kahn, 2004; and Skidmore and Toya, 2007).

In the paper closest to ours in its interest, Raddatz (2007) investigates the external sources of output volatility in low income developing countries. Using a VAR approach, the paper analyses the contribution of various external shocks, natural disasters among them, in explaining output fluctuations. For our purposes, Raddatz's (2007) finding that natural disasters do have an adverse short-run impact on output dynamics is of interest.⁴ Raddatz's (2007) focus on several types of external shocks, and its VAR approach, preclude it from answering the various questions posed here with respect to the determinants of the observed output declines following disasters.

3. Data

The data on natural disasters and their human impact are documented in the EM-DAT database with data collected by the Centre for Research on the Epidemiology of Disasters (CRED).⁵ The EM-DAT database has worldwide coverage, and contains data on the occurrence and effects of natural disasters from 1900 to the present. The database is compiled from various sources, including UN agencies, non-governmental organizations, insurance companies, research institutions and press agencies. The EM-DAT data is publicly available on CRED's web site at: www.cred.be.

CRED defines a disaster as a natural situation or event which overwhelms local capacity, necessitating a request for external assistance. For a disaster to be entered into the EM-DAT database at least one of the following criteria must be fulfilled: (1) 10 or more people reported killed; (2) 100 people reported affected; (3) declaration of a state of

⁴ Yet, Raddatz (2007) concludes that only a small fraction of the output volatility in a typical low income country is explained by external adverse shocks (which include disasters).

⁵ Established in 1973 as a non-profit institution, CRED is based at the Catholic University of Louvain in Belgium.

emergency; or (4) call for international assistance.⁶ These disasters can be hydro-meteorological disasters including floods, wave surges, storms, droughts, landslides and avalanches; geophysical disasters - earthquakes, tsunamis and volcanic eruptions; and biological disasters covering epidemics and insect infestations (these are much more infrequent).

The amount of damage reported in the database consists only of direct damages (e.g. damage to infrastructure, crops, housing) and do not include the indirect or secondary damages – an attempt to estimate these secondary effects is, in part, our aim here. We utilize three reported measures of the magnitude of the disaster: (1) The number of people killed (DKIL); (2) the number of people affected (DAFF); and (3) the amount of direct damage (DDAM). For the years 1970-2003, we have data on the number of people killed for 507 disaster events, the number of people affected for 466 events, and the amount of damage in 428 events.

Since we presume that the impact of a specific natural disaster on the macro-economy depends on the magnitude of the disaster relative to the size of the economy, we standardize our disaster measures. We divide the measures for the number of people killed or affected by the population size in the year prior to the disaster year; and divide the direct cost measure of the disaster by the last year's GDP (since the current year's population and GDP have been affected by the disaster itself). Furthermore, since it is likely that a disaster that occurred in January of 1995 will have a bigger impact on the macro-economy in the same year than a disaster that occurred in December, we weigh

⁶ The number of people killed includes “persons confirmed as dead and persons missing and presumed dead”; people affected are those “requiring immediate assistance during a period of emergency, i.e. requiring basic survival needs such as food, water, shelter, sanitation and immediate medical assistance.”

our measure based on the month in which the disaster occurred (or began).⁷ Specifically, the disaster measures (DMS) we employ in our specifications are calculated based on the cost measure (DM) and the onset month (OM):

$$DMS = DM(12 - OM)/12 . \quad (1)$$

From the outset, it should be clear that doubts have been expressed about the accuracy of data on natural disasters; especially because often the major source of these data (national governments) has an interest in inflating the measured impact. This problem might be especially acute in developing countries where the reported magnitude may have an impact on the amount of support pledged by the donor countries and statistical collection efforts are less transparent. Yet, since biases should be systemic, using data from one source should provide information about the relative magnitude of disasters and should thus be appropriate for the hypotheses we examine here.⁸ A more general problem with regards to the reliability of macroeconomic statistics in developing countries must also be acknowledged. We assume this source of mis-measurement to be unbiased.

Data on GDP growth, per capita income levels, CPI inflation, unemployment rate and population, as well as the other macroeconomic control variables, comes primarily from the World Bank's World Development Indicators. Because of data availability constraints, our panel covers the years 1970-2003 for all countries for which data was available in the WDI. For the benchmark specifications we have data for 109 countries

⁷ A disaster measure that occurs earlier in the year might be more thoroughly offset by the 'increase in investment' response that may follow disasters and thus bias down our coefficient estimates. Given that the possible exaggeration of the cost variable also biases down our estimates, one can consider our results as lower bounds to the actual output decline that follows a disaster.

⁸ Furthermore, if stated damages are indeed biased upward, then the size of the estimated coefficients is biased downward (see Hausman, 2001, for more details).

(on average about 15 annual observations per country). Exact details are provided in the data appendix.

The data on natural disasters is described in tables 1 and 2. In table 1, we provide the main statistical characteristics of the 3 measures of interest; the mean, standard deviation, minimum, and maximum. In table 2, we divide our sample by income level and regional location and describe the means, medians, and number of observations we have for each region. From this table, we note that disasters apparently are significantly more costly for developing countries than they are for developed ones.⁹ Disasters in South-, South-East, and East Asia are also more costly (in both human life and property damage) than those occurring in the Middle East, and Latin America. This might be at least partly a result of the higher population density in Asia. More striking is the difference between island-states and all other geographical regions. Islands are apparently very vulnerable to disasters, with costs to life, the number of people affected, and the property damage incurred all are, on average, twice as large as in any other region.

4. Methodology

Our main aim here is to describe the macro-economic consequences of natural disasters. We start by examining the most parsimonious specification:

$$y_{i,t} = \alpha_i + \beta y_{i,t-1} + \gamma DMS_{i,t} + \phi X_{i,\bullet} + \varepsilon_{it} \quad (2)$$

where $y_{i,t}$ is the annual GDP growth rate, $DMS_{i,t}$ is our measure for disaster magnitude described in the previous section, and $X_{i,\bullet}$ are control variables commonly used in the

⁹ At least some of this difference, though, can plausibly be accounted for by a selection bias due to different reporting practices. It is likely that for developed countries, smaller disasters (in terms of costs to life or property) will also be reported to CRED.

short-run growth literature. Following Islam (1995) and most subsequent empirical models of short-run GDP growth, we add to the specification a GDP growth lag ($y_{i,t-1}$).¹⁰ Country-specific effects are introduced in order to account for the widely varying average growth experiences among different countries over the past two decades. This setup explicitly removes the cross-sectional long-run differences which were the focus of Skidmore and Toya (2002).¹¹

In our estimates we follow a procedure first suggested by Hausman and Taylor (1981) that takes into account the bias in estimation of panels with predetermined and/or endogenous variables.¹² The Hausman-Taylor three-step estimation methodology is an instrumental variable estimator that takes into account the possible correlation between the disturbance term and the variables specified as predetermined/endogenous. The estimated equation is thus:

$$y_{i,t} = \alpha_i + \beta y_{i,t-1} + \gamma DMS_{i,t} + \phi^1 X_{i,\cdot}^1 + \phi^2 X_{i,\cdot}^2 + \varepsilon_{it} \quad (3)$$

where $X_{i,\cdot}^1$ are the control variables assumed to be (weakly) exogenous and $X_{i,\cdot}^2$ are assumed to be predetermined/endogenous and thus correlated with the country specific effects. Given the construction of our disaster variable as ratio of the previous year's domestic product, this variable is clearly predetermined; we thus classify it as such.¹³

In the first step, estimates from a country-fixed-effects model are employed to obtain consistent but inefficient estimates for the variance components for the

¹⁰ The use of only one lag is supported by recent research (e.g., Uribe and Yue, 2006, and Raddatz, 2007).

¹¹ The Hausman and Taylor (1981) algorithm we use involves both a first-stage fixed effects estimation and a final random-effects third stage.

¹² For a rigorous formulation of this bias see Nickel (1981).

¹³ We note that classifying the disaster variable as exogenous does not change any of the results we report (when it is classified as predetermined/endogenous). We generally assume the other control variables are exogenous but this assumption does not change any of our results on the disaster coefficients.

coefficients of the time-varying variables. In the second step, an FGLS procedure is employed to obtain variances for the time-invariant variables. The third step is a weighted IV estimation using deviation from means of lagged values of the time-varying variables as instruments. Identification in the Hausman-Taylor procedure requires that the number of exogenous variables be at least as large as the number of time-invariant predetermined/endogenous variables. The exogeneity assumption requires that the means of the exogenous variables (\overline{X}_i^1) will be uncorrelated with the country effects (α_i).^{14, 15}

The Hausman-Taylor methodology is intended to overcome the possible correlation between the country specific effects and the independent variables in a panel set-up that arises because of endogeneity of some of the control variables. Yet, in order to derive any causal inferences on the effect of the disaster variables on our macroeconomic measures of interest (mainly GDP growth), we require further assumptions. We see no a priori reason to argue that these disaster measures will face any reverse causality from the GDP growth variable (i.e., GDP growth will Granger cause future disasters); we thus assume exogeneity of these measures. This assumption is also adopted by the three other papers that use a disaster measure as an independent variable, albeit in different specifications and for examining different hypotheses (Raddatz, 2007, Ramcharan, 2007

$$^{14} \quad p \lim_{N \rightarrow \infty} \left(\left[\sum_{i=1}^N \alpha_i X_i^1 \right] / N \right) = 0$$

¹⁵ Under the plausible exogeneity assumption described above, the Hausman-Taylor (HT) procedure provides asymptotically consistent estimates, but it is not the most efficient estimator possible. For a dynamic panel set-up, more efficient GMM procedures rely on utilizing more available moment conditions to obtain a more efficient estimation (e.g., Arellano and Bond, 1991). This procedure, however, is usually employed in estimation of panels with a large number of individuals and short time-series and in our case, the number of instruments used will be very large (and the system will be vastly over-identified); see Baltagi (2005). Furthermore, the data makes this procedure difficult to implement for most specifications of the model; see Greene (2002) on the practical difficulty in implementing AB-GMM. Hutchison and Noy (2005) compare these methodologies and show that using the Arellano and Bond (1991) GMM framework in similar growth specifications the coefficients do not change noticeably when compared to the Hausman and Taylor (1981) estimates, though their statistical significance increases as predicted.

and Skidmore and Toya, 2002).¹⁶ To verify that the way we construct the disaster measure using lagged GDP levels (see eq. 1) does not insert any endogeneity into our measure we also run the same specifications using a binary indicator of disaster occurrence and find the qualitative results identical. A further informal test of the exogeneity assumption is to compare the distribution of the independent variables for the disaster and no-disaster observations. We find no statistically observable difference in their means.

5. Estimation results: The impact on GDP growth

The preliminary results presented in table 3, without the control variables, point to two general conclusions. There is no evidence of any correlation between the disaster population variables (number killed or affected) and GDP growth (table 3 columns 2 & 3). However, we obtain strong indication that the amount of property damage incurred during the disaster is a negative determinant of GDP growth performance. This is not an intuitive result, but is very robust. We hypothesize that the reason for this is that the short-term impact of a disaster is caused mostly by damage to the capital stock, to delivery and transportation systems, and other infrastructure. On the other hand, the human cost has an impact which is much more long term in nature and may only be statistically observable in long-term growth specifications as in Skidmore and Toya

¹⁶ Raddatz (2007) uses the number of large disasters, per year, that are recorded in the EM-DAT dataset. Large disasters are events that affect at least half a percent of a country's population, cause damages of at least half a percent of GDP, or results in more than one fatality for every 10,000 people. Skidmore and Toya (2002) use the frequency of disasters (the number of disasters occurring over the period 1960-1990) as their disaster variable in their cross sectional dataset. Ramcharan (2007) uses a binary indicator for whether a disaster occurred in the any country-year observation.

(2002). We also find that larger disasters, or those that happen earlier in the year, have a more adverse affect (table 3 column 1).¹⁷

To further investigate whether there are any reasons to suspect the way we constructed the damage variables created any endogeneity problem, we convert the disaster measures we have into binary indicators (1=disaster, 0=no disaster) to examine whether this changes our results.¹⁸ Again, we find a significant coefficient for the damage variable in these specifications (table 3 columns 4-6).

Next, we examine specifications that also include other control variables commonly found in the empirical growth literature. The additional determinants of output in this model are a set of domestic policy, structural, and external factors, as well as country-specific effects and the lagged output growth already included in the specifications presented in table 3. The domestic policy factors are changes in government budget surpluses, inflation, investment, and credit growth. External factors include the current account and foreign direct investment inflows; and the structural factors we consider are the openness of the economy to international trade (import ratio), a measure of institutional quality and a binary measure for financial crises.¹⁹ All of the variables, with the exception of financial/capital-flows-stop crisis measure, are introduced with a one-year lag in order to capture the delayed response of output to macroeconomic developments. Exact details on measurements and sources are included in a data appendix.

¹⁷ This might be construed as hardly surprising, and is in line with the Raddatz (2007) conclusion. But, it is distinct from the conclusions presented in Skidmore and Toya, (2002) in their research on the long-run effect of disasters, and is also in contrast with some of the descriptive case studies (e.g., Horwich, 2000).

¹⁸ Because the binary approach masks the distinctions between the magnitudes of different disasters, we only record (binary variable =1) those disasters whose magnitude is bigger than the mean for that type of disaster data.

¹⁹ For a discussion of sudden capital inflow stops (financial crises), and their empirical importance in growth dynamics, see Hutchison and Noy (2006).

Since our preliminary investigation in table 3 only yielded significant results for the property damage measure of crises, we focus only on this measure in all the following specifications. In our benchmark specification (table 4 column 1), we include the disaster measure and the other variables previously described. For the control variables, better institutions, lower credit growth, a higher current account surplus, larger FDI inflows and the absence of a financial crisis are all significantly associated with higher GDP growth. Past investment growth, the government deficit, the inflation rate, or imports do not seem to have a discernible impact on output performance in our specifications. We note that since the disaster measures are most likely strongly exogenous, we anyway do not expect their estimated coefficients to be affected by the inclusion of these controls (compare table 4 column 1 to table 3 column 1).

In columns 2 and 3 of table 4, we split our sample into developed countries (defined as 1990 members of the OECD) and developing countries (the rest). The obvious conclusion is that the negative impact of natural disasters on the macro-economy is entirely due to output dynamics in the developing countries sample. This description does not apply to developed countries. One possible reason is the amply documented ability of developed countries to pursue counter-cyclical fiscal and monetary policy following adverse shocks – an ability that does not seem to be enjoyed by lower income countries who often end up pursuing pro-cyclical policies in the face of external shocks.

We further investigate whether big economies are more or less vulnerable to the impact of natural disasters. We now split the sample by the median size of the economy (measured in constant US\$). We find, maybe not surprisingly, that small economies are more vulnerable to an event of the same size (relative to their size). This may be due to

the fact that smaller economies are less diversified, and their ability to withstand external shocks, especially to their agricultural sector, is thus diminished. We investigate these issues further in the next tables.

Since by introducing the disaster variables scaled by the size of each economy we may have introduced endogeneity into our preferred measure, we attempt to examine the robustness of our results using another proxy for the magnitude of the disaster. In particular, we utilize the only two magnitude measures that are available in the EM-DAT dataset: the Richter scale measure for earthquakes and the wind-speed (in km per hour) for storms. We repeat the specifications in columns (1)-(3) of table 3 by replacing the disaster variable with the Richter scale and wind-speed measures. This information is only available for a subset of our disasters so the number of events identified in the estimation is more limited.

For wind-speed, we find no evidence of any correlation between wind-speed and output growth. Maybe this is not surprising since the location (close or far from populated area), and the area covered by the storm are not accounted for.²⁰ For the Richter scale measure, a better measure of disaster magnitude, we find results that are similar to our previous results for the damage variables – i.e., a negative and statistically significant coefficient suggesting a negative impact on GDP growth.

The economic importance of these statistically identifiable effects is very real. A one standard deviation increase in the direct damages of a natural disaster in a developing country will reduce output growth by about 9%. We obtain similar magnitudes for small

²⁰ In the U.S., for example, a very local and limited tornado can have very high wind-speeds while a much bigger hurricane can have much lower top wind-speeds registered.

economies. The effect on developed countries is statistically significant but the economic importance is only marginal with the observed increase lower than 1%.

These impacts are quite large, and are well beyond what could be predicted from standard growth models. We suspect that the origins of the large impacts we found is the disruptions that disasters cause to labor, financial and output markets. Since disasters interrupt communication, transportation and delivery systems, and divert government resources, it may be reasonable to expect that a standard growth model, that identifies disasters with destruction of the capital stock, will not fully capture their impacts on the economy.

In further specifications, we aim to answer several questions regarding the determinants of the output declines identified in the previous tables. Specifically, we would like to examine whether institutional and structural aspects of the ($Z_{i,t}$) of the economies struck by disasters have any bearing on the magnitude of output decline that typically follows. We thus estimate the following specification:

$$y_{i,t} = \alpha_i + \beta y_{i,t-1} + \gamma DMS_{i,t} + \delta(DMS_{i,t} \cdot Z_{i,t}) + \tau Z_{i,t} + \phi X_{i,t-1} + \varepsilon_{it} \quad (4)$$

The coefficient on the interaction of the natural disaster measure and the institutional/structural macroeconomic variable (δ) will define the effect of these characteristics on the magnitude of the output loss.²¹

We describe our hypotheses and the results concerning structural/real characteristics of the economy in table 5 and financial characteristics in table 6. We first examine whether the level of human capital affects the impact of a financial crisis. It is

²¹ We also include the direct affect of the institutional/structural factor (τ) to verify that the identified interaction coefficient is not significant because of the direct correlation of the institutional/structural factor and output growth.

likely that in economies in which the level of human capital is higher, the impact of loss of physical capital on the macro-economy will be lower. We confirm this in table 5 column 1 in which we include the level of illiteracy interacted with our damage variable. We find the coefficient is negative and significant suggesting that countries with higher level of illiteracy will experience a more adverse affect on output growth as a result of a natural disaster.²²

In columns 2 and 3 of table 5, we examine whether a higher institutional quality (as measured in the *Institutional Country Risk Guides*) and higher per capita income levels (in PPP\$) have any impact on the macro-cost of a disaster. We find that indeed both institutional strength and higher per capita incomes are associated with a statistically significant lower macroeconomic cost. The importance of governing institutions can be attributed either to the direct efficiency of the public intervention following the event's onset, or to the indirect impact of an efficient government response in shaping private sector response to the disaster. Our conclusions about income levels corroborate the observations we made in table 4 regarding the difference in output dynamics between developed and developing countries. This result can plausibly be attributed also to the wider diversification observed in higher-income countries and their ability to counter exogenous shocks with counter-cyclical fiscal policy (while fiscal policy in poorer countries is typically pro-cyclical).

We next turn to other structural aspects of the domestic economy and find that a bigger government (measured as government consumption as percent of GDP) and a higher level of exports (as percent of GDP) are both associated with a lower macro-cost

²² A measure of illiteracy is the only proxy for human capital that is available in the *World Development Indicators* database in wide enough coverage to maintain our sample size.

of a natural disaster. Both findings are plausible; it is likely that a bigger government will be able to mobilize more resources more rapidly for reconstruction, and that a country that is more open to trade will experience a smaller negative shock to the demand for its products. Countries open to trade may also be more likely recipients of larger international capital inflows to aid in the reconstruction effort.²³

It has also been hypothesized that geographical location might be a factor in determining the macro-economic secondary costs of disasters. For example, a tropical climate might be conducive to spreading infectious diseases *ex post* and thus slow down the recovery process; especially when needed resources have to be spent to combat this possibility. We measure the percent of the land area in each country which is in the tropics (between the Tropic of Cancer and the Tropic of Capricorn - 22.5 degrees north and south, respectively). Once this tropics measure is interacted with the property damage variable, we find evidence of the opposite effect – a tropical country is likely to experience higher growth than one which is located outside the tropics following a natural disaster. A potential explanation is the greater ability of agriculture to rebound in tropical climates (where there may well be 3 crop cycles per year).

Finally, since insurance, credit, and financial flows all play a role in disaster recovery, we examine whether financial market conditions matter for the consequences of natural disasters. We start by examining whether the depth of the financial system matters for disaster costs. We proxy the financial system with two measures: the size of the

²³ Yang (2006) uses the incidence of hurricanes to examine the consumption smoothing role of international financial flows and finds that foreign aid inflows increase following hurricane events, and, for poorer developing countries, so do remittances. The net aggregate flows to developed countries do not seem to change following hurricane exposure. Raddatz (2007) finds that aid flows increase after climatic disasters but decrease after geological ones.

domestic stock market (stock market capitalization – table 6 column 1) and the level of domestic credit (table 6 column 2). We find no evidence that the stock markets are important in insulating economies from the macroeconomic impact of disasters. On the other hand, we do observe that more domestic credit appears to reduce the costs of disasters in terms of foregone output growth.

We next examine whether the degree of openness of the capital account matters for the output dynamics following the disaster. Yang (2006) finds some evidence of capital flight following disaster events – in his paper: hurricanes. We therefore include a variable that measures the degree of *de jure* openness of the capital account. This measure extends between -2.5 to +2.5 and is described in detail in Chinn and Ito (2006). Maybe not surprisingly in light of Yang's (2006) observations, countries with open capital accounts seem to experience larger drops in their output growth following disasters.

Since this is one of the more surprising results in this paper, we repeat this specification using a different measure of capital account openness (column 4). Our second measure, taken from Edwards (2007), is constructed from different primary sources and measures openness between 0-100. This measure varies less over time than the Chinn-Ito index. Qualitatively, we find the same results for this measure. Though the interaction term, while negative, is no longer statistically distinguishable from the null of no effect.

Finally, we also examine whether the amount of hard-currency reserves held by the central bank matters – reserves can be thought of, in this case, as a buffer stock against the capital outflows documented by Yang (2006). We do find that countries with

larger stocks of reserves (measured in months of imports) experience lower output declines following the disaster events (table 6 column 5).

We found no evidence to support rejections of a further set of hypotheses. Because of the usual statistical weaknesses of macro panels, we hesitate to conclude that we can confirm any of these hypotheses but rather that, for whatever reason, we have been unable to reject them. We have examined, and found no evidence, that: the relative size of the agricultural or mining/minerals sectors matters; that island economies are more vulnerable to the disasters' indirect costs; and that big countries (in land area) are less vulnerable to the adverse effect of disasters on the macro-economy.

6. Estimation results: The impact on other macroeconomic variables

The sole focus on domestic output in this paper is clearly incomplete as a description of the macroeconomic affects of natural disasters. In the research leading up to this paper, we also estimated standard equations examining the impact of disasters on inflation and on employment (using specifications used in previous research). In both cases, the disasters variables we employed here do not seem to have any effect observable in country-wide annual data. This is borne out by the fact, for example, that in Indonesia following the 2004 tsunami (clearly one of the most destructive natural disasters in the past century) while inflation was higher in 2005 by 4pp, it was still lower than that of 2002 or 2003 and well below that experienced following the 1998 crisis (data from the

International Finance Statistics).²⁴ It appears that inflation's volatility in developing countries makes it difficult to identify any impact of disasters.

We estimated several specifications for investment equations relying on the specifications and data used in Joyce and Nabar (2006) but our results do not point to any robust conclusions. In some cases investment indeed increased following disasters (reconstruction investment), but there are also cases in which investment decreased (possibly due to a shift in perceptions regarding the likelihood of future disasters). The coefficient on the disaster variable in investment equations reflects these varied experiences and does not show any robust pattern. We found weak evidence that suggests that investment (measured by gross capital formation) on average increases immediately following the disaster event but then declines significantly in the following year (possibly because capital formation gets shifted temporally).

We also attempted to estimate similar specifications for trade (using [exports+imports]/GDP for the dependent variable). Again, results were inconclusive. For trade, we believe that estimating gravity like equations for bilateral trade may provide a much richer picture of the impact of disasters on trade (especially if those could be estimated using trade data that separates agricultural trade). This project, however, is far beyond the scope of this paper.

The impacts of disasters on poverty and income distribution are salient questions that we did not attempt to examine. Reliable data with comprehensive coverage for both is difficult to find and we reserve this endeavor for a future project.

²⁴ Albala-Bertrand (1993) and Ramcharan (2007) also fail to find any correlation between inflation and disaster events. Ramcharan (2007) also fails to find any overall impact of disasters on exports (over a three year period following a large disaster); but his model has very poor predictive value in general.

7. Conclusions and caveats

Our preliminary empirical investigation on the macroeconomic costs of natural disasters, the first systematic attempt we are aware of, yielded a number of interesting observations. Natural disasters have a statistically observable impact on the macro-economy when these are measured by the amount of property damage incurred. Alternative measures relying on population indicators (number killed and number affected) do not present any statistically identifiable evidence of macroeconomic costs. Furthermore, we found the developing countries face much larger shock to their macro-economies following a disaster of similar relative magnitude than do developed countries. Similarly, small economies seem to be more vulnerable than larger ones to these same natural adverse events.

We follow up and examine the determinants of these output costs and find that countries with higher literacy rates, better institutions, higher per capita incomes, larger governments and higher degree of openness to trade appear to be better able to withstand the initial disaster shock and prevent its effects spilling deeper into the macroeconomy. Financial conditions also seem to matter. Countries with less open capital accounts, more foreign exchange reserves, and higher levels of domestic credit appear more robust and able to endure natural disasters with less spillover to GDP growth rates.

We note several important caveats. In this paper, we do not examine several other possible impacts on the macro-economy, such as the effects on the government budget (and long term indebtedness), crowding out effects of reconstruction spending or monetized deficits. Identifying these channels and their empirical importance is important for policy-making following disasters. For example, it is likely that the fiscal position

before the disaster, and the fiscal consequences after it occurs, may both have important impacts on production. The ex-post fiscal stimulus may cause GDP to rise (if the disaster strikes non-productive assets like housing), may only divert resources from more productive public investment (e.g., providing basic needs instead of financing infrastructure investment), and may also have long-term effect on the government's balance sheet, and thus on its borrowing costs. These various possibilities make it very difficult to find any 'average' affect of disasters on the fiscal variables. More detailed fiscal data (obtained from the IMF's Government Finance Statistics,) for a smaller set of more similar countries, may yield interesting observations.

Our investigation also did not examine the *ex post* policy changes that might be triggered by the disaster onset and should therefore be accounted for as part of the true impact of the crisis. Disasters clearly may be catalysts for dramatic policy changes. These disaster-as-a-catalyst for change effects are harder to identify without a more detailed description of the political economy of post disaster recovery and reconstruction. Empirical identification will require a whole new set of identifying assumptions that we find no support for.

The impact of aid surges that oftentimes follow disasters are also worth exploring. Aid surges are a topic of an active research agenda, but no paper that we are aware of places these within the context of post-disaster recovery. Yet, in a cross-country framework, even the direction of aid flows following disasters appears to be difficult to pin down as Benson and Clay (2004) argue there are no observable increases in aid

inflows (except possibly for very large events), and Yang (2006) and Raddatz (2007) finding the opposite.²⁵

Furthermore, our research focused on rapid-onset disasters and ignored the macro-dynamics of slowly developing natural events such as draughts and famines. The reasons for this omission are two-fold. First, the empirical methodology and data necessary to estimate the impact of slowly developing events will have to be quite distinct from the methodology employed here. Second, famines are not entirely (or even largely) naturally occurring events and can often be considered man-made. As such, a different set of exogeneity assumptions will be necessary in order to evaluate their costs.

Our estimates also do not evaluate the long-run impact of natural disasters on growth. While Skidmore and Toya (2002) do provide estimates of the long-run effects, these rely on a cross sectional dataset, in which it is impossible to control for the obvious time-invariant differences between countries. A possibly more appropriate framework to account for these differences is a methodology similar to that pursued by Barro (1997). This long-run growth accounting necessitates a very different framework and is analyzed in Noy and Nulasri (2007).

More important than the possible avenues for future research mentioned above is the question of the impact of natural disasters on poverty. A framework to identify the interactions between poverty rates, vulnerability to and impacts of natural disasters and the variations in poverty levels should be developed in cross country settings to complement and enrich the work that has already been done on specific case studies.

²⁵ Though both Yang (2006) and Raddatz (2007) restrict their conclusions to specific sub-samples.
